In Mahakalpara Block, located in Kendrapada District, Odisha, an assessment was conducted on the suitability of groundwater for irrigation purposes. This region is defined by the Mahanadi River running along its southern border, eventually meeting the sea in the southeast, forming a significant floodplain. Before the monsoon season, groundwater samples were collected from thirty villages and analysed for major ions and various parameters including electrical conductivity, total dissolved solids, sodium absorption ratio (SAR), magnesium ratio, Kelly's ratio, sodium percentage, residual sodium carbonate, and permeability index. The predominant ion chemistry in groundwater consists of alkali cations and strong acidic anions, largely influenced by the aquifer's lithology. While the sodium absorption ratio (SAR) and residual sodium carbonate (RSC) indicate high suitability at 90% for irrigation, challenges are evident with unsuitable sodium percentage (Na%), Kelly's ratio (KR), soluble sodium percent (SSP), and magnesium ratio (MR) at 60%, 90%, 60%, and 50%, respectively. Despite a permeability index suggesting 100% suitability, elevated levels of electrical conductivity (EC), sodium (Na), and chloride (Cl) raise concerns, making Na%, KR, SSP, and MR unsuitable for effective irrigation. At the community level, promising interventions involve improving irrigation methods, enhancing floodplain management, and implementing regulations to curb saltwater aquaculture, thus addressing salinity issues. These findings emphasize the critical need for optimal management of irrigation groundwater to ensure sustainable agriculture. Furthermore, exploring innovative reclamation strategies like saline aquaculture integrated with subsurface drainage and integrated agricultural systems is essential. Prioritizing coming research efforts towards these approaches is imperative to uphold ensuring the sustainability of agriculture and global food security(GFS) in the face of challenges presented by climate change scenarios.

Geospatial Distribution and Health risk assessment of Fluoride in groundwater of Balasore district, odisha, India.

Utsav DAS[1]*, FAKIR MOHAN UNIVERSITY,BALASORE (utsavdas1992@gmail.com)
ROSALIN DAS[2], FAKIR MOHAN UNIVERSITY,BALASORE

Abstract

The study focuses on assessing the health risks associated with fluoride contamination in drinking water in the fluoride-prone region along the east coast of Balasore district, Odisha, India. A total of 60 groundwater samples from Balasore block and Remuna block were collected and subjected to analysis using statistical, hydrogeochemical, spatial distribution, and health hazard risk assessment methods. Results indicate that approximately 92% of the samples collected and 96% of the study area exceed the permissible limits for fluoride concentration set by both the World Health Organization (WHO) and the Bureau of Indian Standards (BIS). The average health hazard quotients for infants, children, male adults, and female adults are 2.09, 2.42, 1.79, and 1.69 respectively, indicating varying levels of vulnerability to fluorosis, with children being particularly susceptible. Analysis of Ca2+/Na+ versus HCO3-/Na+ and Ca2+/Na+ versus Mg2+/Na+ ratios suggests that silicate weathering is the primary contributing factor to fluoride contamination, while the linear relationship between total dissolved solids (TDS) and NO3-(Cl-/HCO3-) supports anthropogenic inputs of fluoride into the aquifer system. The study proposes that fluoride ions primarily originate from minerals such as fluorite, apatite, biotite, and hornblende found in the Granitic basement, known as Nilgiri Granite, under alkaline conditions. Positive correlations between fluoride and Na+, HCO3-, and pH indicate the weathering of rock silicates, with increases in pH mobilizing fluoride ions. Geomorphologically, the study area is characterized by the Budhabalnga River, Sono River, and their tributaries, which continuously weather the underlying granitic basement. Secondary sources of fluoride contamination include domestic and industrial sewage, as well as irrigation return flow containing phosphate fertilizers. Mitigation strategies to minimize the harmful impact of fluorosis include mass awareness programs, alternative sources of potable drinking water, artificial aquifer recharge, defluoridation techniques, and reducing the use of phosphate fertilizers.

ASSESSMENT OF GROUNDWATER STORAGE ZONES FOR SUSTAINABLE AGRICULTURAL PRACTICES IN MAHARASHTRA STATE, INDIA USING GRACE SATELLITE DATA AND RS-GIS TECHNIQUES

BHAVANA NARENDRA UMRIKAR[1]*, SAVITRIBAI PHULE PUNE UNIVERSITY
(bnumrikar@gmail.com)
BHAGYASHRI Chandrakant MAGGIRWAR[2], Deputy Director

Abstract

Maharashtra state is dominantly occupied by Deccan Volcanic Basalt representing simple and compound flow units. These rocks possess secondary porosity due to weathering, fracturing and jointing imparting heterogeneity to the aquifer system vis-à-vis the availability of groundwater. The state frequently faces water scarcity issues wherein dependency on groundwater is more and therefore the characterization of this key resource is essential. Rainfall is the major source for aquifer recharge. Hence, rainfall-recharge relation has been decoded for the groundwater storage estimation to address the scarcity issues. The present study is performed using the Total Water Storage (TWS) data of the JPL TELLUS GRACE Level-3 Monthly Land Water-Equivalent-Thickness Surface Mass Anomaly in netCDF format to understand the fluctuation of groundwater levels and its correlation with rainfall. The thematic layers of geology, geomorphology, land use pattern, drainage, DEM, slope, NDVI and lineament density have been generated in GIS environment. The weighted overlay tool has been applied to the dataset and the resultant map has been correlated with the GRACE dataset using machine learning algorithm. The resultant map depicts that the groundwater storage is depleting in central Maharashtra due to overexploitation. The western Maharashtra region shows the availability of both surface and ground waters and large area under cultivation. The artificial recharge techniques are recommended in groundwater paucity region.

Remediation Strategies for Elevated Iron Levels in the Lower Reaches of the Mahanadi Delta: A Comprehensive Review

SUHANI SRUJANIKA[1]*, Research Scholar, Department of Geology, Savitribai Phule Pune University, Pune (s.srujanika@gmail.com)
Bhavana Umrikar[2], Professor, Department of Geology, Savitribai Phule Pune University, Pune

Abstract

The Mahanadi Delta, situated on the eastern coast of India, grapples with significant challenges related to water quality, particularly regarding elevated iron levels in its lower reaches. Iron contamination in the delta's water sources poses substantial environmental and public health concerns. This abstract provides an overview of remediation strategies tailored to address the variability of iron concentration, Total Dissolved Solids (TDS), and Electrical Conductivity (EC) in the Mahanadi Delta basin. Analysis of water samples collected from various points within the basin revealed notable fluctuations in iron content, with concentrations ranging from 0.5 to 20.0 mg/L. Similarly, TDS levels exhibited variability, ranging from 100 to 7000 mg/L, while EC values ranged from 150 to 18000 µS/cm. Various remediation approaches, including filtration methods such as activated carbon and specialized iron removal filters, oxidation and filtration techniques employing aeration, chlorination, and potassium permanganate treatment, ion exchange resin systems, and reverse osmosis technology, are evaluated in the context of these observed variations. Additionally, the potential application of chemical treatments, magnetic treatment devices, and advanced membrane filtration processes such as ultrafiltration and nanofiltration is explored. The effectiveness of each remediation strategy is assessed considering factors such as water pH, iron concentration, and local environmental conditions. This comprehensive review aims to provide insights into sustainable solutions for mitigating iron contamination in the Mahanadi Delta, ensuring the preservation of water resources and the welfare of communities reliant on these vital ecosystems.

Abstract

Groundwater contamination by fluoride (F-) poses a significant threat to safe drinking water globally, yet our understanding of the processes involved by linking groundwater and aquifer material chemistry is limited. This study thus focuses on characterizing F-mobilization in the hard-rock aquifers of Central India, an area scarcely explored despite facing severe contamination issues. Through exploratory drilling and lithostratigraphic modeling (using Rockworks) of 45 boreholes, we identified water-bearing rocks, including weathered basalt, vesicular basalt, fractured basalt, sandstone of Lameta, and fractured granite. Groundwater and rock samples were collected from the Mandla district of Madhya Pradesh. Groundwater samples were categorized into aquifers using depth plan view maps of different depths using Rockworks. Major anion and cation analyses were done using IC and ICP-OES, respectively. Major ion and total F- analysis in rock samples were done by XRF and CIC (Combustion ion chromatography), respectively. Analysis revealed that F-contamination (concentration >1.5 mg/L) was confined to deeper depths (>35 m bgl) of fractured basalt and granite aquifers, while shallower basalt, sandstone of Lameta, and granite aquifers are safe. This depth-dependent distribution indicates that F-contamination isn't solely controlled by rock type but by the chemical evolution of groundwater along the flow path. Solute mass balance and mineralogical characterization revealed that silicate and carbonate

mineral weathering, consumed dissolved CO2, and increased pH (>8) in deeper aquifers played a significant role in fluoride release. F-mobilization was primarily attributed to ion exchange between OH- in water and structural F- in hydroxy-silicate minerals and fluorapatite. Additionally, ion exchange-driven fluorite dissolution might contribute to F- mobilization. Based on water quality and aquifer properties, the study suggests targeting the sandstone of Lameta and weathered/vesicular basalts (where Lameta occurs at greater depths) for an F-safe drinking water supply. Generally, focusing on shallow aquifers could be a viable strategy for ensuring F-safe drinking water in similar geological and environmental contexts elsewhere.

Application of Bio-waste derived adsorbent obtained from Acacia nilotica and Neolamarckia cadamba fruits for Removal of fluoride from drinking water

NARENDRA KUMAR[1]*, DEPARTMENT OF ENVIRONMENTAL SCIENCE, BABASAHEB BHIMRAO AMBEDKAR UNIVERSITY, LUCKNOW, U.P., INDIA
(narendrakumar_lko@yahoo.co.in)
Aneet Kumar Yadav[2], DEPARTMENT OF ENVIRONMENTAL SCIENCE, SCHOOL FOR EARTH AND ENVIRONMENTAL SCIENCES, BABASAHEB BHIMRAO AMBEDKAR UNIVERSITY, RAEBARELI ROAD, LUCKNOW - 226025, UTTAR PRADESH, INDIA

Abstract

Globally ground water without any treatment serves as the prime source of drinking. However, its natural and anthropogenic contamination due to various ions is posing a growing threat to human beings. and Fluoride contamination in groundwater is a serious concern for millions of people globally. The dissolution of fluoride-containing rocks viz cryolite, fluorapatite, fluorspar, sellaite, fluorite, etc. are the primary sources of fluoride in groundwater. Further, it is released by iron smelters, coal-based thermal power plants, photovoltaic manufacturing units, and the ceramic industries. Excessive concentration of fluoride in drinking water causes skeletal as well as dental fluorosis besides several other illness issues. Over the last two decades, several methods have been explored and applied for the elimination of excessive fluoride from drinking water. Adsorptive removal of F- is considered to be inexpensive and widely applicable. In this study fruit waste of Acacia nilotica, and Neolamarckia cadamba were converted into activated biochar modified by magnesium and named as AN-MgB & NC-MgB, respectively. Both the Biochars were characterized by the scanning electron microscope (SEM), Energy dispersive X-ray spectroscopy (EDX), Fourier transform infrared spectroscopy (FTIR), X-ray diffraction (XRD), particle size analysis (PSA), and pHZPC for their chemical composition and morphology. The biochar was applied to remove fluoride from the solution prepared in groundwater. The de-fluoridation process was optimized in batch experiments against pH, temperature, fluoride concentration in the solution, dose of adsorbent, and contact time. The adsorptive behavior and adsorption mechanism of fluoride on the surface of biochar was checked by using the adsorption isotherms (Langmuir, Freundlich, and Temkin) and kinetics study (Pseudo first, second order, and intra-particle diffusion model) at various dosages and initial fluoride concentrations. The NC-MgB was found to be more efficient adsorbent compared to the AN-MgB. The de-fluoridation capacity of NC-MgB and AN-MgB was found to be 84 and 80 % with 10 mg/L of initial concentration, and at laboratory temperature (25-28oC) in 60 minutes, respectively. Langmuir adsorption isotherm and pseudo-second-order kinetics were found best fitted to both the adsorbent. Results give direction to the sustainable removal of fluoride from groundwater by the application of biowaste with some chemical modifications. Additionally, the utilization of biowaste shall also address solid waste management simultaneously. The tested process poses the potential for commercial application after few technological interventions.

Geological Influences on Water Quality: Implications for Agriculture and Food Security in the Athgarh Basin, Odisha

Shreerup GOSWAMI[1]*, Department of Geology, Utkal University, Bhubaneswar
(goswamishreerup@utkaluniversity.com)
Rosalin Das[2], Fakir Mohan University
Asim Amitabh Pradhan[3], Fakir Mohan University
Madhumita Das[4], Utkal University

Abstract

Water quality profoundly impacts agriculture and food security, particularly in regions with distinct geological formations. This study delves into the Athgarh Formation of Upper Godwana age within Odisha's Mahanadi master basin, spanning 4470 sq. km, which is bounded by latitudes 200 and 200 45’ N and longitudes 850 30’ and 860 E. The Athgarh Formation, characterized by fresh water and lacustrine sediments, significantly influences hydrological processes and groundwater quality. Geological features like Gondwana sediments and basaltic intrusions contribute to the area's hydrochemical characteristics. In the semi consolidated rocks of Gondwana formation the groundwater occurs under phreatic condition in the near surface shallow aquifers and under semi confined to confined condition in the deeper aquifers.

Hydrochemical facies variation and processes in the Athgarh basin were analyzed using graphical representations such as Piper trilinear diagrams and Chadha’s plots. Results indicate the prevalence of alkaline earth metals (Ca, Mg) over alkalies (Na, K), with weak acidic anions (HCO3) surpassing strong acidic ones (Cl, SO4). Most water samples exhibit a Ca-Mg-HCO3 composition, indicative of temporary hardness and rock weathering. However, heightened fluoride and potassium concentrations pose potential health hazards and affect water suitability for irrigation.

Groundwater quality assessment involved calculating a Water Quality Index (WQI) based on 13 parameters, juxtaposed against WHO drinking water standards. Hydrological facies were also evaluated through Piper's trilinear diagrams and Chadha's plots, offering additional insights into cation and anion distributions.

Understanding the interplay between water quality and geological features is vital for sustainable agriculture and food security in the Athgarh basin and analogous regions. This holistic analysis underscores the significance of integrating geological, hydrological, and chemical data for effective water resource management and environmental preservation. Elevated fluoride content and high potassium levels in water quality can detrimentally impact both agricultural productivity and human health. Excessive fluoride concentration in irrigation water can hinder crop growth and yield. Additionally, fluoride accumulation in soil over time can decrease soil fertility and impair microbial activity, further affecting crop productivity, while surplus potassium levels can disrupt soil nutrient balance, adversely affecting crop quality and yield.

Effect of Climatic Conditions on Groundwater Potability in the Hambantota District in Sri Lanka

Ashvin Kamal Wickramasooriya[1]*, University of Peradeniya (awickramasooriya@gmail.com)

Abstract

The Hambantota district, located in the dry zone of Sri Lanka, primarily people in this area relies on groundwater for its water needs. While the Sri Lankan government has initiated efforts to provide piped water to some areas of the district in recent times, these measures have not been sufficient to cater to the entire population. Variations in groundwater quality throughout the year and across different locations have posed significant challenges for the residents. Thus, this study aims to evaluate the suitability of groundwater for drinking purposes, focusing on dry periods (January to March and June to August) and wet periods (October to December). By analyzing 335 groundwater samples collected by the National Water Supply & Drainage Board, this research assessed the viability of groundwater as a drinking water source in Hambantota. The analysis involves establishing Pearson correlations among eight variables: Total Dissolved Solids, Magnesium, Chloride, Sulphate, Total Iron, Nitrate, Total Hardness, and Fluoride. Furthermore, the Water Quality Index (WQI) is computed using descriptive statistics. Spatial distribution maps for each parameter and the WQI are generated using ArcGIS software based on secondary data. The findings indicate that, during dry periods, only 13% and 28% of the area exhibit excellent and good groundwater quality for drinking, respectively. The majority of the area, comprising 6% poor, 5% very poor, and 48% unsuitable classifications, experiences inadequate groundwater quality during dry periods. Conversely, during wet periods, approximately 19% and 37% of the area demonstrate excellent and good drinkable groundwater quality, while 4%, 3%, and 37% exhibit poor, very poor, and unsuitable drinkable water quality, respectively. Hence, the groundwater quality is notably better during wet periods than dry periods. Additionally, correlation analysis reveals a strong relationship between WQI and total Iron (R= 0.96) as well as between WQI and total alkalinity (R=0.92). These outcomes underscore the impact of climatic conditions on groundwater quality for drinking purposes.

Monitoring studies within the Orto-Alish artesian basin (Kyrgyzstan) under climate change conditions.

Dmitrii PLAKSIN[1]*, KCHGE (dmit.plaksin@gmail.com)
Jaana Lohva[2], GTK
Salla Valpola[3], GTK
Petri Valasti[4], GTK

Abstract

Since 2008, Geological Survey of Finland (GTK) has had cooperation projects in Kyrgyzstan with the Kyrgyz Geological Survey under the Ministry of Natural Resources, Ecology and Technical Supervision of the Kyrgyz Republic (KGS). The projects are funded by the Ministry for Foreign Affairs of Finland.

The ongoing project increases KGS capacity to improve the monitoring and reporting of groundwater and environmental risks as well as the ability to create a sustainable management system of monitoring data for rational use of natural resources and balanced decision making. Advanced capacity to produce information on groundwater resources and environmental impacts is implemented by applying integrated hydrogeological and geophysical monitoring and modelling techniques to a groundwater reservoir. Integrating all monitoring data and interpreted geoscientific observations will provide a basis of the structure of the aquifer as well as a conceptual model of the aquifer. Methods learned during the project can later be applied also on the monitoring of contaminated water and soil. The availability of continuous monitoring data is one key element when assessing the risk pollution can cause to health and environment and adopting appropriate methods to mitigate impact.

The Orto-Alish multilayer groundwater aquifer occupies the western and central parts of the Orto-Alish intra-foothill depression on the northern slope of the Kyrgyz ridge. The slightly undulating surface of the site is formed by the merging alluvial cones of the Alarcha and Alamedin rivers. The depression is bordered from the north and west by Paleogene-Neogene sediments, from the south by the mountain massif of the Kyrgyz ridge, composed of Mesozoic rocks. The bed of the depression is also represented by Paleogene-Neogene sediments.

The Orto-Alish multilayer aquifer in a thick layer of alluvial-proluvial Quarternary sediments is characterized by favorable groundwater recharge conditions and varies from confined to unconfined. The total thickness of the aquifer can reach 450-500m. The hydraulic conductivity varies within a wide range of 10-100m/day. As depth increases, hydraulic conductivity decreases to 5-10 m/day or less.

The main part of Orto-Alish multilayered aquifer, especially confined layers, consists of quaternary, well-washed sediments, represented by boulder-pebble and mixed-pebble sediments, mainly with sand and gravel filler. In some places there are lenses and lumps of loam and sandy loam. In the lower parts of Quaternary sediments - sediment of conglomerates appears. The main chemical composition of water is bicarbonate-calcium, up to 1 g/l.

Monitoring of groundwater wells and geophysical studies has been carried out on the site during 2023-2024. Geophysical fieldwork consisted of 6 ERT- and IP-profiles at three different sites on the aquifer. The aim of the studies was to delineate geological structures for better understanding on groundwater accumulation and flow patterns. Each of the three sites had a groundwater well next to geophysical profile(s). These studies provide the geological framework for the aquifer structure model and upcoming groundwater flow modelling as well as give useful information on water resources managements in the area.

Groundwater change and sustainable management using monitoring wells in the Kanto Groundwater Basin, Japan

Kunio FURUNO[1]*, Former Research Institute of Environment Geology, Chiba
(kuniofurunojp@gmail.com)
Atsushi KAGAWA[2], Research Institute of Environmental Geology, Chiba

Abstract

Background:
The Kanto region including Tokyo has been using groundwater and natural gas from the fluid resources of the Kanto groundwater basin.
However, the land suffered subsidence due to excessive pumping, causing serious damage by the early 1970s.

Monitoring System:
Land subsidence and the groundwater level monitoring system in the Kanto region has been developed mainly by local governments following the progression of land subsidence in the Tokyo metropolitan and surrounding area. In 1952 the Tokyo Metropolitan Government began monitoring land subsidence and groundwater levels by monitoring wells, eventually leading the other local governments throughout the Kanto Region to adopt monitoring their groundwater levels. In the 1960s, monitoring was expanded mainly in the southern Kanto region, after which the monitoring network was aimed at the northern Kanto region as well. The number of monitoring wells is 375 in 1982, 459 in 1991, 476 in 2010, and 377 in 2018 (excluding Ibaraki prefecture).
Recently, the number of monitoring wells is decreasing in many local governments, although the situation is different for each local government. We think that the reason of the decreasing is because the perspective of managing the groundwater basin using monitoring wells for effective utilization is lacking.

Groundwater Level:
The groundwater level maps show that the groundwater levels dropped the most in 1971 in Tokyo's Koto Ward reaching 60m below sea level. However, since the early 1970s, groundwater levels in the southern Kanto region have continuously risen due to regulations on groundwater pumping and changes of economic conditions.
But groundwater levels in the northern Kanto region had declined in some areas. Overall, the groundwater levels have slightly risen more recently. The groundwater level map shows a basin-like shape centered on the contour line of the lowest groundwater level of -50mTP (TP means mean sea level in Japan) in the Koto district of Tokyo in 1964.The lowest groundwater level contour line was -60mTP in 1971, -40mTP in 1975, -30mTP in 1984, and-20mTP in 1990, and gradually increased. The groundwater level continued to rise slightly after that, reaching -10mTP

in 2003. Since then, there has been no significant change, and the lowest contour continues at -10mTP.The groundwater level has increased slightly overall recently.
The groundwater level in 2020 is as below. In the central part of the groundwater basin where the groundwater level is the lowest, the -10mTP contour line is visible. In the northern part of the basin, Gunma Prefecture is +80mTP, Tochigi Prefecture is +70mTP, and in the northwestern part of the groundwater basin, the groundwater level is +60mTP in the northwest of Saitama Prefecture. In the western part, +80mTP is visible in the northwestern part of Tokyo, and +50mTP is visible in the central part of Chiba Prefecture in the southeastern part of the groundwater basin.

Cases of Groundwater Dam Construction in Areas of Poor Water Supply

Hyun Jin PARK[1]*, K-water (ehjpark@kwater.or.kr)

Abstract

Recently, it is becoming more difficult to secure stable water resources in Korea due to weather changes cause by global warming, for instance repeated droughts and unprecedented torrential rains, and reduced stability in dam water supply. In order to an effectively measure to this, a groundwater dam construction has been promoted. This study introduces the construction of domestic groundwater dams as examples of securing water sources.

A groundwater dam is a stable and eco-friendly water resource facility that stores groundwater by raising the groundwater level by installing an artificial water barrier in the underground aquifer. Groundwater dams can retain a certain amount of water by preventing the loss of water due to evaporation or freezing and maintain good water quality by natural filtration of aquifers. In addition, it can minimize environmental destruction because there is no submerged water storage area.

In five places including Ian and Namsong, groundwater dams were constructed for agriculture as part of measures after the severe drought in the early 1980s. Moreover, it has been constructed for living in Ssangcheon, Sokcho. In the past, groundwater dams were used as a city unit water supply plan for agriculture and local water supply, but recently, construction projects are underway in areas where water supply is difficult. The groundwater dam construction project has been carried out in three island areas to realize steady water supply. Starting with Daeijak-do in Ongjin-gun, the first facility in the island, in 2020, it was constructed on Anma-do in Yeonggwang-gun (2021) and Bogil-do, Wando-gun(2023).

In the future, if it is continuously expanded and promoted for the island and inland vulnerable areas of poor water supply, a groundwater dam will be an effective measure for water welfare.

Geospatial Assessment of Drought Vulnerability in Nira River Basin, Western India

PAYAL WAINDESHKAR[1]*, Research Scholar, Department of Geology, Savitribai Phule Pune University, Pune (payalwaindeshkar123@gmail.com)
Bhavana Umrikar[2], Professor, Department of Geology, Savitribai Phule Pune University, Pune

Abstract

The integration of geospatial tools along with the Analytic Hierarchy Process (AHP) proves highly effective in conducting extensive drought vulnerability assessments. Droughts vary in intensity and type based on spatio-temporal contexts, underscoring the importance of understanding their occurrence for effective mitigation planning. This study specifically focuses on delineating drought-prone areas within the sub-watershed of the Nira River Basin in western India. Ten key parameters, including NDVI, rainfall, DEM, slope, land use/land cover (LULC), the density of water harvesting structures, well density, geomorphology, drainage density, and lineament density, are considered in this analytical hierarchy process. AHP is utilized to determine the relative importance of each parameter by constructing pairwise comparison matrices. The cumulative impact of these factors generates a drought severity zonation map, revealing that approximately 20% of the area is experiencing severe drought, with 39% falling within the range of moderate drought. Specific villages such as Palashi, Atit, Jawale, Mirje, Lohom, and Kesurdi fall under moderately drought-prone zones, while parts of Ghadgewadi, Limbachiwadi, Kanheri, and Zagalwadi Karnawadi are situated in severe drought zones. This comprehensive mapping aids in preparedness planning and the provision of relief measures to address drinking water scarcity in affected villages, contributing to more resilient communities in drought-prone regions.

Long term base flow assessment according to land use and climate change on Yeongsan and Seomjin river basins, South Korea

Kyoochul HA[1]*, KIGAM (hasife@kigam.re.kr)
Hyowon An[2], KIGAM

Abstract

Base flow refers to the flow of groundwater from an aquifer into a river. Compared to surface runoff, which flows into a river or onto the surface after rainfall, base flow is the outflow of groundwater from an aquifer into a river. Therefore, river does not dry up even when there is no rainfall due to base flow. Base flow occurs when groundwater from an aquifer flows into a river, so if groundwater use increases, the amount of groundwater that can flow out into the river decreases, so the amount of base flow cannot help but decrease. In addition, base flow is bound to fluctuate due to natural and anthropogenic factors such as land use change and climate change. In this study, we attempted to separate base flow from long term river flow data in the Yeongsan and Seomjin river basins and evaluate and identify the causes of long-term base flow variations. The river discharge data were collected and analyzed from 2006 to 2021 for more than 10 years. We selected basins where river discharge data existed during the relevant period, and 7 locations in the Yeongsan river basin and 14 locations in the Seomjin river basin and established a Database through the hydrological observation yearbook provided by the Korea Flood Control Office. Land use data provided by the Environmental Spatial Information Service (http://egis.me.go.kr) was collected and established in a GIS format. Base flow was analyzed using the USGS PART program. As a result of the analysis, land use decreased in urban areas and farmland (fields, rice fields), and in forests, coniferous forests in particular decreased and broad-leaved forests increased, which is believed to reflect the impact of climate change. It was confirmed that base flow and river discharge vary widely by basins, and are high in the summer when precipitation is high. Accordingly, base flow increases, but base flow ratio relative to total river discharge actually decreases. As a result of reviewing river discharge and base flow data during the periods, they were fluctuating in close relation to precipitation, but did not show a clear trend by year. Larger basins had smaller base flow fluctuations than smaller basins. And, the relationship between groundwater uses and base flow did not appear clearly during the analysis period. This is due to the fact that flow monitoring points have been artificially influenced by the development of dams, reservoirs, and the installation of water resources facilities such as waterworks. In the future, it is necessary to reveal the relationship between base flow and groundwater use, changes in groundwater levels and water quality.

Observation and Characterization of Rapid Infiltration and Runoff Processes in Karst Hillslopes

Jun Zhang[1]*, Institute of Subtropical Agriculture, Chinese Academy of Sciences
(zhangjun@mails.ccnu.edu.cn)
Hongsong Chen[2], Institute of Subtropical Agriculture, Chinese Academy of Sciences

Abstract

Karst landforms are renowned for their rapid surface and subsurface hydrological processes. This can be attributed to the high solubility of carbonate rocks, which contribute to the unique two-dimensional and three-dimensional hydrogeological structure of the surface and subsurface. The surface soil layer is shallow and highly permeable, while underground pipe fractures are common. Describing and quantifying the intricate rapid hydrological processes in karst critical zones has long been a focal point for hydrologists.

In this study, we examined a representative karst slope composed of limestone in southwest China. By conducting long-term monitoring of hydrological and meteorological data, as well as isotopic analysis, we explored the movement, redistribution, runoff generation, and connectivity processes of rainfall at the hillslope scale within the soil-epikarst system in the karst critical zone. We elucidated the effects of the critical zone structure, characterized by varying soil thickness, on runoff components and their sources, infiltration rate, and threshold behavior.

Remarkably, the study discovered that the proportion of "young water" in the soil moisture on the karst upslope can reach 100%. The soil moisture infiltration rate and response time are significantly higher compared to non-karst areas. We highlight the crucial role of the soil-epikarst interface in hillslope hydrological connectivity processes. The research findings can provide a scientific basis for further deepening our understanding of karst hydrological processes and regional water resources management.

[Keynote] Hydrological processes in karst critical zones in southwest China

Hongsong Chen[1], Institute of Subtropical Agriculture, Chinese Academy of Sciences
Zhiyong Fu[2], Institute of Subtropical Agriculture, Chinese Academy of Sciences
Fa Wang[3], Institute of Subtropical Agriculture, Chinese Academy of Sciences
Sheng Wang[4], Nanning Normal University
Jun Zhang[5]*, Institute of Subtropical Agriculture, Chinese Academy of Sciences
(zhangjun@mails.ccnu.edu.cn)

Abstract

The karst region in southwestern China is one of the three major concentrated distribution areas of karst landforms in the world, and it boasts the most diverse karst landscapes. The strong solubility of carbonate rocks makes the hydrogeological structure of the karst critical zone extremely complex. The surface soil layer is shallow, highly permeable, and discontinuous. Underground, a complex network of conduits and fractures forms the epikarst zone, which is distinct from the core area of non-karst critical zones. Since 2004, our research team has conducted long-term hydro-meteorological and isotope tracing monitoring in a typical karst small catchment, aiming to systematically understand the complex multi-interface hydrological processes within the soil-epikarst system. The main contributions are as follows:

(1) The features of the soil-epikarst structures are clearly identified through geophysical exploration. The thickness of the soil and epiakrst co-evolved spatially in the small catchment (~1 km2), with both thickness decreasing with increasing elevation on the hillslopes. The weaker the degree of weathering, the shallower the soil thickness, and the higher the coupling degree between bedrock and surface topography in the small habitat (~100 m2).

(2) The multi-interface runoff mechanism affected by the rock-soil structures is analyzed on the hillslope. The surface runoff coefficient is less than 5% and satisfies the "infiltration-excess and saturation-excess" mode. Simultaneous attaining of rainfall amount and intensity thresholds is a prerequisite for runoff generation. Subsurface runoff is suitable for the "fill and spill" (saturation-excess mechanism) process, with the soil-rock interface acting as the "link" where uphill vertical flow is transformed into lateral flow in low-lying areas. Soil thickness serves as a primary controlling factor to characterize critical zone structure (weathering intensity) and runoff relationships, being positively correlated with surface runoff and negatively correlated with subsurface runoff.

(3) The mechanism of runoff recharge is elucidated in the small catchment. In both seasonal and rainfall event scales, epikarst runoff is the main source (>83%) of recharge for springs and stream water. Fractured soil-rock mediums are prone to the development of perennial springs, with matrix flow and gravity water recharge accounting for 77%, which is related to the increased water residence time associated with thicker soil-epiakrst hydrogeological storage function. Weakly weathered soil-rock mediums form cracks and pipes easily, resulting in the formation of seasonal springs, with poor continuous water recharge capacity, and only 10.5% of the water recharge coming from the matrix flow and gravitational water.

Accordingly, our exploratory and multi-layered research emphasizes the strong influence of soil-rock structure on hydrological processes in karst critical zones. Future work will continue to focus on the coupled mechanisms of the soil-bedrock structure and vegetation in multi-interface runoff processes.

Coupled physically based hydrologic model and transit time theory (SWAT-SAS) for simulating the eco-hydrological process in karst basins

Wuhua LI[1]*, South China University of Technology (ctliwuhua@mail.scut.edu.cn)
Xiangju Cheng[2], South China University of Technology
Dantong Zhu[3], South China University of Technology

Abstract

Heterogeneity is common in hydrological systems and leads to variations in hydrological properties and further differences in eco-hydrological processes. Despite the heterogeneity, it is still popular to consider hydrological systems as homogeneous systems when conducting hydrological simulations based on physical processes. Karst systems are probably the most extreme case of subsurface heterogeneities, and the simulations for karst basins highlight the limitations of the oversimplification of subsurface processes in the present hydrologic models. There have been extensive studies to develop or modify models to capture the karst features. However, these efforts are mainly developed to fit the flow behaviors and may be significantly biased when simulating the solute dynamics. The increasing importance of karst water for human water supply under the influence of climate extremes and, on the other hand, the intensified anthropogenic activities in karst areas require in-depth studies of the eco-hydrological processes in karst areas to cope with the changing environment. The transit time is a descriptor of pathways within a system, which links the flow and solute transport in a unified framework. We propose to use transit time theory to improve the subsurface transport process in hydrological models. The coupled model is more representative of karst subsurface heterogeneity, and the parameters of the transit time model reflect how the system releases water of different ages. With such information, the variations in groundwater pathways and the transport processes in karst areas can be explored and information on the water age in storage and outflows supports the assessment of hydraulic exchange timescales as well as the nutrient legacy.

Geospatial patterns in the hydroecological characteristics of surface waters in the karst area of Samcheok, South Korea

Regina Martha Gabest LUMONGSOD[1]*, Kangwon National University (rmgl@kangwon.ac.kr)
Heejung Kim[2], Kangwon National University

Abstract

Karst environments are unique, especially in terms of hydrology, due to the high solubility of its bedrock. Subsurface drainage is more complex than that of the surface the two are usually directly connected through landforms such as caves and sinkholes, so they are very sensitive to environmental changes. Samcheok, found in the southeast part of Gangwon province, is an area with carbonate bedrock that underwent (and is still undergoing) dissolution, forming an extensive karst landscape. In this study, the hydroecological characteristics of surface water samples from four different streams (Osipcheon River, Yeosam Stream, Sohan Stream, and Gyogok River) located in the northeast part of Samcheok karst which were sampled during two different seasons (February (winter) and April (spring) 2020) were geospatially analyzed through a Geographic Information Software (GIS). Preliminary results reveal that while the abundance of major ions was mostly varied spatially in the study area, they were dependent on the stream where the samples were taken from more than the sampling distance from the coast. Usual patterns for pH and dissolved oxygen with respect to water salinity were absent. Cation and anion concentrations mostly varied between the two seasons and in terms of linear correlation for concentration vs. distance to stream outlet plots. High linear correlation was observed for samples from Gyogok River for Ca2+ (R2 = 0.976), Mg2+ (R2 = 0.9321), SO42- (R2 = 0.879), and HCO3- (R2 = 0.955). The relative abundance of Actinobacteria in sample points along Sohan Stream was lower inland than near the outlet, while the relative abundance of Proteobacteria showed almost the opposite. Observing the geospatial patterns for hydroecological parameters, especially in areas vulnerable to the effects of climate change and pollution such as karst areas, is helpful in identifying priority areas for future work. This research was funded by the Basic Science Research Program through the National Research Foundation of Korea funded by the Ministry of Education (Nos. 2019R1I1A2A01057002, and 2019R1A6A1A03033167).

Hydro-ecological processes of hyporheic zone and the function degradation in karst spring-fed pools

Fang GUO[1]*, Institute of Karst Geology, Chinese Academy of Geological Sciences (gfkarst@126.com)
Guanghui Jiang[2], College of Civil Engineering and Architecture, Guangxi University
Liqiong Wei[3], Institute of Karst Geology, Chinese Academy of Geological Sciences

Abstract

The frequent transformation of groundwater and surface water in karst water systems leads to the formation of diverse hyporheic zones. The interaction mechanism, degree, and impact on karst groundwater environment of these hyporheic zones are still unclear, which hinders the management and sustainable utilization of water resources. Most karst groundwater is highly developed and utilized. Some springs in karst area outcrop along the river. These springs are usually water supply sources and are highly exploited. Under this situation, spring outlets connect with rivers and they have frequently but casually interaction. The hyporheic zone owns the most active biogeochemical processes and plays a variety of functions. Therefore, it is necessary to set up the concept of spring hyporheic zone to study this special kind of hyporheic zone and to explain the reasons of groundwater deterioration. Take three important springs with similar geological background but different patterns of groundwater and surface water and submerged plant degeneration as the case studies, the dynamic processes of spring and river interaction were studied through high-precision hydrological monitoring, dye tracer test and isotope analysis. Based on the different of interaction patterns and degrees, the concept and meaning of spring hyporheic zone were discussed. In karst water systems, in addition to groundwater discharged from spring outlets and surface water, there are also water sources with different properties stored in different karst media, resulting in various forms of interaction. The reason for the formation of spring outlet hyporheic zone is determined by the differences in karst hydrogeological conditions, water storage space, and hydrological conditions. The hydrological process of karst springs is significantly controlled by artificial water storage and flood discharge in rivers. The spring-fed pool water conditions can be distinguished as high, medium, and low-water level periods in a hydrological year. The high-water level accounts for less than 1% in a year, while it is associated with the hydrological regimes of backflooding states. The inflow of river backflow was found to be 4.4 times that of the natural discharge of spring water during a rainfall event. Despite turbidity returning to normal levels after 56 hours, E.coli continued to persist for an extended duration. Based on these, the causes of function degeneration in spring hyporheic zone and the measures to improve the function was provided.

Abstract

Water age in plant transpiration reveals important processes of water dynamics in the soil-plant-atmosphere continuum, which is regulated by the structure-induced water variability and availability in the earth critical zone. In this study, we focus on the similarities and differences in the transpiration water age of typical plants in karst and non-karst critical zones under five different climates. Variations in root-zone water replenishment are estimated based on stable isotope compositions of precipitation and plant xylem water, and a piecewise linear mixing water age model is employed to quantify water ages in plant transpiration. The results show that water ages in transpiration are very dynamic in all climates with a range between 1 and 229 days. Water replenishments in the root-zone reveal whether and how much precipitation enters the root zone. Climate patterns control median (mean) water age in plant transpiration but modified by rooting depth. In wet climates, plants mainly rely on water source that originates from precipitation in the current month (accounting for about 60% on average of their water sources), while plants in dry climates largely rely on water source that originates from precipitation fallen on previous months/seasons. In addition, the mean water age for plant transpiration is shortest in the karst critical zone compared to other critical zones, indicating that the soil-rock structure of the critical zone affects the water age in plant transpiration by regulating the distribution of plant roots and the water storage capacity of the root zone. Our study provides an alternative way to reveal the precipitation partitioning in root-zone and seasonal changes in plant water use of precipitation, which highlights different vegetation responses to water variability between earth critical zones.

Development construction of water resources in karst peak cluster depression based on subsurface and vadose zone hydrological processes

Fan LIU[1]*, Institute of Karst Geology, Chinese Academy of Geological Sciences
(liufancags@126.com)
Guanghui Jiang[2], School of Civil Engineering and Architecture, Guangxi University

Abstract

The karst peak cluster depression is a typical karst landform in southwest China. Rural residents often reside in flat areas at the bottom of karst depressions and engage in agricultural activities on the surrounding flatlands and gentle slopes. The lack of water resources is the main factor restricting the local economic development. The high infiltration coefficient in the bare karst peak cluster depression results in a severe scarcity of surface water resources, which is also the main reason for the vulnerable state of the karst environment. Geological conditions in the karst peak cluster depression contribute to the significant depth of karst groundwater resources in the area. Under extreme climatic conditions, meteorological drought can easily transition into hydrological drought, worsening the scarcity of accessible water resources. The distribution of water resources in the bare karst peak cluster depression showcases the equilibrium between human activities and water within a distinctive geological and geomorphological setting. It is significant to maximize the acquisition of water resources while minimizing environmental impact in such conditions. The subsurface hydrological processes, such as epikarst runoffs and hydrological processes occurring in karst vadose zones, play a vital role in the development of water resources in this area. For subsurface hydrological processes, distributed water tanks are a significant measure to address seasonal water shortages. It involves expanding slope surfaces to collect precipitation, reducing slope infiltration coefficients, stabilizing vegetation and soil, and accumulating epikarst springs. In contrast to transient processes like precipitation and slope runoff, the prolonged discharge of epikarst runoff spanning multiple months significantly contributes to the accumulation of water resources. This enhances the reliability of water resources during dry periods, thereby serving a crucial function in mitigating droughts. According to the analysis of the observed water level duration curve of the epikarst spring, there is an estimated 78% probability that the outflow could serve as an additional water supply for the water tank. In the natural state of a hillside, only 2% of the rainfall contributes to surface runoff. The potential for water supply by the karst vadose zone of peak cluster depressions also deserves attention. The natural pools within cave systems in karst peak cluster areas are formed by the accumulation of cave-dripping water and flowing water, making them focal sites for water resource development. The prolonged dripping in caves can help recharge water resources, with the water showing a relatively low conductivity level of less than 200 μS/cm. This is in contrast to the high conductivity level exceeding 500 μS/cm observed in epikarst water. The elevated location of the karst caves provides favorable conditions for constructing infrastructure for water resource development and utilization.

Examining the Changes in Karst Spring Flow Over an Extended Gauging Period: Impact of Climate and Vegetation Recovery

Guanghui JIANG[1]*, College of Civil Engineering and Architecture, Guangxi University (bmnxz@126.com)
Fang Guo[2], Institute of Karst Geology, Chinese Academy of Geological Sciences

Abstract

To deepen our understanding of the hydrological processes and sensitivity of bared karst in southern China, long-term observations were conducted on a karst spring within a peak-cluster depression to examine trends in flow variation. The selected karst spring watershed encompasses three karst dolines covering an area of only 1 km2. Over the past 40 years, significant changes in vegetation have occurred, with formerly heavily deforested grasslands and shrublands transitioning into shrublands and locally mixed shrub and tree forests under the natural recovery conditions of sustained afforestation. Multi-year observations indicate a range of flow variations in the karst spring, from 0 to 2500 l/s, with average flows ranging from 13 to 58 l/s and annual runoff volumes from 0.4 to 1.8 million m3. Notably, 90% of the flow occurs between May and July, with only 10% occurring between August and January. The longest dry season flow cessation period lasted 154 days. Calculations based on flow recession hydrographs yielded an average porosity of the watershed of only 0.06%, demonstrating an efficient drainage capability and limited storage capacity within the karst spring system. Dynamic observations of cave ceiling stream and hillslope seeps revealed rainfall thresholds of 16 mm and 38 mm, respectively, for hillslope runoff generation, and an overall rainfall threshold of 81 mm for karst spring system recharge, confirming its low storage capacity. Cumulative rainfall infiltration coefficients showed minimal fluctuations over multi-year scales, stabilizing at 0.38 before 2015, increasing to 0.45 after the extreme high-flow year of 2015, and subsequently stabilizing at 0.41. The current rainfall infiltration coefficient shows an increasing trend compared to the 0.37 value observed in 1986. For soil-scare bared karst area, the efficient drainage and limited storage capacity restrict vegetation water consumption. Additionally, vegetation mitigates flash floods, reducing the proportion of rapid runoff while increasing slow runoff, thereby enhancing the karst spring system's storage capacity by retaining more rainfall within the aquifer. Given the complex storage processes of karst aquifer systems, current hydrological models are insufficient to predict changes in storage processes resulting from climate and vegetation variations. The study recommends conducting field experiments and establishing more complex monitoring networks to achieve fine-scale observations of storage processes and elucidate storage mechanisms.

DETERMINATION OF PETROLEUM PRODUCTS IN WASTEWATER BY GRAVIMETRIC METHOD

MUNISXON MEYLIYEVA[1]*, hydrogeology (munisxon.88@mail.ru)

Abstract

Petroleum products are among the most common and dangerous substances that pollute surface and underground water. Most of the oil products enter the water during the transportation of oil, wastewater of enterprises, and domestic water. The presence of petroleum products in water is one of the main reasons why water becomes unfit not only for consumption but also for various household needs.

Therefore, one of the urgent problems is the selection of high-precision and effective methods for periodic chemical analysis of petroleum products contained in wastewater.

An aluminum oxide column was used to separate the organic solvent and hydrocarbon components as an extractant in the gravimetric method.

Chloroform and hexane, a low polar hydrocarbon with a boiling point of 36 oC to 69 oC, were used as extractants. Standard samples such as n-decane (C10H12), n-eicosane (C20H42) or hexadecane (C16H34), and n-tetracontane (C40H82) were used as a test and comparison sample.

The sample of wastewater brought for testing was extracted using an organic extraction agent, and the obtained eluate was dehydrated, first in a water bath, and then dried in the open air. The amount of petroleum products (mg/dm3) was found by weighing the dry residue.

According to the results of gravimetric determination of the amount of oil products in the water samples taken from the monitoring wells located around the Fergana oil refinery, the amount of total oil products in the water sample taken from the wastewater outlet is 25.82 mg/dm3, the amount of oil products in the water sample taken from the monitoring well ˂0.5 mg/dm3.

Summary:

Since the gravimetric method of oil product analysis during our scientific research did not allow us to determine when there is a small number of oil products in water, we concluded that it is not possible to analyze oil products in the samples taken from observation wells and water facilities using the method, and the lower limit of the measurement range is 0.5 mg/dm3 possible Also, the advantage of the method is that no pre-calibration of the measuring instrument is required. Therefore, the method can be accepted as an arbitration method.

The water samples taken for analysis were carried out for quantitative analysis at the "Geoecologist-chemistry" laboratory accredited under the requirements of ISO/IEC 17025: 2017 at the "Institute of Hydrogeology and Engineering Geology" State Establishment, and the method was verified. Based on the obtained results, it was proposed to use the existing "Hydrochemistry" laboratories in our Republic in cases where the amount of oil products in wastewater is higher than 0.5 mg/dm3.

Assessment of Groundwater Drought Evolution Over Two Decades in Korea Using Storage-Based Approach

Anuradha Karunakalage[1]*, Indian Institute of Technology Roorkee (anuradha_s@es.iitr.ac.in)
Jin-Yong Lee[2], Department of Geology, Kangwon National University
Mohammad Taqi Daqiq[3], Indian Institute of Technology Roorkee
Jihye Cha[4], Department of Geology, Kangwon National University
Jiwook Jang[5], Department of Geology, Kangwon National University

Abstract

Groundwater is a vital component of the Earth's freshwater resources, serving as a primary source of drinking water and irrigation worldwide. Moreover, the demand for groundwater resources has been increasing significantly in agricultural sector of the Republic of Korea, a country particularly vulnerable to the impacts of climate change due to its monsoonal climate. Therefore, continuous monitoring, identification, and quantification are essential steps in managing groundwater resources to ensure sustainable water usage. In this context, satellite remote sensing has emerged as a valuable tool, providing regional to global coverage of changes in hydrological cycle fluxes. Among these missions, the Gravity Recovery and Climate Experiment (GRACE) satellite stands out for its integrated measurements of monthly water storage variations in surface and subsurface hydrological fluxes. The GRACE mission has broadened the horizons of the development of more precise identification techniques that can characterize the progression of drought conditions and quantify their severity in space and time. The current study introduces a quantitative method to assess the occurrence and intensity of groundwater droughts, utilizing long-term Groundwater Storage Anomalies (GWSA) derived from GRACE data. GRACE measurements are employed to compute the extent of deviations in monthly GWSAs from the monthly groundwater climatology within the time series, with negative deviations indicating storage deficiencies. The monthly deficits quantify the groundwater storage required to restore normal subsurface water storage conditions. This study integrates the storage deficits with the duration of events to determine the severity of droughts. The workflow of the study has been developed to estimate different possible time scales of drought recovery for identified drought events using the empirical distribution of the rate of change in the groundwater storage deficit. This study has identified thirteen groundwater drought events spanning two decades in Korea, including notable historical droughts in 2012-2013, 2015-2016, and the most recent one in 2019-2020. The study emphasizes the time lag between precipitation deficits and groundwater drought occurrences, alongside the protracted duration required for drought recovery, contrasting with the relatively rapid amelioration of surface drought conditions. Consequently, it underscores the inadequacies of precipitation deficit-based drought indices while suggesting the viability of storage-oriented methodologies for assessing groundwater drought severity and estimating recovery periods. The results of the current study, along with continuous monitoring of groundwater drought and the estimation of drought statistics using new GRACE data, hold the potential to significantly enhance policymaking and groundwater management efforts for sustainability.

Suggestions for Korea's groundwater use and management in the era of climate crisis

Kang Kun LEE[1]*, Seoul National University (kklee@snu.ac.kr)

Abstract

Due to climate change, the amount of precipitation in Korea is gradually increasing, but the annual variability is large and the frequency and intensity of heavy rain are increasing. These changes in precipitation patterns can be a factor that can reduce groundwater recharge. Increasing forest density can also reduce the amount of groundwater recharge. In addition, pollutant emissions from residential areas, industry complex, and agricultural and livestock activities are threatening groundwater quality and are reaching a level that cannot be ignored. The Republic of Korea enacted the Integrated Water Management in 2022 based on law to manage surface water and groundwater in an integrated. Therefore, Korea's water management frame is moving towards analyzing and managing surface water and groundwater in the same watershed unit. As of 2019, total groundwater use amounted to 2.91 billion m3 accounting for 7.64% of the total water use in Korea. 99% of groundwater is used for farming, fishing and agriculture, so in the future, groundwater needs to be utilized for drinking or other purposes with higher economic value. In the current situation, groundwater is used for purposes of low economic value, and there is a lack of motivation to invest budget into groundwater conservation. Based on natural water quality, a systematic direction is needed to utilize and conserve groundwater, which has better water quality than surface water. In Korea, groundwater discharge is occurring in connection with various underground facilities, including subways, and it is recommended to use this as a water resource or as a heating and cooling energy resources. In order to respond to drought by utilizing groundwater, a project to artificially recharge groundwater using artificial reservoirs is also being led by the government. I believe that these efforts are not sufficient to ensure a stable supply of water resources in Korea in the era of climate crisis. In order to respond to the extreme drought caused by the climate crisis, a public groundwater well-network system that can supply all residents a certain amount of water even during severe drought should be established.

Case Study on the Operation of Hybrid Artificial Recharge Circulation System in Drought-Prone Areas

Gyoo-Bum KIM[1]*, Daejeon University (geowater@dju.kr)

Abstract

Recent climate changes on the Korean Peninsula are causing an increase in the frequency and intensity of droughts. In particular, rapid water discharge occurs in the small basins of the upper watershed, leading to a high likelihood of water shortages in the spring. To increase the total amount of water in the upper watershed, a structural system that minimizes water discharge and allows for long-term storage is necessary. Despite the significant reduction in the flow of small streams during the dry season, the base flow discharged from groundwater maintains a consistent level. Utilizing such base flow as the injection source for groundwater artificial recharge and storing it within the basin's strata can increase and maintain the total amount of water over a long period. The hybrid-type groundwater artificial recharge system adopts a method of using base flow as the injection source, storing it within the basin sediments, and then drawing water from horizontal collection wells downstream for supply. The water supplied to farmlands can then be recharged into the strata, creating a cyclical effect. The injection was carried out through four lines within the basin using a mixed method of ditches and wells, with injection volumes ranging from 100 to 400 m^3 per day and withdrawal volumes ranging from 200 to 500 m^3 per day according to water demand. During the two years of operation, there were no significant changes in injection or withdrawal volumes, but continuous evaluation is necessary for clogging caused by iron and manganese. Such artificial groundwater recharge systems are considered to be a good solution for water issues in the era of climate change, and it is hoped that more systematic research on the operation of these facilities will continue.

Sung-Ho Song[9], Korea Rural Community Corporation

Abstract

Groundwater is considered to be the best water resource to solve water shortage problems during drought periods. Even though excessive pumping (overdraft) during short-period may give an unprofitable effect on groundwater hydrology, it has a primary role to solve a lack of water resources and to maintain incomes of farmers. This study was conducted to estimate an amount of the agricultural groundwater demand and supply in a frequent-drought area, where has required an optimal distribution plan of groundwater resources using the well-network system (WNS). The WNS has been considered to be an alternative for evenly supplying groundwater resources to farmlands by connecting groundwater wells physically or virtually, either. The study area has significantly depended on groundwater resources for its irrigation water up to 53% due to a lack of surface water resources. Two kinds of methods, HOMWRS software and FAO approach, were used for estimating irrigation water requirements for paddy and upland fields for the study area, respectively. During the latest 10 years (2010~2019), a total amount of requirements was estimated to be an average 1,106 /day. For the active farming periods (May to September), the requirements were notably increased of ranging in 1,121~4,004 /day, which has already exceeded a total yield of pre-existing groundwater wells (2,356 /day) in this area. Detailed and definite determination for groundwater demand and supply helped to determine an optimal scale of the WNS. The WNS has achieved an optimal distribution of groundwater resources and solved imbalance on irrigation over the study area.

Enhancement of denitrification using agricultural biproducts and limestone for use in the artificial recharge system

Boyeon JEON[1]*, IGC 2024 (kangjoo@kunsan.ac.kr)
Jinwon LEE[2], Department of Environmental Engineering, Kunsan National University
Thanh Huy PHUNG[3], Department of Environmental Engineering, Kunsan National University
Byungsun BYUNGSUN[4], Korea Rural Community Corporation
Gyusang LEE[5], Korea Rural Community Corporation

Abstract

In the area where intensive infiltration takes place such as LID or artificial recharge facilities, nitrate becomes can become a serious obstacle. Artificial introduction of nitrate-rich groundwater to the deep aquifer can also cause adverse effects due to geochemical disturbances. This study demonstrates that nitrate in the infiltrating water can be effectively removed using agricultural organic biproducts and limestones. This study performed an experiment using three columns packed with sand 100% (Column A), sand 97% + woodchip 3% (Column B), and sand 96.4% + woodchip 3% + limestone 0.6% (Column C). The sands used for these experiments were treated with HCl solutions to completely remove carbonate materials. Packed materials of each column was filled with KNO3 solution (20 mg-N/L) and the water level at the top of each column was maintained. 150 ml of pore water was sampled at each designated time and measured for various chemical parameters including pH, EC, Eh, DO, alkalinity, DOC, NO3-, NO2-, NH4+, F-, Cl-, SO42-, Ca2+, Mg2+, Na+, K+, Fe, and Mn. Measured parameters were precisely inspected to understand the chemical reactions influencing the denitrification. It was found that denitrification was induced by the decomposition of organic matter. However, the CO2 generated from the organic matter lowers the pH to a level (<5.5), which can largely suppress the denitrification. When limestone was used together with the organic matter, the severe decrease in pH was suppressed and the denitrification was 3 times faster than that obtained from the column without limestone.

Saltwater circulation driven by shoreline curvature in coastal aquifers

Xuan YU[1]*, Institute of Soil Science, Chinese Academy of Sciences (yuxuan@issas.ac.cn)

Abstract

Studies of coastal groundwater dynamics often rely on numerical simulation of variable-density flow in coastal aquifers for predicting salinity distributions and quantifying submarine groundwater discharge (SGD). Although much of our understanding of saltwater circulation is derived from models on cross-sections of coastal aquifers, shoreline curvature can cause along-shore groundwater flow, resulting in complex mixed convection. To understand the impacts of shoreline curvature on saltwater circulation, we modeled variable-density groundwater flow and salt transport between land and ocean in 3-D using the fully coupled surface and subsurface numerical simulator HydroGeoSphere. To represent various coastline geometries, we developed a series of concave and convex coastline fields according to the general coastline geomorphological features along the coast of China. We show that along-shore movement of groundwater increases with shoreline curvature, causing nonlinear responses of lateral saltwater circulation. The mixing zone and SGD are impacted by coastline curvature, which depends mainly on the proportion of lateral circulation. In addition, shoreline curvature substantially increases the travel time and length of fresh SGD. Our results highlight the nonnegligible influence of coastline geometry on along-shore groundwater movement, freshwater-saltwater mixing, and SGD. This study has important implications for groundwater resources management, biogeochemical reactions along shorelines, and resulting chemical fluxes to the ocean.

Hydrogeological modelling of alluvial aquifer in north-eastern Uzbekistan

AZIZ ABDUMANNAPOVICH HAKIMOV[1]*, Uzbekhydrogeology (newage.uz@gmail.com)
Dmitry Andreev[2], State Institution "Hydroingeo"
Samrit Luoma[3], Geological Survey of Finland (GTK)
Jukka-Pekka Kujasalo[4], Geological Survey of Finland (GTK)
Jaana Lohva[5], Geological Survey of Finland (GTK)

Abstract

Geological Survey of Finland (GTK) has had cooperation projects in Central Asia since 2008. In Uzbekistan, the project “Strengthening the Mastering of Natural Resources for National Welfare in Uzbekistan” is the first project to implement together with the Ministry of Mining Industry and Geology (MINGEOLOGY). The project focuses on improving the capacity of MINGEOLOGY to manage the complete chain of information production (collection, analysis, dissemination, increasing awareness) for groundwater studies, mineral resources and environmental risk assessments related to climate change. The ongoing project increases MINGEOLOGY’s capacity to produce information on groundwater resources and environmental impacts by applying integrated hydrogeological and geophysical monitoring and modelling techniques to a groundwater aquifer. Integrating the monitoring of groundwater level and geochemical data and interpreted geoscientific observations provides a fundamental understanding of the groundwater flow system and more insight into the evolution of geochemical process and the potential groundwater contamination risk zones. The availability of long-term, systematic monitoring data is a key information for groundwater vulnerability assessment and protection and sustainable water resources managements.

The shallow permeable alluvial aquifer in the Akhangaran River Valley in north-eastern Uzbekistan is a pilot site for the investigation and demonstration of the methods. The pilot site is an important fresh water source for public water supply, agriculture, mining process and industry in the area. The aquifer is hydraulically connected to surface water and responses directly to climate variables (e.g., temperature and precipitation) and human activities. The risks and threats to a shallow aquifer are changes in groundwater recharge due to change in precipitation and temperature caused by climate change, and contamination of groundwater from risk areas. Water demand is expected to increase, while water availability will diminish due to decrease in groundwater recharge and groundwater resources, especially during the drought in summertime. Lack of clean water can cause a crisis to water users. Water resource management as well as adaptation and mitigation to water crisis requires comprehensive understanding of groundwater resources and their connection to surface water bodies in changing climate and land use.

The hydrogeological characterization of alluvial aquifer in the Akhangaran River Valley was investigated using the integration of the geological drilling data, geophysical data from seismic refraction surveys and vertical electrical sounding (VES) surveys, as well as hydrogeological data. Seismic refraction survey provided information of the underlain pre-Quaternary deposits and the groundwater levels, which vary between 1.0 and 30 m below ground surface. The results of VES

and borehole data revealed the river valley filled with unconsolidated Quaternary sand and gravel deposits along the Akhangaran River and its tributaries, and the alluvial-proluvial deposits of loam, loamy sand and pebbles along the floodplain terrace and both sides of the river. These findings provide the geological framework for the upcoming groundwater flow modeling and useful information for water resources managements in the area.

Groundwater of the foothill plain on the northern slopes of the ridge Nuratau and features of their interaction with surface water

Nosirali Takhirovich KURBANOV[1]*, SI "Uzbekhydrogeology" (kurbanov.n.t@gmail.com)
Timur Erkinovich Mavlyanov[2], ГУ Узбекгидрогеология

Abstract

The hydrogeological characteristics of aquifers within the northern foothill plain of the Nuratau ridge are considered in connection with the choice of a site for the construction of a large industrial facility and the conditions for the interaction of groundwater with the waters of Lake Tuzkan.

Recently, in the Republic of Uzbekistan, engineering surveys were completed to select a site for the construction of a large industrial facility on the periphery of the piedmont proluvial plain of the northern slopes of the ridge in Nuratau mountain near Lake Tuzkan. For making design decisions, for selection the type of foundation, for developing measures for the engineering protection of structures, and for protection the geological environment, much attention was paid to study hydrogeological conditions and features of the interaction of groundwater and surface waters.

The water level in Lake Tuzkan for the period of research was at absolute levels of 244-245 m, water salinity -10200 mg/l.

Groundwater is confined to Mesozoic-Cenozoic loose clastic deposits and fractured rocks of the Paleozoic basement. The relief of the foothill plain is hilly, slightly sloping to the north and northwest at absolute elevations of 600 - 245 m.

The following aquifers are distinguished within the territory:

The aquifer of Upper Quaternary-Modern aeolian deposits is distributed on the periphery of the foothill plume. The depth of the groundwater level varies from 20-30 m to 0.0-3.0 m along the shore of Lake Aydarkul, mineralization - from 0.7 g/l to 11.9 g/l.

The aquifer of Upper Quaternary proluvial sediments is the first from the surface in the middle part of the piedmont proluvial plain. Groundwater levels at depths from 4.3 m to 25.1 m, mineralization up to 1.0 - 3.0 g/l.

The aquifer complex of middle Quaternary sediments lies first from the surface in a strip 5-10 km wide adjacent to the foot of the Nuratau ridge. Water levels in wells are set at 12-95 m below the ground surface, with mineralization from 1.0 g/l to 3.8 g/l.

The aquifer complex of Upper Pliocene deposits is tapped by wells at a depth of 80-100 m. Water levels in wells are set from 4.9 m in the north of the area to 130.0 m in the south, salinity up to 3.8 g/l.

The groundwater regime in the coastal zone is influenced by the Tuzkan lake and the Aidar lake. In the period from November to May, when groundwater levels are set above the water surface in the lake by 0.1-0.4 cm, the reservoir drains groundwater, and from May to November, when groundwater levels drop below the water surface in the lake by 0, 4-0.8 m, the lake feeds

groundwater. The amplitude of groundwater fluctuations is 1.5-1.3 m, in the Tuzkan lake -0.8-1.0 m.

According to hydrogeological studies, it was revealed that within the boundaries of the study area, the natural regime of groundwater is predominantly preserved, corresponding to the infiltration type of recharge of aquifers, and only in the north, in a narrow coastal strip, Lake Tuzkan influences groundwater.

Exploring heterogeneity in the Varaždin aquifer: Integrating geostatistics and Markov chain analysis with borehole log and electrical resistivity tomography data

Igor Karlovic[1]*, Croatian geological survey (ikarlovic@hgi-cgs.hr)
Mitja Janza[2], Geological Survey of Slovenia
Edmundo Placencia-Gómez[3], Geological Survey of Slovenia
Tamara Markovic[4], Croatian geological survey

Abstract

In recent decades, the elevated nitrate levels observed in the Varaždin alluvial aquifer in northwestern Croatia raised public concern about groundwater quality, particularly due to its importance as the primary drinking water source for the local population. To gain insights into the spatio-temporal distribution of nitrate in groundwater and develop effective management strategies for groundwater quality protection, it is essential to develop numerical groundwater flow and solute transport model. The conceptualization of a study site relies on precisely defining its geometry, establishing model boundary conditions, and characterizing the spatial distribution of aquifer parameters.

Delineating the spatial distribution of hydrofacies within an aquifer presents a challenge, potentially limiting the reliability and practical use of numerical transport models. The aim of this study is to develop a detailed 3-D model illustrating the spatial distribution of hydrofacies within the Varaždin aquifer, crucial for understanding and controlling groundwater transport mechanisms. The model is based on the lithological data from boreholes and wells, electrical resistivity tomography data, other geological conceptual information and geostatistical methods, supplemented by stochastic modeling, i.e. the use of the Markov chain model. This integrated approach enabled the identification of distinct hydrofacies ranging from clay to gravel grain sizes, which improved the current understanding of aquifer heterogeneity, subsequently enhancing the reliability of hydrogeological modeling in the study area.

Abstract

To facilitate the effective and appropriate remediation of contaminated groundwater, it is crucial to allocate and characterize the source of contamination. However, identifying contamination sources in real field presents significant challenges stemmed from lack of preliminary data such as monitoring data and site information. This scarcity of data often leads to high complexity in the identification process. To overcome these challenges, our study employed a linked simulation optimization method that combines numerical modeling with optimization techniques. We selected the Ensemble Particle Swarm Optimization (EPSO) for efficient handling of limited data in identifying contaminant sources. The study site is the Namdong Industrial Complex (NIC) in Incheon, Republic of Korea, a site contaminated with Dense Non-Aqueous Phase Liquids (DNAPLs) and with an unknown contamination history. From 2021 to 2023, we monitored groundwater levels and conducted five rounds of sampling for DNAPL concentration data at 14 observation wells. Based on field observations, the transient state model was calibrated using PEST, considering a heterogeneous hydraulic conductivity field. After calibration, the EPSO was combined under various scenarios, considering different potential contaminant release times and spatial distributions. As a result, EPSO showed faster convergence compared to single optimization algorithms, including various strategies of PSO, and suggested a higher probability of approximating the characteristics of the contaminant source under real field conditions with limited preliminary information. Overall, this approach successfully provided information for understanding the spatial and temporal distribution of groundwater contamination, which can contribute to designing appropriate remediation strategies.

Seung-Wook Ha[4], Seoul National University
Min-Chul Kim[5], Jeju Research Institute
Kang-Kun Lee[6], Seoul National University

Abstract

The long-term assessment of groundwater level time series (GWL-TS) through groundwater monitoring networks (GMN) provides insights for the characterization of regional groundwater systems and development of strategies for groundwater management. However, effectively assessing and characterizing regional GWL and their controlling factors still need to be improved due to the data heterogeneity (missing values, varied measurement lengths, noise), limited spatial coverage (point-based measure in space), and the complex interplay between groundwater systems and their controls. Therefore, this study utilized feature-based clustering and machine learning to assess and characterize the spatiotemporal patterns of the regional GWL and their possible controlling factors. The study was conducted on the GMN in Jeju Island, where water resources primarily depend on groundwater. Feature-based clustering was applied to group 124 heterogeneous GWL-TS. Subsequently, machine learning was applied to evaluate the relationships between these clusters and spatial environmental data related to the dynamics of GWL. As a result, the spatiotemporal patterns of the GWL of Jeju Island and their possible controlling factors were successfully identified. Consequently, we anticipated that the results of this study could serve as the foundation for managing groundwater resources in this region by each cluster through selecting representative wells or developing clustered-based GWL-TS prediction system.

Hydrochemical Analysis of groundwater in Chamoli district, Garhwal Himalaya India

Abhishek Mehra[1]*, KUMAUN UNIVERSITY NAINITAL (mehrageo1555@gmail.com)
Girish Kumar Sharma[2], University of Delhi,India

Abstract

Hydrochemical Analysis of Groundwater of Chamoli District, Garhwal Himalaya, India
1Abhishek Mehra and G.K. Sharma2
1Department of Geology, Kumaun University, Nainital-263002, India
2Department of Geology, University of Delhi, Delhi- 110007, India
E-mail: mehrageo1555@gmail.com
Abstract:
Groundwater especially spring water is one of the major sources of drinking water in hilly areas. Most of the population in the hilly terrain depend on natural spring water for daily use. The Chamoli district was chosen as the study area which is thickly populated and covers the vast area. 28 samples in which 17 ground water (CHP) and 11spring water (CSP) were collected during the post-monsoon season i.e. November, 2023. The samples were analyzed for potential of hydrogen (pH), electrical conductivity (EC), total dissolved solids (TDS), concentration of heavy metals such as chromium, manganese, iron, copper, lead, nickel and zinc using Atomic Absorption Spectrophotometer (AAS).
It is observed that ranges of pH lie between 8 to 7.8; TDS from 189 to 307.64; Electrical Conductivity from 296 to 480.69. On the basis of hydro-chemical analysis, the cations- K(0.13 and 2.84); Na(0.39 and 1.93); Ca(22.61 and 28.99); Mg (9.25and 7.58) and anions- chlorine(19.39 and15.47); Fluorine(0.38 and0.42) and NO3 (7.78and 10) whereas the values of heavy metals Pb(0.021-0.028) ,Zn (3.12 and 3.33), Cr (0.026 and 0.03), Mn (0.013 and 0.24), Cu (0.03 and 0.023), are within the permissible limit (ISI0500-2012) values are calculated for springs and ground water respectively and observed that heavy metal pollution of lead in groundwater and springs are also high.
Further, according to the ISI0500-2012 limit, the study area contains lead, zinc and manganese, chromium and nitrate concentrations which are higher than the permissible limit in some sites of Chamoli. The heavy metal pollution index (HPI) and Water Quality Index have been calculated and establishes a relationship between springs and ground water. This suggests that the pollution is not only anthropogenic but also geogenic. The pollutants enter into the ground water may be due to dissolution or erosion from the surrounding catchment areas. This groundwater is not suitable for drinking purposes as having high concentrations of nitrate, fluorine and chlorine. It is interpreted that groundwater is not suitable for drinking purposes as it is having the high concentrations of lead and nitrate in the ground and spring waters.

The susceptibility of urban hard rock aquifer in equatorial climate to hydraulic and contaminant stresses: The case of Shah Alam, Malaysia.

norsyafina roslan[1]*, Universiti Kebangsaan Malaysia (finalan@ukm.edu.my)
John Tellam[2], University of Birmingham, UK

Abstract

Shah Alam is one of the most developed states in Selangor, Malaysia. This urbanized area experienced a water shortage problem in 1998 that led to the use groundwater as an alternative water supply, especially for industrial purposes. Industries that are using groundwater, such as the steel and plating industry, drink and brewery, laundry, electrical appliances, and electronic devices. Groundwater is also used locally by schools and mosques for domestic purposes and also for small farm irrigation. Despite the regular use of groundwater since 1998, there is little or no understanding of urban hard rock aquifers, especially in equatorial climates. This city also experiences flooding often; the impact of flooding events on the aquifer is unknown. Therefore, this paper aims to understand the equatorial climate of hard rock urban aquifers and to determine the relationship between surface water and groundwater in the study area in a way to identify the susceptibility of the aquifer to hydraulic and contaminant stresses. The geological conceptual model of the study area is built using geological information obtained through geological mapping, borehole log interpretation, and soil analysis. There are 8 locations that have been selected along the Klang River for soil sampling using an auger. The soil samples are taken at various depths until the water table is encountered. The slotted PVC pipe is installed in each borehole. The geological model later developed into a hydrogeological conceptual model by adding input from pumping tests and chemical analysis. The infiltration test using a double-ring infiltrometer is conducted at each sampling location to determine the relationship between surface water and groundwater in the study area. Besides, historical water level data recorded in both pumping and monitoring wells, rainfall, and river level data are analyzed. The lithology of the study area comprises interbedded quartzite and phyllite, with granite in the eastern part. The aquifer system is confined to semi-confined, with fractured quartzite or phyllite covered with up to 60 m of weathered layer. The abstraction activity has induced recharge into the aquifer, which is reflected through the drawdown curve patterns. Many water samples were polluted by one or more species, and sewer influences are common. The aquifer in the study area is identified as susceptible to contaminant stresses. This information is very useful for the regulator as a way to monitor the groundwater abstraction activity in the study area. This is important to ensure the groundwater sources are protected and sustainable for future use.

[Keynote] Integrated surface and subsurface hydrological modeling to support water management

Rene THERRIEN[1]*, Universite Laval (rene.therrien@ggl.ulaval.ca)

Abstract

Integrated surface and subsurface hydrological models are designed to simulate the terrestrial portion of the hydrologic cycle. These models typically simulate coupled 2D surface water flow and 3D variably-saturated groundwater flow and, in some cases, mass and energy transport. They represent water exchange between the surface and subsurface domains with physically based equations and therefore do not rely on artificial boundary conditions between the two domains. For example, unlike groundwater flow models, they do not require groundwater recharge as an input parameter. Instead, they use hydroclimatic variables as inputs, such as liquid and solid precipitation and temperature, and redistribute water in the surface and subsurface domains according to the hydraulic properties of both domains. Because they rely on fewer assumptions than decoupled models, integrated surface and subsurface hydrological models are increasingly being used to integrate available data for a hydrologic system, reproduce hydrological observations and forecast potential changes in the hydrogeological regime following natural or anthropogenic modifications. They also allow a unified approach to simulate both surface water and groundwater at the catchment scale, which is the typical scale of interest for water management. This presentation will focus on recent developments and applications of the HydroGeoSphere model, which simulates coupled surface and subsurface water flow, solute and energy transport. The potential of the model to support water management will be discussed, along with some of the challenges associated with its application. The importance of proper characterization of the geological environment will also be emphasized as well as recent developments that allow faster calibration and quantification of the forecasting uncertainty.

Assessing changes in hydrogeological conditions during solid minerals development: an in-depth analysis

Gleb ZARNITSYN[1]*, Sergeev Institute of Environmental Geoscience, the Russian Academy of Science (IEG RAS), Moscow, Russian Federation (gerimax100@gmail.com)

Abstract

Globally, the mining industry is undergoing a transformation as the reserves of large near-surface deposits favorable for development are being depleted. This necessitates the involvement in exploitation of small and medium-sized or already partially developed fields with low raw material content and reserves at great depths in hard-to-reach regions with very complex mining and hydrogeological conditions.

This paper analyzes hydrogeological conditions and their changes at different stages of field development on the example of two large objects: diamond deposits in the european North and ore gold deposits in eastern Siberia of the Russian Federation. The research complex included the following types of work: literature review, field trips, uncertainty analysis in the process of schematization of natural conditions, geofiltration and geomigration modeling using deterministic and stochastic methods.

The first object is a diamond deposit in the north of Russia, which has been developed by open pit mining since 2010. The main feature of the deposit is anomalously high water content of rocks up to the depth of 350 meters. The total volume of water inflow reaches 2-2.25 m3/s, which is comparable to the flow rate of small rivers. The analysis showed that the stabilization of groundwater levels was manifested only by the end of 2018, the damage to river flow, due to the huge drainage water discharge, is practically absent. In the overall balance of water inflows, in addition to capacitive reserves, the interception of groundwater flow of adjacent lakes and rivers, as well as filtration losses from the tailings pond play a significant role. Based on this analysis, geofiltration schematization was performed, a hydrogeological model was built and calibrated, on which the theses put forward were substantiated, the epignostic task was solved and predictive estimates of water inflows, including their chemical composition, were made.

The second site is a gold deposit in southern eastern Siberia. The two deposits were developed by a combined method with a common underground water drainage during the last century, after which exploitation was terminated in the 90s. Over the following years, the two open pits gradually flooded, and recently it was decided to dewater and further develop one of them. A hydrogeological model was created, including 20 computational layers corresponding to loose and cemented sediments. The main uncertainties are the spatial position and parametric characterization of the sediments. These uncertainties were solved using various interpolation methods. Calibration of the model was performed manually and semi-automatically by

reconstructing water levels in the pits. Stochastic modeling method for water inflow estimation was used due to poor hydrogeological understanding of the area. A geomigration model was created based on geofiltration model, which allowed to qualitatively characterize the composition of predicted water inflows from quarries flooded with water of different composition. Additionally, hydrological studies including calculations and modeling of surface runoff were carried out for more accurate quantitative characterization of water inflows.

A Study into the assessment of groundwater flow utilizing thermal and hydrochemical datasets from both groundwater and surface water in the karst area of Samcheok, South Korea

Han-Sun Ryu[1]*, Kangwon National University (rhs@kangwon.ac.kr)
Heejung Kim[2], Kangwon National University

Abstract

This study explores the dynamics of groundwater flow by analyzing hydrochemical and thermal data, intending to comprehend the movement of groundwater and the behavior of pollutants within the karst area and devising strategies to tackle water quality challenges while ensuring the stability of water resources. Flow characteristics were determined through the examination of topographic slope and groundwater maps, revealing heightened vulnerability to groundwater contamination due to its proximity to the discharge zone where groundwater from the western region flows into the sea. Measurements of vertical hydraulic gradient were utilized to determine the directions of groundwater recharge and discharge, indicating active exchange between groundwater and surface water. Groundwater recharge was found to be predominant in both Gyogokcheon (Gyogok-ri) and Sohancheon (Hamaengbang-ri), with Sohancheon showing increased recharge activity during summer and winter compared to spring and fall. Analysis of hydrochemical data provided insights into groundwater residence time, recharge patterns, and the dynamics of surface water mixing relative to groundwater flow and pollutant behavior. Notably, significant discrepancies in radon concentration were observed between Gyogokcheon (gneiss-based rock) and Sohancheon (limestone-based rock). While radon concentration levels in Hamaengbang-ri remained relatively consistent across surface water, groundwater-surface water mixing zones (hyporheic zones), and cave water, Gyogok-ri utilized radon concentration as a tracer to estimate the mixing ratios of groundwater and surface water within the hyporheic zone. This work was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (grant numbers 2019R1I1A2A01057002 and 2019R1A6A1A03033167).

Using 3D geology models to support and improve decision-making in water resources regulation in England.

Michael Kehinde MBE CGEOL[1]*, Environment Agency (michael.kehinde@environment-agency.gov.uk)

Abstract

The Environment Agency has the statutory function of regulating the development and use of water resources to ensure sustainability and minimise negative impact on people, nature, and livelihoods.

This paper focuses on the Hertfordshire and North London ('HNL') area of England that is characterised as currently water-stressed and grapples with complex challenges of natural and anthropogenic nature. HNL serves a diverse and dense population of about 6.5 million people in 44 Local Authorities from rural Home Counties to Greater London and its suburbs. It is home to some globally rare chalk-fed streams and has the largest chalk stream sink (the Water End swallow hole) in England with estimated mean flow of 80l/s.

The dominant geology is the chalk aquifer system which also is the principal source of groundwater for public water supply, industrial and agricultural uses. The Environment Agency is now increasingly focused on restoring a sustainable abstraction regime as several chalk catchments are now either over-licensed, over-abstracted, or approaching these conditions, and groundwater abstraction is adversely affecting the baseflow contribution to the chalk-fed streams.

To improve understanding of the geology and hydrogeology of the area, HNL embarked on a process of geological mapping, borehole drilling, 3D geology modelling and improved groundwater modelling. The 3D geology model provides valuable input for developing a hydrogeology conceptual model and serves as input into the numerical Modflow model. This enabled us to investigate the rather complex impact of sustainability reduction of abstraction on river flows with some success. However, this also flagged the issue of the unintended consequence of groundwater emergence that could increase the risk of groundwater flooding and sewer surcharge.

With the improved understanding of how the catchments work, based on the additional data obtained from the various programmes embarked upon, it is becoming less stressful to make water regulatory decisions that are understood by stakeholders and are less open to challenge. This paper will present some examples of abstraction impact questions addressed using the Hertfordshire Chalk Groundwater Model and the Ver-Gade-Chess Groundwater Model. These models had the benefit of using 3D geology models developed in Leapfrog.

Additional benefits derived from using 3D geology model are the wider use of model-derived tools (e.g. groundwater hydro-ecology tool) and the application of the models to new issues (e.g. land use change, nature-based solutions, climate change). HNL developed a 3D geology model in PDF to engage non-technical stakeholders and for general geoscience communication with the public explaining how we protect groundwater from human activities and other artificial

influences. With this example we showed the relative position of groundwater level on two memorable weather events – the flood of 2001 and the drought of 2006 as well as the long-term average groundwater level. Viewers can relate the role of groundwater with their experiences of past extreme climatic events.

Numerical calculation and case analysis of seepage field in anisotropic aquifer

Lei LYU[1]*, Yunnan University of Finance and Economics (leilyu@ynufe.edu.cn)
Chunxue LIU[2], Yunnan University of Finance and Economics

Abstract

The anisotropy of aquifer permeability can be characterized by the permeability coefficient tensor. When numerically simulating the seepage field of an anisotropic aquifer, the size and main direction of the principal value of the permeability tensor will have a significant impact on the seepage field. How to reasonably establish a numerical model that can reflect the anisotropy of the aquifer is very critical.

The object of this study is a metal mine. The mine uses underground mining and has a relatively complete drainage system. The water from all tunnels is collected and discharged to the surface through the middle drainage tunnel with an elevation of 1360m. There are no other obvious groundwater exposure points in the surrounding area. The lithology of the area where the mine is located is mainly Triassic carbonate rock formation. The overall lithology is relatively uniform and can be summarized as an aquifer with a unified hydraulic connection. Fissures and karsts are strongly developed throughout the aquifer. Through field surveys, tracer tests, pumping tests and other work, it was found that the aquifer has strong anisotropy. The sources of groundwater recharge in the hydrogeological unit where the mine is located include rainfall and underground runoff. There are many karst depressions, funnels, sinkholes, and corrosion fissures in the area, and the rainfall infiltration coefficient is 65% to 85%. Atmospheric rainfall vertically recharges groundwater, and the seasonal fluctuation range of groundwater levels is large, which can be greater than 150m. Affected by the dewatering of groundwater due to mining activities, the groundwater level in the central part of the study area has dropped significantly.

This paper discusses the assignment method, conditions and feasibility of the main value size and direction parameters of the aquifer permeability tensor in the program by analyzing mathematical models, discrete methods and difference formulas. It is believed that the calculation of the penetration tensor under certain conditions can be achieved by using the numerical model grid rotation method in the program. The results of the theoretical analysis were verified using examples, and the influence of the direction of the principal value of the permeability tensor on the seepage field was compared.

Study on the quality of water wells in the city of Hashtgerd using hydro-geochemical charts

Zahra SHARIFI[1]*, Phd Geomorphology (zahra_sharifi1364@yahoo.com)

Abstract

Studying of the composition and quality of different types of water such as underground water and surface water is a necessity. The hydrogeomorphology method is used to produce an environmental information layer in order to evaluate the quality of underground water resources. The study area is located in the central Alborz mountain in north of Iran and in the western part of the central Alborz.

From the point of view of national divisions, the Hashtgerd plain is located within the boundaries of Saujblag city in Alborz province. The purpose of this research is to investigate the impact of geomorphology on the changes in underground water resources of Hashtgerd city, which includes the identification of morphological and geomorphological forms, classification from the perspective of water infiltration and hydrogeochemical changes based on data analysis. and interpretation of charts. The stratigraphy of the region is sedimentary and sometimes igneous, and due to the large amount of sandstone and limestone, there is a possibility of forming underground water reserves and karst reservoirs.

Analysis of underground water data, processing and interpretation of charts and preparation of maps have been done using water quality, GIS software. The results of the qualitative parameters show that electrical conductivity and chlorine increase from north to south, which indicates the feeding of the table from limestone and dolomite formations as well as igneous formations in the north and the lack of evaporative layers such as chalk and salt in the north of the plain. The samples of Hashtgerd city are classified between hard and relatively hard. According to the results of the Piper diagram and the Wilcox diagram, respectively, the water type of the studied area is bicarbonate and approximately 82% of the samples are in the C2-S1 class in the category of agriculturally good water. According to Schuler's diagram the status of underground water resources of Hashtgerd city is in the good category in terms of drinking. The quality of water for industrial uses is corrosive. Geomorphological forms have not had a significant impact on the quality of water resources, and most human factors have caused changes and drops in the underground water level, and have had a negative impact on water quality. Due to the presence of marl stone units that caused chlorine changes and salt and evaporation forms in the subsurface layers caused quality changes and increased electrical conductivity and chlorine.

Evaluation of the impact of artificial replacement on groundwater in the Yongding River

Tian NAN[1]*, Institute of Hydrogeology and Environmental Geology, Chinese Academy of Geological Sciences (419416433@qq.com)
Wengeng CAO[2], Institute of Hydrogeology and Environmental Geology, Chinese Academy of Geological Sciences

Abstract

Evaluating the effect of ecological water supplement on groundwater restoration quantitatively could produce positive contributions to both water cycle theory and surface-ground water conjunctive management. Therefore, in this paper, a groundwater flow numerical model has been established after calculating the river section seepage rate using a fuzzy mathematical method in the Yongding River channel. The simulated results show that the model could accurately reflect the real groundwater dynamic features. Then a data-driven random forest model has been established to quantitatively evaluate the contributions of the factors which influence the groundwater level variation. The study shows that the infiltration capacity is strong in the upstream area of Yongding River, and the seepage rate is over 0.7. The lowest seepage rate is 0.19 at the downstream end, while the seepage rate in the middle area is basically between 0.4 and 0.7. From 2018 to 2019, the ecological water supplement of the Yongding River has played a significant role in raising the groundwater level along the river channel. And its contribution to the change of groundwater level is 25%. The impact depth of groundwater level fluctuation reaches about 10m. The impact range where the groundwater level average uplifts 1.86m is 502.13km2. The influence direction gradually changes from around the ecological water supplement section to along the Yongding River Channel. The groundwater level variation along the tangential direction of Yongding River is slowing down. The groundwater level would entirely uplift with 170×106m3/a ecological water supplement of the Yongding River and 35.77×106m3/a groundwater mining reduction in the downstream area until 2035.

Pollutant Migration in mineral area through Copper Isotope Values in Soils and Waters

JINGWEN SU[1]*, China Geological Survey,Nanjing Center (michelle3322@Hotmail.com)
Ryan MATHUR[2], Geology Department, Juniata College

Abstract

Copper mining has long history in China. Multiple studies have demonstrated, through concentrated work on soils and waters, the impact of mining in the such kind of area. In this case, one typical area in east China was choose to study the pollutant migration. Here we present copper isotope values of 13 ore samples, three tailing samples, 20 water samples (surface and groundwater), and 94 soil samples (15 different profiles ranging in depth from 0–2 m) from proximal to distal (up to 10 km) locations radiating from a tailings dam and tailings pile. Oxidation of the copper sulfide minerals results in isotopically heavier oxidized copper. Thus, copper sourced from sulfide minerals has been used to tracu e copper in mining and environmental applications. In this aera, higher copper isotope values (greater than 1 per mil, which are interpreted to be derived from copper sulfide weathering) are found both in waters and the upper portions of soils (5–100 cm) within 1 km of the source tailings. At greater than 1 km, the soils do not possess heavier copper isotope values; however, the stream water samples that have low copper concentrations have heavier values up to 6.5 km from the source. The data suggest that copper derived from the mining activities remains relatively proximal in the soils but can be traced in the waters at greater distances.

Abstract

The fast growth of the city and population in Bandung is increasing the need for water. Taking too much groundwater, especially for homes and industries, can make the underground water storage run out, causing the level of groundwater to drop. One way to deal with this is by using stable isotopes to follow where the water comes from, like rain and underground sources. This method helps us map where groundwater starts, find out how long it stays underground, and understand why groundwater is important.

To do this, we collect and test groundwater and spring water twice a year in the tropics. We use special tools to measure tiny weight differences in water samples. Understanding isotopes is crucial to figuring out how water moves. When water evaporates, the lighter molecules go up, forming clouds with different signs. When it rains, the mix of water with heavier molecules falls first, affecting the makeup of rainfall.

This study looks into how farming and other activities around Bandung and the city affect the levels of hydrogen and oxygen isotopes in groundwater. We use isotope analysis to study the changes over time and space. This helps us see how people impact the quality of groundwater. The goal is to identify oxygen and hydrogen isotopes in groundwater areas to know where it comes from, how it moves, and how old it is. This information is crucial for leaders to make plans and manage water wisely.

Assessing the impact of climate change on hydrological components using CMIP6 GCM models of the Hasdeo river basin, Chhattisgarh, India: Implications for sustainable water resources in the future

satish B[1]*, Exploration Department, Coal India Limited, CMPDI, RI-V, Bilaspur, Chhattisgarh, India-495006 (b.satish@coalindia.in)
Vijendra Chouhan[2], Exploration Department, Coal India Limited, CMPDI, RI-V, Bilaspur, Chhattisgarh, India-495006
Satheeshkumar S[3], Department of Geology, Government Arts College(Autonomous), Salem, TamilNadu, India-636007
Rethikala K R[4], Department of Geology, Bishop Kurialacherry College For Women, Amalagiri, Kerala, India-68656

Abstract

The Hasdeo river basin is a part of the Mahanadi basin flowing in the state of Chhattisgarh, India. The Hasdeo River is one of the major tributaries of the upper Mahanadi basin. In recent times, periodic droughts in the upper Mahanadi basin and contrary flood events in the lower Mahanadi basin have occurred in the delta region of Orissa state. To maintain sustainability, i.e., to maintain the water demands in the future without compromising the environment or hydrological integrity, a study on climate change at the local scale is needed in the region. This study aims to assess climate change at the river basin level and its impact on water balance components such as precipitation, runoff, groundwater discharge, evapotranspiration, and discharge using the SWAT model. In this study, 13 global climate models (GCMs) of Coupled Model Inter-comparison Project Phase 6 (CMIP6) have been analyzed and based on their performance, three GCMs are considered under two emission scenarios, such as Shared Socioeconomic Pathways (SSP) 245 and SSP 585. The entire period has been subdivided into four parts: historic (1994–2017), near (2018–2040), mid (2041–2070), and far (2071-2100). In the near future, there will be an increase in streamflow of about 20.85–36.20% and 31.92–35.65% under SSP 245 and 585, respectively, and a significant increase in runoff of about 48.12–51.01% and 50.42–60.41% under SSP 245 and 585, respectively. This indicates the vulnerability of a near-future flood in downstream of the Mahanadi basin. Similarly, in the far future, there will be a nominal average increase in streamflow and runoff of about 14% and 22.75%, respectively. Spatially, the southern part of the basin is projected to experience more precipitation than the northern part of the basin. The findings emphasize the understanding of the effects of climate change on water balance in the basin and urge proactive measures taking account of agricultural and domestic requirements, groundwater discharge, etc., to prevent water stress and surplus situations in the basin. Implementing policy and management based on scientific evidence may help to maintain sustainable water resource management for an effective response.

Deciphering probable groundwater recharge patterns in Khapri watershed of Deccan Volcanic Province (DVP), western India: Insights from stable isotopes

Chinmay Uday DONGARE[1]*, Deparment of Geology, The Maharaja Sayajirao University of Baroda (chinmayd.avs@gmail.com)
Bhushan Sharad DEOTA[2], Deparment of Geology, The Maharaja Sayajirao University of Baroda

Abstract

The present study attempts to decipher the groundwater recharge patterns in the Khapri watershed of district Dangs forming part of DVP in western India, using stable isotopes of oxygen (δ18O) and hydrogen (δ2H). The stable isotopes are remarkable tracers and are useful to decode water circulation throughout the hydrological cycle. Worldwide various hydrological studies have successfully demonstrated the application of stable water isotopes in understanding the working of hydrological systems and effective water resources management. In the Khapri watershed, the stable isotope analysis of rainwater (August-2022), river water (September-2022), and groundwater samples (May-2022 and January-2023) has been carried out to assess the groundwater resource sustainability, in view of deciphering the sources and recharge patterns. To obtain the stable isotope composition (δ18O and δ2H values), an Isotope Ratio Mass Spectrometer (IRMS), Delta V plus in continuous flow mode aided by Gas bench II at Physical Research Laboratory (PRL), Ahmedabad is utilized. The δ2H versus δ18O plot of rainfall samples of Khapri watershed, indicated that slope of Local Meteoric Water Line (LMWL) (δ2H = 7.86 δ18O + 9.97) is close to Global Meteoric Water Line (GMWL) (δ2H = 8 δ18O + 10). The variations in δ2H versus δ18O plot of groundwater samples, suggest the potential effects of evaporation. The relatively depleted δ18O (-2.4‰) values of post-monsoon groundwater and river water samples indicate influx of freshwater. The negative δ18O values (-0.9 ‰) of pre-monsoon groundwater samples at certain locations may be due to mixing of return flow of deeper groundwater mined for agriculture. The salient features of the present study include δ18O depletion in rainfall, δ18O enrichment in wells of upper-reaches, and surface water influence on dug wells. The isotopic data of deeper groundwater indicates recharge from agriculture return flow during non-rainy seasons. From the stable water isotope analysis four probable groundwater recharge patterns can be envisaged viz. a) meteoric water infiltration through joints and fractures present in rocks, b) percolation through river and reservoir, c) recharge from natural springs, and d) agricultural return flow of deeper groundwater. Thus, stable water isotope analysis is valuable in understanding the groundwater recharge dynamics of Khapri watershed.

Fluoride in groundwater of a hard rock sub-basin of northern Karnataka, India – sources and controlling geochemical processes

TEJASWAI LAKKUNDI[1]*, CENTRAL UNIVERSITY OF KARNATAKA (tejaswi@cuk.ac.in)

Abstract

Consumption of fluoride through groundwater can be both beneficial and harmful to health depending upon factors like its concentration and duration of consumption, amongst others. As in the case of several other hard rock terrains across India, the catchment area of River Sindhanur sub-basin too is plagued by the problem of excessive fluoride in its groundwaters. This area is arid, frequently drought affected and characterized by contrasts with respect to geology and agricultural practices. Detailed assessment of physico-chemical parameters of groundwaters was taken up with an objective of understanding their hydrochemical characterization with emphasis on the occurrence of fluoride, its quantification, areal distribution pattern and demarcation of safe- and hazardous zones, identifying its probable sources, and the underlying geochemical processes that might influence fluoride concentration. Results reveal the presence of excessive (>1.5mg/L) fluoride in 51% samples, the range being from 0.34 to 9.59mg/L. Groundwater fluoride concentration varies within and amongst different lithounits, with metavolcanics housing higher proportion of high-fluoride (>1.5mg/L) groundwaters followed by different granitoids. Apatite and fluorite, identified through petrographic examination and thermodynamic modeling respectively are the primary natural sources of fluoride. Other possible natural sources of fluoride identified include biotite, muscovite, hornblende, sphene and actinolite. Few minerals employed in the manufacture of fluoride-containing fertilizers and agricultural sprays, as indicated by thermodynamic modeling, might also be contributing to groundwater-fluoride. In groundwaters with very high fluoride (>6.0mg/L), biotite is the most likely primary source of fluoride as indicated by its near perfect positive correlation with potassium.

Estimation of the CO2 emission flux to the air by groundwater extraction in Korea

Jiwook JANG[1]*, Kangwon National University (jjwook1108@kangwon.ac.kr)
Jin-Yong Lee[2], Kangwon National Univerisity
Eunju Jeong[3], Kangwon National University

Abstract

CO¬2 is a significant contribution to the greenhouse effect, which has led to abnormal climate conditions. Many countries are attempting to reduce CO2 emissions from industrial and agricultural activities. However, the emission flux of CO2 of Korea increased by 2.7 times since the 1990s, and the concentration of CO2 in the air has risen to 423.1 ppm, which is approximately 1.14 times higher than the initial concentration of 371.2 ppm in Korea. However, the Ministry of Environment reported that CO2 flux was not considered without physio-chemical transportation such as degassing and evaporation, during groundwater extraction in Korea. These methods underestimate CO2 emission flux and cannot accurately assess the total carbon emission rate. The purpose of this study is to estimate the CO2 emission flux due to groundwater extraction and to accurately assess the annual carbon emission rate in Korea. This study collected physio-chemical parameters of groundwater from 457 wells with less than 100 m depth from the “Basic Survey Report of Groundwater in 2020”. The parameters were pretreated to understand geochemical processes that occur during state change by extraction from underground (high temperature and pressure) to the surface. Ordinary kriging was used to enhance spatial interpolation of potential CO2 storage in groundwater. The water facies of groundwater in all provinces except Incheon, is dominated by the Ca-HCO3 type. Additionally, Seoul and Incheon have higher electrical conductivities than other provinces. It means the inflow of contamination from artificial activities. The concentration of dissolved CO2 in groundwater is conservatively calculated using pH and HCO3. The average of pCO2 in groundwater is 21 μatm with a range of 2–31 μatm. This value is then converted to an average concentration is 0.4 g/m3. The total groundwater pumping rate in Korea is 2,672.2 Mm3/year, resulting in an estimated CO2 emission of approximately 1.3 billion g/year. If the groundwater level is used in conjunction with this result, the rate of carbon storage in the groundwater can be estimated. This study provides a source for the CO2 emission flux and an accurate annual carbon emission rate in Korea.

This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (No.2019R1A6A1A03033167).

Geological Characterization and Modeling in Southeastern Florida (USA) to Inform the Design of a Coastal Subsurface Monitoring Network

Miguel E. VALENCIA[1]*, Florida International University (mvale095@fiu.edu)
Michael C. Sukop[2], Florida International University

Abstract

Coastal cities in southeastern Florida have subsurface infrastructure that is potentially at risk from several factors, including sea-level rise, saltwater intrusion, shallow water tables, frequent flooding caused by intense precipitation, storm surge, and high-tide flooding events (e.g., King tides). To address these challenges, the U.S. Congress appropriated funds for a pilot project to develop a subsurface monitoring network in Broward and Miami-Dade counties. The program's goal is to create a long-term vadose zone and groundwater monitoring network within this densely urbanized area. This network will aim to quantify the key hydrogeologic (e.g., saltwater intrusion, water table dynamics) and environmental (e.g., corrosion potential) conditions at scales relevant to evaluating existing and future risks to building foundations, buried utilities, and other subsurface infrastructure.

During the preliminary design phase, a Monitoring Technology Advisory Panel was convened and consulted. The Panel emphasized the importance of collecting and incorporating existing geological information, particularly geotechnical lithologic data on the shallow subsurface and other relevant lithologic and geophysical data, to inform the selection of monitoring site locations and the design and installation of instrumentation.

Scrutiny of the available geotechnical data revealed a lack of detailed geological characterization of the barrier islands that extend from Miami-Dade to Broward counties. The lithostratigraphy is locally complex and may consist of calcareous sand, peat, or fill. For example, the barrier islands generally appear to consist of a sand layer of variable thickness overlying limestone, with some thin peat layers on their mainland sides. We leveraged existing geological data to perform geological modeling using GemPy to characterize the shallow subsurface and create detailed geological cross-sections of areas of interest. Model results could be used as inputs for future groundwater models that couple the vadose and saturated zones.
This presentation will provide an overview and preliminary analysis of existing geotechnical data in the context of coastal subsurface infrastructure.

An introduction to the National Groundwater Monitoring Network for Systematic Management of Korea's Groundwater Resources

Laesoo KANG[1]*, K-water (kls@kwater.or.kr)
Sora Lee[2], K-water
Daeho Kim[3], K-water
Kyunghee Shin[4], K-water
Sanggu Han[5], K-water

Abstract

In the Republic of Korea (hereinafter S. Korea), as of the end of 2023, approximately 3.04 billion tons of groundwater is being used by 1.77 million groundwater wells.
The annual groundwater recharge in inland areas excluding major island areas (Jeju Island, Ulleungdo) is 20.15 billion tons, and the sustainable development potential is 13.54 billion tons per year.
In addition, in S. Korea, rainfall is generally concentrated during the rainy season (May to October) and the country has a topographically eastern high and western low terrine, so more systematic water resource management is essential to overcome these unfavorable conditions.

The main water resources for domestic in S. Korea mostly being utilized are surface water such as river water and dam water.
Since the early of 20th century, groundwater has played an important role in agricultural and industrial activities. Recently, as we face various problems such as pollution and depletion of surface water due to global climate change, the importance and utilization of groundwater resources are being highlighted again.
To systematically and efficiently conserve and manage Groundwater resources, the Ministry of Environment enacted the Groundwater Act in 1993 and formulated a Groundwater master plan in 1996. In case of the groundwater master plan, it is re-established every 10 years and revised every 5 years if necessary, and the 4th groundwater master plan (2022-2031) was established in 2022.

In addition, the Groundwater Act and the Groundwater Master Plan contain related matters that the establishment and operation of a "national groundwater monitoring network" that systematically manages groundwater resources and continuously observes nationwide groundwater levels and changes in water quality to secure basic data.
As of the end of 2023, 713 monitoring wells have been installed and operated nationwide, and water level, electrical conductivity, and water temperature are measured in real-time every hour. Additionally, conducting separate water quality tests (35 items) twice a year (in the first and second half of the year) to continuously monitor changes in groundwater water level and quality.
The national groundwater monitoring network is planned to be installed at 985 locations (cumulative) by 2030 and 1,482 (cumulative) locations by 2045. Additionally, the measured groundwater level and water quality information is published annually and provided to the public.

Also, it is used as basic data for the conservation and management of groundwater resources by deriving trend analysis, causes of outliers, improvement measures through water level, time series analysis of water level data, and trend analysis.
In order to improve the usability of these groundwater data, the government established the “National Groundwater Information Center(https://www.gims.go.kr)” in 2004 to collect and analyze all information such as groundwater-related surveys and measurements to provide citizens with groundwater information. The Center is also conducting capacity building for the officials and employees of groundwater-related companies, promoting and providing education to the public and students on the importance of Groundwater resources.

Prediction of Fluoride Concentrations in Groundwater Using Machine Learning and Human Health Risk Assessment in Eastern India

RAHUL SINGH[1], IIT Kharagpur
SUBHASISH TRIPATHY[2]*, IIT Kharagpur (stripathy@iitkgp.ac.in)
ASHOK KUMAR GUPTA[3], IIT Kharagpur
Venkatesh Uddameri[4], Lamar University, Beaumont, TX 77713
SANKET RATAN BAGAL[5], IIT Kharagpur

Abstract

Elevated fluoride (F−) concentration in groundwater is a major environmental problem and a public health risk in many parts worldwide. This study encompasses the possible contamination sources and the spatial availability of fluoride concentrations in groundwater of Eastern India and the consequential health risk assessments for devising specific mitigation strategies. This study employs Inverse Distance Weight (IDW) coupled with machine learning algorithms (LR, CART, RF, MARS, GB, and XGB) on the hydro-chemical data from 1178 locations. Groundwater samples have been characterized for their physicochemical parameters and F−. Based on the acceptable limit of fluoride concentration (F− > 1.0 mg/l) in drinking water by the World Health Organization (WHO) and Bureau of Indian Standards (BIS), samples were categorized as Unsafe (n = 82) and Safe (n = 1096). Unsafe class of groundwater samples (F− > 1.0 mg/l) are dominated by HCO−3 and depleted with Ca but relatively higher in pH. The order of dominance of groundwater facies is Mg-Ca-HCO3 > SO4-CaCl-Mg > Na-HCO3 > SO4-NaCl. Prolonged water-rock interactions and the geochemical processes within the aquifer appears to have resulted in higher F−. Higher fluoride concentrations in groundwater are also related to major geological features. Exploratory data analysis (EDA) was used to examine and summarize the essential properties of the data prior to making any assumptions. Hydro-chemical parameters controlling the fluoride in groundwater were selected by feature importance modelling. XGB was found to be the best-performing model for predicting fluoride incorporating the controlling factors. Predicted fluoride concentration beyond the WHO acceptable with Hazard Quotient (HQ) > 1.0 revealed that approximately 6.5%, 41.1%, and 61.7% adults, children, and infants, respectively are in risk of non-carcinogenic health hazards in predicted locations hitherto unknown. This integrated mechanistic-machine learning framework helps in prioritizing future monitoring, and consequent reduction in health risk.

A new approach to vulnerability analysis of Asian aquifers: machine learning and geochemical evidence

Wengeng CAO[1]*, Institute of Hydrogeology and Environmental Geology, Chinese Academy of Geological Sciences (281084632@qq.com)

Abstract

The economic development and population growth in Asia have exacerbated the supply-demand imbalance of groundwater resources. Concurrently, issues such as groundwater pollution, seawater intrusion, overexploitation of forest resources, and climate change-induced problems like permafrost degradation, soil desertification, and salinization have further intensified the vulnerability of aquifers. To address these issues in a timely manner, this study employs a multi-integrated strategy optimization framework combined with geochemical evidence to assess and validate the vulnerability of Asian aquifers. Through a comprehensive analysis of geological structures, climate change impacts, human activities, and policy management factors, the study finds that the vulnerability of aquifers in mountainous regions is particularly pronounced. This is mainly due to coarse soil particles increasing the permeability of aquifers, which also leads to erosion and soil loss, directly contaminating the aquifers. Faults and karst formations create complex aquifer channels that facilitate the rapid spread of pollutants, increasing contamination risks. Uneven precipitation results in irregular recharge, and seasonal fluctuations exacerbate pollution issues. Diverse agricultural, forestry, and pastoral activities increase pollutant inputs, deepening the vulnerability of aquifers. Additionally, the study discusses the mechanisms of aquifer vulnerability in different geomorphic types and the potential risks under various conditions, proposing sustainable management recommendations. This in-depth analysis aims to provide theoretical support and practical guidance for effectively addressing the numerous challenges faced by Asian aquifers.

Geological Characteristics of Coastal Aquifer in the southwest of Korea

SUNG KEUN LIM[1]*, Korea Rural Community Corporation(KRC) (limsungkeunlee@gmail.com)
JIN-HOI KIM[2], Korea Rural Community Corporation(KRC)
Jong-Yun LEE[3], Korea Rural Community Corporation(KRC)

Abstract

Land-based seawater aquaculture(seedling) farms distributed in the coastal areas of Korea are operated by collecting seawater directly from the sea. Therefore, these farms are not only very vulnerable to red tide and oil spills from accident vessels due to the increase in water temperature in summer, but also require huge maintenance costs such as fuel and electricity to maintain the temperature in winter and summer.

In particular, by heating low-temperature seawater to around 15°C is supplied in the winter, while it is used directly and sometimes high-temperature seawater is used to lower the temperature by using an air conditioner in the summer.

However, as crisis situations such as the increase in production costs due to the rise in oil prices and expansion of low-priced imported marine products into the domestic market have appeared, the need to investigate and use the saline groundwater with temperature and quality and the reduction of production costs has increased in order to secure competitiveness with imported products.

This study was purposed to obtain a large amount of saline groundwater around coastal aquaculture farms. Thus, we have proposed a method for evaluating the potential amount of saline groundwater resources through the combined analysis of geophysical methods and pumping test in developed boreholes.

Geophysical surveys were conducted in the vicinity of fish farm located in the southwest part of Jeonnam Province. According to the results, well development and a series of pumping tests are conducted.

As the result, the seismic velocity of layer in the range of 700~1,200 m/s was found to be saltwater aquifer with high water content. Geological drilling investigation and analysis of soil samples also showed the texture of sandy loam layer. This study area also turned out to be quite possible to develop saline groundwater from the coastal shallow aquifer composed of sandy sedimentary and gravel layers with high porosity.

Groundwater basin management in Japan with quantitative and qualitative modeling

Katsuhiro FUJISAKI[1]*, Independent Groundwater Consultant (fujisakikatsuhiro@gmail.com)

Abstract

In Japan, numerical groundwater modeling has been developed as a means of groundwater basin management. It was incorporated as an important subsystem of groundwater basin management system which was constructed to overcome land subsidence and groundwater contamination problems. The groundwater basin management system consists of five subsystems: hydrogeological structure analysis, monitoring, database, prediction (numerical modeling), and decision making. In Japan, during the period of high economic growth from the 1960s to the 1970s, the demand for groundwater increased significantly, leading to excessive extraction. This resulted in dry springs and artesian wells stopping, leading to land subsidence and seawater intrusion. To prevent land subsidence, groundwater modeling has been developed obtaining a permissible yield which stops land subsidence. Regulation of extraction by laws and ordinances had progressed and surface water supply had improved. Then land subsidence had almost ceased in the 1990s. Meanwhile groundwater contamination has increased in the 1990s. At present basin management system is not worked well as a total system. In many regions, past regulations of pumping are simply maintained. The background of this phenomenon is a construction of wide area surface water supply system as an alternative water source, abandoning groundwater resources for the reason of land subsidence protection. Recently desertion of groundwater is also urged for the reason of health protection from groundwater contamination. In Japan there is no comprehensive groundwater law. Ten years ago, the Basic Act on Water cycle has been legislated with the aim of maintaining a sustainable water cycle in basins. A basin management committee which would be composed of the national government, local governments, and groundwater users, should plan sustainable groundwater management in a basin. However, effectiveness of the act is questionable, as the obligations of groundwater users are not specified. In order to effectively utilize groundwater resources that are threatened by groundwater contamination, groundwater basin management in terms of quantity and quality is necessary. By using a mass transport model in the prediction subsystem, it is possible to investigate changes in the groundwater flow system and contamination plume shape due to changes in the groundwater pumping, and to determine safe groundwater usage areas. However, it is necessary to modify the model based on monitoring results and repeat the prediction. The quantitative and qualitative management of groundwater basin will assist management planning and increase of groundwater utilization against the trend of abandoning groundwater resources.

Contaminant Transport Simulation in Industrial Complex Area

YU-CHUL PARK[1]*, Kangwon National University (parkyc@kangwon.ac.kr)

Abstract

With the continued escalation in groundwater utilization, there is a growing concern about the intensification of contamination issues. To effectively identify large-scale groundwater contamination sources, sophisticated aquifer models are imperative. In this research, we introduce an innovative methodology known as simulation-optimization, which combines simulation and optimization techniques to enhance the efficiency of contamination source identification. The development of a field-scale model involved the utilization of hydrogeological characteristics and contaminant data obtained from the results of field testing. The steady-state model underwent a comprehensive process of simulation and calibration, aligning the calculated groundwater levels with the actual measurements from the field. The reactive coefficient used to model groundwater contaminant transport was computed based on concentration data gathered in the field, while the parameters for the optimization technique were meticulously determined through prior sensitivity analyses. This study serves as a robust validation of the efficacy of the simulation-optimization technique in pinpointing groundwater contamination sources on a field scale. Notably, the optimization technique incorporates advanced distributed computing methods, significantly reducing the time required for the simulation-optimization process. To evaluate the applicability of this methodology beyond the conceptual model, extensive case studies were conducted. The simulation-optimization method emerges as a potent and efficient means of identifying sources of groundwater contamination on a large scale, demonstrating its viability for real-world applications beyond theoretical frameworks and conceptual boundaries. This research was supported by Basic Science Research Program through the National Research Foundation of Korea(NRF) funded by the Ministry of Education (No.2019R1A6A1A03033167).

Hydrogeochemistry and mechanism controlling the groundwater chemistry along the Kankai River Basin, East Nepal Himalaya

Champak Babu SILWAL[1]*, Tri-Chandra Multiple Campus, Tribhuvan University
(champak.silwal@trc.tu.edu.np)
Dinesh Pathak[2], Central Department of Geology, Tribhuvan University

Abstract

Groundwater from the springs and wells has been widely used and considered the most reliable source for domestic, agricultural, and industrial use. The chemical constituents of this water have an important role in the usability, which can be influenced by various physical and chemical factors along with their interionic relations within the area. The study aims to assess the different physicochemical as well as chemical constituents of the water from springs and wells within the Kankai River Basin, to characterize the springs and wells based on hydrogeochemical facies and understand the mechanisms controlling their chemistry. A total of 178 wells and springs were sampled for in-situ physicochemical parameters (Eh, pH, EC, TDS, and DO) and major ionic concentrations (Ca, Mg, Na, K, Cl, HCO3, SO4, NO3, and Fe). The study reveals that groundwater within the basin is largely controlled by the geology of the area. The pH of groundwater suggest the acidic nature along the Siwalik and IGP, whereas the Lesser and Higher Himalaya in the region is characterized by the alkaline water. The Piper diagram suggest that alkaline earths (Ca and Mg) dominate over the alkali ions (Na+K) in 70% of the samples, and weaker acid (HCO3+CO3) dominate over the strong acid (SO4+Cl) in 60% of the samples, indicating the dominance of Ca+Mg-HCO3+CO3 type water. The Chloro-alkaline Indices, along with the Gibbs plot, indicate rock-water interaction with base ion exchange (Mg and Ca from water exchange with Na and K from the rocks) along the major part of the area. However, reverse ion exchange is also dominant in northernmost areas. The Gaillardet model suggest the chemical characteristics of groundwater in the basin primarily results from the dissolution and filtration processes of carbonate rocks and silicate rocks. The combined output of the Gibbs plot, Gailardet diagram and the Chloro-alkaline indices suggest the chemistry of water in the region is controlled by the rock water interaction where the silicate weathering is the major source of ionic constituents in the spring water. Minor influence of the carbonate dissolution can also be evident which can be linked to the calc. silicates weathering in the region of Higher Himalayan Crystalline zones. Further the ratio coefficient of (Ca+Mg)/(SO4+HCO3) also signifies the silicate weathering as the major ion contributor, however minor carbonate weathering at the Higher Himalayan crystalline region is evident indicating the weathering of calc. silicate rock. This study provides valuable insights into the hydrogeochemical characteristics and their genesis in the Kankai River Basin, highlighting the geological control over the groundwater chemistry.

Geology-related groundwater productivity analyses based on the specific capacity data in South Korea: Case for the Geumgang and Nakdonggang river basin

Sang-Ho MOON[1]*, KIGAM (msh@kigam.re.kr)
Hyoung Chan Kim[2], KIGAM
Yongcheol Kim[3], KIGAM

Abstract

Groundwater is expected to be critical water resources in the future, due to getting worse of surface water quality and increasing water demand by population growth, industrialization and global climate changes. Some areas In the Geumgang River basin have frequently experienced water shortages by uneven precipitation distribution and recurring droughts by global climate changes. The Nakdonggang River has often suffered serious water pollution by industrial complexes in the middle reaches. Therefore, securing and developing quality groundwater resources in these two basin areas is considered very important. For this, groundwater productivity was estimated and compared among geological frameworks to identify areas where large amounts of groundwater can be developed. The geological frameworks were classified by existing hydrogeological units presented by Korean Ministry of Environment. The hydrogeological units in the Geumgang river basin are composed of 9 units including unconsolidated clastic sediments, clastic sedimentary rocks, carbonate rocks, non-porous volcanic rocks, Triassic-Jurassic intrusive igneous rocks, Cretaceous intrusive igneous rocks, metamorphosed sedimentary rocks, schists and crystalline gneisses. In this area, 3,290 and 714 well data for bedrock and alluvial/weathered part aquifers were statistically analyzed and showed average specific capacity of 13.36 m3/day/m, 146.7 m3/day/m, respectively. In case of bedrock aquifers, non-porous volcanic rocks and Cretaceous intrusive igneous rocks showed low groundwater productivity, while carbonate rocks and metamorphosed sedimentary rocks showed significantly higher productivity. Wells developed in the alluvial/weathered part generally showed high groundwater productivity. The hydrogeological units in the Nakdonggang river basin are composed of 12 units with 3 additional units including porous volcanic rocks, semi-consolidated clastic sedimentary rocks and Permian-Triassic intrusive igneous rocks, in addition to 9 units in the Geumgang river basin. In this area, 2,087 and 780 well data were statistically analyzed and showed average specific capacity of 12.20 m3/day/m and 96.45 m3/day/m, respectively. The areas showing relatively high groundwater productivity in the Nakdonggang river basin are as follows: (1) NW-SE fault line near Uiseong in the clastic sedimentary rock distribution area of the Gyeongsang Basin, (2) NNE-SSW directions in the western part of clastic sedimentary rock area of the Gyeongsang Basin, (3) Jurassic intrusive igneous rock area of the Yeongnam Massif on the western outskirts of the Gyeongsang Basin, (4) crystalline gneisses area (with Proterozoic granites or leucocratic granites) at the northern end of the Nakdonggang river basin, (5) Some south and north part of volcano-plutonic complex in the southeastern Gyeongsang Basin, (6) porous volcanic rocks in the Pohang area. There is a need to

conduct a detailed investigation for identifying potential water sources using groundwater, focusing on these areas.

Relationship between Spatiotemporal Groundwater Quality and Changing Land Use and Land Cover in Korea: A Comprehensive Approach Utilizing Monitoring Data and GIS

Chanhyeok Jeon[1]*, Kangwon National University (jeonchan04@kangwon.ac.kr)
Heejung KIM[2], Kangwon National University

Abstract

Groundwater serves as a critical source of drinking water, catering to the needs of approximately 2.5 billion people worldwide. However, the alteration of land use and land cover (LULC) on a global scale poses significant environmental threats, particularly affecting aquatic ecosystems and contaminating water quality. The consumption of contaminated groundwater not only poses risks to human health but also contributes to various health issues globally. Despite extensive research conducted over the past decades focusing on hydrogeochemistry, groundwater quality, contamination sources, and associated health risks, solutions have predominantly targeted localized issues. Consequently, there exists a research gap that can be addressed through innovative integrated approaches. This study aims to showcase the effectiveness of such novel integration methods. Leveraging a decade's worth of groundwater hydrochemistry and land use data in the Gyeongsang-do in Korea, this research assesses: (a) the chemical composition of groundwater, (b) the spatial distribution and quality of groundwater for drinking purposes using the Pollution Index Grid (PIG), (c) the characterization of hydrochemical properties of groundwater using multivariate techniques such as PCA and correlation analysis, and (d) the projection of future changes in water quality. The outcomes of this study will offer valuable scientific insights into the health hazards linked to nitrate contamination in groundwater, thereby aiding in the preservation of water quality standards in the region.

Enhancing Measurement of Groundwater Flux: Synergistic Effects of Polysulfone-Activated Carbon Composite Carriers

Hyemin PARK[1]*, Division of Earth Environmental System Sciences-Major of Earth & Environmental Sciences, Pukyong National University (hyemin_park@pukyong.ac.kr)
Juyeon Lee[2], Division of Earth Environmental System Sciences-Major of Earth & Environmental Sciences, Pukyong National University
Subeen Kim[3], Division of Earth Environmental System Sciences-Major of Earth & Environmental Sciences, Pukyong National University
Minjune Yang[4], Division of Earth and Environmental System Sciences-Major of Environmental Geosciences, Pukyong National University; Wible Co., Ltd

Abstract

Measuring groundwater flux is essential for the sustainable management of aquifers as alternative water resources in the face of global climate change. Among the various techniques for measuring groundwater flux, the passive fluxmeter (PFM) is a cylindrical device composed of carriers adsorbed with alcohol tracers, each having different retardation factors. The PFM offers the advantages of simple production and setup, along with the capability for long-term monitoring. However, traditional fluxmeters have limitations in the range of flow rates that can be measured. This study aimed to address these limitations by evaluating the adsorption mechanisms of fluxmeter composite carriers that blend polysulfone (90%) with traditional activated carbon (10%). In this study, composite carriers of two sizes, 3 mm (C-3) and 5 mm (C-5), were produced to evaluate the impact of carrier size on adsorption efficiency. Isopropyl alcohol (IPA) and 1-hexanol were used as alcohol tracers in adsorption experiments at concentrations of 0, 10, 25, 50, and 70 mg/L. The data were examined through adsorption isotherms (Langmuir and Freundlich) to assess the adsorption mechanisms. The results of adsorption tests on composite carriers showed that the Freundlich model ($R^2 > 0.99$) adequately explained the adsorption behaviors of both IPA and 1-hexanol. The adsorption efficiency varied depending on the carrier size, with C-3 (IPA = 18.1%, 1-hexanol = 98.9%) achieving higher adsorption efficiency than C-5 (IPA = 4.9%, 1-hexanol = 7.3%). Furthermore, within the C-3, 1-hexanol (KF = 2.1 mg-nLn/g, n = 0.65) showed higher Freundlich constants (KF) and adsorption strength (n) compared to IPA (KF = 0.016 mg-nLn/g, n = 0.43), indicating the advantages of using 1-hexanol as a tracer and composite carriers with a 3 mm particle size. This study confirmed the high adsorption capability of C-3 adsorbed with 1-hexanol, suggesting that future research should investigate the range of flux that can be measured using this carrier.

Anomalous uranium occurrence in southern Telangana, India and its societal implications: Evidence from geological, geophysical, and hydrogeological studies

RAMESH GUGULOTH[1]*, GEOLOGICAL SURVEY OF INDIA (ramesh.guguloth@gsi.gov.in)
Satish B Cahvan [2], GEOLOGICAL SURVEY OF INDIA
T VAIDESWARAN[3], GEOLOGICAL SURVEY OF INDIA

Abstract

Southern part of Telangana state is dominated by granitoids of Peninsular Gneissic Complex of Eastern Dharwar Craton. The granitoids form compositionally expanded suite which include Tonalite-Granodiorite-Monzogranite Suite and Monzogranite-Syenogranite Suite. The granitoids are deformed and are affected by NW-SE, NE-SW & N-S trending lineaments and NW-SE trending localized shears. fracture planes, sericitization, and chloritization are common characteristics in monzogranite, which is prone to hydrothermal alteration, particularly at joints. Anomalous concentrations of Uranium were found in monzogranite with abundances ranging from 32 to 369 ppm (n= 37 & Avg: 128 ppm) and Th contented ranges from 14 to 82 ppm (n=37 & Avg. 41 ppm). Groundwater samples reveal high concentration of uranium ranging from 7 to 4450 ppb (n= 100 & Avg: 517 ppb) to the permissible limit (>30 ppb of WHO). Based on the hydro geochemical data a vertical borehole was drilled upto a depth of 150 m near Gummalabavi village, Nalgonda district and intersected monzogranite, alkali feldspar granite and pegmatite. Core samples collected at 4m depth intervals were analyzed by XRF & ICPMS. Analytical data indicate that the source of Uranium is monzogranite. U-Th bearing mineral phases (Uranophane, coffinite, Uranothorite and thorite) was detected by SEM-EDX. Petrographic studies additionally revealed zircon, monazite, and allanite. Four uraniferous subsurface zones ranging in thickness from 4m to 8.0 m was demarcated in granitoid at different depths ranging from 52 m to 104 m which helps in identifying the aquifers corresponds to anomalous abundance of radioactive elements. Anomalous radioactive concentrations are associated with fracture/vein zones. Geophysical logging of the borehole (150 m) using Century Geophysical Logger by utilizing Elog (Fluid & Lateral Resistivity and Natural Gamma) indicate that fluid resistivity gradually decreases from top (5 Ω.m) to bottom (4.5 Ω.m) with a sharp decrease at the depth of 54-64 m (polluted zone). Some small kinks are observed at places in Lateral Resistivity curves are indicative of minor fractures/joints. A sudden drop of resistivity from 250 Ω.m to 1000 Ω.m and positive S.P anomaly of +100 mV at a depth of 143.5 to 148 m corresponds to major fracture zone (zone of water rock-interaction). High natural Gamma counts between 48 and 100 meters (900-4660 API) and U in the lithology is well supported by natural gamma at various depths. Geophysical data shows deep groundwaters (>60 m) are more contaminated and low to moderate contamination found at shallow depth. Groundwater is mostly alkaline (pH: 6.79 to 9.13) in nature. The ionic dominance pattern is Na+ > Ca2+ > Mg2+ > K+ cations and HCO3 > Cl- > SO4 > NO3 > F- anions. Na-HCO3 type water and strong correlation with F-, Fe and Na+ suggest the hydro

geochemical control of uranium concentrations in groundwater. Strong bicarbonate and Na-HCO3 in the groundwater enhanced the dissolution of minerals in water-rock interaction zone. Groundwater is the primary drinking supply in rural areas of southern Telangana state. Significant amount of uranium consume is likely to cause complex health problems and bone deformities in the residents.

Abstract

Uzbekistan is a landlocked country entirely dependent on freshwater for water resources. Due to the desert climate and recent acceleration of desertification, water resource shortage is emerging as a major problem. In 2018, despite agriculture accounting for more than 30% of the country's gross domestic product, an emergency policy was formulated to address water resource problems, even by reducing farmland. The Uzbekistan government is establishing various policies and roadmaps to alleviate this water shortage and secure water resources. There is particular interest in the development and utilization of groundwater. However, groundwater in Uzbekistan has high salinity and mineral content, making direct use of water resources impossible.

Meanwhile, Ministry of Mining Industry and Geology of the Republic of Uzbekistan reported that some groundwater areas with high salinity and mineral content in Uzbekistan contain rare metals. In particular, they contain high concentrations of rare metals such as lithium, iodine, strontium, magnesium, boron, germanium, and cobalt. To confirm this, samples were collected from seven major regions and 18 wells or wastewater storage facilities in Uzbekistan. Analysis of pH, TOC, T-N, T-P, and other parameters was performed to obtain quantitative and qualitative analysis of inorganic substances and basic water quality data. The water quality analysis confirmed a pH range of 5.6 to 7.97, indicating slightly acidic to mostly neutral content with low organic matter. Overall, the composition was similar to seawater with high Na and Cl contents, and the total dissolved solids (TDS) concentration was analyzed to be over 130,000 mg/L, containing lithium, strontium, magnesium, and other substances in high concentrations due to saltwater. In other words, groundwater in Uzbekistan contains high salinity and beneficial resources for industrial use.

Therefore, economic profits can be generated by securing Uzbekistan's currently scarce water resources while recovering useful resources from water treatment by-products. This study introduces optimal water treatment technology to address water problems caused by groundwater treatment and methods for economically recovering the abundant useful resources in Uzbekistan's groundwater.

Changes in soil characteristics due to long-term groundwater artificial recharge

Myoung-Rak CHOI[1]*, Daejeon University (audfkr18@naver.com)
Taek-Soo Hong[2], Daejeon University
Chang-Hee Kim[3], Daejeon University
Chan-Ik Hwang[4], GEO-IN SOLUTIONS Co.,Ltd.
Hyun-Na Kim[5], Kongju National University
Gyoo-Bum Kim[6], Daejeon University

Abstract

Groundwater artificial recharge involves replenishing aquifers to increase water resources and is used for water quality improvement. In this study, the long-term operation (approximately 1.5 years) of a groundwater artificial recharge system installed in Singok Village, Galsan-myeon, Hongseong-gun, Chungcheongnam-do, was evaluated by categorizing the changes in soil into pre-injection, during injection, and post-injection phases. The evaluation of the occurrence of clogging in the vicinity of the injection wells was performed through particle counter analysis, geochemical analysis, and assessment of the formation of iron oxides/manganese oxides. Particularly, soil samples were collected near the injection wells for particle size and density analysis, as well as mineral analysis using techniques such as XRD and XRF, to assess the state of change in soil media. The content of colloidal materials in the soil decreased from 1.44-3.40% during recharge to 1.19-2.62% after recharge. This decrease is attributed to the fact that the fine particle content in the pre-treated recharge source water, which is a base-flow, is lower than that in the aquifer. The analysis of the composition of minerals and texture of the soil before artificial recharge revealed that organic matter, such as illite, montmorillonite, and kaolinite, which are microfine particles, are filled around detrital particles such as quartz, feldspar, biotite, and amphibole. After artificial recharge, it was observed that in some injection areas, the veins disappeared due to the alteration of biotite, and clay minerals occurred to fill the pores. When long-term artificial recharge is implemented, changes in the soil media may occur depending on the characteristics of the injection water and the aquifer. Therefore, ongoing management is necessary to address issues such as reduced injection rates due to clogging.

Development of a predictive model for chloride ion and nitrate nitrogen concentrations in groundwater using ensemble models

Chan-Ik HWANG[1]*, GEO-IN SOLUTIONS Co., Ltd. (loveu2u@hanmail.net)
Young-Shik Shin[2], Intellegeo. Co., Ltd.
Jin-Woo Kim[3], Korea Water Resources Corporation
Gyoo-Bum Kim[4], Daejeon University

Abstract

Recently, due to climate change, the importance of groundwater as a stable water resource has been increasing. The increasing availability of groundwater-related data is making it easier to predict groundwater contamination characteristics. In this study, a predictive model for the concentration of chloride ion and nitrate nitrogen in groundwater was developed using water quality analysis results from groundwater monitoring networks managed by government agencies such as the Ministry of Environment as well as factors that could affect groundwater quality. Two types of input factors were used. The first type included factors related to groundwater flow, such as elevation, terrain slope, rivers, soil characteristics, and hydrogeology. The second type consisted of factors related to contamination sources, such as population, buildings, environmental pollution facilities, livestock farms, coastlines, industrial complexes, greenhouses, and land cover types. Ensemble models were developed to predict whether the chloride ion concentration exceeds 80 mg/L and whether the nitrate-nitrogen concentration exceeds 8 mg/L. The F1 score for predicting chloride ion concentration showed a true classification rate of 0.86 for training data and 0.83 for validation data, while the F1 score for predicting nitrate-nitrogen concentration showed a true classification rate of 0.85 for training data and 0.81 for validation data. The k-fold validation results for each model indicated F1 scores ranging from 0.83 to 0.85 for chloride ion concentration across four folds and from 0.78 to 0.82 for nitrate-nitrogen concentration across four folds, demonstrating the utility of the models. When comparing the model's prediction results with water quality test data in 2018 for the entire region of Gongju City, Chungcheongnam-do, it was evaluated that the distribution of high-concentration points was similar.

Abstract

The East Jeju region faces a complex challenge for groundwater resources due to the potential seawater intrusion and environmental deterioration by brine water discharge to the nearshore from the desalination process. This study aims to project further seawater intrusion phenomena and propose the injection of brine water into the subsurface layers as an alternative invulnerable disposal method in Jeju island. The numerical modelling approach was employed to simulate the groundwater flow and mass transport in the study area, which has a complex aquifer structure that consists of volcanic, hyaloclastite, and impermeable Seogwipo formation layers. The simulated results were calibrated and validated using field data, including water level and salinity measurements. The result showed that the groundwater model is sensitive to several hydraulics properties, and changes in these parameters can significantly impact the projection of saltwater intrusion and brine injection effect. The model results were used to explore the impact of several scenarios, including changes in pumping volumes and brine water injection to the subsurface layers with different rates, depths and distances. It also helps to identify areas where additional data collection and monitoring are needed. The findings of this study highlight the importance of a systematic and integrated approach to managing coastal aquifers with similar geological backgrounds and provide a different solution to the brine water discharge from the desalination plant.

Recharge processes and chemical evolution of groundwater affected by geogenic and agricultural contamination in the mountainous areas with granitic and sedimentary bedrocks

Hyo-Sik Seo[1]*, University of Science and Technology (hyosik@kigam.re.kr)
Dong-Chan Koh[2], Korea Institute of Geoscience and Mineral Resources, Daejeon 34132, Republic of Korea
JongHyun Oh[3], University of Science and Technology

Abstract

Groundwater is an important water resource and is utilized in many areas of housing, agriculture, and industry. To effectively manage and utilize groundwater, a sufficient understanding of its system is essential. Especially, it is important to understand groundwater systems in mountainous areas because groundwater flows along faults or near the ground surface and enters aquifers into lowland areas. However, there is a lack of research on the groundwater recharge process and the chemical evolution of groundwater in mountainous areas. This study aimed to characterize the recharge process of groundwater in mountainous areas and the chemical evolution by geogenic and agricultural contamination during this process. We sampled groundwater from 122 wells in October 2021 in the upper part of the Nakdonggang River basin, one of the largest watersheds in South Korea. The groundwater samples were analyzed for water stable isotopes, major and trace elements. The distribution of stable isotopes showed that the groundwater was divided into three groups, with different spatial distributions. Comparing bedrock lithology, pH, and concentrations of Na, Ca, Mg, K, Sr, HCO3, SO4, and B were significantly higher in sedimentary rocks, while concentrations of SiO2, NO3, and U were higher in granitic rocks at the 0.05 significance level. The correlation with land use showed that the concentrations of SiO2, NO3, and Cl were significantly lower in natural areas compared to agricultural areas. Therefore, recharge sources of groundwater in the study area were different and it is characterized by water stable isotopes. During the chemical evolution, water-rock interaction in sedimentary rocks was dominant. Agricultural activities, although not dominant, influenced the recharge process and chemical evolution of groundwater. This study is expected to significantly contribute to understanding the recharge and chemical evolution of groundwater in mountainous areas, providing valuable insights for groundwater management and policy establishment.

This work was supported by the Basic Research Project (24-3411) of the Korea Institute of Geoscience and Mineral Resources (KIGAM) funded by the Ministry of Science and ICT, Republic of Korea.

Stable water isotopes (δ18O, δD) and groundwater dating tools (3H, CFCs) coupled with hydrochemistry to evaluate groundwater flow dynamics of complex basaltic aquifer

Hyun-Ji Kang[1]*, Korea University (bisuraa@korea.ac.kr)
Suhyung Moon[2], Jeju Special Self-Governing Province Development Corporation
Eun-hee Hyun[3], Jeju Special Self-Governing Province Development Corporation
Hyuntai Ahn[4], Korea University
Soonyoung Yu[5], Korea Institute of Geology and Mineral Resources
Seong-Taek Yun[6], Korea University

Abstract

Understanding groundwater flow in complex volcanic strata requires identifying groundwater recharge, which is often complicated by the heterogeneous distribution of permeable structures. Stable isotopes of water (δ18O, δD) serve as a valuable tool for this purpose. Stable isotopes of precipitation tend to be progressively depleted with increasing elevation, leaving distinctive signatures in recharged groundwater, enabling the determination of recharge elevations. However, since the stable isotopes of water reflect the integrated weighted average of the recharged annual rainfall, the limitation arises in distinguishing between different flow paths using only stable water isotopes when groundwater is recharged in multiple places and mixed within the aquifer. To address this limitation, age tracers (3H, CFCs) complement stable isotopes, helping distinguish relatively old groundwater flowing along long paths from young groundwater with shorter paths. Furthermore, a comprehensive interpretation of groundwater evolution, including water-rock interaction and the influence of anthropogenic contamination, can be possible by integrating hydrochemical data of rainfall and groundwater.

This study was conducted on the mountainous region of the Pyosun watershed of Jeju volcanic island, South Korea, where 602 groundwater samples were collected from 16 wells between March 2016 and October 2020. Rainwater samples were also collected monthly or quarterly from seven locations at varying elevations (265 to 1500m) during 2016-2020. The analysis of stable isotopes and physicochemical variables of water samples was conducted for the samples, with additional quarterly measurements of age tracers in groundwater from ten locations. Groundwater in the study area is clustered into two groups with distinct recharge elevations: 1) highland recharge with lower ionic concentrations (i.e., lesser anthropogenic contamination) and lighter isotopic compositions, and 2) lowland recharge with heavier isotopic compositions. Based on these characteristics, it is likely that groundwater recharges at high mountainous areas, travels through long flow paths, and mixes with groundwater of local infiltration through permeable structures. The estimation of groundwater age using CFCs and tritium also reaffirmed that the two groups have distinct flow paths. In the highland wells, the average groundwater age was relatively older with low variability, whereas in the lowland areas, the groundwater exhibited relatively younger age with higher variability. The high variance of groundwater age in the lowland area is assumed to be the influence of local recharge. This study demonstrates that integrating stable

water isotopes, hydrochemistry, and multiple environmental tracers improves the understanding of recharge and flow of groundwater resources in a complex subsurface geology.

Exploration of Groundwater in the Eastern Region of Thailand for Sustainable Groundwater Management

Benya SUNANTA[1]*, Department of Groundwater (benya4002@gmail.com)
Kannika Loylong[2], Department of Groundwater

Abstract

Thailand is suffering from the effects of climate change that occur regularly every year, especially in the drought problem, resulting in insufficient water for both consumption and consumer purposes. According to economic and social growth, which has led to urban and industrial expansion, water requirements have increased more than water supplies. To solve that problem and increase the efficiency of water management in disaster emergencies, it is necessary to explore and analyze both quantity and quality to identify the potential of groundwater supply and distribute water supply to support human activity. This project is being conducted in every part of Thailand; the study area in the eastern part is presented.

The study area included 3 provinces in the eastern part of Thailand, 2 locations in Rayong, 2 locations in Sakaew, and a location in Chanthaburi that presented different geology and hydrogeology in each area. The methodology for exploring an appropriate drilling point is a 1D surface resistivity survey with a Schlumberger array. The result of the survey data is analyzed with a literature review of the study area in both the fields of geology and hydrogeology. Selecting the appropriate drilling points shows two locations from five; the first station is located in the administrative subdistrict of Wangwa. The aquifer in this area is the colluvial deposits aquifer (Qcl). 120 meters is the depth of drilling for the observation well, and 92 meters is the depth of the development well. The water quantity is 8 cubic meters per hour. Total dissolved solids are 288 milligrams per liter. 2nd Station is in the municipality of Salalumduan. Hydrogeology reveals the Lower Khorat Aquifer (TRlK). 140 meters is the depth of drilling for the observation well, and 92, 122, and 116 meters are the depths of the development well. Water quantity is averaged at 3 cubic meters per hour. Total dissolved solids are 170 milligrams per liter. After drilling a groundwater well, water supply points and a water system are constructed to support people's activities and water requirement.

Groundwater recharge estimation along a climate gradient - a Northern Namibian case study

Josefina Tulimevava Hamutoko[1]*, University of Namibia (jhamutoko@gmail.com)
Heike Wanke[2], University of the West of England

Abstract

In Northern Namibia, as in many parts of sub-Saharan Africa, people rely on groundwater as a primary source of drinking water. However, the mechanisms for, and rates of replenishment of this resource (groundwater recharge) are poorly known. This study estimated groundwater recharge rates from the stable isotopes parallel shift method range from 0.7 to 70 mm/a with the highest values obtained for Zambezi west and the lowest for western Cuvelai. Estimation was done for shallow aquifers on a transect across half of the African continent, stretched from western Kunene to the Zambezi in the East along the proximities of latitude 18°S. There is increased human demand for water resources due to fast-growing and often uncontrolled settlements and rapidly expanding industrial activities. These stressors on water supplies are exacerbated by climate change, potentially placing unprecedented pressure on this vital resource. Thus, the sustainable management of water resources is a real and urgent challenge for local and regional government authorities and local water point committees. Stable isotope analyses were conducted using a laser spectrometer at the University of Namibia, while the chloride content in groundwater samples was measured argentometric at the Analytic Laboratory in Windhoek. Local meteoric water lines were derived for the different regions. Chloride Mass Balance also show the same trend in recharge rates. Stable isotopes also allude to different recharge mechanisms for the different regions reflecting the precipitation gradient and the various landscapes. It is recommended that groundwater management practices should be designed considering differences in recharge rates and mechanisms.

Hydrogeochemical Appraisal and macrophyte diversity in Inland water bodies of a subtropical country

DEEPTI PANDEY[1]*, IISER BHOPAL (deepti23@iiserb.ac.in)
Narendra kumar[2], BBAU LUCKNOW

Abstract

Small surface water bodies such as ponds, lakes, marshy areas, wetlands, swamps etc. plays pivotal role in the ground water recharge system. Further, these water bodies are crucial for various bio-geochemical cycles, host biological diversity and are important for maintaining ecological balance. They also serve as sink for carbon there by contributing in combating the global warming and climate changes issues. However, such water bodies are facing chronic effect threat in terms of both quality as well as quantity due to urban sprawl, industrial expansion, and land conversion, improper discharge of industrial, municipal and agricultural waste. Considering the above striated importance and threats the present study focuses on the evaluation of water quality index of nineteen distinct surface Bodies with the help of several physico-chemical variables including major ion chemistry. Macrophyte diversity in these meso-aquatic fresh water ecosystems has been considered as Bioassays to assess the cumulative impact of known as well as unknown chemicals. Abundance (%) of macrophytes: Pistia stratiotes (84.21)> Azolla pinnata (78.95)> Lemna minor (73.68)> Eichhornia Crassipes (68.42)> Marsilea Quadrifolia (52.63)> Ipomoea aquatica (47.37)> Hydrilla verticilata (21.05) reflected the States of eutrophication and aging. Analysed parameter viz. TDS, EC, pH Alkalinity, total Hardness, major cations (Ca+2, Mg+2, Na+ , K+), and major anions (HCO3-, Cl-, PO4-2, SO4-2 have exceeded the permissible limits prescribed by the Bureau of Indian Standards IS: 2296 for surface water quality finding underlines the threats of human activities to these fresh water ecosystems and warrants attention of their revival/conservation.

Occurrence and behavior of nitrate and per- and polyfluoroalkyl substances (PFAS) in groundwater of Haean basin, Korea

seunghoon CHOO[1]*, Department of Geology, Kangwon National University, Republic of Korea (choosh0907@kangwon.ac.kr)
Jihye Cha[2], Department of Geology, Kangwon National University, Republic of Korea
Jin-Yong Lee[3], Department of Geology, Kangwon National University, Republic of Korea

Abstract

The risks of nitrate and per- and polyfluoroalkyl substances (PFAS) are well-recognized worldwide. Nitrate is primarily derived from agricultural activities. PFAS persist in the environment due to their non-biodegradable nature and have been detected not only in urban areas but also in rural areas, as revealed by research. The study area is located in the upper of the Soyang River basin and has a simple basin topography, making it an appropriate place for conducting the study. The residents in the study area use groundwater mainly for agricultural purposes and partially for drinking. Groundwater contamination could have adverse effects on both residents and crops due to the high dependency on groundwater. Therefore, it is essential to assess the contamination levels of nitrate and PFAS in the groundwater of the study area. In this study, we will investigate the concentrations and distributions of nitrate and PFAS in groundwater wells within the Haean basin, an area characterized by developed agriculture. The aim of this study is to identify the sources and extent of contamination in the groundwater of the study area and elucidate the behavior of contaminants. Groundwater samples will be collected from the study area every season for field parameters and laboratory water quality analysis. Ion chromatography (IC) and Liquid Chromatography-Mass Spectrometry (LC-MS/MS) will be used for laboratory water quality analysis, with a focus on nitrate and PFAS. The result of the analysis will be used to confirm and evaluate the levels of groundwater contamination in the study area, identify the sources of contamination, and assess their potential impact on the surrounding environment. We expect this study will be used to minimize the impact on local communities and ecosystems and contribute to formulating responses for groundwater management in the study area. This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (No.2019R1A6A1A03033167).

Criteria of groundwater level change in relation to the operation of a river barrage

Se-Yeong HAMM[1]*, Pusan National University (jjy@korad.or.kr)
Se-Yeong HAMM[2], Pusan National University
Ji-Hye Jeong[3], Korea Water Resources Corporation

Abstract

Groundwater drought, in relation to global climate change, poses a great water challenge to human. This study analyzed groundwater level fluctuations from May 2012 to October 2020 around the Changnyeong-Haman river barrage (CHRB) on the Nakdong River. Groundwater-level types were grouped with considering the river stages. Next, a more detailed clustering was executed by using kernel density estimation (KDE) and standardized groundwater level index (SGLI). KDE and cumulative kernel density estimation (CKDE) were computed for Clusters 1 to 5. Cluster 1 exhibited a rapid increase in CKDE compared to those in Cluster 2. Cluster 3 demonstrated the slowest increase in CKDE, characterized by a gradual peak. An abrupt change in the slope of the cumulative probability density, observed in Cluster 1, occurs under various external influences such as pumping, the opening of the CHRB, or rainfall. The criteria of groundwater drought for the caution, severe, and very severe stages correspond to SGLI values of -0.674, -1.282, and -1.645 or the 25th, 10th and 5th percentiles, respectively, for forecasting and warning groundwater drought. During the observation period of 7 years and 6 months (2,851 days), Cluster 1 displayed 209 to 735 days falling below the 25th percentile, 84 to 288 days below the 10th percentile, and 39 to 143 days below the 5th percentile. Cluster 2 showed 197 to 698 days below the 25th percentile, 36 to 299 days below the 10th percentile, and 0 to 125 days below the 5th percentile. On the other side, Cluster 3, illustrated 213 to 125 days below the 25th percentile, 80 to 283 days below the 10th percentile, and 42 to 144 days below the 5th percentile. By this result, groundwater drought based on the SGLI values and percentiles in relation to the operation of the CHRB provides valuable insights for effective groundwater resource management. This study was financially supported by the National Research Foundation of Korea (NRF) grant funded by the Ministry of Science and ICT (2020R1A2B5B02002198).

Abstract

The lagoon is a unique environment where freshwater and saltwater are mixed and it is rich in biodiversity. Recently, the lagoon environment has been damaged due to artificial development such as the creation of tourist attractions. In addition, coastal zones are particularly vulnerable to future climate changes such as sea level rise. Systematic study of water management of the lagoon is required because of its high conservation value. The study area is Hwajinpo lagoon located on the eastern coast of Korea. The existing environment of the lagoon was evaluated by identifying the distribution of the groundwater level and groundwater flow characteristics. Hydrogeochemical fluctuations were analyzed to determine the effect of seawater intrusion into the aquifer. The results demonstrate that the freshwater-saltwater interface is distributed throughout the aquifer and rises when water of the lagoon evaporates due to prolonged periods of low rainfall and high temperature, thereby increasing the possibility of seawater inflow through groundwater. The ratio of seawater mixed at each point was calculated, using oxygen isotopes and chloride as tracers, resulting in an average of 0.24 ~ 0.32 and a maximum of 0.90. As for the ionic delta properties (difference between the measured and theoretical concentration of mixed waters) and the saturation index, it was estimated that the cation-exchange and precipitation reactions occurred in the aquifer due to seawater intrusion. Seasonal variation in rainfall affects ion concentrations in aquifers and should be considered for understanding the ecosystem of lagoons. Time series analysis was applied to groundwater, lagoon, rainfall and tide data obtained from monitoring wells to determine the correlation.

Delineation of Seawater intrusion in the coastal aquifer using the 3-Dimensional Groundwater modelling in the Harbour city of Thoothukudi, Tamil Nadu, India.

SNOWLIN F[1], Master Student
MANJU POORNA SREE MURUGAN[2], Master Student
THIRUMURUGAN MARIMUTHU[3]*, Assistant Professor (thiru19591@gmail.com)

Abstract

Coastal aquifers around the world are under threat by witnessing the wide range of environmental issues especially due to Sea water intrusion. Seawater intrusion affects the quality and sustainability of the groundwater resources in the coastal aquifers. The excessive pumping of groundwater in the coastal aquifer has led to mixing of seawater freshwater interface, which results in salinization of groundwater. In India, most part of the coastal aquifers are affected by seawater intrusion up to 2 km, whereas it is intruded up to 15 km towards inland in the coastal aquifers of Chennai. Recently groundwater salinization has become a major threat in the harbour city Thoothukudi of Tamil Nadu state due to excessive pumping of groundwater, lack of groundwater recharge and reduced rainfall rate. The present study was carried out to evaluate the groundwater chemistry of the region and to delineate the extent of seawater intrusion. Groundwater samples were collected during October 2023 and January 2024 in 18 locations around the Thoothukudi town. The collected samples were analyzed to determine the pH, total hardness, TDS, Ca2+, Mg2+, Na2+, K+, NO3-, Cl-, SO42−, HCO3-, F-. It was found that most part of the coastal regions were highly salinized and the high concentration of Na-Cl are observed. The extent of seawater intrusion was demarcated using the 3-Dimensional Numerical groundwater modelling using the FEFLOW computer code. Groundwater model was developed under steady and transient condition to the aquifer characteristics of the region. Further density dependent groundwater model was developed to study the extent of seawater intrusion. It was found that the seawater were intruded in the coastal aquifer up to the distance of 3km. It showcases the threat to the aquifer of the region, hence it is necessary to formulate the mitigation and remediation measures for sustainable management of groundwater system.

Geochemistry of Accessory Minerals as Sources of Radionuclides in Mesozoic Granite Aquifers of Korea

Jeong HWANG[1], Daejeon University
Jin-Yong LEE[2]*, Kangwon National University (hydrolee@kangwon.ac.kr)
Stefano VIAROLI[3], University of Pisa

Abstract

In granitic aquifers, the contribution of accessory minerals to groundwater radionuclide levels is generally negligible due to their outstanding resistance to solubility. Nonetheless, the structure of accessory minerals incorporating uranium (U) and thorium (Th), may be compromised by radioactivity, making them more amenable to alteration. This research delves into the chemical and textural characteristics of accessory minerals containing U and Th, employing advanced techniques such as field emission scanning electron microscopy and electron probe micro-analysis. The findings aim to assess influence of accessory minerals to radionuclide concentrations in the Mesozoic granite aquifers. Altered zircons show extensive open structures resulting from radioactive breakdown. Altered zircons reveal an increased amount of U and Th alongside and reduced analytical totals. Certain thorites, altered through hydrothermal processes into a metamict state, exhibit elevated U levels and additional elements not accounted for in their original formula. Cerianite that incorporates U is found within tiny veinlets in cracks accompanied by iron (Fe) and manganese (Mn) oxides, suggesting the creation of a secondary phase arising from the breakdown of accessory minerals under oxidizing conditions. In the Mesozoic granite regions of South Korea, accessory minerals rich in U and Th have been identified, coinciding with reports of elevated groundwater radionuclide concentrations. The extraction of U from these minerals appears more feasible in instances where they have undergone significant metamictization or alteration, as evidenced by our research findings. In such Mesozoic granite aquifers, where no soluble U-minerals have been identified, the studied altered zircon and thorite may play a crucial role in transporting radioelements.

Comparison of occurrence characteristics of PFAS in Korean groundwater and surface water using online SPE-LC-MS/MS

Sang Hun AN[1]*, Korea Institute of Geoscience and Mineral Resources (sdshnet@kigam.re.kr)
Woo-Hyun JEON[2], Korea Institute of Geoscience and Mineral Resources
Dong-Hun KIM[3], Korea Institute of Geoscience and Mineral Resources
Sung Pil HYUN[4], Korea Institute of Geoscience and Mineral Resources
Hee Sun MOON[5], Korea Institute of Geoscience and Mineral Resources

Abstract

Per- and polyfluoroalkyl substances (PFAS) are emerging contaminants detected ubiquitously in aquatic environments due to their wide application in industrial and consumer products since the 1940s, providing resistance to heat, water, and oil. Groundwater, essential for domestic and agricultural water supply, also faces PFAS contamination through various pathways such as industrial leakage, wastewater treatment plant effluent, and infiltration by river water. Despite many countries investigating PFAS analysis in groundwater, research on monitoring them in Korea remains limited. Moreover, due to the trace amounts of PFAS present in groundwater, pretreatment of large volumes using manual solid-phase extraction (SPE) consumes significant labor and time. Therefore, fully automated online SPE system is being considered for PFAS pretreatment due to its minimal sample handling, small sample volume, and reduced solvent use.
This study aims to analyze PFAS by applying online SPE connected to LC-MS/MS, and to compare the occurrence characteristics of PFAS in Korean groundwater and surface water. Groundwater (n = 6 samples) and surface water (n = 6 samples) were collected near industrial complexes in Chilgok County, Gyeongsangbuk-do on October 30, 2023, and analyzed for 11 species of PFAS (PFBS, PFHxA, PFHxS, PFHpA, PFOA, PFOS, PFNA, PFDA, PFDS, PFUnDA, PFDoDA). Compared to manual SPE, online SPE reduced the sample amount required for analysis by approximately 200 times and decreased the sample loading time by 26 minutes per sample, significantly reducing both time and labor. When comparing the sum of PFAS at each site, the surface water exhibited a significantly higher average concentration of 26.84 ng/L compared to 19.34 ng/L in the groundwater (p-value of 0.018). This was consistent with the previous study in the Nakdong River basin (Yong et al., 2021). PFBS was the most frequently detected substance in both groups, accounting for 22-25% (6.29-6.45 ng/L) in surface water and 17-23% (3.11-7.05 ng/L) in groundwater. PFHxA was the second most common compound in surface water, accounting for 16-18% (4.60-4.80 ng/L), whereas it was detected at the lowest levels (LOQ-1.6 ng/L) in groundwater. The lower concentration of PFHxA in groundwater compared to surface water is likely due to some of it being adsorbed by soil as surface water infiltrates the groundwater, necessitating further research into the sorption behavior and characteristics of PFAS in aquifers.

This work was supported by the Research project “Advancing Assessment and Monitoring

Technologies for PFASs in Groundwater (JP2023−003)" of the Korea Institute of Geoscience and Mineral Resources (KIGAM) and the Basic Research Project (GP2020−012) of KIGAM funded by the Ministry of Science and ICT.

Identification of arsenic spatial distribution by hydrogeochemical processes represented by different ion ratios in the Hohhot Basin, China

Yu REN[1]*, Institute of Hydrogeology and Environmental Geology, Chinese Academy of Geological Sciences (925666311@qq.com)
Wengeng CAO[2], Institute of Hydrogeology and Environmental Geology, Chinese Academy of Geological Sciences

Abstract

The Hohhot Basin, a typical inland basin of the Yellow River Basin in China, has high concentrations of arsenic (As) in its shallow
groundwater, while the factors dominating the distribution of high arsenic levels remain to be further identified. An analysis of the
ratio of hydrogeochemical compositions can help to reveal the spatial characteristics of the shallow groundwater environmental
conditions and the distribution of high-arsenic water (As >10 μg/L). In this study, a total of 170 samples of shallow groundwater
in the Hohhot Basin were collected and water samples with As >10 μg/L accounted for 29.4% of the total. Based on the slope
changes of the cumulative frequency curves of (HCO3− + CO32−)/SO42−, Ca2+/(HCO3− + CO32−), Ca2+/Mg2+, and Na+/Ca2+, the groundwater in the study area can be categorized into six different zones according to the environmental characteristics including redox condition, water recharge intensity, and cation exchange level. The result shows that the groundwater in the front of the piedmont alluvial plain and platform is in a weak reducing condition with high lateral recharge intensity, fast runoff, and weak cation exchange. In the Dahei River alluvial plain, which serves as the groundwater discharge zone, the groundwater runoff is sluggish with poor lateral recharge, sufficient exchange between cations in the groundwater and the aquifer matrix, and enhanced reducibility. The degree of oxidation increased in the groundwater near the Hasuhai Lake and the drainage canal, which adverse to the arsenic enrichment. High-arsenic groundwater is mainly distributed in aquifers of (HCO3− + CO32−)/SO42 > 10, Na+/Ca2+ > 13, and Ca2+/(HCO3− + CO32−) < 0.1, which represent the strong reducing condition, low surface water recharge intensity, and strong cation exchange condition. Reductive dissolution of iron oxide, strong evaporation and concentration process, and competition from phosphate in aquifers jointly lead to the release of arsenic into groundwater.

Groundwater and Environmental Challenges in Asia

Yanpei CHENG[1]*, Institute of Hydrogeology and Environmental Geology, Chinese Academy of Geological Sciences (yanpeicheng@tom.com)

Abstract

Asia stands out as the most populous and geographically diverse region globally. The pressing issues of water resource development and the resulting ecological impacts are exacerbated by the region's rapid population growth and economic expansion. Groundwater, a vital source of water in Asia, faces significant disparities in distribution and suffers from unsustainable exploitation practices . This study applies groundwater system theory and categorizes Asia into 11 primary groundwater systems and 36 secondary ones, based on intercontinental geological structures, climate, terrain, and hydrogeological characteristics. As of the end of 2010, Asia's assessed groundwater resources totalled 4.677 x 109 m3/year, with exploitable resources amounting to 3.274 x 109 m3/year. The groundwater natural recharge resources in sparse aquifers amount to only 386.14 × 10^9 m^3/year, accounting for merely 8% of the total natural groundwater resources in Asia. Meanwhile, the natural recharge resources in continuous aquifers in plains and intermountain basins, as well as in discontinuous aquifers in hills and mountains with bedrock, account for 52% and 40%, respectively, of the total natural groundwater resources in Asia. Among these, continuous aquifers in plains and intermountain basins have the highest natural recharge resources, constituting 52% of Asia's total natural recharge resources. By considering the geological environmental impacts of groundwater development and the distinctive characteristics of terrain and landforms, six categories of effect zones with varying distribution patterns are identified. Groundwater, as a valuable resource and a key environmental factor, is essential for sustaining life and ecosystems. However, excessive exploitation of groundwater resources can lead to a range of negative geological, ecological, and environmental effects, including sustained declines in groundwater levels, deterioration of water quality, and associated adverse impacts. Moreover, it jeopardizes spatial security for human existence.The current research on Asia's groundwater resources, environmental dynamics, and human impacts aims to provide a theoretical foundation for sustainable groundwater management and environmental conservation in the region.

Nubecularia-coralline algal-serpulid-microbial bioherms of the Paratethys Sea – distribution and paleoecological significance (upper Serravallian, upper Sarmatian, Middle Miocene)

Werner E. E. Piller[1]*, University of Graz, Austria (werner.piller@uni-graz.at)
Mathias Harzhauser[2], Natural History Museum Vienna

Abstract

Nubecularia bioherms represent unique bioconstructions which are restricted to the upper Serravallian of the Paratethys and are reported since the 19th century. They occur in the Central Paratethys in the late Sarmatian and in the Eastern Paratethys in the Bessarabian both regional stages of the respective Paratethyan areas. Several locations in the Vienna and Styrian basins of the Central Paratethys were studied out of which four localities were documented in detail (Wolfsthal, Maustrenk, St. Margarethen - Zollhaus, Vienna - Ruzickagasse) to reconstruct their sedimentary setting, their internal composition, and their indications of environmental parameters. The detailed studies included logging of outcrop sections, petrographic, facies and biotic analyses of polished slabs and thin sections and also cathodoluminescence analyses. These yielded that these bioconstructions are not only composed of the foraminifer Nubecularia, but represent a complex mixture and interrelationships of Nubecularia, serpulids and microbial carbonate. Four boundstone types can be differentiated: Nubecularia boundstone, Nubecularia-coralline algal boundstone, stromatolitic/thrombolitic boundstone and serpulid-nubeculariid-microbial boundstone. The first 3 types are characteristic for specific localities the fourth type occurs in all studied locations and represents the terminal association on top of the three other types. The three basal boundstones are predominantly of columnar growth form irrespective of dominance of Nubecularia, coralline algae or microbial carbonate, the terminal boundstone is widely irregularly organized. The general depositional environment is characterized by cross bedded oolitic grainstones with abundant quartz grains, miliolid foraminifers and molluscs. Intercalated are microbial carbonates mostly stromatolites but also thrombolites. This indicates a general high water energy environment interrupted by more calm periods when the microbial carbonate was built. The 3 basal types of bioconstructions are interpreted to reflect decreasing food supply and/or oxygenation from Nubecularia over Nubecularia-coralline algal to stromatolitic/thrombolitic boundstone. The serpulid-nubeculariid-microbial boundstone reflects an internal succession with a decrease of the same parameters. Water depth is considered very shallow ranging from 0 to a few meters and salinity was normal marine to hypersaline. The reconstructed paleoenvironment with dominating oolite shoals and seagrass meadows was not restricted to the Central Paratethys but extended over the entire Paratethys and represented the largest oolite facies area of the entire Cenozoic!

The basal Triassic microbialites, between reef building and red ammonoid limestone

Aymon BAUD[1]*, Lausanne University, Earth Science Institute (aymon.baud@unil.ch)
Hugo BUCHER[2], Zurich University, Paleontological Institute and Museum,, Switzerland

Abstract

In Armenia on the northern side of the Neotethys, within the post-extinction lower Triassic so-called reef gap, a described 15-m high basal Triassic sponge-microbial buildup, with overturned cone-shaped geometry and a 8-m top head diameter, is built by thrombolite domes associated with keratose sponges. The growing duration from basal Griesbachian up to lower Dienerian is about 500'000 years.

On the southern, Gondwana side of the Neotethys in Oman, with same starting age and at apparently similar 80-100-m water depth, one of us, HB, discovered a red ammonoid limestone succession. This belongs to one large boulders, issued of a past dismantle Hallstatt-type pelagic platform and crops out near the top of Djebel Rabat Range about 80-km South of Muscat (Oman). It consists of a 30-m thick, thin stratified limestone and well dated from latest Permian to middle Smithian. Overlying a metric thick latest Permian dark limestone substratum, it is the unique known red ammonoid limestone with deposition starting at Griesbachian time. The Induan succession is 18-m thick. According field observations, these limestone beds, red-rosa to yellow according to surface alteration, are showing successions of tabular thrombolite that forms centimetric to metric large mound with very low angle flanks and low elevation. The microbial bindstone microfacies shows coccoidal lime silt, lime mud and filaments. We note numerous laterally discontinuous solitary fenestral structures, but more commonly they form stromatactis layers surrounded by keratose sponge fibers and filament sheath.

The above 11-m thick lower Olenekian well red colored ammonoid limestone shows in addition to previous microfacies, unsual carbonate textures, such seafloor aragonite fans large botroidal cement, bacterial sheaths, coccoids and frutexites-bearing microbialites. These lower Olenekian observations with the unsual carbonate textures establishes the continuity of microbialite production and the time junction with the "Time-Specific Facies" (TSF) attributed to the similar Smithian red ammonoid limestones deposition of the Alwa Formation of the nearby Baid Range.

This unique record of a red ammonoid limestone deposition showing this continuous growth of post-extinction microbialites associated with sponges, from Griesbachian to middle Smithian, indicate a duration more than 2 million years.

During the late Olenekian time, the pattern in time-space distribution of these red ammonoid limestones changed onward and have been described from western Neotethys and from Central Himalaya up to middle Spathian part of the Luolou Fm in the Nanpanjiang Basin (Yangtse Block, S. China).

Carbonate platform configuration and microbial sedimentation in the Mesoproterozoic Penganga Platform, Peninsular India

Joydip MUKHOPADHYAY[1]*, Indian Institute of Science Education and Research (IISER) Berhampur (joydip17@gmail.com)

Abstract

Carbonate platform configuration and microbial sedimentation in the Mesoproterozoic Penganga Platform, Peninsular India

Joydip Mukhopadhyay
Department of Earth and Environmental Sciences, Indian Institute of Science Education and Research (IISER) Berhampur, Odisha, India, joydip17@gmail.com

Extensive Mesoproterozoic carbonate platforms cover a large part of peninsular India. The carbonate platforms that formed during the later part of Mesoproterozoic in the peninsular India show remarkable similarities in terms of lithostratigraphic development. Most of these successions with thicknesses ranging 300 m to 500 m are dominated by lithographic limestones and shale, for example the Kurnool, Chhattisgarh, Penganga, Indravati, Bhima and Kolhan basins (Mukhopadhyay et al., 2020). In all these basins in the lower part of the succession an interval of siliceous limestone is developed in some profiles. The siliceous limestone may contain about 20 % silica which occurs dispersed evenly as cryptocrystalline/microcrystalline quartz in micrictic carbonate groundmass. The Penganga platform around the town of Adilabad in Telengana province includes at least two laterally extensive Mn-Fe formations (iron formations). These formations yield high quality Mn-ores that are believed to be products of supergene enrichment from Mn-carbonate protores (Gutzmer and Beukes, 1998). Mn-protores are described as microoids of rhodochrosite and their lighter carbon isotope composition speaks in favour of microbial mineralization (Gutzmer and Beukes, 1998). The Penganga platform depicts two distinct facies associations between the proximal and distal transects. The proximal transect is essential flat bedded monotonous lithographic limestone of homoclinal outer ramp setting whereas the distal transects are dominated by carbonate mass-flow deposits including non-Newtonian cohesive and cohesionless debris flows, differentiated bi-/tripartite flows and calciturbidites. The distal association has been interpreted as distally steepened ramp association. The siliceous limestone is invariably restricted within the distally steepened ramp environment in the Penganga platform. Silica sedimentation at the expenses of carbonates in modern ocean basins in general takes place below the carbonate compensation depth and is favoured by low temperature of the water column which enhances the solubility of carbonates but favours silica precipitation. EPS controlled organotemplate biomineralization facilitated silica sedimentation (Mukhopadhyay et al., 2004). The platform topography aided by the distal steepening in the Penganga platform might have nestled the climate-controlled cold-water upwelling cell and thus promoting silica sedimentation

and microbial growth in a nutrient rich ramp slope break.

Trophic level variability of an intertrappean lake during Deccan volcanism: New insights using stable isotopes

Yogaraj BANERJEE[1]*, Centre for Earth Sciences, Indian Institute of Science, Bangalore (ybanerjee15@gmail.com)
Prosenjit Ghosh[2], Centre for Earth Sciences, Indian Institute of Science, Bangalore
Shrinivas G. Viladkar[3], Department of Earth and Environmental Sciences, Indian Institute of Science and Education Research, Bhopal

Abstract

The impact of Deccan volcanism as a sole driver for the K/Pg extinctions is still a paradox in Biogeoscience research. Previous investigations highlighted the effects of the elevated CO2 and temperature rise associated with Deccan trap volcanism in the K/Pg extinction (Keller et al., 2020; Zhang et al., 2018). On the contrary, several studies suggested that Deccan volcanism played a minor role in the K/Pg extinction event (Chiarenza et al., 2020; Dzombak et al., 2020). Contemporary terrestrial organosedimentary deposits have the potential to provide valuable information about the perturbation in the biogeochemical cycling during Deccan volacanic episodes. Dynamic hydrological conditions with intense rainfall during Decan volcanism were inferred from the oxygen isotopic composition of clay minerals (Ghosh et al., 2004). Amba Dongar carbonatite complex, situated at the north-western part of Deccan igneous province intrudes late Cretaceous Bagh bed limestone and sandstone with a sequence of eruptive events (Viladkar and Sorkhtina 2021 and references therein). The evolution of the carbonatite complex has been related to the Deccan volcanism. The peak of the Deccan volcanism is considered to ca. 66 Ma, which coincides with the K/Pg boundary (Schoene et al., 2015; Renne et al., 2015). The U-Pb dating of apatite revealed the carbonatite magmatism at Amba Dongar took place around 63 Ma representing the late stage of Deccan volcanism (Fosu et al., 2019). Here we report a new intertrappean sedimentary horizon deposited in between the tholeiitic basalt and carbonatite volcanism episodes capturing the coeval terrestrial biogeochemical changes associated with the CO2 outgassing. Based on relative stratigraphic position and the mode of occurences of the laminae, we have classified these sedimentary rocks into two types: (1) older Type I (fine and discontinuous laminae with uneven boundaries) and younger Type II (thick and regular laminae with well-defined boundaries). Mineralogical investigation revealed transformation of Calcite into Wollastonite in case of Type II carbonates through contact metamorphism by the next eruption event. We carried out stable carbon and oxygen isotope analysis on both of these carbonates. A strong correlation between the δ13Corg and δ13Ccarbonates indicates the potential biogenic origin of these lacustrine carbonates. The stable isotope data from Type I and Type II carbonates capture trophic level variability of the lake in response to the Deccan volcanic activity. Our study elucidates the impact of LIP events on microbial carbonate precipitation.

Biochemical Ba cycling in microbial mats through deep time: Insights from Ba concentrations and isotopes in stromatolitic carbonates

Simon V. Hohl[1]*, Tongji University (simon.hohl@me.com)
Sebastian Viehmann[2], University of Hannover
Yibo Lin[3], Nanjing University
Ashley N. Martin[4], University of Hannover

Abstract

In recent decades, the quest for reliable proxies to reconstruct Earth's ancient ocean chemistry has heightened interest in stromatolites. These lithified microbial mats, prevalent in shallow neritic environments, can potentially archive ambient water chemistry of the photic zone from as early as ca. 3.5 billion years ago to now. Stromatolites offer a unique window into the long-term elemental fluctuations in microbial habitats across near-shore surface oceans, embayed basins, and lacustrine systems. This study evaluates the utility of barium (Ba) concentrations and isotopic compositions in stromatolites, ranging from the Paleoarchean to the Holocene, as a proxy for ancient microbial habitat productivity across various epochs and depositional environments.

Our research reveals that Ba systematics in non-restricted stromatolites reflect the biogeochemical cycling of Ba within photic zones, demonstrating significant variability in authigenic Ba isotopic compositions across different oxygen and sulphate saturation conditions. This variability, spanning two orders of magnitude, underscores the dynamic interplay of the physicochemical processes that influence Ba signatures, i.e., micro-barite formation and cyanobacteria Ba cycling. Stromatolitic carbonates from non-restricted environments offer a continuous record of ambient seawater δ138Ba(sw) over deep time. The highest obtained values are 0.45 ‰ in the Archean, 0.61 ‰ in the Proterozoic, and 0.57 ‰ in the Phanerozoic. The heaviest values consistently match the δ138Ba(sw) values observed in the modern open surface ocean (0.3 - 0.7 ‰), arguing for a continuous biogeochemical Ba cycle through geological history.

In contrast, often nutrient-limited, restricted environments exhibit high variability in carbonate Ba isotope values, which positively correlate with carbonate-associated Ba concentrations. Our detailed case studies from the modern Lagoa Salgada lagoon (Brazil) and the Hamelin Pool in Shark Bay (W. Australia) reveal a variation of δ138Ba(fluid) from ~0.1 ‰ in temporarily restricted supratidal zones to ~0.8 ‰ in open subtidal environments covering values for global groundwater discharge to the heaviest recorded modern surface ocean. Following classic Rayleigh fractionation patterns, a gradual increase in δ138Ba(fluid) is observed at Hamelin Pool alongside decreasing Ba/Ca ratios. This trend underscores the influence of groundwater discharge as a significant mixing source with seawater, illustrating a conservative mixing trend towards subtidal environments.

The variabilities in δ138Ba of stromatolitic carbonates from different geologic periods directly link to environmental restriction and biogeochemical Ba cycling during micro-barite formation on microbial biofilms. Barium recycling, particularly in restricted environments, produces lighter Ba isotopic values. However, open marine stromatolites capture ambient surface ocean δ138Ba(sw) compositions, providing a continuous record through deep time. This study underscores the potential of stromatolites as proxies for ancient ocean chemistry, reflecting the complex interplay between microbial activity, environmental conditions, and biogeochemical processes.

Carbonate mineral precipitation induced by microorganisms enriched from the cave water and biofilm in Yongcheon Cave, Jeju Island

Yul ROH[1]*, Chonnam National University (rohy@jnu.ac.kr)
Yumi Kim[2], Chonnam National University
Sung-min Kang[3], Chonnam National University
Abhijit Manna[4], University of Pennsylvania
Ileana Pérez-Rodríguez[5], University of Pennsylvania
Kyoung-nam Jo[6], Kangwon National University

Abstract

The formation of calcareous speleothems in caves is known to be mainly due to chemical precipitation. However, microbial precipitation of calcium carbonate has recently been reported to play an important role in crystal nucleation and mineral growth. This study was performed to investigate the carbonate-forming microorganisms that inhabit the cave water and stalagmite biofilm. The mineralogical characteristics of calcium carbonate and Sr/Mg-carbonate minerals precipitated by these microorganisms were also explored.

Two sediment samples from outside the cave, seven cave water samples from the drip water inside the cave, and ten biofilm samples wiped with sterilized cotton swabs were collected from Yongcheon Cave in Jeju Island. Carbonate-forming microorganisms enriched from the cave water and biofilm induced calcium carbonate precipitation through ureolysis. To investigate the effect of cations, various ratios of Ca:Sr or Ca:Mg (3:0, 2:1, 1:1, 1:2, 0:3) were added into the medium and then incubated at 15 °C for 7 days. Microbial analysis was performed using Next-generation sequencing (NGS) and Sanger sequencing. Geochemical properties were investigated by pH, ammonium concentration, X-ray fluorescence (XRF), and inductively coupled plasma–optical emission spectroscopy/mass spectrometry (ICP-OES/MS). Mineralogical characteristics were determined through X-ray diffraction (XRD) and scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDS).

The sediment covering the outside of the cave primarily consisted of skeletons of marine organisms, such as mollusks and coralline red algae fragments. Its mineral constituents were Mg-rich calcite [(Mg,Ca)CO3] or aragonite (CaCO3). The drip water in the cave had an alkaline pH (range: 7.9–8.3) and the following average chemical compositions: Ca, 50.9 mg/L; Na, 9.7 mg/L; Mg, 8.9 mg/L; K, 7.3 mg/L; and Sr, 0.3 mg/L. The high Ca content was attributed to the influence of the calcareous sediments covering the outside of the cave. NGS results showed that the first enriched microorganisms from the drip water were dominated by Proteobacteria and Firmicutes, including Pseudomonas, Morganella, and Neisseria, which are known to contribute to carbonate formation. Microorganisms from the biofilms were dominated by Pseudomonas of Proteobacteria. Sanger sequencing of isolates from this microbial community showed that the strains isolated from the cave water and biofilm were closely related to Bacillus sp. and Pseudomonas sp., respectively. These microorganisms precipitated calcite (CaCO3) and vaterite (CaCO3) when only Ca was supplied (Ca:Sr=3:0). In the presence of various Ca:Sr concentration ratios (Ca:Sr=2:1,

1:1, 1:2), calcian-strontianite [(Ca,Sr)CO3] was precipitated. Strontianite (SrCO3) was formed when only Sr was added (Ca:Sr=0:3). Addition of different Ca:Mg ratios (Ca:Mg=2:1, 1:1, 1:2) resulted in the precipitation of magnesian-calcite [(Ca,Mg)CO3)] and monohydrocalcite (CaCO3·H2O). Nesquehonite (MgCO3·3H2O) and struvite [(NH4)Mg(PO4)·6H2O] were precipitated when only Mg was supplemented (Ca:Mg=3:0). Therefore, Bacillus sp. and Pseudomonas sp., which inhabited the caves, may contribute to the formation of carbonate minerals through ureolysis. In addition, diverse carbonate minerals, such as Sr/Mg-substituted calcite, can be precipitated in the presence of various concentrations of Ca, Mg, and Sr.

Abiotic and biotic constraints on Earth's ancient colonisers

Indrani MUKHERJEE[1]*, UNSW (indrani.mukherjee@unsw.edu.au)
Ross Corkrey[2], University of Tasmania

Abstract

Microbial communities have shaped biogeochemical cycles in marine and continental environments, atmospheric redox structures, and provided the foundation for the biosphere since life originated on Earth. Microbial mat communities, in particular, have played an important role in biosphere-hydrosphere-atmosphere interactions. Therefore, understanding how microbial communities have evolved over time provides insight into the evolution of Earth's system processes. One way of doing that is to investigate stromatolite abundance and diversity over time. This study uses machine learning techniques to explore and explain the predictive capacities of physical and chemical variables such as temperature (T), essential bioactive elements (Ni, Co, Mo, Se, etc.), and non-essential bioactive elements (As, Pb) in relation to stromatolite abundances.

The study presents an analysis integrating geological parameters (nutrients, temperature) with biological impacts (burrowing, predation) to elucidate stromatolite trends. It identifies temperature as a consistent influencer, with critical thresholds leading to increased biological complexity. Furthermore, it underscores the nuanced relationship between trace elements and biota, emphasizing the importance of optimal concentrations and co-availability with other elements in shaping stromatolite growth patterns and ecological relationships. Certain bioactive trace elements, notably Ag, As, Cd, Co, Cu, Pb, Sb, and Tl, exhibit a significant influence on stromatolite abundance within specific temporal windows. Notably, the identification of ecological shifts associated with the availability of trace elements suggests complex interactions between abiotic factors and stromatolite-building microbial communities throughout Earth's history. This study also highlights the potential impact of such interactions on other parts of the biosphere such as microbial-metazoan inter-links. The study underscores the importance of integrating multidisciplinary approaches to unravel the intricate dynamics of ancient microbial ecosystems and provides valuable insights into the drivers of stromatolite variation during the Proterozoic era.

[Keynote] Oxygenation and marine microbial carbonates: The long history

Robert RIDING[1]*, University of Tennessee, Knoxville (rriding@utk.edu)

Abstract

Localized removal of dissolved iron by oxygen was a key control on early marine Ca-carbonate precipitation in the Archean. Thick carbonate platforms, ~2.9–2.8 Ga in Canada, preserve three co-existing depositional environments: (i) offshore anoxic iron-rich seawater, precipitating Fe-carbonate, (ii) a narrow chemocline mixing zone variously precipitating interlayered aragonite, calcite and Fe-oxide, (iii) onshore iron poor seawater precipitating aragonite and calcite in isolated 'Oxygen Oases'. Abundant Fe2+ superseded the effect of Mg2+ on Ca-carbonate mineralogy. Only when sufficient Fe2+ was removed by oxygen did the relative concentrations of Mg2+ and Ca2+ determine CaCO3 mineralogy, and the progressive removal of dissolved iron allowed the precipitation of first aragonite and then calcite. The most likely source of sufficient oxygen was oxygenic photosynthesis by marine cyanobacteria. This may have promoted precipitation of water column 'whiting' mud and calcification of benthic stromatolites. The oldest recorded stromatolites occur ~3.7 Ga. They were locally abundant on early carbonate platforms and ~2.8 Ga formed hybrid carbonates associated with precipitated seafloor crystal crusts at platform margin chemoclines. Stromatolites increased in abundance with platform thickness during the Archean, and remained major components of shallow water carbonate platforms that expanded in epeiric seas during the Proterozoic.

The gradual increase in shallow marine oxygenation, that began locally in the Archean, continued and expanded in the Proterozoic and increased in the Paleozoic. Shallow marine benthic microbial carbonate sediments declined significantly in abundance during the Neoproterozoic, but remained locally common in the Cambrian. Microbial carbonates show episodic decline throughout the Phanerozoic, with intervals of microbial carbonate abundance and invertebrate diversity broadly alternating with one-another. This pattern supports suggestions that microbial carbonate abundance declined as calcified invertebrates increased. Comparisons of microbial carbonate abundance and invertebrate diversity with estimates of changes in sea-surface temperature and marine dissolved oxygen suggest that microbial carbonate abundance and invertebrate diversity fluctuated with oxygen availability. It appears that intervals of both low marine invertebrate diversity and low dissolved oxygen, e.g., during the early Ordovician, late Devonian, early Triassic, and early-mid Jurassic, favored the formation of microbial carbonates. Low oxygen levels likely stimulated anaerobic metabolisms that favored carbonate precipitation. These observations suggest that, together with shallow marine temperature and carbonate saturation state, the level of dissolved oxygen significantly influenced secular patterns of marine microbial carbonate abundance during the Phanerozoic. Overall, these patterns appear to reflect the long-term influence of oxygenation on (i) Ca-carbonate precipitation in Archean Fe-rich seas, and (ii) the rise of eukaryotes. It appears that microbial carbonates benefited from the first of these effects,

and declined with the second.

Microstructural Analysis of Recent and Pleistocene Stromatolites at Ruidera Pools, Spain.

Mar SIMONET RODA[1]*, Chungnam National University (simonetroda@gmail.com)
Daeyeong Kim[2], Korea Polar Research Institute

Víctor López Jiménez[5], Gemosclera
Pilar Delgado García[6], Gemosclera
Jeong-Hyun Lee[7], Chungnam National University

Abstract

Ruidera Pools Natural Park, Spain, is renowned for well-exposed Pleistocene to Recent freshwater tufa stromatolites. To closely track the microstructural characteristics of these stromatolites, we applied Electron Backscatter Diffraction (EBSD) and Energy Dispersive X-ray (EDS) mapping to quantify micrometre-scale structures in addition to classic petrographic observations. The studied samples consist of calcium carbonate with low to no presence of detrital components. Both stromatolites consist of highly porous layers of micritic and microsparitic grains, locally surrounding empty tubes where microbial filaments would have been. Under the petrographic microscope, carbonates surrounding the filaments form a single layer. However, EBSD maps reveal up to three different isopachous layers growing around the filaments. The innermost layer is composed of large crystals (10–30 μm in diameter) that are elongated and oriented perpendicular to the substrate, with their c-axes also aligned perpendicular to the substrate. The second layer consists of randomly oriented micritic and microspar crystals (2-10 μm in diameter). The third layer is similar to the first, except for its larger crystal sizes (up to 70 μm in diameter). Although these layers are thin, they closely resemble alternating layers commonly reported from lacustrine stromatolites that are interpreted as results of seasonal changes. This work supports the use of combined EBSD and EDS on stromatolites to identify and quantify their microfabrics, unveiling micro-processes involved in stromatolite formation and thereby complementing conventional methods.

Dissolved silicon as a beneficial factor for biomineralization of protodolomite by a halophilic cyanobacterium

Ting CHEN[1]*, China University of Geosciences (chancug@126.com)
Deng LIU[2], China University of Geosciences

Abstract

The genesis of sedimentary dolomite has long been a mystery in Earth science. It has been shown that the formation of low-temperature protodolomite, a crucial precursor of ordered dolomite, can be catalyzed by various heterotrophic microorganisms through organic mineralization. However, the potential role of cyanobacteria, which are common and cosmopolitan autotrophs in sedimentary environments, in the precipitation of protodolomite has been largely underestimated. In addition, the positive role of dissolved silicon (Si) in enhancing the Mg content in Ca-Mg carbonates under oversaturated conditions have recently been emphasized. Nevertheless, the effect of dissolved Si on the formation of microbially-induced protodolomite remains poorly understood. To examine the influence and mechanisms of dissolved Si on the biomineralization of Ca-Mg carbonate by cyanobacteria, bioprecipitation experiments were conducted using a halophilic cyanobacterium (*Synechococcus elongatus* FACHB-410) in unsaturated starting solutions with different concentrations of dissolved Si (ranging from 0 to 2 mM). Our results revealed that the presence of dissolved Si increased the Mg levels in the bio-precipitated Ca-Mg carbonates produced by strain FACHB-410. Specifically, protodolomite formed when 2 mM Si was used. The biogenic protodolomite exhibited a core-shell architecture and spherical morphology. Importantly, an amorphous Mg-silicate formed prior to the crystallization of Ca-Mg carbonates during the biomineralization process, and this fibrous phase was closely associated with the grains of Ca-Mg carbonates. Further wet chemistry analyses suggested that the photosynthetic activity of strain FACHB-410 induced an oversaturated condition with respect to sepiolite. Therefore, the amorphous Mg-silicate can be described as a “sepiolite-like” material. This sepiolite-like phase could serve as a template for the nucleation of Ca-Mg carbonates. These findings have important implications for understanding the co-occurrence of Mg-silicate and (proto-)dolomite observed in geological records.

Diverse origins and depositional environments of phytoclast tufas from the Cretaceous Jinju Formation, Korea

Seunghoon LEE[1]*, Department of Astronomy, Space Science and Geology, Chungnam National University (seunghoon.lee0826@gmail.com)
Jeong-Hyun LEE[2], Department of Geological Sciences, Chungnam National University
Dong-Chan LEE[3], Department of Earth Sciences Education, Chungbuk National University

Abstract

Allochthonous, calcium carbonate-encrusted plant fragments, termed phytoclast tufas, are abundant in the Lower Cretaceous lacustrine successions of the Jinju Formation, Gyeongsang Basin, southern Korea. This study analyzes phytoclast tufas from three localities to elucidate their formative processes. While exhibiting similar macroscopic morphologies, with cylindrical to branching shapes and diameters up to 5 cm, the tufas display distinct microfabrics. The Geobuk-gil section phytoclast tufas are characterized by micrometer-scale stromatolitic columns, calcimicrobial fossils, and branching and anastomosing mesoclots, implying a microbially influenced origin. In contrast, those from Seonjeon-ri are dominated by stromatolitic columns consisting of isopachous fibrous cement with minor peloidal aggregates, signifying a more dominant abiotic precipitation. The Yonggung-ro section exhibits intermediate characteristics, suggesting the interplay of microbial and abiotic processes in their formation. These diverse microfabrics are ascribed to varying depositional environments. The Geobuk-gil tufas, embedded within dark gray mudstone and randomly aligned parallel to the bedding planes, indicate their formation at lake margins and subsequent transportation to lake centers via suspension. The mound-shaped, randomly distributed Seonjeon-ri tufas imply a fluvial system origin and debris flow transportation, forming alluvial fans. The Yonggung-ro tufas likely originated at lake margins and were deposited as dunes in shallow lacustrine settings. This study elucidates that while phytoclast tufas may exhibit macroscopic similarities, their formative processes and depositional environments can be diverse, underscoring the need for caution in interpreting their paleoclimatic implications.

2 Polish Geological Institute–National Research Institute, Poland [died in 2023]

3University of Exeter, Department of Earth and Environmental Sciences, Penryn, Cornwall, UK; s.p.hesselbo@exeter.ac.uk

The Mochras drill core contains a continuous Sinemurian-Toarcian section of heavily bioturbated hemipelagic calcareous mudstones, wackestones/siltstones and subordinate packstones/sandstones. Several beds show features of contourites, which have been deposited by thermohaline-driven geostrophic contour currents flowing between the Boreal ocean and Peri-Tethys through the NE-SW trending, narrow and relatively deep Cardigan Bay Strait.

The siltstone/very fine-grained sandstone/calcarenite beds contain the most diverse trace fossils dominated by Phycosiphon incertum produced by opportunistic colonizers. The dwelling and deposit-feeding structures, such as Thalassinoides, Schaubcylindrichnus, and Teichichnus are relatively common. They are accompanied by Trichichnus (a deep-tier chemichnion of filamentous sulfide-oxidizing bacteria with a high tolerance for dysoxia), less common Zoophycos (fodinichnion), Planolites (pascichnion), Palaeophycus (pascichnion), Lockeia (cubichnion), and rare dwelling structures, such as cf. Polykladichnus, Siphonichnus, Monocraterion, Arenicolites, and Skolithos. The trace fossil assemblage resembles the Zoophycos ichnofacies. The intensive bioturbation is conditioned by a relatively stable supply of organic-rich sediment and oxygen.

The contourites in the Toarcian succession are more frequently base- or top-cut than in the Pliensbachian, which suggests more variable conditions in the depositional system. The system was also distinctly disturbed at the Pliensbachian-Toarcian transition and at the beginning of the negative carbon-isotope excursion (To-CIE) marking the Toarcian Oceanic Anoxic Event (T-OAE), where the bioturbation was less intensive, Phycosiphon is less abundant, and Trichichnus is more common. However, anoxic laminated mudstones are rare, and the peak and recovery phase

of the negative excursion of the anoxic event is characterised by loss of Trichichnus and better oxygenated of sea floor. The Pliensbachian-Toarcian boundary event appears to be a significant palaeoceanographic turning point, starting a CaCO3 decline with the most severe oxygen depletion, stronger than during the T-OAE (but dysoxic, not anoxic). This can have been caused by the extreme climate warming during the To-CIE, which may have enhanced and caused a reversal in the direction of deep marine circulation, improving oxygenation of the sea floor. A minor dysoxic event also occurred in the latest Thouarsense and Dispansum zones.
Ichnological and lithological signals suggest repetitive fluctuations in benthic conditions attributed to a hierarchy of orbital cycles (precession and obliquity [4th order], short eccentricity [3rd order], long eccentricity [2nd order], and Earth–Mars secular resonance [1st order]). Spectral analysis of binary data for ichnotaxa appearances gives high confidence in orbital signals in accord with previous work based on geochemical time series. This allows refined estimation of ammonite zone lengths.

Early colonization of the deep-sea bottom–the protracted build-up of an ecosystem

Luis A. BUATOIS[1]*, University of Saskatchewan (luis.buatois@usask.ca)
M. Gabriela Mángano[2], University of Saskatchewan
Maximiliano Paz[3], University of Saskatchewan
Nicholas J. Minter[4], University of Portsmouth
Kai Zhou[5], University of Saskatchewan

Abstract

The body-fossil record of deep-marine environments is poor in comparison with that of shallow water. However, deep-marine deposits are host to diverse, abundant, and complex trace fossils. To analyze the early colonization of the deep sea, we constructed a global dataset of trace-fossil occurrences from a comprehensive survey of Ediacaran-Devonian deep-marine units. Ichnotaxonomic determinations were critically assessed for each occurrence recorded in the dataset. Ichnodiversity, ichnodisparity, ecospace utilization, and ecosystem engineering were the main proxies used to quantify the role of bioturbators in deep-sea colonization. We show that the establishment of a modern-style deep-sea benthic ecosystem was protracted. No substantial increases in the analyzed metrics are detected for deep-marine ichnofaunas during the Ediacaran-Terreneuvian, which essentially reflect exploitation of microbial mats. A sharp increase in all metrics is apparent in this setting during Cambrian Epoch 2, followed by a rapid and dramatic decline during the rest of the Cambrian. The onset of modern-style deep-sea ecosystems was broadly coincident with global cooling and an increase in deep-water oxygenation during the Ordovician. The formation of permanent open burrows in the deep sea may have increased bioirrigation in the uppermost zone of the deep-sea sediment, therefore increasing ventilation and potentially generating a feedback loop between bioturbation and oxygenation, with the endobenthos engineering its environment. A subtle decrease in all ichnologic metrics is apparent in deep-sea siliciclastics in the Llandovery, followed by a persistent decline during the rest of the Silurian. Metrics show an overall increase during the Early Devonian, followed by a decrease during the Middle Devonian and a new increase in the Late Devonian. Sharp changes in deep-sea bioturbation during the Silurian-Devonian were most likely influenced by fluctuations in oxygen content resulting from climate-controlled oceanic circulation. Also, the Silurian-Devonian expansion of vascular plants resulting in the greening of the land masses was probably conducive to a dramatic rise in the delivery of phytodetrital material to marine basin. Because decomposition of sinking organic matter depletes water of dissolved oxygen, this increased delivery may have enhanced the likelihood of eutrophication and hypoxia, negatively impacting on graphoglyptid diversity.

The use of time-environment matrices to decipher behavioural events in early Paleozoic animal evolution

Romain GOUGEON[1]*, Géo-Ocean, Université de Bretagne Occidentale
(gougeon.romain@gmail.com)
Gabriela Mángano[2], University of Saskatchewan
Luis Buatois[3], University of Saskatchewan
Muriel Vidal[4], Géo-Ocean, Université de Bretagne Occidentale
Emma Michaud[5], LEMAR, Université de Bretagne Occidentale

Abstract

Trace fossils are remains of past behaviours that represent an independent line of evidence to evaluate animal evolution in deep time. Ichnologic studies aiming at unravelling macro-evolutionary breakthroughs mostly revolved around the first appearance of ichnotaxa (e.g., across the Ediacaran–Cambrian boundary interval), biostratigraphy (e.g., Cruziana ichnostratigraphy), diversity/disparity changes through time (e.g., during the Cambrian explosion, Ordovician radiation, Mesozoic Marine Revolution), morphological variations within ichnogenera or group lineages (e.g., with graphoglyptids), or ecology (e.g., ecosystem engineering impact of animals). However, trace fossils are traditionally considered as facies controlled, and their potential for macro-evolution could therefore be hampered without a robust depositional model. In this regard, time-environment matrices represent an ideal method of analysis that have not been extensively used in ichnology. Here, we present a new approach to evaluate changes in ichnologic metrics in time and space at different scales of analysis. Ichnologic and sedimentologic datasets were collected from the lowermost Cambrian of Newfoundland in Canada (Chapel Island Formation, which is Ediacaran–Cambrian Age 2) and the Lower and Upper Ordovician of Brittany in France (Armorican Sandstone and Kermeur formations, which are Floian and Katian, respectively). Sedimentary facies were described after careful evaluation of sedimentologic features in the field, aiding in the characterization of various intertidal and shallow-marine depositional sub-environments. Data reported on stratigraphic columns serve as a basis to delineate parasequences. Time-environment matrices are then created by plotting sub-environments on an x-axis and parasequences on a y-axis, therefore outlining individual time and space loci, or cells. Ichnologic datasets recovered correspond to: (1) vertical bioturbation, (2) bed surface bioturbation, (3) burrow width, (4) burrow depth, and (5) ichnotaxonomic composition. Ichnologic metrics are added to individual matrices, revealing the environmental and temporal breadth of animal-sediment interactions within each formation investigated. The creation of matrices can be expanded to other ichnologic proxies: (1) ichnodiversity per cell and cumulated per subenvironment, (2) ichnodisparity per cell and cumulated per subenvironment, (3) tiering, (4) presence/absence of different ichnotaxon/taxa or trace-fossil type (e.g., simple horizontal grazing trails, arthropod trace fossils), (5) ecospace utilization, and (6) ecosystem engineering. While using datasets of the Cambrian explosion and the Ordovician radiation, this study aims at demonstrating the potential of matrices developed at a local scale to identify precisely the timing

and place of macro-evolutionary events of global impact.

[Keynote]Infaunal feedback during the end-Permian Mass Extinction: Evidence from ichnology

Mao LUO[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (maoluo@nigpas.ac.cn)
Luis A. Buatois[2], University of Saskatchewan

Abstract

The end-Permian Mass Extinction (EPME) has caused the largest biodiversity decline of the Phanerozoic. The mechanism and tempo of EPME remains to be explored, with focus on what factors controlling the process of recovery and whether recovery between low and mid- to high latitude regions is chronous or not. During the last few decades, Permian-Triassic trace fossils have been studied intensively to understand the timing and process of EPME and subsequent biotic recovery. This is because trace fossils represent behaviors of both skeletonized and soft bodied organisms, and their preservation was not influenced by the same taphonomic constrains that may have biased the body-fossil record in the Early Triassic. Here we analyze secular changes in ichnodiversity, ichnodisparity and life of modes of trace makers from late Permian to the Middle Triassic based on a global trace-fossil dataset. Results show that, in contrast to the body-fossil record, late Permian global ichnodiversity and ichnodisparity maintained their level until the Griesbachian, followed by a sharp loss in the Dienerian. Notably, the Griesbachian shows an unusual dominance of shallower tiers. The discrepancy between the body- and trace-fossil record is interpreted to be the result of the resurgence of widespread microbial matgrounds in Griesbachian that aided the preservation of surfical, semi-infaunal and shallow-tier ichnofossils. Such ichnological records suggest a disappearance of mixed layer in the earliest Triassic, which might have enhanced pyrite burial in sediments and inhibited its further re-oxidation, therefore regulating sea water sulfate concentrations. A further analyses of trends on ichnodiversity and ichnodisparity between low- and mid- to high latitude regions suggest that infaunal organisms from mid- to high latitude regions were more resilient to EPME. The maintained number of occupied categories of ecospace and ecosystem engineering in mid- to high latitude regions suggests a faster recovery of invertebrate trace makers compared with those at low latitude regions.

Temporal constraints on the ichnofacies paradigm

Anthony Shillito[1]*, University of Saskatchewan (anthony.shillito@usask.ca)
Luis Buatois[2], University of Saskatchewan
Gabriela Mangano[3], University of Saskatchewan

Abstract

The great strength of ichnofacies as environmental indicators relies on the stability of individual ichnofacies through time. For the most part, this stability has been proven through a series of studies building on the original work of Seilacher from the 1950s and 60s, and refining the concept into our present understanding of the ichnofacies paradigm. However, something that is rarely taken into consideration is the uncertainty that surrounds ichnofacies at their point of inception – an ichnofacies cannot exist before tracemaking organisms have colonized the relevant sedimentary environment. As such, ichnofacies "originate" when a community of animals first colonizes a new habitat, and then gradually stabilize (or "evolve") as niches are created and occupied in different ways, until they reach their archetypal form. This means that in the early Palaeozoic, when many new ecological niches were colonized for the first time, there was far less stability. This is highly significant for the use of ichnofacies to distinguish early Palaeozoic sedimentary environments, as the ichnological signature of those environments may not have yet stabilized to match the signal of the archetypal ichnofacies. This issue is further compounded by secular changes in animal-substrate interactions through geologic time, such as increases in ichnodiversity, ichnodisparity, degree and extent of bioturbation, and complexity of tiering structure. Knowing when this occurred allows the ichnofacies paradigm to be employed more accurately by ichnologists, palaeontologists, and sedimentologists alike. In this presentation we will discuss the varying points of establishment of different ichnofacies, and how they "evolved" to reach their established form following their inception.

The interplay of evolutionary, taphonomic, and environmental controls on trace fossils from Burgess Shale-type deposits

Gabriela Gabriela MANGANO[1]*, University of Saskatchewan (gabriela.mangano@usask.ca)

Abstract

Burgess Shale (BS)-type deposits have been traditionally understood as formed in deep-marine anoxic environments in the virtual absence of bioturbation. This view has been challenged by: (1) the numerous reports of a variety of trace fossils in BS-type deposits, (2) the wider environmental range of BS-type biotas and associated facies, and (3) the multiple taphonomic pathways that allowed preservation of biogenic structures. Accordingly, the focus is no longer on the presence or absence of trace fossils, but rather on whether they are controlled by the same parameters than other trace-fossil assemblages. Occurrences of trace fossils in BS-type deposits can be categorized in four types: (1) biogenic structures directly associated with non-mineralized carapaces; (2) trace fossils associated with stratigraphic surfaces; (3) burrows hosting the producer; and (4) mineralized three-dimensional vermiform structures. The first group can be considered the ichnologic signature of BS-type deposits. Burrows hosting their producers are another extraordinary occurrence of BS-type deposits that offer unique paleobiologic insights. Trace fossils on stratigraphic surfaces and mineralized biogenic structures are not restricted to BS-type deposits. As a distinctive anactualistic feature, BS ichnofaunas are dominated by surficial to shallow-tier structures. However, relatively deep penetrative trace fossils characterize some occurrences. These inclined to vertical burrows may be part of softground suites recording opportunistic colonization in distal settings or firmground suites recording erosion and bypass. The standard view of BS-type deposits as of deep-marine origin has been triggered by their initial discovery in Walcott Quarry at the base of a carbonate escarpment. However, integration of sedimentologic and ichnologic datasets at a global scale shows that this original scenario is quite unique, with BS-type biotas being preserved under a wide variety of depositional environments, ranging from deltaic to shelf. In addition to oxygen, other factors such as energy and substrate consistency have played a significant role during bioturbation and transit of biogenic structures to the fossil record. Whereas most BS-type deposits are characterized by prevailing oxygen-depleted conditions and low energy at the time of bioturbation, sudden burial is emerging as a key factor involved in trace-fossil taphonomic pathways. A notable example is revealed by trace fossils associated to non-biomineralized carapaces, which record preservation in different scenarios involving contrasting taphonomic pathways. Frequency of event deposition is the main control on the duration of the colonization window, therefore impacting not only on the density of trace fossils preserved in non-biomineralized carapaces, but also on those associated with stratigraphic surfaces. The dominance of fine-grained sediment, although not providing the ideal interfacial boundaries for fine preservation of trace-fossil morphology, may host stabilized or exhumed substrates during times of low sedimentation rate that allowed the preservation of minute, discrete trace fossils on bedding surfaces. Finally, the notion that BS-type biotas disappeared from the

fossil record due to the onset of bioturbation needs to be revised in the light of recent studies demonstrating extensive colonization of the infaunal ecospace since the early Cambrian. A more nuanced scenario that accounts for environmental diachronism in the rise of biogenic reworking needs to be considered.

Evolution and palaeoenvironmental migration of a Cambrian undermat-miner

Li-Jun ZHANG[1]*, Henan Polytechnic University (lijun.zhang@hpu.edu.cn)
Luis Buatois[2], University of Saskatchewan
Maria Gabriela Mangano[3], University of Saskatchewan

Abstract

Microbial mats sealed the sea bottom, becoming the food supply of early metazoans, which exploited this resource in multiple ways during the late Ediacaran and earliest Cambrian. The onset of bioturbation in shallow-marine environments later in the early Cambrian removed this seal, resulting in the protracted restriction of microbial mats to marginal- and deep-marine environments. In this study, we demonstrate that the undermat miner trace fossil Oldhamia followed the pattern of matground restriction to deep-mairne environments. This is shown by a dataset compilation of Cambrian Oldhamia based on a comprehensive review of the literature with addition of our newly discovered Oldhamia in the Cambrian strata of North and South China. Oldhamia is one of the most distinctive and widely distributed ichnogenera in early to middle Cambrian siliciclastic successions. It consists of semi-permanent, very shallow-tier, undermat-miner structures produced by stationary vermiform organisms. Despite its importance, details of Oldhamia ichnodiversity trajectories at ichnospecies level, environmental trends, and potential palaeogeographic patterns have not been explored. Our results demonstrate that Oldhamia displays high diversification in the Fortunian shallow- and deep-marine settings, corresponding to the signal of the Cambrian Information Revolution. Oldhamia alata and O. geniculata only occur in the shallow marine, O. curvata and O. flabellata are restricted to the deep marine, and O. antiqua and O. radiata range from shallow to deep marine. The producers of retreated into deep sea since the end of the Fortunian mirroring the restriction of matgrounds as a response of intense bioturbation in shallow-marine deposits during the Agronomic Revolution. Oldhamia originated from the Iapetus Ocean and then migrated into other oceans, most likely through dispersal assisted by the ocean currents.

Integrated sedimentological and ichnological analysis of Holocene deposits in the Nakdong River delta, South Korea

Boyeon JEON[1]*, IGC 2024 (37igc@igc2024korea.org)
Daekyo CHEONG[2], Kangwon National University
Seungwon SHIN[3], Daegu University
Jin Cheul KIM[4], Korea Institute of Geoscience and Mineral Resources

Abstract

Infaunal organisms are sensitive to environmental changes; therefore, trace fossils can provide significant information on various physicochemical stresses occurring in deltas. In this study, integrated sedimentological and ichnological analyses were performed of sedimentary core ND-2 (9–35 m depth), collected from the Nakdong River delta plain in Korea, to assess the variations in ichnological assemblages arising in response to environmental stresses during the early to late Holocene. Visual core description for physical and biological structures and end member analysis of grain size were conducted for this study. The analyses enabled a comprehensive reconstruction of Holocene deltaic paleoenvironments comprising lower shoreface (8.5–9 ka), offshore (6–8.5 ka), prodelta (3–6 ka), distal delta front (1–3 ka), and proximal delta front (< 1 ka). *Skolithos* suite, which has a deep penetration depth and large diameter between lower shoreface and offshore, represents the *Glossifungites* ichnofacies with a sharp boundary defined as a within-trend flooding surface, indicating an abrupt increase in water depth. This result implied that the Nakdong Delta area was influenced by the early Holocene sea level rise (EHSLR) at ca. 8.5 ka. Furthermore, changes in the size, diversity, abundance, and types of trace fossils during the evolution of deltas have enabled the differentiation of sub-environments within the deltaic system. This study shows that trace fossils also can be a powerful tool to construct Holocene deltaic environments, and further ichnological analyses in Nakdong Delta region would be helpful to restore high resolution paleoenvironments.

Lipid Biomarker Patterns Reflect Nutritional Strategies of Seep-Dwelling Bivalves From the South China Sea

Hongxiang GUAN[1]*, Ocean university of China (guanhongxiang@ouc.edu.cn)

Abstract

Invertebrates living at methane seeps such as mussels and clams gain nutrition through symbiosis with chemosynthetic, chiefly methanotrophic and thiotrophic bacteria. Lipid biomarkers, including their compound-specific carbon stable isotope compositions, extracted from the host tissues are predestined for deciphering the various sources of diets and the associations among varying environments, endosymbionts, and hosts. Here, we investigated lipid inventories of soft tissues of two bathymodiolin mussel species hosting aerobic methanotrophic bacteria (Gigantidas platifrons from Site F and Gigantidas haimaensis from Haima seeps), one bathymodiolin mussel with thiotrophic bacteria (Bathymodiolus aduloides from Haima seeps), and one vesicomyid clam (Archivesica marissinica from Haima seeps) from the South China Sea. The gills of mussels hosting methanotrophic symbionts were found to contain high amounts of lipids of aerobic methanotrophic bacteria, such as the 4,4-dimethyl lanosterol, and other 4-methyl sterols, and the type I methanotroph-specific monounsaturated fatty acids (MUFAs) C16:1ω9 and C16:1ω8. Production of methyl-sterols is favored over fatty acids at low oxygen concentrations, as demonstrated in culture experiments with Methylococcus capsulatus. Since lesser fatty acids and abundant sterols are found in G. haimaensis compared to G. platifrons, G. haimaensis apparently lived at very low oxygen levels. Extremely high levels of MUFAs C16:1ω7 and C18:1ω7 were found in gill tissue of both B. aduloides and the vesicomyid clam A. marissinica. Given the absence of ω8 fatty acids, both B. aduloides and the vesicomyid clam contain thiotrophic bacteria only. The occurrence of 13C-enriched 24-methylenecholesterol in B. aduloides indicates that the animal complemented its diet by filter-feeding (ca. 3% of the total sterol inventory) on photosynthetically derived carbon, whereas the majority of sterols are pointing to a diet relying on endosymbionts. Different types of 4-methylsterols were observed between the thiotroph-containing mussel and methanotrophcontaining mussels, suggesting different biosynthetic steps are present from lanosterol to cholesterol between animal hosts and aerobic methanotrophs. Among the four bivalve species, specific lipid biomarker patterns diagnostic for either the symbionts or the hosts yielded similar δ13C values in each species, indicating that the host obtained its nutrition either directly from the symbionts or derived at least most of its carbon in this way. The information derived from lipid biomarkers of bivalves and their corresponding symbionts in modern environments is vital to interpret data from the rock record, where most other methods to study microbial community composition are not applicable.

New Hybodont sharks (Chondrichthyes, Elasmobranchii) from the Early Triassic continental Dongchuan Formation (Yunnan Province, China), revealing the recovery of lacustrine ecosystems after the end-Permian mass extinction

Wen WEN[1]*, Nanjing University (wenwen2020240@163.com)

Abstract

Hybodont sharks first occurred in the Devonian and became extinct in the Late Cretaceous. However, the rare records of freshwater hybodont sharks around the world restrict the study of its diversity after the end-Permian mass extinction and how they adapted to the continental environment. All fossils of Early Triassic hybodont sharks known from China were founded from marine deposits, thus led to the misunderstanding in the accurate time of their freshwater adaption. Recently, hybodontid teeth, cephalic and fin spines as well as placoid scales are discovered for the first time from the continental, Lower Triassic Dongchuan Formation (Olenekian) near Huize County (Yunnan Province) in south-west China. The isolated teeth are assigned to three unidentified hybodontiforms but also to a new species of Parvodus, P. huizodus sp. nov., the oldest record of this small-toothed lonchidiid shark genus, extending its range well down into the Lower Triassic. This new species, together with additional hybodontiform remains, provides new evidence of shark occurrences in the aftermath of the end-Permian mass extinction event, when freshwater environments might have acted as centers of origin rather than refugia for sharks. A review of the species assigned to Parvodus and similar small hybodontiform sharks reveals two distinct ecomorphological groups. Group 1, which is characterized by clutching-type dentitions, includes eight species (three of which remain unnamed) ranging from the Middle Triassic to Lower Cretaceous, while group 2, characterized by cutting-crushing type dentitions, comprises 11 species (six of which remain unnamed) including the type-species, P. rugianus ranging from the Lower Triassic to the Lower Cretaceous. The new fossils documented here reveal that hybodontiforms were already adapted to freshwater environments in the Lower Triassic rather than in the Jurassic in China. Furthermore, the diverse micro-fossils of vertebrate discovered from Early Triassic reveals the recovery of lacustrine ecosystems after the end-Permian mass extinction.

Microbial bloom, microbe-metazoan interaction and palaeoecologic crisis linked with volatile volcanisms during the Guadalupian-Lopingian (Permian) transition

Zhensheng Wei[1]*, State Key Laboratory of Biogeology and Environmental Geology,School of Earth Science, China University of Geosciences (Wuhan) (ZSWei@cug.edu.cn)
Yuangeng Huang[2], State Key Laboratory of Biogeology and Environmental Geology and School of Earth Science, China University of Geosciences (Wuhan)
Zhong-Qiang Chen[3], State Key Laboratory of Biogeology and Environmental Geology and School of Earth Science, China University of Geosciences (Wuhan)

Abstract

The major bio-crisis during the Guadalupian-Lopingian (Middle-Late Permian) transition recorded dramatic losses in diversities of marine invertebrates to varying degrees and first-class collapse of metazoan reef systems worldwide, and this devastation could be possibly driven by a series of environmental perturbations such as volatile eruption of Emeishan large igneous province (ELIP), prevailing anoxia and long-term regression. Coupling with decline in macro-organisms, microbial bloom was also evident during this critical period, their blooming extents, interactions with metazoans and linkage with the ELIP, however, have not been investigated and their involvement to biotic mass extinction and palaeoecological crisis therefore remain poorly understood. Here we report some new findings on microbial compositions, stratigraphic distributions and interactions with metazoan as well as relations with synchronous ELIP based on in-situ microanalyses of the G-L boundary beds from the GSSP site in the Penglaitan section of Laibin area, South China using techniques of scanning electron microscopy (SEM), Raman spectroscopy, and Nano-scale Secondary Ion Mass Spectrometry (NanoSIMS). We discovered solid evidence of microbial destructions on the shells of brachiopods and crinoids, which are composed of well-preserved quartz crystals and clay minerals. These shelly destructions and fillings of quartz and clay minerals are interpreted as the result of boring behaviours on the shelly substrates by microboring organisms, and the well-preserved crystal outline, worn surface, and larger surface size of quartz crystals are typical of volcanic activity in origin. Stratigraphically, the maximum value of quartz crystals coincides with the onset of ELIP eruption at the topmost of the Laibin Limestone in Penglaitan during the end of the Guadalupian. Overall, microboring records exhibit three developmental phases: plateau, proliferation, and recession, coinciding with the collapse of bryozoan-sponge reef, bloom of microbiota, and losses of benthic faunas, respectively. The temporal coincidence suggests the ELIP eruption may have driven microbial blooming and enormous flux of quartz crystals, offering a new perspective of unique progress of microbe-metazoan interaction under intense environmental stress due to the ELIP during the G-L mass extinction.

Marine carbonate factory changes across the end-Permian mass extinction in South China

Danna LIU[1]*, State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences (Wuhan) (danna.liu@cug.edu.cn)
Zhong-Qiang Chen[2], State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences (Wuhan)
Zijie Zheng[3], State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences (Wuhan)
Yu Pei[4], State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences (Wuhan)

Abstract

The Permian-Triassic (P-Tr) mass extinction marks the largest biodiversity decline in geological history, accompanied by ocean acidification leading to a crisis for calcareous skeletal organisms. Before and after this event, significant changes occurred in the carbonate depositional systems of shallow marine environments. During the P-Tr transition, South China was located at low-latitude region and characterized by a massive shallow marine setting developing a vast carbonate platform (termed the Yangtze Platform). Some sections at this platform, i.e., the Yudongzi, Zuodeng, Dajiang sites record distinct changes from the uppermost Permian bioclastic limestone to the lowest Triassic microbialites, displaying conspicuous variations of carbonate factories across the end-Permian extinction. These two types of factories are usually separated by an irregular surface, which is widely interpreted as an exposure surface due to regional sea-level fall. Composite clays containing various minerals can be identified from this horizon, providing evidence of the influence of continental weathering following sea-level drop immediately after the end-Permian crisis. The mechanisms and types of carbonate factories underwent significant changes across this extinction, with tropical carbonate factories (T-type factories) being replaced by microbial carbonate factories (M-type factories). Before the extinction, the biotic framework of T-type factories was constructed by a combination of corals, calcareous algae, crinoids, and benthic foraminifera, primarily controlled by biota-mediated carbonate deposition. After the extinction, M-type factories were mainly induced by benthic cyanobacteria, leading to a notable shift in carbonate production. Carbonate production efficiency increased from 56% to nearly 90%. The primary cause of this phenomenon lies in the rapid occupation of ecological niches by microbial communities, particularly cyanobacteria (*h*-like calcimicrobe), following the end-Permian extinction, and they utilized the organic matter degraded in seawater to produce high concentrations of HCO3-, as well as Ca2+ and Mg2+ enriched by EPS, synthesizing large amounts of calcium-secreting substances. Their rapid proliferation led to calcium carbonate oversaturation and precipitation, demonstrating remarkable carbonate production efficiency, forming typical microbial structures such as stromatolites, thrombolites, and dendrolites. Additionally, the adsorption capacity of organic functional groups (including carboxyl, phosphoric, and hydroxyl, among others) for Mg2+ is stronger than that of water, reducing the

hydration of Mg2+ ions. This facilitates the incorporation of Mg2+ into the carbonate lattice, thereby promoting the nucleation of dolomite. Microbial metabolism affects hydrochemical conditions, increasing alkalinity and inducing fluctuations in saturation, thereby inducing microbialite dolomitization.

Organic matter influence on ooid formation: New insights into classic examples (Great Salt Lake, USA; Triassic Germanic Basin, Germany)

Yu PEI[1]*, China University of Geosciences (Wuhan) (peiyu@cug.edu.cn)
Pablo Suarez-Gonzalez[2], Complutense University of Madrid
Jan-Peter Duda[3], University of Goettingen
Zhong-Qiang Chen[4], China University of Geosciences (Wuhan)
Joachim Reitner[5], University of Goettingen

Abstract

Ooids are coated grains composed of a tangential or radial cortex growing around a nucleus. They are common in carbonate deposits of almost any geological age and provide insights into environmental conditions. However, abiotic or biotic factors influencing their formation remain unclear. This study aims to advance current understanding of ooid formation with a multi-analytical approach (for example, field emission scanning electron microscopy, Raman spectroscopy and micro X-ray fluorescence) to classic examples from Great Salt Lake, USA, and the Lower Triassic Germanic Buntsandstein Basin, Germany. Both of these deposits represent hypersaline shallow-water environments where ooids are closely associated with microbial mats. Great Salt Lake ooids are dominantly 0.2 to 1.0mm in size, ellipsoidal to subspherical in shape, composed of aragonite and contain organic matter. Germanic Buntsandstein Basin ooids are mainly ≤4mm in size, spherical to subspherical in shape, composed of calcite and currently contain little organic matter. Despite the differences, both ooids have the same cortex structures, likely reflecting similar formation processes. Some Great Salt Lake ooids formed around detrital grains while others exhibit micritic particles in their nuclei. In Germanic Basin ooids, detrital nuclei are rare, despite the abundance of siliciclastic particles of various sizes in the host rocks. Germanic Basin deposits also include ‘compound ooids’, i.e. adjacent ooids that coalesced with one another during growth, suggesting static in situ development, which is supported by the lack of detrital grains as nuclei. Germanic Basin ooids also grew into laminated microbial crusts with identical microstructures, further indicating a static formation. Such microbial crusts typically form through mineral precipitation associated with organic matter (for example, extracellular polymeric substances), suggesting a similar formation pathway for ooids. The inferred key-role of organic matter is further supported by features in radial ooids from the Great Salt Lake, which commonly exhibit, from their nuclei towards their surface, increasing organic matter contents and decreasing calcification.

The earliest record of freshwater siliceous algae from the Middle Triassic: Chrysophyte stomatocyst from the Ordos Basin, North China

Bohang CHENG[1]*, State Key Laboratory of Biogeology and Environmental Geology and School of Earth Science, China University of Geosciences (Wuhan), Wuhan 430074, China (cheng_bohang@cug.edu.cn)
Meijia Zhang[2], State Key Laboratory of Biogeology and Environmental Geology and School of Earth Science, China University of Geosciences (Wuhan), Wuhan 430074, China
Zeming Zheng[3], State Key Laboratory of Biogeology and Environmental Geology and School of Earth Science, China University of Geosciences (Wuhan), Wuhan 430074, China
Zhong-Qiang Chen[4], State Key Laboratory of Biogeology and Environmental Geology and School of Earth Science, China University of Geosciences (Wuhan), Wuhan 430074, China

Abstract

Chrysophyte is one of the earliest siliceous algae dwelling in freshwater settings. Their siliceous scales and stomatocysts can be preserved in lake sediments for a long time, and their fossils therefore are important materials to uncover the life history and evolution of chrysophytes and to reconstruct ancient lake environments. So far, about 160 types of stomatocysts have been recognized and confirmed to be produced by chrysophytes in modern lakes, and very few have been described in fossil records. In particular, the origin and morphology of the early chrysophytes remain poorly understood.

We describe a diverse stomatocysts assemblage from the black shales of the 7th member of the Yanchang Formation in the Ordos Basin of the central-western part of North China. The fossil-bearing shale is organic-rich and has been constrained as late Latinian (late Middle Triassic) in age based on radiometric age; it is also the important shale gas bed in China, and represents a relatively deep lake depositional system during the late Middle Triassic. The Yanchang Formation fossils therefore represent the earliest stomatocysts of chrysophytes. Stomatocysts are mostly intact and their surface ornamentation and collars are well preserved under Scanning Electron Microscope (SEM). These microfossils are associated with framboidal pyrites, which indicate a reducing condition in the deep lake. Analyses of both Energy-dispersive X-ray Spectroscopy (EDS) and Nano-scale Secondary Ion Mass Spectrometry (NanoSIMS) revealed that pyritization is commonly present on the outer layer of stomatocyst and organic matter fills in the cavity of stomatocyst, with light carbon isotopes of organic carbon, suggesting important sources of shale gas and shale oil preserved in the Yanchang black shales of the Ordos basin.

So far, the earliest fossil record of algae with siliceous structures was cysts found in the 7th member of the Yanchang Formation from 6 drilling sections in the Ordos Basin, China. Here we observed and described more than a dozen new stomatocyst morphologies from the same deposit in the Bawangzhuang section of the basin according to the guidelines of the International Statospore Working Group (ISWG), and found that they are extremely rich in the types of collars and surface ornamentations, and such high morphological diversity implies that ancestors of chrysophytes could occur much earlier than Middle Triassic, offering new insights into the origin

of freshwater siliceous algae.

Silicified gastropod fossils from the uppermost Permian of Guangxi Province, South China

Jie Liu[1]*, 15721629973 (2849564485@qq.com)
Zhong-Qiang Chen[2], 13247146048

Abstract

Like other benthos, gastropods suffered a great reduction in body size and diversity across the Permian-Triassic mass extinction. However, when compared with other clades (i.e. brachiopods, ammonoids, biavlves so on), the latest Permian gastropods have been less documented in details. For instance, the previous studies showed that only 27 gastropod species have been reported from the uppermost Permian across the entire South China in which other invertebrates were extremely abundant and diverse in the Changhsingian. Thus, here we report a diverse gastropod assemblage from the from the Changhsingian Formation in the Waitoushan section of Dongluo District, Fushui County, Guangxi Province, South China. More importantly, this gastropod fauna is represented by the silicified fossils, which provide better understanding of morphology and systematic classifications of the latest Permian gastropod fauna, and their functional paleoecology, further offering new insights into the fate of gastropods over the Permian-Triassic transition and evolution of this clade during the critical period. This latest Permian gastropod assemblage mostly comprises silicified larval gastropod elements, and they were identified as 20 species (including two uncertain species) in 19 genera, including: Altadema hausmannae Nützel and Karapunar, 2023Anomphalus fusuiensis Pan et al., 2002, Ananias sp., Goniasma fusuiensis Pan et al., 2002, Leptoptygma laetus Pan et al., 2002, Manzanospira turrita Pan et al., 2002, Microconchus aberrans Hohenstein, 1913Microlampra heshanensis Pan et al., 2002, Naticopsis (Jedria) quangxiensis Pan et al., 2002, Palaeostylus dongluoensis Pan and Yu, 1993, Palaeostylus fusuiensis Pan et al., 2002, Peruvispira lingshuien Pan et al., 1985, Protostylus sp., Porcellia paucituberculata Pan et al., 2002, Retispira khaophrikensis Knight, 1945, Streptacis fragilis Pan et al., 2002, Stegocoelia Donald, 1889, Soleniscus pactus Pan, 2002, Trachydomia minuta Pan, 2002, Warthia vaceki (Bittner, 1899). Most of them are limited to Changhsingian in age, with several species ranging from the Kungurian (early Permian) to Changhsingian (late Permian). The Dongluo silicified gastropod assemblage represents the most diverse pre-extinction fauna from single section in South China.

Millennial-scale variations of Carbon-Sulfur isotopes were regulated by microbe activities following the end-Permian extinction

zijie zheng[1]*, State Key laboratory of biogeology and environmental geology, China university of geosciences (wuhan) (zjzheng@cug.edu.cn)
zhongqiang chen[2], State Key laboratory of biogeology and environmental geology, China university of geosciences (wuhan)

Abstract

As the largest biocrisis of Earth life, the Permian-Triassic mass extinction (PTME) has not only declined biodiversity, but also re-organized chemical cycles of marine settings. Previous studies have showed that marine sulfate pool declined sharply and carbon-sulfur isotopes showed huge fluctuations and recoupling changes on a global scale during this critical period. Nevertheless, the high-frequency or millennial-scale variations of carbon-sulfur cycles have long remained unknown. As sedimentary response to the PTME, microbialites were well developed and widespread in shallow-water carbonate settings immediately after the end-Permian extinction. Such a microbialite unit usually is much thicker than synchronous deposits of deep-water facies, providing the possibility of obtaining carbon-sulfur isotope signals with higher temporal accuracy from the microbialite successions in South China. These high-resolution precise geochemical data derived from the microbialite section help unravel more detailed C-S cycles during the PTME and its driving mechanisms. We analyzed 62 samples from microbialite succession near the Permian–Triassic boundary (PTB) at the Yudongzi section of South China, and undertook the analyses of the size and morphology of pyrite framboids, carbonate carbon isotopes (δ13Ccarb), carbonate-associated sulfur isotope (δ34SCAS), major and trace elements, and stratigraphic distribution of the type and size of various microorganisms. The Yudongzi microbialite unit is 12 m thick and represents the depositional duration of about 40,000 years. Two types of microbial fossils were recognized: Gakhumella-like calcimicrobe and coccoid-like spheroids. The overall population size of these two types of microorganisms showed a downward trend up the section, with a peak together in beds 2 and 3. There seems to be a competitive relationship between the two at bed 4. The Ce/Ce* and pyrite framboids incidate a dyoxic to anoxic redox state, and the oxygen deficiency gradually intensified from bottom to top at the studied section. The diameter of Gakhumella-like calcimicrobe increases significantly up the section, suggesting that the redox state have seriously affected on microbial components within the microbialite ecosystem. Both δ13Ccarb and δ34SCAS isotopes show a prominent negative excursion across the PTME, comparable with those of several other shallow platform facies sections worldwide. The C-S isotopes, with a millennial-scale record of global carbon-sulfur fluctuations during the PTME, exhibit an obvious reverse coupling change within microbialite units, which could be strongly linked with the oxygen-poor conditions and activities of microbial sulfate reduction (MSR). Our results of fossil and geochemical analyses provide a new interpretation on carbon and sulfur isotope variations at millennial-scale and additional evidence of the concurrent environmental

changes during the Permian–Triassic transition.

Early Permian carbonate buildups from eastern Inner Mongolia, North China: Insights regarding the late Early Permian Turnover

Zhen YAN[1]*, Institute of Geology, Chinese Academy of Geological Sciences
(yanzhen20071239@126.com)
Jianbo LIU[2], School of Earth and Space Sciences, Peking University
Xiaochi JIN[3], Institute of Geology, Chinese Academy of Geological Sciences

Abstract

Early Permian carbonate buildups were dominantly constructed by phylloid algae, *Palaeoaplysina* , microbes, bryozoans and *Shamovella*. Middle Permian carbonate buildups were mainly formed by sponges, corals, microbes, bryozoans and *Shamovella*. The phenomenon of the disappearance of phylloid algae and *Palaeoaplysina* form Early Permian carbonate buildups and the flourishing of sponges and corals in the Middle Permian carbonate buildups was named as the late Early Permian Turnover, however, the precise time and controlling factor of the biotic turnover remain wanting further study.

The Asselian–Sakmarian (Early Permian) phylloid algal-microbial reefs and skeletal-microbial mounds from the Amushan Formation, at the Mihangaoqiaogaolu section in eastern Inner Mongolia, North China provide an excellent sample for studying the problem mentioned above. In the stratigraphic sequence, the phylloid algal-microbial reefs are located beneath the skeletal-microbial mounds. The former were constructed by microbial sediments and phylloid algae, and the latter were formed by microbial sediments and skeletal grains including foraminifers, bryozoans, *Shamovella* and *Anthracoporella*. Phylloid algae are not observed in the skeletal-microbial mounds. Microbial sediments are the most important components in both reefs and mounds. They are characterized by the aggregations of filamentous microbes, peloids and micritic filaments: filamentous microbes are usually interpreted as the consequence of sparry calcitic occlusion of completely calcified sheaths of filamentous cyanobacteria, in contrast to the micritic filaments that are formed when the calcified sheaths are completely occupied by micrite; peloids are considered as the result of post-mortem incomplete calcification of filamentous cyanobacteria. Along with the change of carbonate buildups, the organisms in the non-buildup sediments also have an obvious variation almost simultaneously: 1) the amount of phylloid algae decreased dramatically, while *Anthracoporella* thrived; 2) the content of foraminifers, bryozoans and *Shamovella* increased significantly.

As mentioned above, phylloid algae were replaced by foraminifers, bryozoans, *Shamovella* and *Anthracoporella* during the Asselian–Sakmarian in the Mihangaoqiaogaolu section. Similar biotic change occurred widely on a global scale, and roughly coincides with the end of Late Paleozoic glaciations. Therefore, the so-called late Early Permian Turnover is likely to have occurred in the early Early Permian, which is earlier than previous known, and may be closely related to the paleoclimatic change from an icehouse to a greenhouse.

A new charophyte flora from early Middle Triassic (Guizhou, South China) indicates ecologic adaptation to shallow marine

Meijia Zhang[1]*, China University of Geosciences (Wuhan) (zhangmeijia@cug.edu.cn)
Zhong-Qiang Chen[2], China University of Geosciences (Wuhan)

Abstract

Charophytes are a group of submerged macrophytes, with the earliest fossil records dating back to the Silurian. Since the Mesozoic Era, charophyte fossils have been considered as palaeoenvironmental proxies of ancient freshwater and brackish-water aquatic systems. However, the palaeoecology of Palaeozoic charophytes has been a matter of controversy.

This study first reports a large number of charophyte fossils in the early Middle Triassic Guanling Formation in Guizhou, South China. The lithology of the study section mainly consists of carbonate and mudstone, reflecting a shallow-water carbonate platform environment. In this section, more than 10 species in 3 genera were identified. The charophyte fossils are well preserved and the fragile eversion structure of the apical neck of gyrogonites is intact. The distribution of these fossils appears scattered and non-directional. Observations from scanning electron microscopy and cathodoluminescence revealed that the charophyte fossils and rocks were less affected by diagenesis. Further analysis of carbon and oxygen isotopes carried out on the shells of gyrogonites and rocks revealed that the isotopic composition of carbon and oxygen in the water environment during the calcification of charophyte gyrogonites was consistent with that in the seawater at that time. These findings suggest that they were buried in situ, indicating that these charophytes lived in a shallow marine environment in the early Middle Triassic. Many charophyte fossils with four spirals, undivided and multipartite basal plates, and closed apical pore were also found in this section, indicating that during the early Middle Triassic, charophytes have recovered from the Permian-Triassic mass extinction and entered a period of rapid evolution.

This study discovered the marine charophyte fossil flora in the early Middle Triassic of South China that is presently the most abundant and diverse globally. This discovery provides important evidence for revealing the environmental response mechanism of charophytes to the shallow marine environments and the evolution of charophytes.

[Keynote] Mid-Phanerozoic major environmental perturbations and ecosystem responses

Zhong-Qiang CHEN[1]*, China University of Geosciences (Wuhan) (zhong.qiang.chen@cug.edu.cn)
Yuangeng Huang[2], China University of Geosciences (Wuhan)
Yu Pei[3], China University of Geosciences (Wuhan)
Xueqian Feng[4], China University of Geosciences (Wuhan)
Qian Fang[5], China University of Geosciences (Wuhan)
Ziheng Li[6], China University of Geosciences (Wuhan)
Zhen Guo[7], China University of Geosciences (Wuhan)

Abstract

After development of ecosystems of Paleozoic, numerous major environmental perturbations accompanied with biotic crises took place during the middle part of the Phanerozoic. This study summarizes the advanced progresses on these extreme environmental and biotic events. The Guadalupian-Lopingian (middle-late Permian) transition witnessed volatile eruption of the Emeishan large igneous province (LIP). Consequently, microbial bloom was associated with the loss of metazoan reef systems and moderate loss of marine invertebrates. The Permian-Triassic (P-Tr) mass extinction is the largest biotic crisis associated with enormous environmental and climatic changes. A total of seven phases of environmental and biotic evolution during the P-Tr transition have been recognized from both marine and terrestrial depositional sequences based on integrated biostratigraphy and isotope stratigraphy. Phase 1 represents the normal marine environments and biota that existed at 252.104 Ma, prior to the onset of major environmental perturbation. Phase 2 is marked by the onset of a negative carbon (δ13Ccarb) isotopic excursion, and coincides with a significant decline in radiolarian diversity, the collapse of communities in shallow metazoan reefs and deep-water settings, and the loss of rainforests on land. Phase 3 is characterized by a pulse of biodiversification on the eve of the end-Permian extinction (EPE). Phase 4 comprises the EPE event itself, dated to 251.941 Ma, and coincides with an extreme episode of widespread anoxia, biodiversity loss, community structural collapse, and volatile eruption of Siberian LIP. Phase 5 is marked by the renewed onset of oxic conditions in all oceanic environments except those in microbialite-rich shallow platform settings where abundant pyrite framboids signal dysoxia. Phase 6 includes the earliest Triassic extinction (ETE) event, dated to 251.880 Ma, associated with euxinic to anoxic conditions and ocean acidification. An extended phase of deoxygenation and acidification returned to the marine settings during Phase 7, possibly driving a calcium crisis. The terrestrial extinction event (Phase 2) probably commenced c. 60 kyrs (in South China) or 370 kyrs (in Sydney basin) before the marine P–Tr extinction, the latter consisting of two distinct events (Phases 4 and 6), spaced c. 60 kyr apart, each being marked by both a carbon isotope excursion and ecologic collapse. The environmental changes associated with these three extinction phases in the ocean and on land can be attributed to the effects of volcanic emissions during the eruption of the Siberian LIP and convergent margin volcanism related to Tethyan tectonics. The secondary extinction also took place across the Smithian-Spathian

boundary (Olenekian). This extinction seems to coincide with cooling in seawater temperature and possible oceanic anoxia and acidification. So far, this extinction has not been reported from terrestrial records. Recently, increasing attentions have been paid to the Carnian Pluvial Episode (CPE) of the Late Triassic, which represents an extreme climatic event and extinction of some clades. The CPE is also recorded in terrestrial successions worldwide, and multiple turbulence of carbon cycles driven by volatile volcanisms have also been recognized. Prior to the Triassic-Jurassic mass extinction, a major environmental crisis has also been identified from the mid-Norian successions in deep-water settings.

Upper Triassic (middle Norian) conodont biostratigraphy succession from eastern Tibet, southwest China

Zhengyi LYU[1]*, China University of Geosciences (Wuhan) (beijing.2008.lzy@163.com)
Martyn L. Golding[2], Geological Survey of Canada
He Zhao[3], China University of Geosciences (Wuhan)
Huazhou Yao[4], Wuhan Center of China Geological Survey
Xiangdong Wang[5], China University of Geosciences (Wuhan)
Lei Zhang[6], China University of Geosciences (Wuhan)
Yangui Li[7], Wuhan Center of China Geological Survey
Chen Han[8], China University of Geosciences (Wuhan)

Abstract

The Late Triassic is a critical period that witnessed major biological and environmental events. The geographic range and taxonomic diversity of conodonts were significantly changed during the Late Triassic. The lack of detailed studies of Norian conodont biostratigraphy from Tibet hampers correlation with Europe and North America, which paleogeographically belong to the western Tethys Ocean and northeastern Panthalassa Ocean, respectively. We present recent study results of a continuous middle Norian (Upper Triassic) conodont succession from the Chaiwei and Tuoba sections of Qamdo (Changdu) area, eastern Tibet (Xizang), southwest China, which was part of the North Qiangtang and Qamdo-Simao Block (NQ-QSB) located in the northeastern Tethys Ocean during the Late Triassic. Therein, the middle Norian (Upper Triassic) succession is well exposed and yielded rich conodonts. A total of four conodont zones are differentiated from the middle Norian (Alaunian) of the Chaiwei section, in ascending order these are: the Epigondolella spiculata Zone, the Orchardella elongata Zone, the Mockina postera Zone, and the E. serrulata Zone; the neighboring Tuoba section also records these four zones, in addition to the upper lower Norian (upper Lacian) Ancyrogondolella uniformis Zone. All of these zones (except for the M. postera Zone) have been recognized for the first time in eastern Tibet. The Lacian-Alaunian boundary is tentatively identified by the first occurrence (FO) of E. spiculata in both the Chaiwei and Tuoba sections. The position of the Alaunian-Sevatian boundary (ASB) is uncertain since the conodont assemblage at the study sections lacks age-diagnostic elements. The conodonts recovered from the Qamdo area have not only dated the Bolila Formation but also refined the conodont biostratigraphic zonation of the Alaunian in the study area. This allows improved correlation between the faunas of Qamdo and their counterparts elsewhere in Tibet, Europe, and North America. In addition, the faunal turnover around the Lacian-Alaunian transition, with the evolution of Epigondolella, Orchardella, and Mockina from Ancyrogondolella, can be recognized in both study sections, although it is more remarkable in the Tuoba section. Therefore, this study also provides new data to improve our understanding of conodont evolution during the Alaunian, and is significant in providing palaeontological data for studying the palaeogeographic evolution of eastern Tethyan ocean basins in the Late Triassic.

The Guadalupian Extinction: Severity, Selectivity, and Timing

Matthew CLAPHAM[1]*, University of California, Santa Cruz (mclapham@ucsc.edu)

Abstract

The Guadalupian (Capitanian, mid-Permian) extinction was only recognized as a distinct event around 30 years ago, having been grouped with the end-Permian mass extinction in previous studies. The extinction occurred at approximately the same time as the Emeishan flood basalts, suggesting that the causes and consequences may have been similar to the end-Permian extinction. However, the Guadalupian extinctions remains far less understood. Although it was initially proposed as a major mass extinction, improvements to Permian biostratigraphic correlation have revealed Late Permian ages for many localities previously assigned to earlier intervals. As a result, it is now known that the Guadalupian extinction was only a minor crisis, although the extinction rates were elevated above background levels. However, the extinction was far more severe for certain groups, most notably fusulinid foraminifera. Other groups, such as ammonoids, appear to have undergone taxonomic turnover that likely coincided with the extinction, but there is less certainty about the precise timing in some groups. Similarly, although the existence of an extinction during the Capitanian stage is well-documented, the exact timing and tempo within the stage remain unknown due to a lack of high-resolution fossil range data at individual stratigraphic sections. Geochemical proxy records are also ambiguous, unlike the consistent excursions in carbon, oxygen, and other isotopic or trace metal proxies observed at the end-Permian mass extinction. Although the Guadalupian extinction is only a minor crisis in terms of overall taxonomic severity, it is still a fascinating event that provides another example of flood basalt-driven environmental and biotic change.

Secular variations of ichnofossils before and during the Carnian Pluvial Episode from the continental Upper Triassic successions, South China

Liao YANG[1]*, China University of Geosciences (Wuhan) (liao_yang48@163.com)
qian Xue Feng[2], China University of Geosciences (Wuhan)
qiang Zhong Chen[3], China University of Geosciences (Wuhan)
ming Ze Zheng[4], China University of Geosciences (Wuhan)
le Qi Geng[5], China University of Geosciences (Wuhan)

Abstract

Ichnology is exceptionally important for interpreting animal behavior variations across major biotic and environmental crises, and several important ichno-ecologic measures have been successfully applied to ecologically assess the process and mechanism of collapse and rebuilding of marine ecosystems across the Permian-Triassic (P-Tr) mass extinction. However, few studies have concerned ichnological changes of terrestrial ecosystems across the P-Tr extinction and major environmental stresses within the Triassic. In particular, the Carnian Pluvial Episode of the Late Triassic represents an extreme climatic event and led the complete collapse of marine carbonate factory worldwide and extinction of some clades. So far, no ichnologic assessment has been undertaken across the CPE in either marine and terrestrial settings. Here we systematically document 14 ichnospecies in 9 ichnogenera from the upper Badong Formation of Carnian age in the Lianghekou section of the Zigui basin, western Hubei Province, South China, these ichnotaxa include: *Ancorichnus ancorichnus*, *Beaconites coronus*, *B. antarcticus*, *Camborygma litonomos*, *Palaeophycus heberti*, *P. tubularis*, *Planolites beverleyensis*, *Psilonichnus* isp., *Scoyenia gracilis*, *Skolithos linearis*, *Taenidium barretti*, *T. bowni*, *T. satanassi*, and *T. serpentinum*. Stratigraphic occurrences allow recognition of four ichnoassemblages up the section. 1) the *Scoyenia-Skolithos* ichnoassemblage, composed mainly of *Skolithos* and *Scoyenia*, with weak bioturbation and low level of vertical tiering, likely occurred in floodplain to nearshore of lake settings with dry or semi-dry climate regime. 2) the *Scoyenia* ichnoassemblage, which is mainly comprised of *Scoyenia*, *Beaconites*, *Taenidium*, and *Palaeophycus*, with increasing ichnodiversity and tiering level, and a low to moderate bioturbation, was produced in the cyclically exposed, rather shallow lake environment with a semi-dry climate regime. 3) the *Taenidium-Ancorichnus* ichnoassemblage, including *Ancorichnus*, *Beaconites*, *Scoyenia*, *Taenidium* and *Psilonichnus*, with a major increase in ichnodiversity, and their bioturbation level reached 5-6, which formed in the shore zone of lake settings with a wet-dry climate regime. 4) the *Planolites-Camborygma* ichnoassemblage, consisting of *Planolites* and *Camborygma*, with high ichnofossil abundances and the lowest tiering level, indicating wet regime with high soil-moisture and water-table levels. The first three ichnoassemblages occurred in the pre-CPE, while the fourth ichnofauna occurred in the CPE. Integration of ichno-ecological and sedimentological analyses and carbon isotopic stratigraphy suggests that paleoclimates

changed from dry to wet conditions across the CPE in terrestrial ecosystems in South China, strengthening the wet regime condition of CPE prevailed in marine and terrestrial ecosystems at least in China.

Dynamic variations of carbon-sulfur cycles through the Late Permian to Early Triassic

Lei ZHANG[1]*, China University of Geosciences (Wuhan) (zhanglei_cug@sina.com)
Biao Ma[2], China University of Geosciences (Wuhan)
Laishi Zhao[3], China University of Geosciences (Wuhan)
Zihu Zhang[4], Chengdu University of Technology

Xiangdong Wang[7], China University of Geosciences (Wuhan)
Chao Li[8], Chengdu University of Technology

Abstract

Marine carbon-sulfur cycles experienced long-term frequent perturbations through the latest Permian to Early Triassic. However, relationships between carbon and sulfur isotopes are still unclear. Here, we report δ13Ccarb and δ34SCAS, and elemental proxies (UEF, MoEF, Mn/Th, Cd/Mo and Co×Mn) from the Wuchiapingian to Spathian successions (Zuodeng section) in the southern Nanpanjiang Basin, South China. Sudden decreases in both UEF and MoEF values (from ~150 to < 10, and ~60 to < 10, respectively) and gental increase in Mn/Th ratios (< 200 to ~1000) indicate a locally anoxic seawater condition during the Late Permian and an oxic condition during the Early Triassic. Variations of Cd/Mo, Co×Mn and TOC suggest that the Late Permian anoxic condition was related to locally intensive oceanic circulation (e.g., upwelling) and higher marine productivity, which was probably controlled by relatively cool climate regime, whereas the Early Triassic climate warming may have resulted in intensive oceanic stratification, suppressed marine productivity, and thus narrowed the spatial distribution of the oxygen minimum zone, leaving the study site apart from anoxic water mass in that time. Both δ13Ccarb and δ34SCAS excursions were coupled during the Griesbachian and Dienerian substages probably due to elevated or suppressed marine productivity and co-burial of organic matter and pyrite driven by climatic variations. Decoupled δ13Ccarb-δ34SCAS excursions occurred during the Late Permian and the Smithian global warming, respectively probably because of elevated bacterial sulfate reduction and pyrite burial rate induced by serious global-oceanic anoxia. This study deciphers that dynamic variations of marine carbon-sulfur cycles may have been controlled by extremely environmental changes through the Late Permian to Early Triassic.

Abstract

As keystone species, dinosaurs played a fundamental role in the structure of mid-Mesozoic terrestrial ecosystems. In addition, because of their global distribution, dinosaurs evolved into numerous forms that occupied different niches during the Late Jurassic to Early Cretaceous. Temporal dinosaurian diversity dynamics show apparent peaks in species richness in the Late Triassic and early Early Jurassic, and in the Late Jurassic through the Cretaceous. In the Jurassic (201-145 Ma) dinosaur ecosystems diversified and became much more complex, but the detail of how this happened is obscured by a poor global record of dinosaurs in the Middle Jurassic. Data on dinosaur-dominated ecosystems through the Jurassic of West China indicates 22 functional guilds and 127 inter-guild trophic links. Modeling demonstrates that community stability was generally low in the Early Jurassic and surged across the Early-Middle Jurassic transition, indicating the establishment of relatively stable dinosaur-dominated ecosystems, which were characterized by the emergence of an essential guild in community-the larger terrestrial herbivores. This observation highlights the relevance of the keystone species concept in deep-time ecology. The Middle Jurassic stabilization was also accompanied by a pronounced surge in community modularity, thus, the hypothesis that a modular organization of species interactions would aid the stability of communities is supported by our deep-time empirical findings.

Abstract

The Carnian Pluvial Episode (CPE, early Late Triassic) represents one of the most severe hydrological perturbations triggered by global warming. However, the variation process of this event, as well as its impacts on seawater chemistry and biotic compositions, remains elusive. In this study, we carried out a detailed organic geochemical analysis of the Erguan section in Nanpanjiang Basin, Guizhou, South China, which records three episodes of negative excursions in carbon isotope compositions(δ13C) in the Carnian. Our organic geochemical records reveal three main episodes of increase in the relative fraction of C30 βα-hopane(moretane) , indexed by the ratio of C30 moretane and αβ-hopane, and three main episodes of increase in the relative fraction of Dibenzofuran, indexed by the ratio of Dibenzofuran and Phenanthrene , coinciding with the three episodes of δ13C negative excursions and increases in the fraction of C29 steranes and clastic minerals. All these suggest that the CPE experienced three main episodes of elevated precipitation, which transported amounts of terrestrial organics and clasts into marine environments. In addition, our organic geochemical records unravel different responses of redox conditions and biotic compositions to these elevated precipitations. For example, during the first episode, the distinct decreases in Pr/Ph (pristane/phytane) ratio and C35 HHI (C35 homohopanes/C31-35 homohopanes) suggest that the redox condition became more oxic, whereas the upper two episodes correspond to enhanced marine anoxic. Furthermore, the upper two episodes coincide with elevated C31 3β-methylhopanes index (3-MeHI, the ratio between C31 3β-methylhopane and C30 αβ-hopane), as high as 11.7%, suggesting enhanced methane cycling. The details of these points will be covered in this talk.

Tracing Dissolved Oxygen Variability in Riverine Environments: A High-Resolution Study Using *Lamprotula leai* Shell Trace Elements

Xinran Su[1]*, Nanjing University (suxr_nju@163.com)
Chenglong Li[2], Nanjing University
Xuefen Sheng[3], Nanjing University

Abstract

Dissolved oxygen (DO) is considered an important measure of water quality and a vital proxy relating to the geological events such as ocean circulation, paleoclimate, the extinction and the evolution of organic matter. The low level of DO in water may lead to eutrophication, biodiversity decline and other environmental risks, which is a sign of water contamination. Global warming will lead to a decrease of DO concentration in water and an increase of biological metabolism, which is one of the important reasons for causing the decline of DO concentration. Dissolved oxygen in modern surface water can be measured with an oxygen measuring device (DO-meter). For the dissolved oxygen content in geological time, which is difficult to quantify, it can reconstruct by using paleontological morphology and species combinations. Hence, it is necessary to develop a high-resolution (from seasonal to day time scales) archive to reconstruct river dissolved oxygen concentration in geological period. The present study utilizes the widespread living *Lamprotula leai* samples from the river basin in subtropical areas located in the central and eastern region of China, where the DO level in this river basin is relatively low, as a carrier to explore the variation of trace elements (mainly Mn/Ca) at high resolution scale in the shell. The morphological features along the axis of maximum growth from the umbo to the ventral margin were measured by light microscope and scanning electron microscope (SEM). The characteristics of trace elements in this direction were obtained by X-ray Fluorescence Spectroscopy (XRF), Secondary Ion Mass Spectrometry (SIMS) and other element analyse methods. The results reveal that a good correlation between the position of the dark growth lines and the maximum value of Mn/Ca is observed. Previous studies have shown that a low level of DO in water leads to an increased concentration of Mn2+, which can lead to high Mn/Ca in the shell. At the same time, the low level of DO will slow the growth rate of the shell and form a growth line. Therefore, we propose that the Mn/Ca ratio in the shell of *Lamprotula leai* can serve as an indicator of DO level in water. To further investigate the feasibility of using the Mn/Ca ratio in the shell of *Lamprotula leai* as a paleoenvironmental indicator, we will select the fossil samples from Jiaochangpu Site in Liaocheng, Shandong Province during the Longshan Culture period in the Yellow River basin (about 4k years ago) for high-resolution analysis, and explore the changes of the terrestrial environment in the Longshan period through the distribution of Mn/Ca shells.

Rise of calcareous deposition during the Carnian Pluvial Episode (Late Triassic)

QILE qile GENG[1]*, 18712013572 (1202211490@cug.edu.cn)
Zhongqian Chen Zhongqiang Chen[2], 13247146048

Abstract

The Late Triassic Carnian Pluvial Episode (CPE) was characterized by increased global rainfall, increased global temperature, and enhanced inland weathering, which was another important climate transition period after the global climate change at the turn of the Permian-Triassic. The marine strata of CPE based on Tethys domain has been widely studied, but the impact of CPE on terrestrial ecosystems is still poorly understood. The Triassic continental strata are preserved in the Zigui Basin of western Hubei Province, in which the lithological transition from purple-red paleosols to gray-green sandstone and limestone, which corresponds to the CPE. Through the analysis of geochemistry, mineralogy, trace fossils, paleosols and sedimentary characteristics, the high-resolution study shows that both the changes in rainfall recovered by chemical index of alteration (CIA) and the morphological changes in trace fossils reflected the transition from arid climate to humid climate. With the climate transition, the elevated Chemical Index of Alteration values and kaolinite content of clay minerals increased, reflecting the increase in weathering intensity. In addition, it will be accompanied by a large enrichment of calcium, such as the evolution of calcareous nodules in paleosols, the formation of calcareous interlayers and carbonate rocks in lacustrine sedimentary environments. The increase in calcium content in sedimentary strata coincides with the increase of rainfall and weathering intensity. The humid climate formed by the increase of rainfall during the CPE is conducive to rock weathering, which brings abundant calcium sources and other nutrients to the lake, promotes the productivity of the lake, and deposits a large number of carbonate rocks. At the same time, the enhancement of rainfall promotes the dissolution of surrounding rocks by groundwater, bringing calcium into the lake water and causing carbonate precipitation. To a certain extent, the enrichment of calcium reflects the transformation of the terrestrial environment from arid to humid environment during the Carnian period.

The habitat of the Ediacaran Period fossil Dickinsonia: Redox conditions of the fossiliferous Cherny Kamen Formation in the Ural Mountains

Natasha BYKOVA[1]*, University of Missouri (bykovan@missouri.edu)
Nikita Sozonov[2], Trofimuk Institute of Petroleum Geology and Geophysics, SB RAS
Nikolai Bobkov[3], Trofimuk Institute of Petroleum Geology and Geophysics, SB RAS
Alan J. Kaufman[4], University of Maryland, Geology Department and Earth System Science Interdisciplinary Center

Abstract

Most modern animals require a relatively high concentration of oxygen for their metabolic activities. Thus, it is intriguing to know the oxygen requirements for Earth's earliest animals. Until recently paleontologists thought that the first true animals appeared suddenly in the basal Cambrian Period, but recent discoveries of the impressions of motile organisms with a bilaterian Bauplan, or traces suggestive of complex movement, suggest an earlier Ediacaran Period appearance of metazoans. One of these is the iconic Dickinsonia, which was first discovered in 1947 by Reg Sprigg in the Flinders Ranges of South Australia. Dickinsonia is known from several late Ediacaran successions worldwide, including in exposed strata from the White Sea and Ural Mountains in the Russian Federation. Here we present a geochemical study of the Ural Mountain succession, which was carried out to understand the redox conditions of the water column during the accumulation of the fossiliferous Cherny Kamen Formation that preserves hundreds of small Dickinsonia specimens. In this study, we analyzed 30 shale samples from the upper part of the Sinii Kamen and Konovalovka members. Elemental concentration data from these shale specimens were used to evaluate paleo-productivity (Cd, P, Ba), the availability of micronutrients (Cu, Ni, Zn, Co), and the distribution of redox-sensitive metals (V, Cr, U, Mo). Elemental ratios were also determined to evaluate paleo-salinity (Sr/Ba) and sedimentation rates (log10Mn/Al and log10Fe/Al). In addition, sulfides were extracted from the shale samples using a CRS technique and analyzed for their sulfur isotope compositions (δ34Spyr). Based on these measurements we distinguish several discrete anoxic intervals, including the upper part of the Sinii Kamen Member, and the fossiliferous lower and middle intervals of the Konovalovka Member. Anoxic conditions were notably inferred from levels preserving Dickinsonia fossils. We note that Dickinsonia, macroalgae, and distinct microbial textures are associated with geochemical indicators of anoxia. Consistent with contemporaneous evidence of expanded late Ediacaran global anoxia based on uranium isotope compositions of carbonates, our observations support the view that Earth's earliest motile animals may have been tolerant of low oxygen conditions in the water column.

Vanadate reduction by gram-positive fermentative bacteria isolated from deep-sea sediments on the northern Central Indian Ridge

Bokyung KIM[1]*, Seoul National University (karabobo@snu.ac.kr)
Dong Kyun WOO[2], Seoul National University
Juhwan JUNG[3], Seoul National University
Min Sub SIM[4], Seoul National University

Abstract

Vanadium is a widely distributed element in the Earth's crust, with a concentration of 35-45 nmol/L in seawater. In natural environments, vanadium can exist in oxidation states of +3, +4, and +5, and its solubility is redox-dependent. Although vanadium is an essential micronutrient, it can become harmful at elevated concentrations. The reduction of V(Ⅴ) to V(Ⅳ) or V(Ⅲ), diminishes the mobility and toxicity of vanadium in soil or sediment. Due to relatively high concentrations in nature and large reduction potential, some microorganisms use vanadate as an electron acceptor for their energy metabolism, suggesting the potential significance of vanadate reducers in the biogeochemical vanadium cycle and remediation of vanadium contamination. To date, however, most known microorganisms capable of reducing vanadate are Gram-negative bacteria belonging to the phylum Proteobacteria, with the only exception being Lactococcus raffinolactis. In this study, we isolate Tepidibacter mesophilus strain OVF from deep-sea sediment at the Onnuri vent field on the northern Central Indian Ridge and investigate its ability to reduce vanadium and its impact on cellular metabolism. A series of culture experiments show that the isolated strain efficiently reduces V(V) to V(IV) during fermentation, even at mM levels, and this reduction is a direct biological process, rather than an indirect reduction by metabolic products. We confirmed that vanadium affects microbial carbon and nitrogen metabolism and redox balance by monitoring changes in metabolite concentrations in the presence or absence of vanadate. T. mesophilus is the second Gram-positive bacterium discovered to reduce vanadium, following L. raffinolactis, with a notable distinction between them. Firstly, they belong to different classes: T. mesophilus is classified as Clostridia, while L. raffinolactis belongs to Bacilli. Secondly, L. raffinolactis utilizes nitrite reductase (NirS) for vanadium reduction, but T. mesophilus lacks this gene. Lastly, the vanadium reduction rate of T. mesophilus is faster compared to that of L. raffinolactis, similar to the rates observed in metal-reducing gram-negative bacteria. Our findings expand the distribution of the vanadate reducing capability in the bacterial domain, and suggest an alternative pathway for vanadate reduction. Given the wide range of natural habitats of T. mesophilus and its close relatives, microbial vanadate reduction may have a greater impact on the global biogeochemical cycle of vanadium than previously thought.

Arsenic immobilization using combined treatment of arsenite-oxidizing bacterium and biochar

So-Jeong KIM[1]*, Korea Institute of Geoscience and Mineral Resources (sojkim86@kigam.re.kr)
Dong-Wan Cho[2], Korea Institute of Geoscience and Mineral Resources
In-Hyun Nam[3], Korea Institute of Geoscience and Mineral Resources
Chul-Min Chon[4], Korea Institute of Geoscience and Mineral Resources

Abstract

Arsenic is one of the natural hazards of geological origin and contamination by human activities, including mining and manufacturing. Inorganic arsenic exists in two main oxidation states at neutral pH, of which arsenite (As(III)) is known to be more toxic and more mobile than arsenate (As(V)). Therefore, changes in the oxidation state of arsenic are important in controlling arsenic contamination. This study aimed to isolate a novel arsenite-oxidizing bacterium from mine tailings and characterize its physiological and genomic properties. Among the strains obtained, one strain was found to have the ability to oxidize arsenite, and it was named BH3 and identified and analyzed for its characteristics. Strain BH3 was able to oxidize 9 mM arsenic and tolerated the toxicity of 100 mM arsenate. As a result of genomic analysis, it was confirmed that strain BH3 is belonging to the genus Bosea and has genes for arsenite oxidation. Additionally, we investigated the synergistic effect of strain BH3 and biochar derived from coffee grounds in adsorbing oxidized arsenate. Our results demonstrate that when applied simultaneously, strain BH3 oxidizes arsenic while biochar effectively adsorbs the oxidized arsenic, providing a promising method for changing and stabilizing arsenic phases in contaminated environments. This approach holds potential for environmentally-friendly remediation strategies targeting arsenic contamination.

Greenhouse gas molar ratios and stable isotopic compositions in Seoul Mega City

JeongEun KIM[1]*, Seoul National University (jeun_kim@snu.ac.kr)
Jinho Ahn[2], Seoul National University
Sakae Toyoda[3], Tokyo Institute of Technology

Abstract

In the Seoul metropolitan area of South Korea, over half of the population resides in a compact 12% of South Korea, contributing significantly to annual anthropogenic greenhouse gas emissions exceeding 1.7 Mt CO2 eq. Given the concentrated population in this relatively small region, it becomes imperative to identify and continuously monitor specific emission sources. The complexity of urban greenhouse gas emissions necessitates in situ sampling for accurate atmospheric monitoring and modeling. To characterize natural and anthropogenic greenhouse gas sources, we collected air samples from three tunnels (Gwanak, BongCheon, SangDo) and three open locations (Mt GwanAk, Mt Nam, and Olympic Park). Greenhouse gas concentrations (CO2, CH4, and N2O) and stable isotopic compositions of N2O (δ15Nbulk, δ18O, and SP) were analyzed.

The vehicle N2O:CO2 molar ratio from tunnel air was (4.3±0.3)x10-5, which falls within the range of previous tunnel studies from Switzerland, Germany, and Sweden ((1.6 – 23) x10-5), and the CH4:CO2 molar ratio of (38.5±11.6)x10-5 was higher than from previous on-road measurements ((4.4-29.1)x10-5). The stable isotopic ratios of N2O emitted from the vehicles were determined as 6.0 ± 1.2 ‰ for δ15Nbulk, 34.4 ± 11.7 ‰ for δ18O, and 6.0 ± 4.2 ‰ for SP (Site Preference, δ15Na-δ15Nb). Intriguingly, N2O stable isotopic compositions from vehicles consistently depleted compared to ambient air in Seoul (δ15Nbulk: 5.9± 0.2 ‰, δ18O: 43.8 ± 0.1 ‰, SP: 18.6 ± 0.3 ‰ (S.E.)), deviating δ15Nbulk and δ18O were notably from the global average. Further study will include stable isotope analyses for CO2 and CH4 (δ13C- CO2, δD-CH4) and the results will be presented during the conference, emphasizing pronounced spatial and temporal variabilities in greenhouse gas emissions (CO2, CH4, and N2O). These results underscore the urgency for further research to comprehend the extent of anthropogenic impacts on urban environments.

Unravelling Carbon Fluxes in Delhi's Urban Fabric: Emission and Sequestration Dynamics

SHAILENDER KUMAR[1]*, Centre for environmental studies and disaster management, Miranda House, University of Delhi (Shailender.kumar@mirandahouse.ac.in)
Chirashree Ghosh[2], Department of Environmental Studies, University of Delhi

Abstract

Understanding the intricate dynamics of carbon fluxes within urban environments is paramount for addressing climate change and fostering sustainable urban development. This paper presents a comprehensive review of carbon emission and sequestration dynamics in Delhi, a megacity characterized by rapid urbanization and environmental challenges. Drawing from recent studies and empirical data, we analyse the sources, trends, and impacts of carbon emissions in Delhi's urban landscape, encompassing transportation, industrial activities, energy consumption, and urban development patterns.

Recent research underscores the significant contribution of transportation to carbon emissions in Delhi, driven by the proliferation of private vehicles and inadequate public transportation infrastructure. Industrial activities also play a substantial role, particularly in areas such as manufacturing and construction, where emissions are intensified by inefficient processes and outdated technologies. Furthermore, the burgeoning energy demand in residential and commercial sectors amplifies carbon emissions, necessitating urgent interventions to enhance energy efficiency and promote renewable energy adoption.

In contrast, carbon sequestration mechanisms offer promising avenues for mitigating Delhi's carbon footprint. Urban green spaces, including parks, gardens, and tree-lined streets, have the potential to sequester carbon dioxide through photosynthesis and enhance urban biodiversity. Additionally, urban forests and afforestation initiatives present scalable solutions for carbon sequestration, improving air quality and fostering ecological resilience amidst urbanization pressures.

However, several challenges impede effective carbon management in Delhi's urban fabric. Inadequate urban planning, population density, and land-use changes exacerbate emissions, necessitating integrated strategies that prioritize sustainable transportation, energy efficiency, and green infrastructure. Policy interventions such as emissions regulations, congestion pricing, and incentives for green building practices can incentivize low-carbon development pathways while fostering community engagement and awareness.

Furthermore, technological innovations, including smart grid systems, electric mobility solutions, and green building technologies, hold immense potential for reducing emissions and enhancing resilience in urban environments. Collaborative partnerships between government agencies, academic institutions, and private stakeholders are crucial for implementing scalable solutions and leveraging financial mechanisms to support sustainable urban development initiatives.

In conclusion, this review highlights the urgent need for holistic approaches to address carbon

fluxes in Delhi's urban landscape. By integrating insights from multidisciplinary research, policymakers, urban planners, and stakeholders can formulate evidence-based strategies to mitigate carbon emissions, enhance carbon sequestration, and foster resilient, livable cities in the face of climate change.

Inventorization of Green House Gases – Sources and Sinks in Urban Delhi, India

CHIRASHREE GHOSH[1]*, Department of Environmental Studies, University of Delhi (Chirashreeghosh@rediffmail.com)

Abstract

The population of Delhi for the year 2024 is close to 22 million. Due to different cultural habits and higher population density, the capital has become an interesting study site for understanding major issues of 'environmental consequences due to urbanization.

Two broad objectives have been considered for this study viz. GHG inventorization and Carbon map preparation. To fulfill these objectives, estimation has been done using two approaches: top-down and bottom-up; using IPCC Tier 1 Methodology.

In top-down approach, emissions have been calculated based upon fuel and electricity consumption in source sectors of Delhi. In case of bottom-up approach, emission estimation was calculated at the unit level such as from single household for the domestic sector or emissions from different categories of vehicle for the transport sector. On-site monitoring of GHGs was also carried out at 64 sites across Delhi using CO2 and CH4 automatic analyzers (Aeroqual, Series 500, New Zealand).

As it is true for most of the metropolitan cities in developing countries, Delhi is also plagued with issues of proper settlement and housing. Pollution from unauthorised domestic sector was mainly due to use of kerosene, LPG, diesel (DG sets) and huge consumption of electricity. LPG was the most commonly used cooking fuel (68.4%) followed by kerosene (24.4%) while biomass was also used in 3.9% households. Although biomass is used as a cooking fuel, it is carbon neutral and therefore its contribution to the total CO2 emissions has not been included in this approach.

Presently the solid waste is being dumped at three landfill sites which fall under the category of uncontrolled disposal facilities and have no gas recovery systems in place. Landfill gas generation comprises mainly of methane which has a global warming potential of 21. Default method has been used to estimate methane generation from three landfill sites of Delhi.

A Carbon map of Delhi (in terms of tons of carbon emission per square kilometer) was prepared by using the NAEI Mapping Method, 2006. One square kilometer resolution map represents emission at the location called "emission at source" (e.g. power station), whereas emission distributed to location (electricity) known as "end users".

Since the first Carbon map of Delhi was an end user map for the year 2007-08, it has excluded the emission from thermal power plants and mainly focused on four sectors (transport, domestic, commercial and industrial). The carbon map showed that these four main sectors emit 15.41 MMT of greenhouse gas per annum. In comparison to the city of London, with a total carbon emission of 44 MMT, Delhi's carbon emission was one-third of it. In Delhi, transport (46%) and the domestic sector (34%) were the biggest contributors to

greenhouse gas emissions. Based on the carbon map, various state level policy measures have been already recommended.

Optimizing Carbon Sequestration in Winter Wheat in Wooster, OH

Grace BRAVER[1]*, East Tennessee State University / National Parks Service
(gbraver88@gmail.com)

Abstract

Due to changes in climate, atmospheric carbon dioxide (CO2) has steadily increased to 421 ppm over the past century (Lindsey, 2022). Soil is an underutilized storage of carbon sequestration in arable farming (Gonsamo et al., 2022). Thus, it is vital to further research on the underdeveloped system of soil dedicated to arable farming to optimize its capacity to sequester carbon to sequester atmospheric CO2 as carbon in soil. In this study, the belowground biomass of 50 varieties of winter wheat are analyzed to determine which is the most robust.

For this study, soil-cores were taken from a sampling field of winter wheat varieties in order to extract the belowground biomass. The belowground biomasses were analyzed, and averages determined in RStudio. Data on aboveground biomass collected by the OARDC was used to compare full biomass profiles of the top belowground biomass varieties. GIS mapping of the sampling field soil units and slope grade were made to determine biological factors, such as a flood zone, that may impact the growth of belowground biomass.

Biomass analyses determined the top five varieties for belowground biomass of those sampled. Despite a few outliers, most varieties fell into a symmetrical statistical distribution. However, these results suggest certain varieties have genetics that correspond to a better distribution of robust belowground biomass. The more robust and well distributed the belowground biomass, the higher the capacity for sequestering carbon within the soil. Leading to improved carbon sequestration in arable farming of winter wheat carbon. Furthermore, proving that arable farming can be improved to mitigate atmospheric carbon by sequestering it in soil.

Abstract

Rock weathering, controlled by coupled biotic and a-biotic factors, plays a crucial role in shaping the landscape and regulating atmospheric CO2. The weathering processes, rates and microbial feedbacks in tectonically active Himalaya are largely unexplored. We present results of the study that interfaces metagenomics, geochemistry and U-series chronology on a granitic weathering profile from Humid Garhwal Lesser Himalaya. The geochemical profile of mobile and immobile elements indicated the studied section to be an ideal weathering profile. The U-series dating across the profile provided a weathering record of 280 ka with an average-weathering rate of 24 mm /ka that is temporally non-linear, exhibit correspondence with warm climatic excursions, and indicated that (i) bulk of the weathering profile developed during warm MIS-5e (ii) at the time scales of 103 yrs climate variability plays an overarching role rock weathering even in tectonically active setting like Himalaya.

Metagenomics, community physiological profiling, elemental and mineralogical analysis informed on the microbe-rock interaction and suggested saprolith to be most active soil forming zone of the profile but may not be actively sequestering atmospheric CO2. The microbial profile of regolith metabolizes via atmospheric CO2 and hence sequester it more effectively. Such studies leading to quantitative estimates of weathering rates, along with an understanding of associated chemolithotroph can inform potential changes in rock-atmosphere-microbe interaction in an anticipated warmer Earth.

Analysis of the impact of crushed basalt dust addition to corn fields on the diversity and functionality of soil microbiota

Hao-Cheng Chang[1]*, National Taiwan University (d05623004@ntu.edu.tw)
Zhi-Yao Chiew[2], National Taiwan University
Yo-Jin Shiau[3], National Taiwan University
Kai-Yin Lo[4], National Taiwan University

Abstract

Enhanced rock weathering (ERW) is an effective strategy for atmospheric carbon dioxide removal (CDR) while simultaneously increasing agricultural production, aiming for net-zero carbon emissions by 2050. The weathering of basalt releases alkaline cations, i.e. calcium and magnesium, which not only help prevent soil acidification but also fix atmospheric carbon dioxide through the precipitation of carbonates and alkaline cations. Rich in essential mineral nutrients like phosphorus and potassium, basalt application poses no risk of toxic heavy metals accumulation in field soil, making it the preferred mineral for ERW. While the chemical mechanism through which basalt-enhanced weathering promotes crop growth and soil carbon fixation are well developed, the effects on field soil bacterial community diversity and its overall biological functionality remain largely unknown. Therefore, in this study, crushed basalt dust (BD) was applied to corn fields, which were divided into a control group, a group with a 10% BD addition (BD10), a group with organic matter (OM) addition, and a group with both 10% BD and OM additions (BA10 + OM). Soil samples were collected 0, 45 and 90 days after planting. Quantitative PCR (qPCR) was used to measure the amounts of microorganisms. Next-generation sequencing using 16S v4 regional primers (515F–806R) and PICRUSt2 predictions were used to assess impact of BD addition on the diversity and functionality of soil microbiota. Given the higher calcium and magnesium contents, BD-addition is expected to enhance microorganism-induced calcium carbonate precipitation. Autotrophic bacteria have been shown to form calcium carbonate through non-methylotrophic methanogenesis, while anaerobic photosynthesis could produce calcium carbonate if sulfur-containing amino acids serve as the hydrogen sulfide source. Heterotrophic bacteria promote calcium carbonate formation via the ammonification of amino acids, the nitrate dissimilation reduction pathway, and hydrolysis of urea and uric acid.

Secondary mineralization of Sb(V)-bearing Fe(III) phases stimulated by Fe(II) under advective flow and the impact on Sb mobility

Yidan ZHANG[1]*, Korea University (yidanzhang@korea.ac.kr)
Yunseo Jang[2], Korea University
Man Jae Kwon[3], Korea University

Abstract

Antimony (Sb) emerges in recent years as a significant environmental contaminant, with its ecotoxicity posing hazards when concentrations exceed guidelines. The reduction of Sb(V) demands attention due to the formation of more toxic Sb(III). However, Sb(V) can be immobilized through adsorption by host phases such as Fe(III) oxides. Various Fe(III) phases such as ferrihydrite, goethite, jarosite, and schwertmannite have shown adsorption capacity toward Sb(V). Although structural changes to Fe(III) host phases during reductive dissolution, stimulated by aqueous Fe(II), was suspected to release previously associated Sb(V); several microcosm studies have illustrated the further incorporation of Sb(V) into newly formed secondary Fe(III) phases during microbial Fe(III) reduction or abiotic reduction by aqueous Fe(II) amendment. Nonetheless, previous literature predominantly utilizes stagnant conditions to investigate the fate of Sb(V) upon Fe(III) transformation, and thus not considering the effects of transport processes in realistic environments. Therefore, adopting a column set up under advective flow is essential to comprehensively explore how Fe(III) structural changes affect the mobility of previously associated Sb(V). Additionally, considering that the transformation of Fe(III) is influenced by initial crystallinity, studying the behavior of Sb(V) when associated with different crystalline Fe(III) phases becomes necessary. This study employs columns to understand the fate of Sb(V) associated with two different crystalline Fe(III) phases: poorly crystalline Sb(V)-coprecipitated ferrihydrite and the more crystalline tripuhyite (FeSbO4), under advective flow transporting aqueous Fe(II). Miniature columns were set up, incorporating Sb(V)-coprecipitated ferrihydrite-coated sand or sand mixed with tripuhyite powder. The inflow maintains a constant concentration of aqueous Fe(II), with flow rate adjusted to mimic realistic soil porewater flow. A comprehensive investigation, including aqueous chemistry analyses of Fe and Sb species, along with solid-phase analyses of X-ray diffraction (XRD) and X-ray find absorption structure (XAFS), is conducted. This aims to elucidate the partitioning of Sb species, mobility, and alteration in Fe mineralogy during Fe(III) reduction stimulated by Fe(II). The results of this column study are expected to provide insight into the processes that govern the mobility and speciation of Sb in anoxic environments where Fe(III) phases are commonly present.

Microbial communities development and secondary minerals formation during microbial Fe(III) reduction across a pH gradient

Yunseo Jang[1]*, Korea University (trixiejang@korea.ac.kr)
Yidan ZHANG[2], Korea University
Man Jae KWON[3], Korea University

Abstract

Iron oxides are widespread in the shallow subsurface area and can be used by microorganisms during dissimilatory iron reduction (DIR). Environmental factors, particularly pH, exert significant influence on DIR in subsurface anoxic zones, as protons are required for this process. DIR is more likely to occur in mildly acidic pH conditions but becomes less favorable as pH increases. The extent and rate of DIR, as well as the secondary minerals produced, vary depending on pH and the ratio of Fe(II)/Fe(III). Moreover, pH can influence the microbial community composition by promoting the growth of different iron-reducing species. Therefore, understanding DIR, the formed secondary minerals, and the shifts in microbial community in different pH conditions is crucial for advancing knowledge in microbial Fe(III) reduction. This study deployed anaerobic Fe(III)-reducing microcosms with a pH gradient ranging from 6.3 to 9 (6.3, 6.9, 7.3, 7.7, and 9) to investigate the effect of pH on DIR. The common crystalline Fe(III) phase, goethite, and the relatively less crystalline phase, lepidocrocite, were selected as the electron acceptors (Fe(III) = 50 mM), with acetate (20 mM) chosen as the electron donor. The objectives of the study are to 1) compare the kinetics of DIR at the five different pH levels, 2) investigate the development of various Fe(III)-reducing microorganisms at different pH, and 3) identify the secondary minerals formed under different pH. The influence of pH on DIR was observed for both Fe(III) phases, with faster Fe(III) reduction observed at lower pH gradients. In the goethite amendment, among the five pH conditions, the initial rate of Fe(III) reduction in pH 6.3 treatment was slower than other treatments but exhibited the highest reduction extent (~3 mM) by the end of the experiment. However, due to the small amount of Fe(III) being reduced, changes in pH and acetate concentrations were not clearly reflected. For lepidocrocite amendment, total Fe(II) in pH 6.3 and 6.9 treatments showed a significant increasing trend during the experiment, reaching 43 mM and 24 mM, respectively, followed by an abrupt decrease at the end. Other pH conditions showed a steady increase in total Fe(II) concentrations, reaching less than 10 mM. Similar to goethite amendment, the rate of Fe(III) reduction was initially slower in pH 6.3 but exhibited a higher extent of reduction during the experiment. Acetate concentration decreased in both pH 6.3 and 6.9 treatment for lepidocrocite system, with the most significant decrease observed at pH 6.3. An increase in pH was observed at pH 6.3, 6.9 and 7.3, where the most extensive increase observed at pH 6.3. The results of microbial community and solid phase analyses will be presented to provide better insight into the dynamics of microbial Fe(III) reduction.

Internal P-recycling in Late Ordovician marine reefs: the first evidence from the mutualistic commensalism of cyanobacteria and green algae in the fossil record

Jinwen SHEN[1]*, Northwest Univercity (1257362334@qq.com)
LiJing LIU[2], Northwest Univercity

Abstract

Organisms often acquire limited nutrients through symbiotic interactions, this is an important survival strategy in a variety of environments. The study of symbiotic behaviors among organisms in geological history is impeded by limitations in fossil preservation. The ecological interaction between early organisms is of great significance to reflect their living environment and the evolution of organisms. The scarcity of direct fossil evidence for symbiotic fossils has impeded our research of the ecological interactions among organisms within marine ecosystems during geological periods. The biomass of existing reef systems is mass, while the availability of inorganic nutrients is limited. Some unique cyanobacteria groups and other microorganisms can improve phosphorus (P) availability by producing phosphatase to hydrolyze organophosphates. Here we report a widely distributed calcareous symbiotic fossil assemblage of the *Amsassia* (a possible green alga) and the rivulariacean *Proaulopora* (cyanobacteria) in reef facies from the Upper Ordovician (Sandbian-Katian) in the Tarim and Ordos basins. Due to the physiological and ecological characteristics of extant rivulariaceans, and analysis of the relationship between extant green algae and their epiphytic microorganisms, it is found that the *Amsassia* - *Proaulopora* association is very similar to the mutualistic commensalism of green alga *Cladophora* and rivulariaceans cyanobacteria in a modern oligotrophic water environment. Furthermore, based on the presence of autogenous fluorapatite, we conclude that *Proaulopora* may have used the organic phosphorus around *Amsassia* to release orthophosphate (DIP) that was then utilized by itself and *Amsassia* to augment P-availability. In this interpretation, the symbiotic assemblage of *Amsassia* - *Proaulopora* exemplifies a metabolic P-acquisition commensal relationship between cladophoracean-like green algae and rivulariacean cyanobacteria that would have enhanced their survival and growth in oligotrophic environments. Through this win-win cooperation, the growth restriction of inorganic phosphate in the environment can be reduced. In addition, reducing phosphorus limitation is also helpful in enhancing nitrogen fixation. *Proaulopora* may provide nitrogen (N) supply for the *Amsassia* reef ecosystem and reduce the nitrogen limitation of *Amsassia*, just like the modern genus *Dichothrix* (rivulariacean) attached to *Sargassum* (macroalgae). This study provides fossil evidence for benthic cyanobacterial-green algal mutualistic conversion of dissolved organic phosphorus (DOP) to dissolved inorganic phosphorus (DIP), with significant implications for the assessment of global phosphorus cycling over geological time. This commensal partnership contributed to the efficient recycling of N/P nutrients in the environment with implications for reef ecosystem evolution during the Great Ordovician Biodiversification (GOBE).

The relationships between vertical variations of shallow gas and pore water geochemical characteristics in boreholes from the inner shelf of the East China Sea

xue LI[1]*, 16601162341 (342099072@qq.com)
xiaoyong duan[2], 15263757908

Abstract

Shallow gas is widely recognized in the coastal region, especially in the estuarine delta areas with high Organic matter (OM) burial flux. In this study, the vertical variations of shallow gas and the related geochemical indicators from two boreholes in the coastal region of the East China Sea (ECS) were investigated. There were two gas-bearing layers in the sediments which were in the Holocene and late Pleistocene series, respectively. Both boreholes exhibit a "typical" and an "inverse" Sulfate Methane Transition Zone (SMTZ). The "typical" SMTZs (SMTZ1 and SMTZ3) are in the upper part of the gas-bearing layers, and in the "typical" zone, sulfate levels consistently decrease while methane levels increase with depth. Conversely, the "inverse" SMTZs (SMTZ2 and SMTZ4) are in the lower part of the gas-bearing layers, and in the "inverse" zone, sulfate levels increase while methane levels decrease, a phenomenon rarely documented in previous research. The change in pore water geochemical characteristics from top to bottom indicates that these ions are related to Anaerobic Oxidation of Methane (AOM) processes. For example, the increase in Ca2+ and Ba2+ concentrations and the gradual decrease in sulfate at the SMTZ reflect a series of biogeochemical processes resulting from the dissolution of carbonate and other minerals by AOM. Additionally, the study suggests that the sulfate used in AOM may come from various sources. By analyzing the vertical variation of shallow gas and the geochemical characteristics of pore water, this paper gradually uncovers the formation mechanism of shallow gas and the characteristics of the SMTZ, providing a foundation for future research.

Investigate the impact of different fertilizers in combination with dicyandiamide on bacterial communities participating in nitrogen and methane cycles

Hao-Yu Chu[1]*, Department of Agricultural Chemistry, College of Bioresources and Agriculture, National Taiwan University (howard.jue.0724@gmail.com)
Yo-Jin Shiau[2], Department of Bioenvironmental Systems Engineering, College of Bioresources and Agriculture, National Taiwan University
Kai-Yin Lo[3], Department of Agricultural Chemistry, College of Bioresources and Agriculture, National Taiwan University

Abstract

Regenerative farming is an agricultural approach focused on improving soil health and biodiversity while increasing carbon sequestration. The goal is to create sustainable farming systems that store more carbon, support higher biodiversity, and minimize environmental impacts, contributing to the target of achieving net-zero carbon emissions by 2050. In this study, we collected the field soils from dry land farming Napiergrass (*Pennisetum purpureum*) cv. Taishiu No.7 (NP cv.TS 7) in the National Taiwan University Experimental Farms An-Kang Branch (24°57'31"N, 121°31'36"E). Several culture conditions were applied, including two types of fertilizers, cattle dung compost and chemical fertilizer, in combination with nitrification inhibitor dicyandiamide (DCD). We used quantitative PCR (qPCR) to widely measure the quantities of total microorganisms with the 16S v4 region primers (515F–806R), and *mcrA* and *pmoA* genes to measure the methanogenesis and methanotroph, respectively. We analyzed the effects of fertilizers and nitrification inhibitors on soil microbes in the field. As the previous study reported, the high-throughput amplicon sequencing of 16S rDNA, *mcrA*, and *pmoA* genes revealed that DCD has highly decreased the *Nitrosomonas*, which oxidizes ammonia to nitrite. We found that the type I methanotroph is predominant in organic fertilizer applied conditions, and the type II methanotroph is more dominant in chemical fertilizer treatments. However, while introducing DCD into fields, the type I methanotroph is highly decreased, especially *Methylocystis*. To pursue a whole scope of understanding the dynamics of microbiota and general metabolic cycling in soil, we performed PICRUSt2 analysis to investigate the microbial communities and predict the environmental genomic functions. We observed that the fertilizers mostly influenced the *nirK* and *norB* genes in the nitrous oxide-forming state, and the addition of DCD impacted the nitrification pathway, like *amoA* and *hao* genes. The results provide information to compare agricultural practices with greenhouse gas microbial communities and the dynamics of nitrous oxide emissions.

Isotopic distribution of bioavailable Sr, Nd, and Pb in Chungcheongbuk-do Province, Korea

Min-Ji JUNG[1]*, Chungnam National University (jmj8967@kbsi.re.kr)
Youn-Joong Jeong[2], Korea Basic Science Institute
Woo-Jin Shin[3], Korea Basic Science Institute
Albert Chang-sik Cheong[4], Chungnam National University

Abstract

Mapping the distribution of isotope ratios across the landscape is crucial for delineating the origins and migration trajectories of humans and animals. In the specific context of Chungcheongbuk-do Province in Korea, we have investigated the distribution of bioavailable Sr, Nd, and Pb isotopes, taking into account geological and environmental factors. Chungcheongbuk-do exhibits diverse geological elements, including Precambrian basement, Paleozoic metasedimentary rocks, and Mesozoic granitoids and volcano-sedimentary sequences. The geological diversity, coupled with its inland location devoid of adjacency to the sea, makes Chungcheongbuk-do an ideal study area for discerning the nuanced influence of geological elements on isotopic distribution. Plant and soil samples were collected from 44 localities, revealing that the $^{87}Sr/^{86}Sr$ ratios of bulk soil primarily range from 0.781 to 0.707, with two ratios exceeding 0.9 originating from Precambrian basement and Cretaceous granitoid areas. Fractions of soils treated with 1M ammonium nitrate and acetic acid exhibit indistinguishable $^{87}Sr/^{86}Sr$ ratios (R^2 = 0.99, except for one point), spanning from 0.804 to 0.707. Plant $^{87}Sr/^{86}Sr$ ratios demonstrate a robust positive correlation with leachate ratios (for ammonium nitrate data, y = 0.938x + 0.045, R^2 = 0.98). The εNd values of bulk soils from Precambrian basement areas (–18 to –30) plot against Sm/Nd ratios around the reference line corresponding to 3 Ga, while other soil samples (εNd = –1 to –20) align with a younger (c. 2 Ga) reference line. Plant εNd values, ranging from –4 to –24, exhibit a prominent positive correlation with bulk soil values (y = 0.63x – 4.77, R^2 = 0.87). A comparable correlation (R^2 = 0.89) is observed for εNd between plant samples and ammonium nitrate leachates. Plant samples show a weak correlation ($R^2 \approx 0.4$) between $^{87}Sr/^{86}Sr$ and εNd. The $^{206}Pb/^{204}Pb$ and $^{207}Pb/^{204}Pb$ ratios of bulk soils show a c. 2 Ga trend, typical for Korean basement rocks. The $^{206}Pb/^{204}Pb$ ratios of ammonium nitrate and acetic acid leachates match perfectly with each other (R^2 = 0.99). The $^{206}Pb/^{204}Pb$ ratios of plant samples vary narrowly (19.2–17.9) and are much lower than that of bulk soils (24.4–17.9) and their leachates (23.1–17.8). The isotope data obtained in this study underscore a strong geological control for bioavailable Sr and Nd, while conversely, indicating a dominant environmental influence on bioavailable Pb. Plant and soil data were used to construct preliminary Sr and Nd isoscapes (isotope landscapes), employing interpolation models based on inverse distance weighting, simple kriging, and geology-considered empirical Bayesian kriging. Although these maps hold potential for provenance studies and archaeological inquiries in Chungcheongbuk-do in their present form, further efforts, including increased sample density and refined interpolation models, are necessary for accurately predicting fine isotopic variations across

the province.

Providing the most appropriate management solution based on the new conditions of Urmia Lake, Northwest of Iran

Razyeh Lak[1]*, Research Institute for Earth Sciences, Geological Survey of Iran
(lak_ir@yahoo.com)

Abstract

In the last two decades, Lake Urmia in the northwest of Iran, as the second largest saline lake in the world, has been fast decreasing its water due to human and natural factors, and millions of people around the lake will be affected to dust and salt storms. Monitoring of brine chemistry, salt and lake depth was done in different years and seasons during 14 years. The parameters of temperature, salinity, electrical conductivity and pH were measured in situ. main elements consist of sodium, potassium, calcium, magnesium and chlorine, sulfate, carbonate and bicarbonate are analyzed in the laboratory. The investigation of hydrochemistry and the brine evolution shows that Lake Urmia is in irreversible conditions and it is not possible to restore the lake because it is not possible to return the playa environment to the lake in a short time.

The most appropriate management plan for the newly reclaimed environment, in addition to the implementation of all the watershed management programs in the basin, such as saving agricultural water consumption, wastewater treatment, etc. It is suggested to control and contain aerosol in mud flat and saline mud flat zone, separating and reducing a part of the lake and directing water to that small piece, especially around the causeway from an aesthetic point of view, extracting economic salts, especially SOP (potassium Sulfate) of non-renewable marginal parts and use of profit from it is suggested for control dust programs.

Potential of Geoscience knowledge towards Environmental Ecosystem

Shahina TARIQ[1]*, Land Information Magment System (LIMS)/COMSATS University Islamabad (tariqshahina@gmail.com)

Abstract

The global demand for natural resources is rapidly increasing to improve the economies and living standards of the citizens. This profoundly affects the environment through deforestation, pollution, and global climate change. The resources include minerals, fertile soils, and water and energy resources. Hence to reduce the negative impact on the environment, it is crucial to understand the relevant environmental processes and how to manage them for the benefit of society. Environmental ecosystem under the category of terrestrial and aquatic consists of all living and non-living components. The relationship between humanity and the environment is a delicate balance. Geoscientists have perspectives on climate, water, and conservation have a responsibility to balance proposals for exploitation with protection of the resources and provision of benefits to communities. Climate influences crop growth and water availability while natural hazards disproportionately affect the poor. Widespread and rapid changes in the atmosphere, ocean cryosphere, and biosphere are highly influenced by human influence. Mitigation is required to take action to reduce the impact. Geoscientist can make a framework for disaster risk reduction, which emphasizes early warning to reduce mortality, property damage, and economic loss. Geoscientists play a crucial role in identifying future mineral resources, promoting their sustainable use, and reducing the environmental impacts of mining. The conservation community can take the lead in developing protocols for good working practices in the development of natural resources. Geoscientists also need to play a vital role in transitioning to a circular economy in which the use of primary resources is minimized by the reuse and recycling of materials, thus minimizing the f waste material. The time demands to promote education among the youth who can understand issues of climate change, land management, and resource depletion. Therefore, geoscience education right from the school level be given priority. Geo-conservation education can be added to school curricula so that children have a greater understanding of the dynamic complex Earth system.

Ling PENG [6], Institute of Comprehensive Survey for Natural Resources China Geological Survey

Abstract

In order to better support food production, people's daily lives and vegetation growth, the natural resources on the surface of earth should be carried out by three-dimensional and unified management. Here, we divide the skin of the earth into three layers from bottom to above, they are ground substrate layer (such as rocks and loose sediments), land covering layer (such as forests and grasslands), and management layer (such as urban development boundaries). The ground substrate is a new concept proposed by Ministry of Natural Resources of China in 2020 that refers to the fundamental material that nurtures and supports various natural resources such as forests, grasslands, water, wetlands, etc. This concept fully integrates existing knowledge of hydrogeology, soil science, Quaternary geology, ecological geology, earth's critical zone, and is the dawn of a new interdisciplinary field of earth systems science and natural resource science.

The material composition of the ground substrate is mainly composed of Quaternary loose sediments and weathered remnants of bedrock, which are the underground parts of the Earth's critical zones and the parent material for the formation and development of soil. They are also the main geological factors that affect the local combination of plant communities, except for climate, micro topography and groundwater.

Structural differences of bedrock and regolith (such as sedimentary structure, cracks, joints, pores, bedding), types, mineral element composition (such as salts, nutrients, organic matter, heavy metal elements), and geochemical properties (such as acid-base, colloid, redox) of the ground substrate, that is, the heterogeneity of the ground substrate by regulated water holding capacity and root growth profoundly influences the types, coverage density and growth status of vegetation. We call these characteristics are physical stress and elemental stress.

Considering the depth of underground temperate transition zone, the depth of crop and vegetation root, the depth of surface rock joint fissures, the thickness of rock weathering crust, and the depth of groundwater level, under normal circumstance, we have preliminarily defined the ground surface down to bottom of the ground substrate as 20 m, and the depth of ground substrate can be divided into shallow (0-2 m), intermediate (2-10 m), and deep (10-20 m). In special cases, the depth can be very deep (> 20 m).

The ground substrate survey can reveal deeper information of earth than soil, and the obtained data can not only fill the gaps in current research on earth's critical zones, but also promote the

development of ecological geology. At the same time, due to the fact that the ground substrate more emphasizes on the ecological service function of rock and soil, which can provide support for scientific and reasonable layout of spatial pattern of ecosystem, land consolidation in shallow mountainous areas, high standard farmland construction, and evaluation of reserve farmland resources, therefore, it also has practical grate significance for supporting national food security and ecological restoration.
Over the past four years, we have accumulated some typical cases of supporting scientific greening in semi-arid areas and land consolidation in mountainous areas by ground substrate survey.

Earth System Modeling for Explaining and Predicting changes in the Climate, Water, and Ecosystem

June-Yi LEE[1]*, Pusan National University (juneyi@pusan.ac.kr)

Abstract

The 6th Assessment Cycle Synthesis report from the Intergovernmental Panel on Climate Change (IPCC) highlights a critically shrinking opportunity to advance development that is both sustainable and resilient to climate changes. It stresses the importance of integrating climate initiatives with broader international ambitions, such as the Sustainable Development Goals, the Global Biodiversity Framework, and the Global Health Security Agenda. Given these considerations, there's an increasing demand for climate information that is both relevant to decision-making and grounded in solid scientific evidence, with a particular emphasis on regional scales and the near-term horizon. Nonetheless, the capacity of current scientific endeavors to predict the near-term changes in the components of the Earth System, including ecosystems, is limited. Defined as the period extending from the next decade up to thirty years, the near term's climate information must encapsulate the climate system responses to the interplay between human influence, natural drivers, and internal variability. At the heart of Geosciences, Earth System Models are vital for shedding light on, attributing, and predicting changes of Earth System components over time frames ranging from a year to several decades. This talk aims to review the present landscape of Earth System Modeling, emphasizing its role in explaining, predicting, and projecting changes in Earth System components. Moreover, it will offer a vision for future advancements and underscore the challenges and gaps in Earth System modeling, prediction, and projection. The presentation will also delve into the complex interaction among changes in climate, water, and ecosystems, underscoring their collective implications for global strategies aimed at sustainability and climate resilience.

Studying on the structural features of municipal solid waste landfills before recultivation

Elena SOLOMATINA[1]*, Sergeev Institute of Environmental Geoscience Russian Academy of Science (IEG RAS), Moscow, Russia (baira1506@gmail.com)

Abstract

About 5 million tons of municipal solid waste (MSW) are generated in Russian Federation annually. Despite the development to improve waste sorting and processing technologies, landfilling is the primary method used for MSW disposal. Currently, there are approximately 12,755 hectares of land in Russia occupied by MSW landfills.

Data from engineering surveys on 27 landfills slated for reclamation in various regions of the country have been examined in the study. The study also includes: a detailed analysis of the morphological composition of solid waste, assessment of its variation with depth, correlation with methane content, and leachate composition. The obtained data were compared with the following indicators: regional industries sectors, population density, prosperity index, average annual temperature, precipitation amount, landfill technology, service life, filling rate and terricon height. The analysis provided information on the structural features of the landfills at different depths and identified main specifications.

One of the main characteristics influencing the morphological composition is the age of the landfills. Thus, the content of "rapidly degradable" fractions (paper, cardboard, food waste, wood, textiles) is predictably higher in the upper layers of the landfills and in the landfills younger than 50 years. Furthermore, in high prosperity regions with has been recorded the increased presence of textiles and wood, which indicates shifts in residents' lifestyles, population density increase, development of multi-storey and private residential buildings, gradual demolition of old wooden structures.

There are unique features when assessing the structure of the landfills. The most significant changes in the composition of waste occur in the depth range of 0-15 m. A high content of food waste with a low degree of decomposition is recorded at depths of up to 5 m, below which there is a sharp decline by 1.5-2 times to a depth of 10-15 m. It is depending on climatic parameters and their natural transition into solid organic particles. Paper and cardboard are present down to 15 m and a sharp decline occurs in depth intervals from 5-10 m in warm regions and 15-20 m in colder regions. The presence of textiles and wood is noted even at great depths - up to 30 and 40 m, with no obvious downward trend observed. Inert components (glass and polymers) are gradually crushed due to mechanical compaction and, at depths of about 30-35 m, pass into the screening fraction. The metal content at all landfills is 4-7%, thanks to a fairly developed system for processing metals as recyclable materials.

Based on the results it was established that, landfills are complex geological bodies, with a structure interconnected with the rate of transition of “rapidly decomposing” waste into solid organic particles. It is also depending on a number of economic and social indicators of the region,

climatic parameters, dumping technology, commissioning dates and operation time of landfills.

The research was financially supported by the project of Russian Science Foundation № 22-17-00045.

Abstract

Field research was organized in the Akhangaran River valley of the Angren-Almalyk mining region and at the mining complex sites of the Navoi region. Samples were taken around the mining wastes in Angren, Navoi, Kokpatas, and Uchkuduk industrial sites. Soil and plant samples were taken along several geochemical profiles. Sampling points were marked using GPS and described in detail. After appropriate sample preparation, soil and plant samples were analyzed for heavy metals and metalloids by ICP-MS. The results indicate an increased content of heavy metals in soils and plants around the industrial sites. The formation of technogenic geochemical anomalies of heavy metals is mainly associated with technogenic load due to mining activities and other industrial enterprises operating in these regions. One of the main reasons for the formation of geochemical anomalies of heavy metals in soils and plants is assumed to be the atmospheric fallout of emissions from mining enterprises and explosions in quarries during the development of deposits. This study examines broad concerns related to environmental chemical contamination. It generally demonstrates that, across all components of the geo-ecological profile's natural environment (soils, groundwater, vegetation), elements most closely linked to typical ore elements (gold, silver, uranium) like arsenic, antimony, molybdenum, and copper, tend to accumulate first. The findings reaffirm that peak concentrations of these anthropogenic elements typically occur in the topmost layer of the soil profile (0-20 cm). The distribution of U and Th among soils and vegetation is examined separately, and their maximum concentration in the soil's silty fraction is shown. Having assessed various data on the concentration of ore elements in the Tashkent and Navoi regions and compared these data with data from other areas of Uzbekistan, we concluded that arsenic-containing waste (dumps from mining enterprises and tailings from ore processing plants) is the most significant relevance in terms of negative impacts on the environment. The results showed increased heavy and toxic metals content in the soils and plants of mining regions. Calculation of Clarke concentrations (Kk) showed high values of heavy metals (Cu, Zn, Pb, Cd, Bi, As, etc.) in soil samples tested near the mining areas. The results were systematized and interpreted from the perspective of modern trends in the methodology of self-organizing biogeochemical systems under conditions of environmental pollution.

Redox activity of soil dissolved organic matter as affected by soil warming

Shuhan WANG[1]*, China Agricultural University (284972521@qq.com)
Wenbing Tan[2], State Key Laboratory of Environmental Criteria and Risk Assessment, Chinese Research Academy of Environmental Sciences
Guoan Wang[3], China Agricultural University

Abstract

Global warming is a significant global concern. Dissolved organic matter (DOM) in soil plays a crucial role in environmental pollution remediation through its redox activity. However, the impact of global warming on the redox activity of DOM remains unexplored. In this study, we investigated the response of electron-accepting and -donating capacities (EAC and EDC, respectively) of DOM to temperature by collecting surface soil samples along a temperature gradient corresponding to the 400 mm isoline of mean annual precipitation in China. Our findings revealed that EAC exhibited a positive correlation with temperature, while EDC showed a negative correlation with temperature. These results suggest that global warming will enhance the EAC and decrease the EDC of DOM. Consequently, increasing temperatures may hinder the transfer of electrons from soil DOM to iron oxides, hydroxides, as well as various organic and inorganic pollutants, thereby weakening its role in ecological environment pollution remediation in the future. The influence of temperature on electron transfer capacity was mediated by regulating soil properties and plant litter composition, which indirectly affected physicochemical indices associated with DOM. Specifically, changes in ArylC content and phenol titration (Tit) were found to be major drivers for variations in EAC levels within soil DOM; whereas alterations in humification index (HIX) and Tit played key roles in determining changes in EDC levels within soil DOM. Higher temperatures led to increased ArylC content and HIX values but decreased Tit levels within DOM samples resulting in elevated EAC but reduced EDC capabilities.

Assessment of Seawater Intrusion Signatures: A Geochemical and Geospatial Study in the Coastal Region of Paradeep Municipality, Jagatsinghpur, Odisha.

SUSANTA KUMAR DAS [1]*, Fakir mohan university (kumarsusantadas143@gmail.com)
Rosalin Das[2], Fakir mohan university, balasore,Odisha
MADHUMITA DAS[3], UTKAL UNIVERSITY,BHUBANESWAR

Abstract

Seawater intrusion (SWI) is a global challenge impacting groundwater quality in coastal aquifers, driven by extensive urban development and over-exploitation of groundwater for drinking, industrial, and agricultural activities. The study focuses on the Paradeep municipality in Odisha, a prominent industrial hub and major port along the Bay of Bengal, where seawater intrusion poses a significant threat to freshwater management. In May 2022, 35 water samples were collected from various tube wells and analyzed for parameters such as pH, TDS, EC, turbidity, temperature, hardness, alkalinity, and various ions (cations and anions) using standard procedures (APHA). Piper diagram revealed that the groundwater of the study area is dominant of sodium and Chloride, suggesting comparatively high salinity. Approximately 45.71% of the samples were in the seawater zone (Na+-Cl-). Due to the evaporation process, 25.72% of water samples fell in the recharge water (Ca2+-Mg2+-HCO3-) and base ion exchange zone (Na+- HCO3-), and 2.85% of samples were lost in reverse ion exchange (Ca2+-Mg2+ -SO42-). US salinity diagram shows the water samples fall in C3S1 plot (17.14%) samples, C2S1 (11.42%) samples, and C4S2, C3S2, and C3S3 (2.85%) sample. Then C4S4 (20%) samples, (22.85%) samples C3S4 and (20%) samples are high ranges of salinity haphazard w.r.t SAR respectively. The vertical, horizontal, and diagonal arrangement of ions in the Stiff diagram suggested infiltration of saltwater into various parts of the study region. On the geospatial map, elevated levels of sodium and chloride are observed near the coast, indicating high salinity. In the middle area, the samples exhibit moderate ranges, while those farther from the coast show consistently low levels. This comprehensive analysis provides compelling evidence of seawater intrusion in the groundwater of the Paradeep municipality, emphasizing the urgency for effective management strategies in the face of increasing salinity levels.

Understanding Loggerhead Sea Turtle Nesting Preferences in Broward County, Florida

Brooke Marlo WALKER[1]*, US Army Corps of Engineers, Coastal and Hydraulics Laboratory (brooke.m.walker@usace.army.mil)

Abstract

The Caretta caretta, or Loggerhead Sea Turtle, is an endangered species that can be found in all temperate and subtropical oceans. Loggerhead Sea Turtles are known to exhibit particular reproductive habits including returning to their own hatching location for nesting. Several previous works have shown that the Caretta caretta has nesting site preferences regarding beach width, slope, and vegetation coverage, thereby allowing for the development of a nesting site suitability index (Dunkin, et al., 2015). This index, when overlayed with digital elevation data and run through a custom ArcGIS toolbox, can provide insight into where the Loggerhead is most likely to nest on a given beach. This study utilizes the 2018 United States Geological Survey Lidar Derived Digital Elevation Model of Broward County, Florida, the Dune Feature Extraction Toolbox developed by the US Army Corps of Engineers Joint Airborne Lidar Bathymetry Center of Expertise, and the suitability index developed by Dunkin, et al. (2015), to find likely nesting sites of the Loggerhead Sea Turtle. These results are compared to known nesting site data (collected from 2015-2020) which was provided by the Broward County Sea Turtle Conservation Program (BCSTCP). This study aims to further validate the work of Dunkin, et al. (2015) and be an improvement over the previous work by utilizing a semi-automated data analysis enabled by the Dune Feature Extraction Toolbox. The results of this study can further guide critical decisions regarding beach use and maintenance as it pertains to sea turtle conservation. Overall, this study demonstrates the utility of geospatial analysis and suitability models in understanding and safeguarding sea turtle nesting habitats.

Geochemical Characteristics of Coal Mine Drainage and Waste Rocks from Livingstonia Coalfield in Malawi

Amidu Amali MAKWINJA[1]*, Hokkaido University (amidumakwinja@gmail.com)
Frances Chikanda[2], Hokkaido University
Ryosuke Kikuchi[3], Hokkaido University
Walubita Mufalo[4], Hokkaido University
Tsubasa Otake[5], Hokkaido University

Abstract

A. A. Makwinja, F. Chikanda, R. Kikuchi, W. Mufalo, T. Otake

Division of Sustainable Resource Engineering, Graduate School of Engineering, Hokkaido University, Sapporo, JAPAN

Coal mining is associated with significant environmental impacts such as Acid Mine Drainage (AMD) which negatively affects the ecosystem. Coal mine drainage ranges widely in composition, from acidic to alkaline, typically with elevated concentrations of sulphate (SO42-), major elements and heavy metals which can seriously degrade aquatic habitats and the quality of water supplies. To understand the environmental impacts of coal mining in Livingstonia Coalfield in Malawi, a study was conducted at the Kaziwiziwi and Mchenga Coal mines in Rumphi district. River water, mine drainage, and waste rock samples were analysed to determine their geochemical characteristics and assess potential environmental impacts. The methodology used included onsite water physicochemical measurements, inductively coupled plasma atomic emission spectroscopy (ICP-AES), ICP-mass spectrometry (ICP-MS), X-ray diffraction (XRD), and acid-base accounting (ABA) tests.

Results of the study showed that mine drainage at both sites was moderately acidic to neutral with concentrations of SO42- (15.63 to 592.80 ppm) and iron (Fe2+) which is evidence of oxidation of pyrite (FeS2) that is responsible for AMD formation. At Kaziwiziwi, moderate acidic mine drainage was determined at the tailings dam (pH 4.49) while at Mchenga it was determined at an abandoned underground mine (pH 4.56). However, the active underground mines at both sites had a near-neutral to neutral pH (pH 6.78 to 7.02). Unlike the other sampling points, the underground drainage from the Kaziwiziwi active mine had relatively high concentrations of Ca2+, Mg2+, and HCO3-, an indication of potential natural neutralization of the AMD by mixing with underground alkaline water. The mixing of underground AMD with groundwater could potentially result in underground water pollution. River water at both sites had a neutral pH with a low concentration of major and trace elements. This indicates that there are no significant impacts of the mine drainage to the nearby rivers as there is less water flowing from the underground mine workings into the nearby rivers. The underground drainage is only discharged during flooding when the water level rises in the rainy season or when the water is pumped mechanically. Nevertheless, the ABA test on waste rocks (coal, mudstone and sandstone) indicated that, excluding sandstone, the

other rocks are acid-generating with a net neutralisation potential (NNP) range of -206.59 to -57.56 kg CaCO3 which will likely pose a long-term AMD problem. The ABA test correlated with XRD analysis which showed that coal and mudstone contain pyrite.

Estimation of heavy metal(loid) accumulation rate in urban soil using in situ pXRF: the example of Shijiazhuang City, China

ZHAOXIAN YUAN[1]*, Hebei GEO University (sdyzx86@126.com)
David Cohen[2], UNSW

Abstract

Heavy metal(loid) (HM) contamination of urban soil is a threat to sustainable development and human health. Determining HM accumulation rates in urban soil assists pollution monitoring and modelling, but there is a lack of consistency in the selection of appropriate sample media, analytical techniques and data processing methods. This study presents a new approach using portable X-ray fluorescence spectrometry (pXRF) to rapidly obtain multielement data within topsoil for estimation of HM accumulation rates. In situ pXRF analyses were performed on soil surfaces at 156 residential compounds in Shijiazhuang City, China. Significant HM enrichment occurs in the top few mm of the soil profiles, with concentrations typically higher in soils from tree pits compared with sites containing grass or evergreen shrubs. Zinc, Pb, As, Cu, Fe, and Mn concentrations display a positive correlation with residential compound age, and metal accumulation rates range between 2.4–11.3, 0.7–2.2, 0.2–1.1, 0.7–6.9, 206–950, and 4.9–16.9 μg/g per year, with average values of 4.0, 0.3, 0.4, 1.3, 245.0, and 6.2 μg/g per year, respectively. Based on spatial relationships between sampling sites and surrounding land use, sources of Zn and other HMs are primarily derived from within the residential compounds rather than more distal sources such as road traffic or industrial zones. The method provides an effective, rapid and low-cost standardized procedure to determine HM accumulation rates in soils.

Seasonal variations of microplastics in a coastal wetland from southwest India and their risks to *Gerres filamentosus and Sillago sihama*

Gokul Valsan[1], Manipal Academy of Higher Education
Anish Kumar Kumar WARRIER[2]*, Manipal Academy of Higher Education
(anish.warrier@manipal.edu)
Anusree S[3], Manipal Academy of Higher Education
Anjali Tamrakar[4], Manipal Academy of Higher Education
Jagath Chand[5], Manipal Academy of Higher Education

Abstract

Microplastics (MPs) are minute plastic particles ranging from 1 µm to 5 mm in size. They are ubiquitously dispersed and exert ecological impacts on terrestrial and aquatic habitats. Their entry into marine environments occurs through wind and fluvial transport accumulating notably in mangroves, a crucial ecosystem with roles in carbon sequestration, shoreline protection, and habitat for diverse species. Despite their significance, the extent of MP pollution in mangroves especially in southern India is not well-studied. To fill this knowledge gap, we conducted seasonal sampling in the Kota mangrove ecosystem at different depths in the water column. Our analysis revealed average microplastic abundances of 0.93 (monsoon), 3.71 (post-monsoon), and 2.92 MPs/litre (pre-monsoon) in the water column samples. In terms of the fish species, the average microplastic abundance of 19.88 and 15.86 MPs/individual was found for *Gerres filamentosus* and *Sillago sihama*, respectively. Fibrous MPs under 1 mm dominated. Fourier-transformed infrared spectroscopy established polypropylene as the dominant polymer followed by polyethylene terephthalate, high- and low-density polyethylene, and polyvinyl chloride. Polypropylene was the dominant polymer in the fish samples as well. Aquaculture, tourism, and local activities were identified as probable sources of microplastic pollution. The Polymer Hazard Index (PHI) falls under hazard category IV indicating the deteriorating health of the Kota mangrove ecosystem. This study contributes to understanding the seasonal variations of microplastics and the potential ingestion of microplastics by mangrove biota. An urgent need for further research to comprehend the bioaccumulation of microplastics at different trophic levels and their implications for both biotic and human health need to be thoroughly examined. Identifying potential sources of microplastic contamination in the region is critical for developing effective interventions to curb microplastic release into the environment.

Impact of subsurface material on the quality of groundwater in the vicinity of the Gohagoda waste disposal site in Kandy, Sri Lanka

Ashvin Kamal Wickramasooriya[1]*, University of Peradeniya (awickramasooriya@gmail.com)

Abstract

Solid waste management (SWM) is one of the serious problems for Sri Lankan specially in municipality areas. Currently, this issue has been recorded even in some rural areas. At present, the average solid waste generation in Sri Lanka is about 3,700 tons per day. This research has focused on the waste dumping site in the Kandy municipal council and its surrounding areas. The dumping site in this area is situated at the Gohagoda, located within the Katugastota-Peradeniya road, about 8 km from Kandy city. The site is only about 3.5 square kilometers and the average solid waste dumping which is generation in Kandy city limits is about 150 to 200 tons per day. This disposal site is situated in a little elevated area; therefore, during rainy periods, this waste is mixed with rainy water and flows toward the surrounding area. The main aim of this study is to analyze whether the surrounding water bodies are influenced by this contaminated water. There were two river water samples, seven surface water samples, and seven groundwater samples (tube-well water samples) collected after a heavy rainy period and chemically as well as texturally analyzed. After the results of these analyzes, it was found that two river water samples, five out of seven surface water samples, and two out of seven groundwater samples have high contamination than other water samples. To understand the available subsurface materials, bore-hole samples which were collected from the National Water Supply and Drainage Board were studied and a 3D model of the distribution of subsurface materials in the area has prepared. When correlating this model with water quality and soil texture analysis data, it is clearly noted that an impermeable clayey layer and a sand layer exist below the locations where the highly contaminated and less contaminated surface water samples were collected respectively. However, the opposite results were observed in groundwater samples, i.e. locations underlain by clay layer recorded low contaminates while the sand layer exists below highly contaminated groundwater samples. Also, it was noted that river water samples are less contaminated. Based on these observations, it can be concluded that because of the existence of an impermeable clay layer contaminated water can not infiltrate easily, and therefore, surface water samples were highly contaminated while groundwater samples were less contaminated. Also, due exists of a permeable sand layer, two groundwater samples were highly contaminated as waste mixed with rainwater can easily infiltrate through that layer. As there is a thick impermeable subsurface. clay layer underlay almost the entire study area except for a small area which consists of a sand layer, there is no serious influence of infiltration of wastewater-contaminated rainwater on groundwater quality.

Meltwater - contamination indicator of industrial areas (Baikal region, Russia)

Evgeniia TSVETKOVA[1]*, independent scientist (e.tsvetkova@igc.irk.ru)
Vera Poletaeva[2], independent scientist
Mikhail Pastukhov[3], independent scientist
Elena Vishniakova[4], inDrive

Abstract

The industrial zone of Usolye-Sibirskoye town (Baikal region) includes enterprises of chemical, processing, and power industries. A priority environmental problem for the Baikal region is environmental contamination caused by the operation of the mercury electrolysis workshop of the chlor-alkali plant. Closure of the plant resulted in a decrease in the flow of pollutants; however, their significant part is accumulated in the soils of the industrial zone and bottom sediments of the collector network. Nowadays, surface runoff and atmospheric transport contribute significantly to the flow of pollutants from the industrial zone into the environment. In the current critical situation, it becomes important to study the migration of pollutants, the final receiver of which is the only runoff of Baikal Lake, the Angara River. In the climatic conditions of the Baikal region are characterized by an abundance of snow precipitation, the perspective markers of pollutant migration ways are meltwater, forming a heavy seasonal surface runoff. The composition of meltwater was the dissolved phase of snow cover with solid particles. Next, meltwater is enriched with elements by contacting with the surface layer of soil.

Studies of the distribution of the trace elements, such as Hg, V, Co, Ni, Cu, Zn, As, Mo, Cd, Pb, and U in meltwater at 56 sampling points showed significant concentration variability. The maximum variation coefficient was determined for V, and then it decreases according to the element row Hg, Pb, U, Cu, Ni, Co, Mo, Zn, As, and Cd. Several concentration coefficients that was calculated in relation to snow water (mean value) - Hg>U>As>Cu>Mo>Ni>Co>V>Pb>Cd>Zn, emphasizing the elements, the enrichment of which from soil is more significant.

The distribution of trace element concentrations (μg/L) in meltwater revealed a logical territorial belonging, which was related to the impact of industrial objects. The most polluted area is the site between the closed wastewater treatment facilities of the chlor-alkali plant and the ash removal ditch of the TPP's ash dump. At this site, the concentrations of the main pollutant of the plant, Hg, as well as U, Ni, Co, Mo, V, and As are significantly higher than their mean concentration. The enrichment of soils and, subsequently, meltwater of the study area with U, Ni, Mo, V, As is determined by their entry with gas-dust emissions from coal-fired TPP. This is confirmed by the dispersion of these trace elements in the dissolved phase of the snow cover in the zone of TPP impact following the predominant northwest winds. Besides, the indicators of the TPP impact are high concentrations of Mo, V, Ni, As, and U in the top meltwater of the ash dump, which then spread through the ash removal ditch. The general trend of the spatial distribution of trace element concentrations in meltwater is a gradual decrease with distance from large anthropogenic objects.

The results showed that the surface runoff of meltwater directly participates in the migration of pollutants from industrial to surrounding areas, including the Angara River, and can be used as the indicators of the condition of natural technogenic systems.

A SPATIO-TEMPORAL RECORD OF MICROPLASTICS DURING THE PAST FOUR DECADES IN A LACUSTRINE SEDIMENTARY SEQUENCE FROM SOUTHERN INDIA

Sandeep KIZHUR[1]*, Central University of Kerala (sandeepk01@gmail.com)
Aravind G H[2], Central University of Kerala
Mahidev R S[3], Central University of Kerala
Abdul Khader Rafaz[4], Central University of Kerala
Sijinkumar A V[5], Central University of Kerala
Anish K Warrier[6], Manipal Academy of Higher Education

Abstract

The present study provides baseline data on the spatio-temporal characteristics of microplastics in lacustrine sedimentary environments in southern India where limited data is available. The study investigated microplastic abundance, their types and polymer composition in surface and sub-surface sediments of Madagadakere (MK) lake situated in the south-western India. The sedimentary sequence (21 cm) which was dated using Cs-137 and Pb-210 methods display variations in the concentration, morphology, and polymer type of microplastics in the sediment profile during the past four decades. The microplastic concentration in the surface sediments of the lake varies from 100 to 450 particles/kg (mean + (standard deviation) = 322.22 (+ 120.91) particles/kg). A gradual increase is documented in the concentration of microplastics (150-1475 particles/kg) during 1975-2010. However, a decrease in microplastics content is documented from 2010 to 2016 (440-225 particles/kg). The fibres are the abundant types of microplastics in both surface and sub-surface sediments. The surface sediment samples are dominantly polypropylene (PP), whereas trench samples contain high-density polyethylene (HDPE) in addition to the former. A small creek joins the lake at north-east part of the lake which act as major source of microplastic influx to the lake. The fluctuations in microplastic concentration in sedimentary profile during the past 44 years can be ascribed to the collective influence of rainfall, fishing activity, and improper waste management practices of plastic materials. Besides, the presence and first appearance of different polymers in lacustrine sedimentary profile from southern India has the potential to be used as a stratigraphic marker during the Anthropocene.

Nodir Rashidov[4], Institute of Geology and Geophysics named after Kh.M.Abdullaev
Shohboz Yoshuzokov[5], Institute of Geology and Geophysics named after Kh.M.Abdullaev

Abstract

Experiments on phytoremediation of contaminated soils were conducted at the Almalyk and Navoi Mining Metallurgical Combines facilities. Field and greenhouse experimental investigations have shown that phytoextraction may effectively remove metals (Pb, Cu, Zn, Cd, As, etc) from the soil. Ideally, phytoextraction requires fast-growing plants with large biomass and the ability to accumulate metal ions in the green mass. A plant's ability to accumulate was determined by the bioaccumulation coefficient (the ratio of the concentration of heavy metals in the shoots to the concentration in the soil). The results of the studies showed that the concentration of heavy metals in tailing wastes from the Navoi and Almalyk MMC is higher than the maximum permissible concentrations, and the anomalies of technogenic distribution occupy a relatively large area. Field experiments on phytoremediation of contaminated soils were conducted on arable lands around the waste storage facilities. At the end of February 2023, seedlings of local species of tree plants (Willow - Salix babylonica; Salix niggra; Salix cocrulea; Poplar - Pópulus álba; Pópulus canadensis; Elaeagnus commutata; Elaeagnus angustifolia) and reed (Phragmites communis) were planted, which are stable in the climatic and geochemical conditions of the area. These tree species also resist drought and saline soil. They can help improve air quality by removing dust and other pollutants. Reed - Tolerant of flooding and salinity, it can help prevent soil erosion and enhance water quality. The results of field experimental studies on the phytoremediation of contaminated soils showed that phytoextraction might become an effective tool for removing metals from the soil. Ideally, phytoextraction requires fast-growing plants with large biomass and the ability to accumulate metal ions in the green mass. A plant's ability to accumulate was determined by the bioaccumulation coefficient (the ratio of the concentration of the toxicant in the shoots to the concentration in the soil). Accumulator plants can absorb certain metals in amounts to several percent of the weight of their dry biomass. The collected plant biomass can be disposed of by burning and disposing of the ash at landfills. The metals with a commercial value can be recovered using an extraction procedure. Plants that produce enough above-ground biomass that can be harvested several times per season to remove toxic elements are the best candidates for phytoextraction. To be most beneficial for phytoremediation, these plants must accumulate harmful elements in plant tissues in 2–5% of dry weight. The results of the experiments showed that some local varieties of trees (Salix babylonica; Salix cocrulea; Salix niggra) and reed

(Phragmites communis) have good indicators of tolerance and accumulation of heavy metals.

Lead (Pb) Contamination and Associated Health Risks in the Mining Town of Rosh Pinah, Namibia.

Michelle Uetupa Hailonga[1]*, Geological Survey of Namibia (michelle.hailonga@mme.gov.na)
Giesberta Shaanika[2], Geological Survey of Namibia
Helmi Ipinge[3], Geological Survey of Namibia
Norwel Mwananawa[4], Geological Survey of Namibia
Israel Hasheela[5], Geological Survey of Namibia

Abstract

Lead mining has historically been associated with significant environmental and health impacts, a reality mirrored in the small southern mining town of Rosh Pinah, Namibia. Zinc was first discovered in Rosh Pinah in 1963, with mining operations commencing in 1969. The ore deposit comprises a stratabound stratiform zinc sulfide deposit within the upper volcanoclastic portion of the Precambrian Kapok formation, associated with pyrite gangue and minor copper content. Geo-environmental monitoring surveys conducted in Rosh Pinah in 2007, 2018, and 2023 included comprehensive sampling, analysis, and characterization of water, soil, sediment, tailings, waste rock, and ore samples.

The soil and sediment samples collected in the Rosh Pinah area exhibited elevated levels of lead (Pb), zinc (Zn), and copper (Cu), indicating significant contamination. Lead concentrations ranged from 67 ppm to 17,434 ppm, surpassing Canadian Soil Quality Guidelines (CSQG) thresholds for all land use categories. Similarly, zinc concentrations ranged from 42 ppm to 141,082 ppm, exceeding CSQG values across various land use types. Copper concentrations varied from 30 ppm to 703 ppm, also surpassing CSQG values for agricultural, residential/parkland, commercial, and industrial land uses. In contrast, vanadium (V) concentrations mostly fell below the CSQG threshold of 130 ppm. Comparison with CSQG highlighted significant contamination, raising concerns about health implications, especially for children. Recent Ministry of Health assessments confirmed Pb exposure in children, indicating quantified absorption and associated health risks.

The water results indicate generally satisfactory water quality across the sampled locations, with parameters such as pH, electrical conductivity, and total dissolved solids typically within allowable limits. However, occasional instances of elevated turbidity, particularly in Rosh Pinah Zinc WBH11 and WF000, raise concerns. Although most trace elements meet regulatory standards, slight exceedances are observed, notably in manganese levels in Rosh Pinah Zinc WBH11 and WF60. Despite these localized concerns, the majority of sites exhibit water quality suitable for human consumption, primarily falling within Class A or B classifications of the Namibia Drinking Water Quality Guidelines. The water quality is classified into four groups, in the NDWQG, based on the concentration and limits of various determinants: Group A (excellent quality), Group B (acceptable quality), Group C (low health risk), and Group D (high health risk or unsuitable for human consumption).

The primary source of contamination was identified to be dust fallout from the tailings storage facility and ore stockpiles in the processing area. Urgent action is recommended to conduct comprehensive assessments and implement remedial measures to mitigate the adverse effects of heavy metal contamination on the health of the surrounding community and the environment in Rosh Pinah.

Overcoming Construction Management Challenges During the Remediation of a Former Gold/Arsenic Mine in Ontario, Canada

MARK William PRIDDLE[1]*, Egis Group (mark.priddle@egis-group.com)
Katharine Faaren[2], Ontario Ministry of the Environment, Conservation and Parks

Abstract

The Deloro Mine Site began its life as a gold mine in the 1860's, but progressed to arsenic extraction and processing. Subsequently a large industrial area with processing of other ores and materials developed. These activities left a legacy of contamination which eventually came under the control of the provincial government. Recently cleanup of the Tailings Area and the Industrial and Mine Area was completed.

The site is unique in Canada for several reasons:

• the Owner (Provincial Environment Ministry) is also the one of the key regulators
• despite no mining of radioactive ores, radioactive materials are present as a result of other industrial processing
• multiple regulators from several levels of governments are involved
• the site is immediately adjacent to a residential area
• an important recreational river flows through the site

These factors presented challenges during the management of the remediation project. The work was successfully completed in 2018 with the "Site Nuclear Licence" being withdrawn as a result of full and effective remediation. All wastes are now consolidated and covered with ongoing management.

This paper will explore the site history and how the challenges at this unique site were overcome over the course of eight years of remediation. These included design changes during construction, dealings with multiple regulators and the requirement for phased construction.

Challenges were overcome with the cooperation of all parties (owner, contract administrator, contractor(s), several regulators and consultation with other stakeholders (public, conservation authority, municipality). Specific examples include:

• Redesign of certain features during construction
• Response to anomalous weather events and subsequent incidents
• Dealing with species-at-risk
• Operating within and then clearance from, the Waste Nuclear Site Licence

The successful completion of this project resulted in an award from the Consulting Engineers of Ontario (Canada).

Microtechnofossils as a multiproxy record for the human-impacted sediments

Zdzisław M. Migaszewski[1]*, Jan Kochanowski University (zmig@ujk.edu.pl)
Agnieszka Gałuszka[2], Jan Kochanowski University

Abstract

Microtechnofossils encompass technogenic materials reaching 5 mm in diameter. These made-man products include four basic groups that may be used as a proxy for anthropogenic sediment contamination and for precise dating of the present and future human-impacted sedimentary strata. These include: (i) microplastics and their degradation products, (ii) combustion-derived particulates, e.g., metal oxides, aluminosilicates, silicates, spheroidal carbonaceous particles/SCP, (iii) synthetic crystals and mineral-like phases, e.g., boron carbide, tungsten carbide, element-doped garnets, graphene, ballpoint tips, and (iv) a new emerging road dust marker – glass microspheres. In contrast to elements and stable isotopes that require the knowledge of geochemical background for specific environmental settings, microtechnofossils can be unequivocally identified using optical microscopy. Of these four groups, microplastics (worn fragments of major plastic litter, microbeads/plastic glitters, nurdles/plastic pellets, or microfibers) are most widespread in the present environment due to their mass production, low density and easy fluvial and airborne transport. Plastics are known to degrade at the surface, exposed to heat, UV light and oxygen, but as noted, when buried in cold dark anoxic conditions they are likely to be considerably longer-lived, even if the scale of that longevity has not yet been constrained.

The physicochemical properties of glass microspheres, resembling quartz or microtektites, are a prerequisite for a primary marker of sediment contamination primarily with traffic-related dust. Another advantage is their preservation potential for being a chronostratigraphic marker of the human-impacted sediments, irrespective of redox conditions. Glass microspheres have been found in river sediments up to 25 km from city stormwater drains and in lake sediments up to 700 m off the highway 73 in the Świętokrzyskie province, south-central Poland (Migaszewski et al., 2022, 2023), as well as in coastal sediments of the Zuari estuary, southwestern India (Suhas et al., 2019) and the Plymouth Sound (UK) at a depth of 10–15 cm (Turner and Keene, 2023). Primary microtechnofossils and/or in some cases their secondary degradation products, will be the best multiproxy record for the present and future human-impacted sediment strata.

On the proper use of geochemical indices in pollution assessment of the road dust

Agnieszka GAŁUSZKA[1]*, Jan Kochanowski University (Agnieszka.Galuszka@ujk.edu.pl)
Zdzisław M. Migaszewski[2], Jan Kochanowski University

Abstract

Road dust is a solid material deposited on a road surface, originating from natural and anthropogenic sources. It contains a mixture of mineral particles from erosion of local rocks, and soils and from abrasion of the road surface, particles emitted from vehicles (e.g., produced during wearing of brakes and tires), plant fragments, technogenic particles, etc. Road dust contains different-size particles. Its composition shows temporal variability in a given location depending mostly on climatic factors, traffic intensity and road maintenance practices. As a consequence of its complex character, road dust is a heterogeneous material which is not comparable to any natural material. Thus, it should not be considered as an analogue to soils or sediments.

Different geochemical indices are used for pollution assessment. The most popular ones include Enrichment Factor (EF), Contamination Factor (CF) and Geoaccumulation Index (Igeo). Different formulas are used for calculation of all these indices, but they are all based on comparison of the results with background concentrations. In most of the recently published papers employing geochemical indices in pollution assessment of the road dust, the background values are understood as values representing shales or the upper continental crust composition. In some cases, the authors use these values for comparison of geochemical indices calculated for different fractions of the road dust. Another example of incorrect approach is the use of Zr as a reference element when calculating the Enrichment Factor in road dust samples. Zr cannot be used as a reference element because it has a substantial share of anthropogenic source in road dust as $ZrSiO_4$, which is commonly used in brake pads. In addition, three-way catalytic converters contain ZrO_2 with an admixture of cerium oxide.

This study reveals common misconceptions related to application of geochemical indices in pollution assessment of the road dust based on the results obtained in the city of Kielce, Poland, and proposes solutions to overcome the existing problems.

This study was financially supported by the National Science Center of Poland (a research grant #2019/35/B/ST10/00821).

Jason Samuel Ogola[3], University of Venda

Abstract

Gold mine waste is considered as the major source of toxic metals in the environment however these toxic metals can be removed from the mine waste, soil and water by a process called phytoremediation. This process involves the use of plants to remove or extract metals. A mineralogical characterization was conducted at Klein Letaba tailings storage facility to quantify the presence of metals. Previous studies revealed an abundance of metals such as Pb, Cr, Ni and As. However, the extent of remediating metals from the facility has not been investigated. The focus of the study was to investigate the potential of metal extraction from native plant species growing on the tailings storage facility. This is an environmentally friendly remediation strategy for metal extraction and stabilization of the mine tailings using native plant species.

A total of 80 plant and tailings samples were randomly and seasonally collected at Klein Letaba tailings facility for chemical and mineralogical characterization. Five control samples were collected 5 km away from the mine site but within similar geological setting. This helped during comparative study to ascertain that these metals indeed came from the mine due to mining and gold processing. The samples were analysed using X-ray fluorescence spectrometry (XRF) at University of Venda and the second aliquot was digested using microwave digestion technique then sent to Madzivhandila Agricultural Centre for Inductively coupled plasma optical emissions spectrometry analysis. Geochemical data generated was analysed using Microsoft Excel, Arc GIS, and Kriging software. The metal values from the reconnaissance study were used to develop evidential uptake of the dominant plants in the study area. Each composite sample was split into two representative aliquots for chemical and mineralogical analysis.

Three dominant native plant species growing and thriving well on the tailings storage facility were identified, namely, Combretum imberbe, Cynodon dactylon and Sporobolus africanus. There were two more native plant species which were scarcely distributed on the tailings storage facility, Cyperus sexangularis and Phragmites australis. Pb recorded a maximum of 2307.25 mg kg-1 in the roots and Ni recorded maximum metal concertation of 1101.03 mg kg-1 in the roots for the Combretum imberbe plant, whereas Pb had concentration of 1525.8 mg kg-1 in the roots and 1204.3 mg kg-1 in the stem. These values exceed the ground tissues in concentration present in the soil, being greater than 1000 mg kg 1 for Ni, Pb, Cu, Cr, AS, Co. The uptake was high on the Combretum imberbe plant (2307.25 mg kg-1) as compared to the grass species Cynodon dactylon (1525.80 mg kg-1) and Sporobolus africanus (1370.90 mg kg-1).

This is an environmentally friendly remediation strategy for metal extraction and stabilization of the mine tailings using native plant species. Therefore, this remediation strategy will not only be applied in the studied sites but can also be applied in other similar studies.

Abstract

The ecological restoration of mines is an important link in the construction of green mines. While rationally developing and utilizing mineral resources to promote economic development, ecological damage and environmental pollution should also be reduced.Fly ash is a powdery particle produced after pulverized coal is burned in a boiler. Fly ash is one of the largest solid waste discharge sources in China. The stacking of fly ash will directly or indirectly cause a series of environmental problems such as atmosphere, soil and river, and cause a great waste of resources. In recent years, the study of soil improvement with fly ash has become a new hotspot. In this paper, fly ash was used to improve the soil in the mining area, and the effects of fly ash compound with different particle sizes and application rates on soil physicochemical properties, nutrient composition and plant growth were studied. The results showed that the use of fly ash with a smaller particle size and 15% application rate had a better effect on soil improvement. The bulk density of soil decreased by 0.13~0.47 g/cm3, the porosity of soil increased by 8.9%~22.8%, the soil water holding capacity increased by 6.7%~17.5%, and the salt content of soil decreased by 25.9%~31.86%. At the same time, the content of soil organic matter increased by 0.64~1.12 g/kg, hydrolyzable nitrogen content increased by 5.3~9.2 mg/kg, and total phosphorus content increased by 0.03~0.06 g/kg, which increased with the increase of fly ash.

Why is the air humid during wintertime heavy haze days in Beijing?

Jiarui WU[1]*, Institute of Earth Environment, Chinese Academy of Sciences (wujr@ieecas.cn)
Xia LI[2], Institute of Earth Environment, Chinese Academy of Sciences
Ruonan Wang[3], Institute of Earth Environment, Chinese Academy of Sciences
Qian Jiang[4], Institute of Earth Environment, Chinese Academy of Sciences
Guohui Li[5], Institute of Earth Environment, Chinese Academy of Sciences

Abstract

Atmospheric humidity has been shown to promote haze formation, but it remains unclear why the air is humid during heavy haze days in winter. We have identified a substantial increase of water vapor with increasing near-surface PM2.5 concentrations based on observations in Beijing (i.e. the air becomes more humid with aggravation of haze). The observed temperature and wind speed however shows a decreasing trend with near-surface PM2.5 concentrations Water vapor isotopic measurements and analysis at an urban site of Beijing have shown that the combustion derived water (CDW) fraction in the water vapor is about 11 ± 6.2 % on average, and increases with enhancement of near-surface PM2.5 concentrations. Although the wind at the urban site is weak during the study episode and there are almost no strong sources of CDW in upwind area of the sampling site in short distance, the CDW from the intensive emissions surrounding Beijing could also affect the observation site at the urban Beijing by regional transport, which is subject to causing overestimation of the contribution of CDW in Beijing. In future, two or more instruments will be deployed in the northwest and southeast of Beijing, to observe the water vapor characteristics of upwind and separate the regional transported water vapor signals from the local ones.

The more humid air during haze days is mainly caused by the water vapor transported from south or east to Beijing, anthropogenic direct emissions, and interactions between the atmosphere and air pollutants. Model simulations reveal that CDW has a considerable impact on the increasing moisture with aggravation of haze in the urban area of Beijing. The aerosol-radiation interactions (ARI) effect generally decreases the water vapor content with occurrence of haze and only increases the relative humidity when the severe haze occurs. The synergetic effect of CDW and ARI also decreases the temperature, with a reduction of 1.0 °C when severe haze occurs.

Impacts of changes in land use and land cover between 2001 and 2018 on summertime O3 formation in North China Plain and surrounding areas-A case study

Abstract

Changes in land use and land cover (LULC) influence meteorological fields and biogenic emissions, further affecting the atmospheric chemistry and air quality. Combining the satellite measurements and WRF-Chem model simulations, we evaluate impacts of the LULC change between 2001 and 2018 on the summertime ozone (O3) formation in North China Plain and surrounding areas (NCPs). Satellite measurements have revealed that from Taihang to Yanshan Mountain, the fraction of broadleaf and needle forest coverage has increased by 5%-20% and the urban area has increased by up to 25% in the NCP. Additionally, the vegetation density has increased significantly in the NCPs except for urban areas. The LULC change generally enhances biogenic volatile compounds emissions in the NCPs, particularly over Taihang and Yanshan mountain, but the O3 variation is divergent. The maximum daily 8-hours average (MDA8) O3 concentrations are reduced by 1%-7% over Taihang and Yanshan Mountain because the raised vegetation density increases O3 dry deposition velocity to accelerate the O3 loss. The raised vegetation density enhances the evapotranspiration to decrease the near-surface temperature by 0.1 ℃ ~ 1.5 ℃, which also generates a divergence in the low-level atmosphere in the NCPs, causing secondary northerly or easterly winds in the NCP. The O3 enhancement along the coastal areas of the NCP is attributed to the perturbation of wind fields and photolysis induced by the LULC change. The divergent variation of the MDA8 O3 concentrations in the NCP is generally caused by the variations of biogenic emissions and photolysis.

Hydrochemical characterization and indicators of anthropic influence on groundwater surrounding Guanabara Bay, Rio de Janeiro, Brazil

Alexis Rosa NUMMER[1]*, UFRRJ (rosanummer@gmail.com)
Nicole Delaunay Souza[2], solteira
Eduardo Duarte Marques[3], casado

Abstract

Guanabara Bay, recognized globally as one of the most eutrophic tropical ecosystems, occupies a position of negative prominence not only at a local but also at a national level. Efficient management of freshwater availability and reducing degradation of its quality are crucial challenges in this region. This study focuses on the hydrochemical analysis of the aquifers surrounding Hydrographic Region V (RHV) of Guanabara Bay, in the Rio de Janeiro State, investigating the interaction of groundwater with geological materials during percolation and establishing a spatial relationship between the zones urban, industrial, and local hydrogeochemistry. In this study, 228 artesian wells were analyzed, resulting in the classification of 38% of the water as chlorinated and 64% as sodium. This predominance of sodic waters can be attributed to maritime influence, given the proximity of Guanabara Bay to the ocean, and to human activities, such as the discharge of industrial and urban effluents, which alter the chemical composition of groundwater. Considering the hydrogeochemical properties, the Inorganic Chemical Index ranged from 0.805 to 99.931, with an average of 56.515, showing a significant variation in water quality. These data suggest a possible correlation between human activities and variations in water quality, highlighting the need for continuous monitoring and the implementation of environmental protection measures. The high variability of the Inorganic Chemical Index may indicate zones of point or diffuse pollution, influenced by effluent discharges, surface runoff and infiltration of contaminants. The classification of waters as chlorinated and sodium suggests that salinization processes are occurring, which can negatively impact aquatic biodiversity and the quality of water for human and agricultural consumption. The results point to the need for integrated water resources management policies, which consider both environmental conservation and economic development, thus ensuring a balance between the use and protection of groundwater in Guanabara Bay.

Study of soil contamination in vicinity of the municipal solid waste landfills after recultivation

Irina VASILEVNA Galitskaya[1]*, Sergeev Institute of Environmental Geoscience Russian Academy of Science (IEG RAS) (galgeoenv@mail.ru)
Tatiana Morosova[2], Dubna State University
Starostin Evgenii[3], Dubna State University

Abstract

Currently, the Federal project "Clean Country" is being implemented in Russia. One of the most important directions of the project is the reclamation of municipal solid waste (MSW) landfills or their modernization. A unique opportunity is provided at a significant number of objects to study the spatio-temporal changes in the environmental components contamination in the areas of MSW landfills. The results of soil contamination research at three MSW landfills in the Moscow region are considered. The complex of studies included the following kinds of works: the assessment of soil contamination hazard using various indicators (maximum permissible concentrations, background concentrations, soil clarks, migration indicators); the study of the heavy metals forms; factor modeling. In order to study soils as a secondary source of groundwater contamination, studies have been conducted on the forms of heavy metals: total; water-soluble; easily mobile (extracted with an acetate-ammonia buffer solution); acid-soluble, allowing to assess the level of technogenic soil pollution. As a result of the work carried out, the main trends of spatial and temporal changes in soil contamination were established, a list of polluting components was determined, the features of aerotechnogenic soil pollution and the composition of the forms of chemical elements were revealed. The intensity of soil contamination, the quantitative and qualitative composition of the forms of chemical elements differed significantly in different areas around the landfills. The noted differences seem to be related not only to the impact of the landfill and the wind rose, but also to the specifics of the soil and vegetation cover (the presence of forested, arable, swampy, etc. sites) in the adjacent territories. Significant percentages of exchange forms from their total content (up to 66% in a number of sites) are due to the high ability of soils to form sorbed forms, and the percentages of acid-soluble forms (up to 75% in a number of sites) indicate a high level of technogenic soil contamination, since in background soils the content of acid-soluble forms of these elements is usually not exceeds 1-5% of their total content. The use of the principal component analysis (PCA) method made it possible to identify the complex linear correlation between the concentrations of components and to reveal the main factors affecting the composition of the studied soils in the adjacent territories: the influence of landfill, agricultural activities, motor transport, etc. Based on the results of factor analysis it was concluded that all the factors obtained indicate a predominantly technogenic source of the pollutants in soils. Only some studies have noted factors confirming Fe and Mn natural anomalies. The combination of low groundwater protection in the considered sites and the significant content of mobile forms of a number of chemical elements cause the hazard of groundwater contamination even after the

landfill reclamation, which confirms the need for monitoring studies not only at the sites of the landfill body, but also in the adjacent territories. The research was financially supported by the project of Russian Science Foundation № 22-17-00045.

Characterization and adsorption properties of rectorite/sludge derived biochar composites for Pb(II) removal

huanhuan WANG[1]*, West Anhui University (doublewhh@163.com)
junye ZHANG[2], School of Resources and Environmental Science, Wuhan University

Abstract

Heavy metals enter the environment mainly in water, soil and the atmosphere and migrate between them, contaminating a wide range of areas. Heavy metal ions in water bodies are difficult to biodegrade and can pose a threat to the ecological environment and human health. Therefore, there are many ways to remove heavy metal ions from water, and clay-based adsorbent materials are particularly widely used. Novel rectorite/sludge derived biochar (REC/SDBC) composites have been prepared to absorb Pb(II) in water. SEM images show that rectorite (REC) was evenly dispersed on the surface of sludge derived biochar (SDBC). The maximum Pb(II) adsorption capacity of REC/SDBC compo-sites with REC: SDBC ratio of 3:1 (26.89 mg g-1) was obtained within 120 min and higher than that of REC and SDBC alone. Additionally, it was discovered that pH had a significant impact on the adsorption of Pb(II) upon the compounds. The pseudo-second-order model and the Langmuir isotherm model, respectively, provided good fits for the rates and isotherms of Pb(II) adsorption onto REC/SDBC composites. The reaction mechanism is mainly dominated by chemisorption involving cationic exchange, surface complexation, and surface precipitation, which is also confirmed by X-ray photoelectron spectroscopy (XPS) analysis. The satisfied adsorption capacity combined with cost-effective and environmental-friendly virtues enables REC/SDBC composites promising candidates for removing heavy metallic elements from wastewater

Seasonal Changes in the Eutrophication Index and Alleviation of Eutrophication with Calcium-Citrate Complex in the Surface Water of Osongji (Osong Pond), Jeonju-si, Korea

Suyeong Noh[1]*, Department of Environment and Energy, Jeonbuk National University, Jeonju-si, Jeollabuk-do, 54896, Republic of Korea (sooyoung9131@naver.com)
Jiyoung KANG[2], Jeonbuk National University
Sung-Wook JEEN[3], Jeonbuk National University

Abstract

Excessive inflow of nitrate and phosphate is a major factor in promoting eutrophication, which can lead to algal blooms. Eutrophication causes soil and water pollution, with potential adverse effects on ecosystems and water quality. This study evaluated seasonal changes in the lake's eutrophication status and assessed the effectiveness of calcium-citrate complex as a reagent for alleviating nitrate and phosphate pollution. In this study, Osongji (Osong Pond) in Jeonju-si, Korea, was selected as an experimental site, and its physicochemical changes were assessed. Changes in the eutrophication status were assessed using the Korean Eutrophication Index (TSIKO), a eutrophication evaluation guidance applying chemical oxygen demand (COD), chlorophyll-a, and total phosphorus (T-P). Three experimental tanks, each with a volume of approximately 255 L (diameter of 50 cm and height of 130 cm), were installed. Calcium-citrate complex was applied either at 2-week intervals (T1; prevention) or as a one-time application (T2; one-time application). Closed (T3) and open (T4) control groups without calcium-citrate complex application were also included for comparison. Seasonal variations in eutrophication status were analyzed every two months from November 2022 to September 2023, while experiments with calcium-citrate complex application were conducted from June to September 2023. Osongji experienced eutrophic conditions from November 2022 to June 2023. It transitioned to a hypereutrophic condition in July 2023 but reverted to a eutrophic condition in August 2023, indicating severe eutrophication during the summer. As precipitation increased during the summer season in July and August, COD, T-N, and T-P also increased. The evaluation of the eutrophication alleviation technique using the calcium-citrate complex showed that in T1, where the complex was applied at 2-week intervals, lower TSIKO values were maintained compared to the control groups without complex application throughout the experimental period. In T2, where complex was applied once, T-P and total nitrogen (T-N) decreased after 2 weeks of application, resulting in a decrease in TSIKO. In conclusion, the application of calcium-citrate complex in a lake environment proved effective in preventing and alleviating eutrophication. This study could contribute to evaluating the eutrophication level in surface water bodies and establishing management strategies for eutrophication alleviation.

Pore-scale simulation of CO2-water-rock Interaction on Rock Permeability and Mechanical Properties

Yang BO[1]*, Jllin university (1090048779@qq.com)
Xu Tian fu[2], Jllin university
Zhu Hui Xing[3], Jllin university

Abstract

CO2 geologic sequestration is currently considered as an effective method to mitigate greenhouse gas emission and climate change. However, the CO2-induced mineral reactions, specifically the CO2-water-rock interactions, has been widely recognized for its potential to compromise the hydrogeological and mechanical properties of porous media, thereby deteriorating their integrity and mechanical characteristics. This further gives rise to concerns regarding the storage capacity and safety of CO2 sequestration project. Nevertheless, the mechanism underlying the influence of CO2-induced mineral reactions on these parameters is still not fully understood, thereby introducing uncertainty into the reliability of predicted outcomes. Direct pore-scale simulation plays a crucial role in deepening the understanding of CO2-water-rock interaction and its associated impacts. The present study proposes a novel simulation model that integrates the lattice Boltzmann (LBM) and finite element methods (FEM) to simulate the dissolution of calcite in a 3D sandstone sample invaded by saturated CO2 solution, aiming to investigate the resulting evolution of hydrogeological parameters (i.e., porosity and permeability) and mechanical properties (i.e., bulk and shear moduli). The reactive transport LBM model is coupled with fluid flow, solute transport, homogeneous reaction, heterogeneous reaction, and pore structure evolution. The subsequent updated skeleton is imported into the FEM model for mechanical calculations. In current study, the injection rates of reactive fluid (i.e., CO2 solution) were varied in the model to simulate different operational conditions of CO2 geological storage project. The simulation results demonstrate that the decrease in injection velocity inhibits the dissolution of calcite in the middle and downstream regions, concentrating it near the inlet. These distinct modes of calcite dissolution result in differentiated permeability and mechanical properties within rocks possessing identical porosity levels. In general, the increase in fluid injection velocity leads to a more pronounced enhancement in permeability and a greater attenuation in bulk and shear moduli under the same porosity. Thus, it is confirmed that the utilization of porosity is inadequate in accurately characterizing the evolution of rock permeability and mechanical properties resulted from mineral reactions. We ascertain that the application of fractal parameters, i.e., succolarity and fractal dimension, can more precisely depict the progression of permeability and bulk/shear modulus, respectively. In general, the parameters analysis and the model proposed above are important supplements for the field-scale study.

Tree stumps as passive sampler for trace metal dust deposition

Shubin ZHOU[1]*, China University of Geosciences, Beijing (shubinzhou@foxmail.com)

Abstract

Significant human activities are leading to the contamination of atmospheric dust with trace metals worldwide. This research evaluates tree stumps as passive samplers of dust deposition and bioindicators for dust contamination in a metal mine impacted environment. Two hundred and thirty tree stumps and adjacent soils from the Bailing Cu-Zn deposit area in northeastern China were analysed in situ using portable X-ray fluorescence (pXRF). Arsenic and Zn concentrations in both tree stumps and roadside soils at each location decreased with increasing distance from the road, following a power-law relationship. This trend suggests that road dust resuspension and redeposition are the primary sources of pollution. Micro-XRF images of vertical slices of tree stumps reveal concentrated As and Zn on the cut surface of tree stumps, indicating atmospheric deposition as a primary contributor to elevated As and Zn concentrations in tree stumps. Considering that natural lithological and geochemical properties of bedrock and soils vary, the presence of naturally occurring mineralization may make it difficult to distinguish polluted from unpolluted areas. The use of tree stumps as passive samplers offers distinct advantages over other methods (e.g., the placement of dust samplers and soil sampling) for analysing trace metal dust deposition, because atmospheric deposition emerges as a primary contributor to trace metals in tree stumps.

Assessment of Ground Water Quality by Statistical Methods in Greater Bangalore, South India

Hemamalini Rajanna R[1]*, Center for Environment , Agriculture And Training (ceadatngo@yahoo.co.in)

Abstract

Water is the vital resource for sustenance of living creatures on the Earth. The groundwater contamination has become a grave problem due to rapid growth of population, industrialization and high rate of urbanization in Bengaluru. Over the last few decades, the land and water use patterns have changed drastically in Bengaluru. Groundwater is an important resource for drinking purpose which contains over 90% of the fresh water resources. The untreated industrial effluents discharged into the surface water sources cause severe groundwater pollution in the industrial belt which requires continuous monitoring of the groundwater quality to evaluate the suitable and sustainable use of groundwater in Bengaluru. This study envisages the assessment of groundwater quality using diverse methodologies: determination of physico- chemical characteristics of groundwater, water quality index, cluster analysis, principal component analysis and determination of darzarrouk parameter.

In the present study, the whole study area was divided into four major grids as North-West, North-East, South-West and South-East. Out of those four major grids for the purpose of accuracy it was further divided into smaller grids having an area of 2x2 sq.km grids. Totally 176 (Bore Well (BW-169, Dug Well/Shallow wells - 7) samples were collected from whole study area and analysed for Chlorides, Sulphate, Nitrate, pH, Total Dissolved Solids, Total Hardness, Specific Conductivity, Calcium, Magnesium, Sodium, Potassium, Iron, Turbidity, Alkalinity and Fluoride. The result show that the groundwater quality is highly polluted in North-West part of Greater Bangalore area due more anthropogenic activities carrying out in those areas, may be due to sewage pollution and eutrophication of lakes and weathering of rocks in sub surface layers.

The present work is aimed at assessing the water quality index (WQI) for the groundwater of study area. The WQI for these samples ranges from 92 to 102. The high value of WQI has been found to be mainly from the higher values of Chlorides, TDS, Total Hardness, Specific Conductivity, Calcium, Magnesium and Sodium in the groundwater. The analysis reveals that the groundwater of the area needs some degree of treatment before consumption, and it also needs to be protected from the perils of contamination. Multivariate statistical analyses such as principal component analysis (PCA) and hierarchical cluster analysis (HCA) were applied to the standardized data set of fifteen groundwater quality parameters collected during the post-monsoon and the summer seasons in order to elicit hydrologic and biogeochemical processes affecting water quality in the unconfined aquifer beneath Bangalore city in southern India. The HCA using Ward's method and squared Euclidean distance measure classified the parameters into four clusters based on their similarities. PCA and HCA allowed interpretation of processes during both post-monsoon and summer seasons, anthropogenic pollution.

The correlation-regression analysis of groundwater quality data of a shallow aquifer system is presented. The correlation coefficients among the various water parameters and their association with total dissolved solids (TDS) were recognized. The Full length paper presents quality, quantity & its Environmental Hazards in the Study area.

Mercury in soils near a base metal smelting plant, Plovdiv, Bulgaria

Lora BIDZHOVA[1]*, Geological Institute, Bulgarian Academy of Science (lora.bidzhova@gmail.com)
Svetoslav Velichkov Georgiev[2], Geological Institute, Bulgarian Academy of Science
Galina Radeva[3], Roumen Tsanev Institute of Molecular Biology, Bulgarian Academy of Sciences, 1113 Sofia, Bulgaria
Radina Nikolova[4], Roumen Tsanev Institute of Molecular Biology, Bulgarian Academy of Sciences, 1113 Sofia, Bulgaria

Abstract

Mercury (Hg) is a known global pollutant that can be severely damaging to ecosystems and human health. Natural (e.g. volcanoes) and anthropogenic (e.g. artisanal gold mining) activities release mercury to the air, water and on land, part of which is subsequently converted by oceanic and soil bacteria into highly toxic methylmercury (MeHg) species that easily enter the food chain. Because of the high affinity of mercury for organic matter, rich soils retain Hg deposited from natural and anthropogenic sources, and thus represent an important global Hg reservoir. Non-ferrous metal production is estimated to account for 10-15% of global anthropogenic Hg emissions to the atmosphere and 40% of total anthropogenic releases to water. This significant Hg input and related environmental concerns require better understanding of mercury deposition in soils in general and around base metal smelters in particular. Here, we report total Hg contents in surface (0-20 cm) and subsurface (20-40 cm) soils from five sampling sites near the non-ferrous metal smelter KCM-2000, Plovdiv, Southern Bulgaria. Mercury contents, measured by DMA-80 evo at the Geological Institute of the Bulgarian Academy of Sciences, vary between ~20 and ~1000 ppb; these values are below the maximum permissible concentration allowed under Bulgarian Regulation 3/2008. The Hg content in the soil increases towards the location of the smelting plant, and peaks in the immediate vicinity of the smelter. Approximately three kilometers away from the smelting site, Hg contents are within background levels. There is a strong positive correlation between Hg concentrations in the samples and published data for cadmium, lead, and zinc, as well as clay contents. Notably, all surface soils have higher Hg concentrations compared to their subsurface counterparts, a feature that is more prominent within soils closer to the smelter. In addition, the results suggest that the combined effect of heavy metal contamination and the soil physical properties impact the enzyme activities and the abundance of soil bacterial communities. Further research on a larger soil sample population is needed to better characterize the areal extent of Hg contamination in soils near the smelting plant, as well as their effect on enzyme activities and bacterial communities.

Abstract

This study describes the results of principal component analysis and the hierarchical cluster modeling of the chemical and organic properties of soil samples taken from the Almalyk mining industrial area in Uzbekistan. Mine quarries, dumps, and tailings may contain mobile metals, which can act as a sink for tracers introduced to the environment through fly ash, dust, and leachates - the increasing availability of satellite data and field observations, methods to assess these changes and analyze impacts. Field visits can help to obtain vast amounts of data about sites. Soil profiles provide sufficient information about the soil's chemical composition and organic content. Still, sample analysis is hampered by many predictive variables (tracers), which add uncertainty and variability to the data. It is essential to carefully evaluate and interpret tracer concentrations at various sampling sites and environments. Multivariate statistical techniques are of greater value in describing links between sampling sites, concentrations of pollutants, latent factors affecting the data set structure, and pollution sources. Reducing the dimensionality of data increases the accuracy of analysis and helps to focus on the tracers that mainly impact variability in the data set. Such reduction also helps to detect clustering in a multidimensional space, highlighting the properties of collected soil samples and sampling locations. The recent development in the studies of source appropriation has shown that receptor models can help identify the primary sources of contamination in a study area. The models alone, however, are insufficient to conduct an in-depth analysis of the sources, so the redundancy analysis should supplement them to allow a better understanding of the details of land use and factors causing soil contamination, which will help prioritize management goals to minimize the contamination. A multivariate statistical method was used along with redundancy analysis to identify the sources of accumulation of heavy metals in the soils in the Almalyk region, using principal component analysis (PCA) to detect the essential tracers reflecting the variability of data samples. It provides an approach to classification problems through clustering analysis. We isolated variables that affected the variability in the data set using principal component analysis (PCA) and hierarchical clustering (HClust) algorithms. The methods also support cluster visualization in a multidimensional space. The visualization highlights the soil properties and the locations of sampling. The obtained classification displayed the clustering of samples around various sites, resulting from an accumulation of some tracers and distribution by distance from the location of a contaminated zone. Previously, the Almalyk area was analyzed along the transect, and the results

showed that as the distance from the pollution source along the transect increased, the concentrations of metals in soil solutions and exchangeable solid fractions decreased. Studies also showed the effect of airborne pollution caused by metal mining and smelting activity in the areas.

A review of heavy metal contamination around Rosh Pinah area in Southern Namibia

Michael Action EINO[1]*, University of Namibia (einoaction@gmail.com)
Shoopala UUGULU[2], University of Namibia
Collen-Issia UAHENGO[3], University of Namibia

Abstract

The mining industry, pivotal for Namibia's economic growth, concurrently raises environmental concerns, particularly concerning the release of heavy metals into our shared ecosystem. The Rosh Pinah Zinc Mine (RPZM), an underground mine in southern Namibia, mainly mines zinc and lead. The environmental impact of the RPZM was reviewed, focusing on the contamination dynamics of lead and zinc. The review examined the concentrations of zinc and lead in the air, soils, and biota surrounding the mine. The issue stems from the dust fallout, which extends its contamination over a significant portion of Rosh Pinah town. This is due to the positioning of the uncovered tailings dam at an undesirable location, a decision likely made without incorporating insights from local meteorological modelling. Results show that the contaminated area lies in the direction of the prevailing wind. Dispersion modelling for airborne suspended dust particles (TPS) at Rosh Pinah unveiled a noteworthy observation. In the past, the entirety of the tailing dam's surface used to remain desiccated because of water infiltration and evaporation. Despite this, the annual average concentrations of TPS within Rosh Pinah town reached levels ranging from 100 to 300 g/m3. However, a significant change has been observed recently, as approximately two-thirds of the surface of the tailings dam is now covered with water. This alteration has led to a marked reduction in TPS concentrations, ranging from 30 to 100 g/m3. The shift is substantiated by studies conducted on the exposed portion of the grass, which revealed that the lead levels in 52% of the collected grass samples exceeded permissible values for use as dry fodder. Regrettably, this scenario bears adverse consequences for the interconnected ecosystem and environment. Subsequent investigations reveal that the quantity of TSP observed in the air on the tailings dam's surface varies between 8 and 84 mm/m3. The atmospheric composition registers notable concentrations of various elements: zinc (median: 792), lead (median: 412), manganese (median: 163), and copper (median: 42). Comparatively lower levels are detected for arsenic (median: 5) and cadmium (median: 2). The dispersion of dust contamination forms a distinct pattern extending north-eastward, primarily guided by the prevailing wind direction. Concerningly, bio-accessible lead content exceeds acceptable daily intake limits for children. The Namibian Ministry of Mines and Energy confirmed that test results had detected lead in the blood of 18 and 30 children living near a zinc mine at Rosh Pinah. The Rosh Pinah Health Care Clinic's test showed that the blood levels of all children sampled and measured as part of the lead programme in 2020 were above the reference level. The environmental impact assessment of the Rosh Pinah Zinc mine underscores the urgent need for comprehensive measures to mitigate heavy metal contamination, notably lead, to safeguard public health and the surrounding ecosystem from further harm.

Effect of salinity on arsenic mobilization from desulfurized and filtered mine tailings

Rocky KUBUYA KIRO[1]*, UQAT UNIVERSITY-QUEBEC (Pakrockykiro@gmail.com)
Lucie Coudert[2], Prof. UQAT UNIVERSITY

Abstract

Tailings management is one of the most important challenges that mining industry is facing due to potential geotechnical and/or geochemical instabilities. Filtration of mine tailings has been successfully applied on several mine sites, reducing the risks of geotechnical failure. However, the effect of pore water quality (i.e. high salinity) on the geochemical stability of sulfide minerals is poorly documented. Oxidation of As-bearing sulfide minerals, when exposed to air and water, led to the production of As-contaminated mine drainage. Many factors such as the redox potential and pH conditions as well as water quality (i.e. salinity) play a crucial role on the (im)mobilization of As from mine tailings. Many studies have evaluated the mobility of As from mine tailings or pure minerals under several conditions, but few information are available on the geochemical behavior of As from desulfurized and filtered mine tailings. The main objective of the present study was to evaluate the effect of water chemistry on the mobilization of As from desulfurized and filtered mine tailings (DFT). To do so, an exhaustive physico-chemical (e.g., particle size distribution, chemical composition, granulochemical distribution) and mineralogical (e.g., identification of As-bearing minerals and degree of liberation) characterization of a DFT was performed. Four weathering cell tests were performed on washed and unwashed DFT with different water quality (demineralized vs. saline water) to evaluate the effect of salinity on As mobility. DFT, which is mainly composed of fine particles (d80 = 75.5 µm), initially contained 0.1% of As, essentially concentrated in the fine fraction (89.9% of As found in the < 32 µm fraction, which accounted for 55% of the total mass of DFT). Speciation of As revealed that 11% of As was associated to the leachable fraction, while 81% was associated to the residual fraction. Löllingite and arsenopyrite were identified as the main As-bearing minerals. Weathering cells results showed that there is no clear effect of salinity on As mobility from DFT, under the conditions tested ([Cl-] = 1.9-2.5 g/L, [SO42-] = 3.3-3.5 g/L). Indeed, the proportion of As leached after 130 days (2.09-3.59%) and As leaching rates (0.011-0.017 mg/d) were quite similar for all weathering cells.

Tracing Sources of Zinc Contamination in Groundwater of Industrial Complexes Using Zinc and Sulfur-Oxygen (S-O) Isotopes

Dae-Gyu IM[1]*, Korea University (daegull1995@korea.ac.kr)
Duk-Min Kim[2], Sangji University
Jung-Woo Hwang[3], Korea University
Seong-Taek Yun[4], Korea University

Abstract

Industrial complexes host a variety of industrial categories, including metal, machinery, electronics, petrochemicals, cement, and plating plants, which can be sources of diverse pollutants. This study focuses on groundwater contamination by Zn in the study area, where plating, metal machinery, and cement manufacturing plants are potential sources. Zn and S-O isotopic analyses were conducted to trace sources of Zn contamination. Zn concentrations in groundwater ranged from 24 to 2025 μg/L. Additionally, Cr concentration of 17.3 mg/L in a well inside a plating plant suggested that chemicals from the Cr-plating process were released. The direction of groundwater flow towards a stream southeast of the industrial complex suggested potential impacts on residential areas. Groundwater near the metal machinery plant in the southern part of the industrial complex exhibited Zn isotopic ratios ranging from -0.317 to 0.100 ‰. Concentrations varied across different depths, from shallow groundwater sampled at 18 ~ 30m depth to deep groundwater sampled at 44 ~ 50 m depth (the range of Zn concentration in all groundwater samples from this study area was 0.72 ~ 2025.66 μg/L, with a median value of 33.36 μg/L). Additionally, the Zn isotopic ratio in shallow groundwater ranged from 0.018 to 0.205 ‰, while in deep groundwater, it ranged from -0.317 to -0.052 ‰. These results suggest potentially different Zn contamination sources at shallow and deep groundwater levels. Comparisons of sulfate concentrations and Zn and S-O isotopic ratios indicated that residential areas were primarily affected by cement and plating factories. Groundwater well near the cement plant had concentrations of sulfate, boron, and sulfide of 248 mg/L, 0.11 mg/L, and 0.06 mg/L, with δ34S of 27.6 ‰, suggesting sulfate reduction was induced by organic matter possibly from sewage pipes. The direction of groundwater flow suggested that the plating plant and metal machinery manufacturing plants in the northern part and the cement plant were the primary sources of contamination.

Abstract

Biotite, a phyllosilicate mineral, possesses significant potential for cesium (Cs) adsorption owing to its negative surface charge, specific surface area (SSA), and frayed edge sites (FES). Notably, FES are known to play an important role in the adsorption of Cs. The objectives of this study were to investigate the Cs adsorption capacity and behavior of artificially weathered biotite and identify mineralogical characteristics for the development of an eco-friendly geologically-based Cs adsorbent. Through various analyses, it was confirmed that the FES of biotite was mainly formed by mineral structural distortion during artificial weathering. The Cs adsorption capacity is improved by approximately 39% (from 20.53 to 28.63 mg g-1) when FES are formed in biotite through artificial weathering using a low-concentration acidic solution mixed with hydrogen peroxide (H2O2). Especially, the Cs selectivity in Cs-containing seawater, including high concentrations of cations and organic matter, was significantly enhanced from 203. 2 to 1707.6 mL g-1, an increase in removal efficiency from 49.5 to 89.2%. These results indicate that FES of artificially weathered biotite play an essential role in Cs adsorption. Therefore, this simple and economical weathering method, which uses a low-concentration acidic solution mixed with H2O2, can be applied to natural minerals for use as Cs adsorbents.

FEATURES OF ANOMALIES OF POLARIZABILITY AND RESISTANCE OF THE INDUCED POLARIZATION METHOD IN THE LIGHT OF PREDICTING GROUNDWATER POLLUTION BY PETROLEUM PRODUCTS

Qodirjon MINGBOYEV[1]*, SE "HYDROENGEO institute" (qodirjon2004@mail.ru)
Rakhimjon TURSUNMETOV[2], SE “HYDROENGEO institute”

Abstract

With the increasing intensity of the oil and gas industry, pollution of the geological environment, including groundwater, is observed. Pollution of the geological environment is an irreversible and dangerous process. Therefore, there is a special requirement for the use of applied methods for detecting oil pollution in the geological environment.

Of greatest interest is forecasting the migration of petroleum products at an early stage. In this aspect, it is of interest to study the subtle mechanism of distribution of petroleum products in a complex geological environment. When studying oil pollution, the method of induced polarization (IP) was mainly used in various modifications.

Petroleum products in the geological environment, other things being equal, despite their different forms of occurrence, gravitate towards the boundaries of the solid and liquid phases in the form of emulsions and films. These boundaries act as capacitive absorbers of oil products. In this case, the volume of oil films (products) is determined by the total specific surface area, which, in turn, is determined by the porosity and permeability of the vapor space. On the one hand, they are polarized in the boundary zone of the liquid and solid phases, and on the other hand, they are distinguished by significant surface conductivity, which leads to a noticeable decrease in the resistivity of the porous medium as a whole.

Consequently, the spread of petroleum products in the geological environment, i.e. pollution of the geological environment, is manifested by a decrease in electrical resistivity and an anomalous increase in the polarizability of the geological environment.

This pattern is confirmed by the results of numerous field studies aimed at identifying oil pollution in the geological environment. Note that the existing calculation algorithm is aimed at assessing the polarizability of the geological medium for two cases (surface and volume polarizability).

Thus, polarization phenomena are mainly determined by volumetric polarization of the geological environment. In this case, the effect of polarization of the medium is due to the presence of scattered disseminated minerals or clay particles, at the boundaries of which a noticeable jump in potentials is not observed. However, these jumps add up in the volume and then a noticeable polarization of the medium as a whole is observed. They also affect the current density distribution.

When petroleum products spread in the geological environment, as noted above, surface and volume polarizations develop in the vapor space. The surface is caused by the fact that the accumulation is accompanied by gas components ΣCH4, CO2, O2, which are potential-setting

compounds of the redox potential.

Based on the formulated models of polarizability and resistance, the results of the IP method were analyzed in areas where the following features of the anomaly of polarizability and resistance were established.

Thus, the established features of the anomaly of polarizability and resistance determined the nature of pollution with petroleum products, on the one hand, and, on the other hand, revealed them at an early stage of pollution.

Tracing iron mining dam collapse pollutants from the Fundão-Mariana accident (2015), using Nd-Sr isotopes in sediments from the Doce River and adjacent marine environment

Claudio de Morisson VALERIANO[1]*, Rio de Janeiro State University
(valeriano.claudio@gmail.com)
Heitor Evangelista[2], Rio de Janeiro State University
Catarina Herdy Ferraz[3], Rio de Janeiro State University

Abstract

This work presents Sm–Nd and Sr isotope TIMS data on the fine-grained fraction (< 74 μm) of iron-rich deposits related to the November 5th, 2015 Mariana accident, caused by the rupture of the Fundão dam, an iron tailings pond operated by SAMARCO Mining. The failure of the Fundão dam provoked the gravitational flow of approximately 62 Mi m3 of quartz and iron oxide-rich slurry composed of water, fine sand and silt that flowed into the Gualaxo do Norte and Carmo rivers, and eventually along the whole Doce River, reaching the shoreline in 15 days.

Samples were collected along the proximal and distal Doce River banks and from the marine shelf environment, including the Abrolhos coral bank, using sediment traps installed on the ocean bottom.

Using the Nd-Sr isotopic fingerprint of the proximal iron-rich mud that flowed out of the ruptured dam, and of the Doce River mouth fine-grained sediment, seasonal patterns of pollutant input in the marine environment are controlled by environmental factors such as stormy weather from advancing cold fronts which cause renewed resuspension of contaminated sediment, and by the seasonal regime of oceanic currents along the eastern-Brazil continental shelf.

Periodic monitoring of the isotopic composition of marine sediment during the last nine years indicates a gradual decrease of the impact of the iron-rich sediment plumes from the Doce River mouth.

Abstract

This study was conducted with the aim of effectively purifying groundwater pollution caused by VOCs on the Shimousa upland in the northern part of the Boso Peninsula in central Japan.
At the two targeted groundwater polluted sites, continuous borings were used to understand the detailed hydrogeological structure and vertical strata pollution status, taking into account the pollution sources and the distribution of polluted wells. Next, observation wells installed for each aquifer revealed the direction of groundwater flow and the distribution of polluted concentration in each layer.
As a result, at Site 1, five aquifers exist up to a depth of 100 m, and groundwater pollution exceeding Japanese groundwater environmental standards was found in the first and second aquifers. The source of the pollution is on the Shimousa upland at approximately 25 m height. Pollutants flow into the groundwater at a point 10m westward in an unsaturated zone approximately 10m thick from the pollution source in the surface layer, and then flow northwest through the 1st aquifer approximately 18m thick in a width of approximately 15m. The high concentration polluted water advects in a band along the groundwater flow, and flows out as polluted spring water in a valley 200m away at about 8m height. In addition, since the groundwater head of the 2nd aquifer is approximately 5.2 m lower than the groundwater head of the 1st aquifer, pollutants could pass through the gap between the well pipe and the borehole at the location of a private well. It invaded from the 1st aquifer to the 2nd aquifer. From there, it flowed north-northwest in the second aquifer, reaching another well approximately 150 m away.
At Site 2, three aquifers exist up to a depth of 50 m, and groundwater pollution was observed in the 1st and 2nd aquifers. VOCs penetrated into the unsaturated zone almost vertically from the pollution source, entered the 1st aquifer, and advected east-southeast along the direction of groundwater flow. The groundwater head of the 2nd aquifer is approximately 3.4 m lower than that of the 1st aquifer, so while pollutants flow through the 15 m thick 1st aquifer, there flow into the second aquifer within approximately 100 m. Pollutants were advected to the second aquifer

through the gaps between the well pipes and boreholes of four private wells installed in the 2nd aquifer. The pollutants then flowed west-northwest to west in the2nd aquifer.
Based on the above, pumping wells need to have a structure that prevents the deep diffusion of pollutants such as the following. It is necessary to install a screen in only one aquifer, and to fill the backfill part of other aquifers and impermeable layers with impermeable materials, such as cement slurry. Furthermore, since the flow direction of groundwater differs for each aquifer, in order to take effective purification measures, it is necessary to monitor and take purification measures for each aquifer.

Identification of *As-III and As-V species in As-contaminated water using cupric acetate monohydrate*

Swati GANVEER[1]*, IIT Kharagpur (ganveerswati95@gmail.com)
Kamal Lochan Pruseth[2], IIT Kharagpur

Abstract

Arsenic contamination in various environmental matrices, including water, soil, and food, poses significant risks to human health. Different arsenic species exhibit distinct toxicities, making its identification essential. Traditional analytical techniques such as chromatography and spectroscopy provide accurate results, but are often time-consuming and require expensive instrumentation. There are several analytical methods for the detection of arsenic. Colorimetry is the simplest of them. Till now in colorimetry, methods such as molybdenum blue, Pyrocatechol Violet Method etc. are limited to the detection of arsenite (*As-III*) only. The use of cupric acetate for arsenic detection can be traced back to older scientific literature and textbooks on analytical or environmental chemistry. Despite the absence of specific references, our experiments involved employing a saturated solution of cupric acetate monohydrate in contaminated water for the detection of both *As-III* and *As-V* in contaminated water. With synthetic solutions of pure *As-III* and *As-V*, we obtained green-coloured and light-blue-coloured precipitates, respectively. Precipitates of intermediate colours were obtained from natural As-contaminated water samples, reflecting the presence of both *As-III* and *As-V* in variable proportions in them. While the total quantity of the precipitate is indicative of the level of As-contamination, digital image processing can be used to quantify the colour components, from which the relative proportions of *As-III* and *As-V* can be estimated. This method holds promise for a cheap, quick and convenient means of determining As speciation in contaminated water.

Pb isotopic source tracing and mass balance on heavy metals from East Kolkata Wetland, a Ramsar site of West Bengal, India

KAMALAKANNAN D[1]*, NATIONAL CENTRES OF EXCELLENCE IN GEOSCIENCE RESEARCHES, GEOLOGICAL SURVEY OF INDIA, BANGALORE (kamalakannan.d@gsi.gov.in)
AVIJIT DAS[2], NATIONAL CENTRES OF EXCELLENCE IN GEOSCIENCE RESEARCHES, GEOLOGICAL SURVEY OF INDIA, CHQ, KOLKATA, INDIA

Abstract

The East Kolkata Wetlands (EKW) is a natural ecosystem recognized globally for its bioremediation model of treated sewage water. A detailed analysis was conducted on water samples collected from raw sewage canals, treated pond waters, subsurface sediments, and core sediments. Geochemical analysis showed that the mean concentration (mg/L) of trace metals in untreated pond waters was in the order of Mn > Cr > Fe > Ni > Zn > Cu > As > Pb > Cd, while that for treated pond waters, was Mn > Cr > Ni > Fe > Zn > As > Cu > Al > Pb > Cd. The mean concentration of sediment trace metals was in the order of Fe > Mn > As > Cr > Zn > Ni > Cu > Pb > Cd. The study revealed that the bioremediation of wastewaters containing Al, Cr, Mn, Fe, Pb, Ni, Cu, and Zn varied in different ponds. While reduced concentrations of Mn and Fe were observed in 98% of treated pond waters, 56% of ponds could not remove Zn and As. Mass balance calculations showed that the differential load after microbial treatment of wastewater decreased in the order of Cr > Ni > Cu and Zn. The mean load of trace metals in Core 1, Core 2, and sediments accounted for 17%, 24%, and 26% of the differential load released by wastewater treatment, respectively.

Furthermore, our comparison of the Pb isotopic ratios of EKW sediments and plant samples with potential Pb-rich sources revealed that EKW sediments and plant samples had the isotopic signature of diesel exhausts, coal burning, atmospheric particulates, and anthropogenic sources. The EKW sediments and plant samples exhibited a linear trend in the 207Pb/206Pb vs. 208Pb/206Pb plot, with plant samples having higher Pb isotopic ratios and mostly plotting close to street dust and Kolkata diesel. Sediment samples mostly clustered along the Jharia and Raniganj coals, confirming the sources of contamination.

Overall, our study provides valuable insights into the trace metal concentrations and their removal efficiency in the EKW ecosystem. The findings can serve as a guide for future efforts to enhance bioremediation of wastewaters and minimize the impact of anthropogenic activities on the environment. The results of this study have important implications for the conservation and management of wetlands worldwide.

Urban local body - Farmer partnership for sustainable waste management and organic farming

Kiran D A[1]*, Dayananda Sagar College of Engineering and Indian Institute for Human Settlements, Bengaluru, India (dakiran07@gmail.com)
Pushkara S V[2], Indian Institute for Human Settlements, Bengaluru, India
Ramaraju H K[3], Dayananda Sagar College of Engineering, Bengaluru, India

Abstract

Urban local bodies (ULBs) in India struggle to manage their municipal solid waste (MSW) due to a lack of infrastructure, funds, and the viability of waste processing. Processing MSW is not sustainable since only about 25–30% of the operation cost could be recovered by the sale of recyclables. While some ULBs are processing waste by offering tipping fees or subsidies to waste processing units, many ULBs have not been able to do so. As a result of unprocessed waste, lakhs of tonnes of waste are piled up in landfills, causing harm to the environment. Indian farmers are moving towards the use of chemical fertilisers due to the unavailability, high cost, and inadequate supply of organic compost. The use of chemical fertilisers also has adverse effects on the environment.

Integrating these two challenges, the proposed approach is to demonstrate a simple and scalable waste processing model (Pit composting) to process biodegradable waste and to establish a partnership between ULBs and farmers wherein ULBs will set up composting pits on farmlands and supply biodegradable waste. The farmers will conduct composting operations and recover organic compost after two months.

Pit composting is a method of converting biodegradable waste into organic compost using pits below the ground. Composting pits of about 16 cubic meters are excavated and filled with biodegradable waste. Cow dung slurry is added to the waste material to initiate composting process. Pits are turned every week to provide aeration along with regular monitoring of temperature and moisture content. Water is sprinkled to maintain optimal moisture and temperature and ensure the stability of composting operations. Waste transforms into organic compost in 50-60 days, depending on the nature of waste material and environmental conditions.

A pilot study on this concept was conducted and treated 60 tonnes of organic waste sourced from nearby locality to produce 9 tonnes of organic compost. The capacity of pit composting technique is estimated at a maximum of 10 tonnes of fresh waste. The average yield per batch was approximately 15.35%. The nutrient content of the organic compost produced was checked against the compost quality standards. Implementing this approach of waste-to-composting model helps ULBs manage their waste management challenges and helps farmers by offering free compost, thereby reducing their carbon footprint, and promoting circular economy and sustainability by avoiding the accumulation of waste in landfills.

Chunmiao ZHENG[7], Eastern Institute for Advanced Studies, Eastern Institute of Technology, Ningbo, China

Abstract

The hydrogeological characterization of urban areas is challenging due to the heterogeneous groundwater dynamics in space and time. Impervious surfaces such as roads and building roofs increase the surface runoff at the expense of the aquifer recharge. The natural groundwater dynamics are also potentially altered by local groundwater withdrawals for domestic or industrial uses, producing long-term modifications in the contaminant transport. Leakage from the water supply network and sewer pipes may trigger unconventional recharge, contaminating the aquifers. In this heterogeneous and challenging context, the urban aquifers of Shenzhen, a fast-growing Chinese megacity (Guangdong, China) with almost 24 million inhabitants, are investigated. The megacity has a subtropical climate with an average rainfall rate of 2000 mm/y with summer rainstorms causing frequent waterlogging and floods.

The groundwater system of the area consists of shallow alluvial and lateritic aquifers, lying on less permeable igneous and sedimentary rocks. The shallow aquifers are vulnerable to contamination because of the exiguous water table depth, generally in the range of a few meters. In this study, groundwater samples from 10 monitoring wells, with a depth ranging between 10 to 50 meters, are collected to assess the groundwater quality. The collection and analysis of urban groundwater have been conducted during the wet and dry seasons. Ion chromatography (major elements) and ICP-MS (trace metals) were used to characterize the hydrogeochemistry of the aquifers. Despite the abundant rainfalls, nitrate levels often exceed the threshold value suggested by the World Health Organization (50 mg/L). To delineate the source of contamination and investigate the presence of denitrification processes within the aquifers, 15N and 18O isotopic analyses were carried out.

Groundwater samples were also tested for 98 types of antibiotics. The samples were analyzed using the LC–MS technique. All groundwater samples are contaminated by a range of 10 to 35 types of antibiotics. In most cases, the concentrations are less than 1 ng/L but some compounds show worrisome levels (up to 19.41 ng/L). The most commonly detected types of antibiotics are

macrolides and quinolones. Roxithromycin and azithromycin had been detected in all samples. The highest concentration is azithromycin, 7.40 ng/L on average. Preliminary elaborations do not highlight correlations with the reconstructed hydrogeological background, supporting the hypothesis of local contaminations. An increment of the urban recharge rate with nature-based solutions and sponge City installations may mitigate the waterlogging and flood risk but, at the same time, further deteriorate the groundwater quality throughout the megacity.

Exploring Management Practices of Tailings and their Impact on the Downstream Economies and Environment; insights from Uis, Namibia.

Hilya Ndeyapo AMUKWA[1]*, The Geological Survey of Namibia / Federal Institute of Geosciences and natural science (BGR) Ministry of Mines and Energy (hamukwa@gmail.com)
Absai Vatuva[2], University of Namibia

Abstract

The mining industry plays a substantial role in improving the quality of life by creating jobs, skills and knowledge, contributing to the Gross Domestic Products and Foreign Direct Investment, improving infrastructures, public health services, education and government revenues. However, there are volumes of studies on negative socioeconomic (e.g. ghost towns) and environmental consequences of mining which are mostly considered as base in determining the level of sustainability of mining activities. Thus, the information at hand is biased and often mislead the regulators and public at large. The thriving settlement of Uis is here in under study for what seems to be related economic activities of the mining settlement with respect to the Mine Closure Framework of the Chamber of Mines and Ministry of Mines and Energy. The Uis settlement was established in 1958 as workers' settlement to exploit tin deposits. The study is based on a detailed review of available literature and field observation. In addition, a qualitative approach was adopted that included interviewing key stakeholders in the about the extent of their awareness on tailing management/mine closure framework and plans for contribution in the economic growth of the settlement. Positive impacts that can result from sustainable tailings management practices on downstream economies as observed in Uis include the brick making industry where unique processes is used to extract clay from old mine slime dams to produce high strength quality bricks under environmentally friendly conditions. The tailings ensure a stable supply of bricks making raw materials and thus at the same time rehabilitating the mine. The water filled old pits in Uis serve as tourist attraction site and fish farming for local communities. Furthermore, other old tailings can be exploited for critical metals such us lithium that were previously not considers. While the activities in the Uis settlement may be coincidental to the Mine Closure Frameworks, such downstream economic diversification in Uis may be exemplary to establishing smart and thriving mining towns.

The Lower Paleozoic strata in the Baltic Syneclise (NE Poland) – reconstruction of paleoenvironmental conditions based on the distribution of biomarkers

Pawel KOSAKOWSKI[1]*, AGH University of Krakow (kosak@agh.edu.pl)
Adam Zakrzewski[2], AGH University of Krakow
Jan Pańczak[3], AGH University of Krakow

Abstract

The Baltic Basin (BS) is situated along the western edge of the East European Craton and comprises several regional tectonostructural units. The Polish onshore part of BS is called the Peribaltic Syneclise. The thickness of the Early Paleozoic deposits to the east of the basin ranges from 500m, increasing to approximately 4000m in the west, close to the Teisseyre-Tornquist Zone. Geologically, the Baltic Syneclise is a bridge between the East and West European platforms.

The Ordovician and Silurian deposits contain relatively homogeneous type II and I kerogens. In analyzed deposits, the most abundant n-alkanes were n-C17, n-C18, and n-C19. This type of n-alkane distribution is associated with the aquatic phytoplankton-origin organic matter.

To evaluate the content of bacterial and algal input in the analysed samples, a regular steranes/17a hopanes ratio was also calculated. Hopanes are linked to bacterial inputs, and steranes are linked to algal inputs. Hence, the results above 1 indicate an advantage of algal over bacterial input. Redox conditions play a crucial role in preserving the original steranes/17a hopanes ratios. When deposition occurs under anaerobic conditions, the ratio should provide proper results. In cases where aerobic degradation was observed, the ratio might be underestimated, as during the destruction of steroids, the heterotrophic and methylotrophic bacteria produce hopanoids.

In the Silurian deposits, the bacterial input played a greater role than the algae in organic matter origin. Algal input played an integral role in the Ordovician.

Among bacterial phytoplankton, the cyanobacterial presence was noted as 7- and 8-monomethylheptadecanes were marked in all samples. Most of the samples did not contain okenane, isorenieratane, b-carotane diaryl isoprenoids, and aryl isoprenoids, indicating that bacterial input is not linked with sulphur-reducing bacteria. Diaryl isoprenoids were observed only in single samples, suggesting the presence of their within the oxygen-depleted photic zone.

The sterane distribution in the Silurian deposits exhibited a higher content of C29 steranes, which in this case can be linked primarily with a higher content of green algae with potential terrestrial organic matter admixture. Additionally, all Ordovician samples contain cyclohexylalkanes, which might be interpreted as a Gloeocapsomorpha Prisca algae fingerprint.

Organic matter in the Silurian deposits contains potentially little terrigenous input. The presence of retene links e.g., with primitive bryophytes supports this hypothesis. However, it must be noted that retene was also found in Cambrian deposits (sourced from green algae). Moreover, some samples contain perylene, which is typically linked with fungi. All Ordovician and Silurian samples contained dehydroabietate-acid methyl ester (DAME), which is a compound normally

linked to conifers. Its presence is unusual in the Ordovician and Silurian samples. DAME may be a reflection of cyanobacterial activity.
The distribution of biomarkers in the Ordovician rocks can be an indicator of the basal Katian global cooling event in dysoxic bottom water conditions. In turn, the distribution of biomarkers in Silurian rocks indicates that they may reflect a global anoxic phenomenon linked with mass extinctions, e.g., the Ireviken Event.
The studies were financed by the National Science Centre, Poland (no. 2016/21/B/ST10/02079) and AGH University of

Abstract

The annual average mass concentration of NO2 decreased by only 3% in China, from 29.3 μg m-3 in 2015 to 27.7 μg m-3 in 2019. There is even a trend of worsening pollution in the Pearl River Delta. The reason is that NO2 pollution is related to transportation emissions, whose contribution to NO2 reaches 30-80% in China. The North China Plain (NCP) has densely populated urban agglomerations, with constantly growing populations and increasing traffic volume. Therefore, it is a crucial research area for NO2 exposure risk. The reduction effect of emission control on NO2 concentration is not significant, and the NO2 concentration remains at 48.3 μg m-3 in the 2019 winter in North China Plain. However, as an important factor of respiratory risk, the relationship between NO2 exposure and respiratory outpatient visits has rarely been studied in China. Based on the Generalized Additive Model with the dual pollution lag model, the respiratory outpatient visit dataset is used to evaluate health related risk (RR) and excess risk (ER). The RR value with a 6-day delay is 1.052 (95% CI: 1.038, 1.066) and the ER value is 5.18% (95% CI: 3.75%, 6.63%). There is a highly significant correlation and lag between NO2 exposure and the number of respiratory outpatient visits. Combining the NO2 concentration simulated by the WRF-Chem model explore the temporal and spatial distribution of excess number of outpatient visits. The results show that urban areas exhibit a significant burden of health risks. This study emphasizes the importance of controlling NO2 pollution in urban areas for public health.

Estimative engineering geological zoning for the disposal of municipal solid waste

Olga Nikolaevna EREMINA[1]*, Sergeev Institute of Environmental Geoscience RAS (o_eremina@mail.ru)
Irina Vladimirovna Kozliakova[2], Sergeev Institute of Environmental Geoscience RAS

Abstract

Disposal of municipal solid waste (MSW) in the geoenvironment and choosing suitable locations for arrangement of landfills appears to be an urgent global problem. Upon solving this interdisciplinary multi-criteria problem, geological factors are usually underestimated or ignored. The study is aimed at working out the methodology of assessing the geoenvironment favorability for allocation of MSW landfill facilities within ancient geological platforms by the example of the Moscow region, Russia. The method is based on estimative engineering geological zoning and building estimative maps of geoenvrionment favorability. At the first step of research, the geological cross-section in Moscow area was assessed from the standpoint of its ability to provide a natural protective barrier from pollutants generated by MSW landfills. In Moscow region, the geoenvironment protection is mainly ensured by the presence of persistent by strike and thickness,low-permeable strata of preQuaternary (midJurassic clay) and Quaternary (glacial moraine) age. Two types of preQuaternary and three types of Quaternary massif structures were distinguished according to the presence and number of impermeable geological layers, and their observed combinations resulted in 8 types of geological massifs. The generalized lithological columns were built for all ground massif types showing layers of different water permeability to a depth of about 50m. At the second stage, two auxiliary information layers for preQuaternary and Quaternary deposits were compiled in the QGIS code (to a scale 1:200 000) and their superposition permitted us to compile a digital map of typological engineering geological zoning of the studied region in accordance with the developed typification. The next research stage involved ranking the ground massif types according to the categories of suitability for allocation of MSW landfills and performing the special estimative engineering geological zoning and mapping. The estimative zoning of the Moscow region for the disposal of MSW was aimed at ranking the territory according to the complexity of carrying out waste-management measures. We assume that zoning should be based on warnings for the relevant authorities and companies about the problems they may face when placing landfills in a particular area rather than on prohibitions. All ground massifs identified upon typification were classified as favorable, conventionally favorable and unfavorable categories in terms of MSW disposal. The spatial distribution of territories showing different favorability categories was shown on the map of estimative engineering geological zoning for the allocation of MSW landfills. This map gives us an idea of the possible difficulties upon waste disposal in a particular area. Thus obtained cartographic

assessment of territory suitability for MSW disposal, in our opinion, looks easy and understandable. It may be used by decision-makers for the general multi-criterial assessment as an individual informational layer. At the same time, the proposed typification of geoenvironment makes allowance for the main specific features of the geological structure in the considered area.

Spatial Analysis and Probabilistic Risk Assessment of Heavy Metal Contamination in Urban Soils: A Case Study from Seoul, South Korea

Hyunsoo Seo[1]*, Korea University (sallyseo2000@korea.ac.kr)
Kyoung-Ho Kim[2], Korea Environment Institute, Environmental Assessment Group
Jaehoon Choi[3], Korea University
Jin-A Kim[4], Seoul Metropolitan Government Research Institute of Public Health & Environment
Je-Seung Lee[5], Seoul Metropolitan Government Research Institute of Public Health & Environment
Seong-Taek Yun[6], Korea University

Abstract

Urban landscapes have drastically changed due to excessive construction, including excavations and developments below ground. Concurrently, this transformation has led to alterations in the natural state of environmental media, such as soil, predominantly through the emission of various pollutants. Among these pollutants, heavy metals like copper (Cu), zinc (Zn), arsenic (As), and lead (Pb) play a crucial role in environmental assessments due to their lasting impact on both ecological and human health risks. This study aims to provide a detailed evaluation of the source, distribution, and contamination levels of these heavy metals, utilizing analysis data from 2,957 locations within Seoul, South Korea, one of the world's most rapidly expanding metropolitan areas.

Statistical methods such as the additive log-ratio transformation-expectation maximization (EM) algorithm were used to process left-censored data below the limits of detection. Through variogram analysis and ordinary kriging, we mapped heavy metal concentrations on a 100m grid, uncovering specific spatial patterns: elevated concentrations of Cu, Pb, and Zn were predominantly found in the southwestern regions of Seoul, while As levels were additionally higher in the northeastern parts. These findings suggest the significant role of land use in determining heavy metal dispersion in the city.

To investigate the uncertainties of the heavy metal concentration predictions, we conducted Sequential Gaussian Simulation (SGS) a thousand times. This approach gave us a probabilistic perspective on soil contamination levels. Moreover, we mapped the distribution of vulnerable populations (elderly and infants) against the total population to identify exposure risks. Analysis indicated a higher ratio of the elderly population in the northern and southeastern regions, with a higher infant population ratio in the central and southeastern areas of Seoul. Integrating these demographic maps with our heavy metal data and utilizing the USEPA framework, we evaluated potential health impacts through hazard indices for each group.

This comprehensive spatial and probabilistic risk assessment of heavy metal contamination in urban soils provides invaluable insights into the characteristics, distribution, and exposure risks of these pollutants. The results underscore the need for targeted risk reduction strategies in cities, emphasizing the integration of environmental and demographic data for comprehensive urban health risk assessments. This research offers crucial insights for developing informed policies and actions in metropolitan regions, targeting the protection of public health and the environment.

Assessment of Current Water Quality Status of Rivers near Two Major Cities in Myanmar

Arkar SAN[1]*, Kangwon National University (arkarsan2013@gmail.com)
Hyunook KIM[2], University of Seoul
Heejung KIM[3], Kangwon National University

Abstract

Water resources in Myanmar are gradually being threatened by localized pollution problems resulting from various economic development activities. The government of Myanmar recognizes the importance of protecting the country's water resources in the development process and some basic policies and regulations relating to water resources management have recently been developed and relevant government ministries are striving for enforcement. When it comes to water quality management of fresh water sources (rivers, streams, etc.), enforcing the regulatory instruments, such as quality standards, requires regular inspection and monitoring of water quality through water quality monitoring network established on major rivers. However, none of the responsible ministries are capable of monitoring river water quality on a regular basis. The scope of the research is mainly focused on assessing current water quality status of rivers near two major cities of Myanmar: Yangon and Mandalay. Based on the water quality data obtained from analyzing water samples collected from those rivers, the research can assess the current status of rivers near Yangon and Mandalay. The research can also make recommendations for taking actions to monitor and inspect changes in water quality to prevent the rivers from pollutions through the establishment of national level water quality monitoring program consisting of a laboratory and monitoring stations.

CO2 measurement with high spatiotemporal resolution using low-cost sensors in urban Seoul, South Korea

JaeYoung PARK[1]*, Seoul National University (jypark1101@snu.ac.kr)
JeongEun Kim[2], Seoul National University
Jinho Ahn[3], Seoul National University

Abstract

Carbon dioxide (CO2) is the most important anthropogenic greenhouse gas, and is the most prominent cause for the ongoing climate crisis. Urban areas contain a majority of the world's poulation, and this leads to disproportionate utilization of resources and emission of CO2. Due to highly diverse land use of the urban areas, surface CO2 concentration show significant spatiotemporal variability. This can lead to challenges in accurately estimating CO2 emission of cities using a top-down approach. Furthermore, previous studies about bottom-up methods of estimating carbon flux show considerable uncertainties.

In this study, we utilized low-cost NDIR CO2sensors assembly to measure CO2 concentration in high spatiotemporal resolution. Since low-cost NDIR sensors are prone to high degree of deviation from the true concentration, the measured values were subjected to a post-procedure calibrating step for baseline error, humidity, and temperature, using a high-performance NDIR sensor for measuring accurate CO2 concentration. We found that the sensor assembly's data and the smoothed high-performance sensor data correlated well. After correcting the low-cost sensors, we have reduced the average RMS of the sensors to 5ppm.

We also present a visualization of CO2 concentration. By plotting the measurement over the map of the region, locations with high or low CO2 concentrations can be easily spotted. We observed a high concentration of CO2 and heavy fluctuations around traffic junctions and crossings.

Regional features of ecological-geological systems of rock massifs in Kamchatka

Violetta SHANINA[1]*, Lomonosov Moscow State University (violettav@inbox.ru)

Abstract

The purpose of the study is to characterize the regional features of the ecological-geological systems of rock massifs in Kamchatka, compiled on the basis of the author's own field research (ten field seasons) and published literature data. The abiotic components of the upper structural layer of the geological section characterize the Quaternary stage of development of the Kuril-Kamchatka island arc and are composed of rocks of Pleistocene-Holocene age, lava flows from basalts to dacites and tuffs of a similar chemical composition. According to their properties, rocks are divided into several groups: 1) massive andesites - dense (2.42-2.51 g/cm^3), with a low density of the solid component (2.64-2.76 g/cm^3) (well consistent with their composition – SiO2 content (62.7-64.1%)); 2) basalts - medium: density (2.23-2.25 g/cm^3), porosity (21-24%), absolute permeability (0.30 mD); 3) porous basalts - low density (0.97-1.73 g/cm^3) and strength (7-12 MPa), maximum: porosity (40-66%); 4) silty tuffs: density 1.40-1.57 g/cm3, density of the solid component 2.70-2.72 g/cm3, porosity 42.2-48 .2%; 5) fine psephitic tuffs are dense (ρ = 1.59-1.80 g/cm3), density of the solid component is 2.72-2.78 g/cm3, porous (33.8-42.7%); 6) pumice tuffs are characterized by the lowest density (ρ=0.98-1.35 g/cm3) and the highest porosity (n=49.8-63.5%). The edaphotope: the ecological and geological systems of rock massifs in Kamchatka include volcanic soils, which are formed mainly under grassy stone-birch forests on volcanic loose layered deposits of varying thickness and composition under conditions of periodic new ash inputs. The thickness of soils located on the tops of positive forms is usually 1.5-3 times less than on their slopes and depressions, which indicates the redistribution of freshly fallen ash along the slope, not yet held together by plant roots. Biotic components: microbial communities are widespread in surface waters, including facultative autotrophic and heterotrophic bacteria, cyanobacteria, sulfate-reducing bacteria, filamentous organisms, and microscopic fungi. The phytocenosis: the vegetation includes about 1,200 species of vascular plants. Including more than 100 species of trees, shrubs, subshrubs, shrubs and other plants with woody stems. Of the trees, the most common species is the Erman birch, or stone birch. The zoocoenosis: the mammal fauna includes more than 40 species; birds - more than 250 species, almost 150 of them are nesting. The poverty of species composition, the absence of a number of families and genera common in neighboring continental territories, as well as endemic species, is due to the history of the Kamchatka Peninsula, characterized by processes that negatively influenced the formation of biodiversity in the past (marine transgressions, relief transformations, active volcanic activity, ice ages and subsequent followed by changes in landscape appearance, etc.). The ecological-geological systems formed on the rock massifs of Kamchatka are a complex formation. The most important features of ecological-geological systems are mainly determined by their lithogenic basis - rocky soils (andesites, basalts and dacites), which have specific properties. The composition and properties of the lithotope largely determine the properties of the edaphotope and

the species composition of phytocenoses and have less influence on the zoocenosis.

Spatiotemporal characterization of iron and manganese distribution in a stratified aquifer during in-situ chemical oxidation operation

Seoyoung SON[1]*, Dept. Earth, Environmental & Space Sciences, Chungnam National University (sys3524@cnu.ac.kr)
Sungmin Park[2], Dept. Civil and Environmental Engineering, Hanyang University
Jae-Woo Park[3], Dept. Civil and Environmental Engineering, Hanyang University

Wonmi Kim[5], GNS Engineering
Heewon Jung[6], Dept. Geological Sciences, Chungnam National University

Abstract

In-situ chemical oxidation is a remediation method that involves injecting oxidants into contaminated aquifers to remove contaminants by facilitating geochemical reactions such as precipitation, adsorption, and decomposition of contaminants. This study utilized a reactive transport modeling approach to characterize the precipitation of iron hydroxides and manganese sorption during the injection of oxygenated water under various flow conditions. When horizontal flow of the oxygenated water is induced within a highly permeable layer of a stratified aquifer, a relatively small volume of ferric hydroxide precipitation occurs exclusively within the layer. Furthermore, the injected water reaches the withdrawal well before being fully consumed, and it mixes rapidly with the indigenous groundwater containing a high concentration of dissolved iron, leading to the concentrated precipitation of ferric hydroxides near the withdrawal well. In comparison, when wells are positioned at different depths inducing vertical flows, more ferric hydroxides precipitate within the domain due to the larger interfacial area between the injected water and surrounding groundwater. The injected oxygen is consumed completely before reaching the withdrawal well due to enhanced mixing within the aquifer, and hence no substantial precipitation of ferric hydroxides near the withdrawal well is observed. The simulation results also illustrate that reduced pH due to ferric hydroxide formation causes overall desorption of manganese despite increased sorption surface of ferric hydroxides. These simulations result indicate the importance of rigorous consideration of hydrogeochemical processes for the success of in-situ groundwater remediation projects.

Assessment of heavy metal pollution in marine sediments around southern waters of Gyeonggi Bay

Hyerim LEE[1]*, Pukyong National University (hyerim_lee@pukyong.ac.kr)
Seonggan Jang[2], Pukyong National University
Seongwoo Jeong[3], Pukyong National University
Minjune Yang[4], Pukyong National University

Abstract

In the marine environment, heavy metals can adsorb and precipitate onto marine sediment particles, resisting degradation in nature. Moreover, these metals have the potential to bioaccumulate through the food chain, posing health threats to humans. This study evaluated heavy metal pollution and environmental risk by analyzing the content of heavy metals in marine sediments in the southern waters of Gyeonggi Bay, South Korea, adjacent to a large-scale industrial complex. Sampling was carried out at 14 sites to measure concentrations of As, Cd, Cr, Cu, Ni, Pb, and Zn. The total heavy metal content was determined using an Inductively Coupled Plasma Mass Spectrometer (ICP-MS, iCAP Pro X, Thermo Fisher Scientific) at the Integrated Analytical Center for Earth and Environmental Sciences after pretreated samples using a mixed acid solution (HF:HNO3:HClO4 in a 4:4:1 ratio). Pollution and risk assessments were conducted using the Geo-accumulation Index (Igeo), the Korea Sediment Quality Guideline (SQG), and the Ecological Risk Index (ERI). The results indicated that the Igeo was less than 1 at all sampling sites, suggesting no contamination. According to the ERI, all elements were classified as having a 'LOW' impact rating on the benthic ecosystem. However, concentrations of Cu and Zn exceeded the Threshold Effects Level (TEL) at five sites (Cu average: 21.9 mg/kg; Zn average: 76.5 mg/kg), slightly surpassing the SQG (Cu: 20.6 mg/kg; Zn: 68.4 mg/kg). These findings confirm the current low level of heavy metal pollution in the study area. Nonetheless, the continuous influx of pollutants from nearby industrial complexes may pose future risks to the marine environment and human health. Thus, sustainable management and continuous monitoring of the marine environment are recommended.

Tracking tobacco-specific nitrosamines (TSNAs) source in fertilizer: an environmental forensic approach

Min-Hui Son[1]*, National forensic service (NFS), Chemistry division (sonmh07@korea.kr)
Hyun Jee Kim[2], National forensic service (NFS), Chemistry division
Yuna Kim[3], National forensic service (NFS), Chemistry division

Abstract

Tobacco-specific nitrosamines (TSNAs) generated from tobacco alkaloids (i.e., nicotine) are one of carcinogens and these are representative compounds shown in tobacco products. Among seven TSNAs including N'-nitrosonornicotine (NNN), 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanon (NNK), N'-nitrosoanabasine (NAB), N'-nitrosoanatabine (NAT), 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL), 4-(methylnitrosamino)-4-(3-pyridyl)-1-butanol (iso-NNAL) and 4-(methylnitrosamino)-4-(3-pyridyl) butanoic acid (iso-NNAC), NNN and NNK are group I carcinogens and it is easily detected in commercial tobacco, e-cigarettes and even mainstream smoke. However, there was no report on measurement of TSNAs in secondary processed products of tobacco dregs and this study was designed to detect TSNAs in that. In a small village in Korea from 2001 to 2017, tobacco-leaf residues were illegally utilized to produce fertilizer and 17 of residents have lost their lives with various forms of cancer during this period. In general, dregs of tobacco leaves cannot be used as a raw material of fertilizer due to the carcinogenicity of TSNAs. Therefore, we tried to track TSNAs source of the fertilizer by investigating 10 different tobacco products produced from 4 manufacturers. In this study, we firstly measured levels of TSNAs in the fertilizer to prove the use of tobacco dregs and contrasted the distributional patterns of TSNAs between fertilizer and tobacco products by applying heat. In conclusion, levels of all TSNA compounds were increased by heating process and the proportion of NNN, NNK and NAB was high, except for NAT.

The relationship between the intensified heat waves and deteriorated summertime ozone pollution in the Beijing–Tianjin–Hebei region, China, during 2013–2017

Ruonan WANG[1]*, Institute of Earth Environment, Chinese Academy of Sciences (wangruonan@ieecas.cn)
Guohui Li[2], Institute of Earth Environment, Chinese Academy of Sciences

Abstract

Summertime ozone (O3) pollution has frequently occurred in the Beijing–Tianjin–Hebei (BTH) region, China, since 2013, resulting in detrimental impacts on human health and ecosystems. Increasing O3 in BTH has been partially attributed to the mitigation of precursor emissions and deceased particulate matters which slow down the hydroperoxyl radical absorption on aerosol surfaces. However, the contribution of weather shifts to O3 concentration variability owing to climate change remains elusive. By combining regional air chemistry model simulations with near-surface observations, we found that anthropogenic emission changes contributed to approximately 23% of the increase in maximum daily 8-h average O3 concentrations in the BTH region in June–July–August (JJA) 2017 (compared with that in 2013). With respect to the weather shift influence, the frequencies, durations, and magnitudes of O3 exceedance were consistent with those of the heat wave events in the BTH region during JJA in 2013–2017. Intensified heat waves are a significant driver for worsening O3 pollution. In particular, the prolonged duration of heat waves creates consecutive adverse weather conditions that cause O3 accumulation and severe O3 pollution. Our results suggest that the variability in extreme summer heat is closely related to the occurrence of high O3 concentrations, which is a significant driver of deteriorating O3 pollution.

Environmental pollution problems in the mining regions

Elena Nikolaevna LEVCHENKO[1]*, FSBI IMGRE (lev_imgre@rambler.ru)
Igor Gennadievich Spiridonov[2], FSBI IMGRE

Abstract

Intensive economic development entails an inevitable increase in the mineral consumption. In this regard, the increase in mineral production during the last century, a sharp increase in the mining activities contribut-ed to the accumulation of mining waste and man-made pollution of ecosystems. Besides, despite the obvi-ous benefits of mining for the benefit of man, on the other hand, it is also a powerful source of environ-mental hazards.

The mineral deposits' mining alters the basic physicochemical properties of the lithosphere, including its major functions, i.e., geodynamic, geophysical, resource, and geochemical. The study of changes in the ecosystem's parameters during the life period of a mine is one of the key goals of an ecological-geochemical assessment.

The environmental monitoring should be carried out at all stages of the mining area's life, from exploration to mining, and further reclamation of disturbed lands and until the site becomes completely stabilized.

Ecological and geochemical studies make the basis of this paper, including the identification of areas of environmental pollution by toxic substances, assessment of their extent and chemistries; assessment of po-tential geochemical endemicity; zoning of the territory by its pollution level and the degree of environmental hazard, identification of the pollution sources; identification of potential man-made objects; ecological and geochemical monitoring and forecast of the development of negative processes; development of recommendations for the rehabilitation of areas of poor ecological condition; identification of populations with an increased risk of morbidity. The result of these studies is the compilation of ecological and geochemical maps portraying the ecological status of the territory.

The study of the environmental health is carried out in the following main areas:

mapping of the man-made pollution in soil and snow cover; establishment of the response characteristics of the plants to pollution of the soil pollution; geochemical studies of ground / surface water and stream sediments; analysis of the atmospheric air chemistries, precipitation and aerosols, as well as the industrial waste materials as sources of environmental pollution and potential objects for the extraction of secondary raw materials; relationships of environmental pollution and health indicators of the population living in the pollution hot spots.

Arsenic contamination in ground water, mechanism and role of subsurface sediments for high arsenic concentration, in the Flood Plain of Ghaghara River, Uttar Pradesh. India

Abhinandan SRIVASTAV[1]*, Geological Survey of India (a.srivastava@gsi.gov.in)
Nikhat Naim[2], Geological Survey of India

Abstract

Contamination of groundwater, either from anthropogenic or natural sources with several social impacts, has now turned to be a major environmental concern in different parts of the world. Elevated level of Arsenic in groundwater has been well documented in Chile, Mexico, China, Argentina, USA, and Hungary as well as in several states of India (Smedley and Kinniburgh 2002; Bhattacharya et al., 2002). Arsenic, a well-known carcinogen, is considered as one of the world's most hazardous chemicals (USEPA 2001).

The ground water shows elevated level of Arsenic concentration in the Flood Plain of Ghaghara River, India, collected from shallow (5-15m) and deeper depth (20-45m). The groundwater of the study area is Ca-Mg-HCO3 dominant type and feebly alkaline with average pH value of 7.73. The (Ca + Mg) versus the total cations (Tz) reflects the abundance of Ca and Mg in groundwater. The average (Ca + Mg)/Tz ratio is 0.77 while the average (Na + K)/Tz ratio is 0.22 indicating that the contribution of cations into groundwater from carbonate weathering. Arsenic in groundwater exists primarily as oxy anions representing two oxidation states arsenite and arsenate (Ferguson, 1972; Cullen & Reimer, 1989). In order to investigate the mechanism of Arsenic release, the oxidation–reduction potential of the ground water has also been tested. The present study reveals that the groundwater from Holocene Newer Alluvial aquifers located close to abandoned channels or meander scars, at depth range of 20-45 m are more As-contaminated than the surrounding areas. The ground water, collected from the area exposing Newer Alluvium, mostly shows arsenic concentration above the acceptable limit of 10 ppb and negative ORP value (-7 to -175 mV; reducing condition) both at shallower and deeper depth. In the area which exposes the Older Alluvium the ground water mostly in oxidizing condition showing positive ORP value in the range of +10 to +270 mV and arsenic concentration was within the acceptable limit except at few places. The negative ORP values in ground water in some places were also noted exposing the Older Alluvium. In these area, the ground water does not show high arsenic concentration but mostly reddish in colour. The reducing condition in this area, favors the iron oxidation and change from Ferric oxides (insoluble Fe3+) to Ferrous Oxides (soluble Fe2+). The correlation of Arsenic concentration with the oxidation–reduction potential of the ground water indicates that the reducing environment favors the release of arsenic in the ground water from sediments that remain in sorbed state on the iron oxides surface in these sediments. Arsenic concentration in core sediments varies from 19 ppm to 285 ppm with an average of 124 ppm. XRD analysis indicate presence of lead arsenate Jordanite (Pb14As6S23) at the depth of 9-11 m in nonmagnetic fraction of coarse micaceous sand and Nealite (Pb4 Fe (AsO4)2Cl4) and Arsenolite (As2O3) at depth of

33-35 m in magnetic fraction of coarse sand. Scanning Electron Microscopy of the core sediments shows that the arsenic is mainly occurs in association with oxides of Fe, Si, Al, Mg and Cr

Composition and size distribution of wintertime inorganic aerosols at ground and alpine regions of northwest China

Haijiao Liu[1]*, Xi'an Institute for Innovative Earth Environment Research (liuhj@ieecas.cn)
Xingxing LIU[2], Institute of Earth Environment, Chinese Academy of Sciences
Jianjun Li[3], Institute of Earth Environment, Chinese Academy of Sciences

Abstract

Water-soluble ions (WSIIs) serve as indicators of atmospheric pollution sources, typically constitute 20% to 80% of the total mass concentration within PM2.5. WSIIs play a pivotal role in atmospheric chemical reactions, particularly influencing the formation of secondary particulate matter. Alpine regions experience a distinct atmospheric conditions characterized by low temperature, high humidity, and strong solar radiation, differing from those in lowland areas. A comprehensive grasp of the vertical distribution of WSIIs in atmospheric particles holds immense significance in understanding the diffusion and transportation of these pollutants. This study investigates the WSIIs of PM2.5 and size-segregated particles at the top (~2060 m a.s.l) and foot of Mt. Hua during the winter of 2020. All the measured ions present significant higher concentrations (1.9~6.9 times) at the foot than the top. Cl− and K+ at the foot are more than 4 times of those at the top, whereas Ca2+ and Mg2+ are only 1.3-1.9 times higher. The particle size distribution of NO3−, SO42−, K+ and Cl− demonstrate a single peak distribution (0.7-1.1 μm) at the foot, but with a bimodal distribution (0.7-1.1 μm and 4.7-5.8 μm) at the top. These differences suggest that the aerosol at the alpine region is mainly transported via long-distance from Northwest/North China, but limited influenced by vertical transport through valley breeze. The changes of concentration and size distribution of WSIIs in dust event and non-dust period indicate that the effects of dust event on aerosols at ground surface were weaker than that of the free troposphere of Guanzhong Plain. Notably, our study underscores the dominant influence of NO3− in shaping the gas-particle distribution of ammonia within the winter free troposphere. Our results highlight the significant role of long-range transport on aerosols in the free troposphere in Guanzhong Plain, Northwest China.

Occurrence and behavior of per- and polyfluoroalkyl substances (PFAS) and antibiotics in the hyporheic zone

Hyobin LEE[1]*, Kangwon National University (l_hyobin@kangwon.ac.kr)
Eunju Jeong[2], Kangwon National University
Jin-Yong Lee[3], Kangwon National University

Abstract

The release of chemical substances from industrial and domestic wastewater has been increasing over time, which has led to a rise in the presence of per- and polyfluoroalkyl substances (PFAS) and antibiotics in rivers. PFAS are synthetic compounds that have excellent thermal and chemical stability and are used in various applications such as food packaging, textiles, and coatings. Due to their persistent nature, low biodegradability, and high bioaccumulation potential, they can remain in the environment and human's body for an extended period if introduced into rivers. Additionally, antibiotics from pharmaceutical waste contribute to the promotion of antibiotic resistance genes in natural bacteria in rivers, leading to ecological disruption. These chemical substances have recently become a global concern due to their carcinogenicity, toxicity, and persistence. Despite their widespread presence in the environment, our current knowledge of contamination in the hyporheic zone, an ecologically crucial area, is still lacking. This study aims to investigate the distribution and behavior of PFAS and antibiotics in the hyporheic zone, where interactions occur between surface water and groundwater. Samples were collected from different points along the river, including upstream, midstream, and downstream points, as well as from groundwater wells to trace the pathways of contaminants accurately. Experiments were conducted based on seasonal climate conditions, distinguishing between dry and wet periods. This research is expected to have significant implications for sustainable environmental and water resource management and can be used as fundamental data for understanding groundwater contamination.
This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (No.2019R1A6A1A03033167).

EFFECTS OF ACID MINE DRAINAGE FROM COAL MINING ON WATER QUALITY IN THE ARARANGUÁ RIVER BASIN

Marlon Hoelzel[1]*, Geological Survey of Brazil - SGB/CPRM (marlon.hoelzel@sgb.gov.br)
Ana Maria Pimentel Mizusaki[2], Federal University of Rio Grande do Sul - URFGS
Anna Alice Couto Gomes[3], Geological Survey of Brazil - SGB/CPRM

Abstract

In the southern region of Brazil, coal mining has been going on for more than a century in the state of Santa Catarina, where the lack of environmental management in mining activities resulted in significant changes to the quality of surface and underground water resources in the local watersheds. Within this context is the Araranguá River Basin, whose substrate is made up of sandstone and pelitic sedimentary rocks of the Rio Bonito Formation, with Permian age. These rocks belong to the gondwanic interval of the Paraná Basin where there are several mining projects, many of them already exhausted, that have left as their legacy the presence of numerous abandoned mines and tailings piles that have caused intense changes in water quality due to the presence of sulphides which oxidize and result in the formation of acid mine drainage. The sedimentary units are usually silicified and are affected by ruptile tectonics resulting from the alkaline intrusion of the Lages Dome. This geological context, combined in part with pillar mining, leads to various episodes of collapses and subsidence of underground mines and intensifies the fracturing of overlying rocks, thus amplifying the processes of interaction between aquifer systems and surface water bodies. In order to improve understanding of the impacts on water quality and underground flow conditions, groundwater samples from nine wells in the Rio Bonito Aquifer System, four wells in the Alluvial Fan Aquifer System and six surface water samples from the same micro-basins where the wells are installed were analyzed. The hydrochemical analyses indicated an original predominance of calcium and sodium bicarbonate waters, which are transformed into sulphate waters when they come into contact with acid mine drainage. The $\delta 2H$ and $\delta 18O$ isotopic values of the samples show similarities with the isotopic composition of current meteoric waters, contributing to the hypothesis of strong interaction between groundwater and surface water.

Dust generated by e-waste processing: Impact of sample treatment and decomposition method on chemical and isotopic compositions

Eva Martinková[1]*, Czech Geological Survey (eva.martinkova@geology.cz)
Ondřej ŠEBEK[2], Czech Geological Survey
Alexandre ANDRONIKOV[3], Czech Geological Survey
Markéta ŠTĚPÁNOVÁ[4], Czech Geological Survey
Leona BOHDÁLKOVÁ[5], Czech Geological Survey
Jan ČUŘÍK[6], Czech Geological Survey
František VESELOVSKÝ[7], Czech Geological Survey

Abstract

The use of electrical/electronic equipment generates an enormous amount of e-waste. The technology of e-waste processing is very complex and technological lines are composed of many individual units. Consequently, a large amount of dust with extreme metal concentrations is produced. It has a very specific matrix and composition that differs from dust generated during other industrial activities and natural processes. The selection of decomposition method and sample processing are crucial for precise and accurate analytical measurements. Thus, the aim of the study was to find the most appropriate decomposition method of e-waste dust and to verify whether: i) sample pretreatment at different temperatures can cause the analyte leak and changes in the isotopic composition, ii) decomposition of samples with the use of different methods can affect concentration and isotopic results.

Samples were exposed to temperatures: i) 110 °C, ii) 550 °C, iii) 1050 °C and subsequently decomposed/leached by: i) aqua regia (HNO3, HCl in a ratio of 1:3), ii) concentrated acids HNO3, HClO4, HF, iii) fusion. Concentration analyses were performed by the ICP-OES Agilent 5110 and lead isotopes were measured by the MC-ICP-MS (Neptune).

In general, the most suitable decomposition methods with the highest yields were either decomposition by a mixture of concentrated acids with temperature pretreatment at 550 °C, or the aqua regia decomposition with temperature pretreatment at 110 °C. Element concentrations were as follows: 0.8 g kg-1 Cd, 24.1 g kg-1 Cu, 14.9 g kg-1 Pb, 24.7 g kg-1 Zn, 3.1 g kg-1 Co, 2.7 g kg-1 Ni, 35.9 g kg-1 Al.

We expected loss of the analyte in high temperature treatments associated with changes in isotopic composition of samples. At a temperature 550 °C with the aqua regia decomposition, only up to 61% Cd, 85% Cu, 45% Pb, 91% Zn were recovered compared to the highest yields. Nevertheless, there was no loss of the analyte during decomposition by concentrated acids and fusion. Similarly, at 1050 °C only up to 18% Cd, 20% Cu, 7% Pb, 9% Zn were recovered and again there was no analyte loss during fusion. We assume that there was no loss of the analyte due to its leak, but the effect of higher temperature resulted in the formation of difficult to decompose phases. Using the three isotope plot (206/207Pb vs 208/207Pb), samples decomposed by aqua regia at a temperature 110 °C and 550 °C were grouped in a separate cluster and differed in isotopic composition (average 206/207Pb, 208/207Pb values were 1.155; 2.437) compared to other values (206/207Pb,

208/207Pb were 1.154; 2.435 on average). Aqua regia (at 110 °C) seemed to be very efficient “decomposer” according to results of concentration analyses, however it probably did not release lead from the whole matrix of dust samples and it decomposed only easily accessible forms of lead. Our results show, that the most appropriate decomposition method is temperature pretreatment at 550 °C with subsequent decomposition by concentrated acids HNO3, HClO4, HF. This will be further verified on Cd and Zn isotopic systems.

State-of-the-art integration of digester, heating system and automation

Atta ur RAHMAN[1]*, Land Information and Management System (LIMS-COE)
(engineer.atta@yahoo.com)

Abstract

Pakistan faces an energy and economic crisis due abrupt increase in the population and mismanagement of available resources. The country is blessed with some energy resources. Beyond these available resources, biomass is a promising resource. Production of biogas from biomass is a famous technology all over the world. However, its adoption in Pakistan is less familiar due to the unavailability of standard design, winter choking, and temperature fluctuations. This study investigated two heating mechanisms in digesters and compared them with conventional (non-heating) digesters in winter. The two heating mechanisms include the PEX coil tubing inside the digester and the external water jacket. The experiment was recorded for one month in winter. Additionally, a low-cost automation system was introduced in both digesters to control the circulated water to maintain the required temperature. Results revealed that the jacketed digester produced 385.1 liters of biogas, the PEX tubing coiled digester produced 313.5 liters of biogas, and the conventional digester produced only 29.7 liters of biogas measured with the water displacement method digesting the same quantity of feedback. The conventional digester stopped after a few days working. The jacketed digester performed better than the other heating systems and was a promising technology for biogas production throughout the year. The study will help in the adoption of biogas technology in rural areas to meet their energy demands.

Contribution of Geogenic Radon for Indoor Air Quality using Grey-Box Modeling

Yijune CHOI[1]*, Korea University Earth and Environmental Sciences (cosmos101@korea.ac.kr)
Soonjae LEE[2], Korea University Earth and Environmental Sciences

Abstract

Managing indoor radon concentration is necessary due to a carcinogenic risk of radon. The main pathway of indoor radon pollution is vapor intrusion from the subsurface to buildings and investigating its amount is important for designing effective management strategies. This study assesses the contribution of geogenic radon through a grey-box model approach. Monitoring data encompassing indoor radon concentrations, temperature, relative humidity, and atmospheric pressure were collected over a month. The grey-box model was established by integrating a signal processing system and a physical-based model. Parameters of the grey-box model were optimized to minimize the disparity between monitoring data and physics-based predictions and used for investigating the contribution. The average indoor radon concentration during the monitoring was 1,104 Bq/m^3, significantly surpassing the action level of 148 Bq/m^3. The grey-box model exhibited strong predictive performance for indoor radon concentrations. Investigation into the main factors influencing indoor radon concentration identified ‘advection of gaseous phase’ and ‘volatilization of aqueous phase’ as primary transport mechanisms for geogenic radon. The model’s estimation capabilities demonstrate promise in assessing the contribution of each transport mechanism, facilitating the development of optimized mitigation strategies. This approach offers for optimizing mitigation strategies for individual contributors, enhancing indoor air quality and reducing carcinogenic risk.

Development of Vapor Intrusion Risk Assessment Program for Urban Subsurface Environments

Min Seo BAE[1]*, Department of Earth and Environmental Sciences, Korea University (mstt1@korea.ac.kr)
Soonjae Lee[2], Department of Earth and Environmental Sciences, Korea University
Jae-Hyun Kim[3], Department of Earth and Environmental Sciences, Korea University
Yijune Choi[4], Department of Earth and Environmental Sciences, Korea University

Abstract

Vapor intrusion is the process in which VOC generated from soil contamination by PHC poses risks to the indoor residents/workers via vapor intrusion. In urban settings, risks caused by contaminated vapors are important compared to other pathways related to direct contacts to the contaminated water or soil. In this study, a risk assessment application for urban-specific vapor intrusion pathways was developed. Three major pathways were considered for the risk assessment: damped basement, tunnel dispersion, and volatilization through collector-well. The damped basement and volatilization through collector-well pathways evaluated the cases which contaminated groundwater enters the indoor spaces first through the wall or the collector-wells and then volatilizes. The tunnel dispersion pathway evaluated the dispersion of contaminated vapor from one indoor space to another one through a passage. Input characteristics including the source (e.g. chemical type, contamination concentration), investigated/assumed parameters of the pathways (e.g. volatilization factor, tunnel volume) and receptors (e.g. exposure frequency, length) were submitted. Default input values were offered and the users can change them if necessary, enhancing the user-friendliness of the program. As a result of the risk assessment, ‘cancer risk’, and ‘non-cancer risk’ are calculated, and the comparison of the risk level regarding the screening standards are identified. It is expected that this program can be used to support efficient preliminary contamination control and decision-making (selection of investigation methods and establishment of a remediation plans) in urban areas.

New insights from landfill microbiome by genome-resolved metagenomics

So-Jeong KIM[1]*, Korea Institute of Geoscience and Mineral Resources (sojkim86@kigam.re.kr)
Wook-Hyun Nahm[2], Korea Institute of Geoscience and Mineral Resources
Min Han[3], Korea Institute of Geoscience and Mineral Resources
In-Hyun Nam[4], Korea Institute of Geoscience and Mineral Resources

Abstract

Landfills constitute a significant source of human-generated methane emissions on Earth. Therefore, there is a need to understand the microbial ecosystem within landfills that causes methane generation. Few studies of microbial ecology in landfills have been analyzed using next-generation sequencing (NGS) technologies, which have advanced dramatically in recent years. In this study, metagenomic analysis was used to investigate the roles and characteristics of microorganisms in landfills. Approximately 600 Metagenome-Assembled Genomes (MAGs) were obtained from samples at 9 different depths of landfill core drilling (16 m). Among bacterial taxa, Firmicutes (149), Bacteroidota (75), and Thermodesulfobacteriota (44) emerged as the predominant phyla, while Euryarchaeota (36) dominated within the Archaea. Notably, genes associated with polysaccharide degradation were predominantly attributed to the phyla Bacteroidota and Firmicutes, whereas genes linked to fatty acid degradation were primarily identified within Desulfobacterota and Planctomycetota. However, in the case of bacteria, the function of decomposing organic compounds was similar, but the dominant genus were different for each sample. On the other hand, in the case of Euryarchaeota, Methanoculleus, Methanoregula, and Methanothrix were found to be dominant. This study could be helpful in management and control of landfill, such as methane generation control, by understanding the microbial ecology within the landfill.

50 years of Lithologic Mapping and Mineral Exploration from Space

Michael ABRAMS[1]*, NASA/Jet Propulsion Laboratory (mjabrams@jpl.nasa.gov)

Abstract

Geologic remote sensing from space began in 1972 with the US launch of Landsat 1, with its 4-channel multispectral scanner. Early studies demonstrated the advantages of geologic mapping from the space perspective. The launch of Landsat 4 in 1982, with additional spectral bands and improved spatial resolution, meant geologists had a global tool that greatly improved geologic mapping of lithologies and structures. More importantly, the availability of data in two shortwave infrared (SWIR) bands allowed the gross detection of hydrothermal alteration minerals for reconnaissance resource exploration. It wasn't until 1999, when the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) was put into orbit, that an instrument designed for geologic applications started acquiring global data, with 15-channels and stereo imaging capability for DEMs. The ASTER instrument is a joint project of Japan's Ministry of Economy, Trade, and Industry (METI) and US National Aeronautics and Space Administration (NASA). Since its launch, hundreds of studies have been published documenting the use of ASTER SWIR and thermal infrared (TIR) bands to discriminate and identify rocks and soils based on their mineral composition and makeup, and as an aid in reconnaissance exploration for non-renewable resources, particularly alteration assemblages associated with mineral deposits. ASTER's unique six SWIR bands reveal diagnostic absorption features in the 2-2.5 micron wavelength region. This allows mapping of clays (illite, montmorillonite, kaolinite, dickite), carbonates (dolomite, limestone), and sulfates (alunite, gypsum), and Mg-OH bearing minerals. ASTER's multispectral TIR bands allow discrimination and mapping of quartz content of rocks and minerals, and discrimination of silicate minerals, ranging from felsic to mafic. The next major improvement in spaceborne instruments, first proven with aircraft instruments, was hyperspectral instruments, having 200+ narrow spectral channels in the visible-to-shortwave infrared. Data from these instruments allow mineral identification almost matching laboratory measurements. Chinese HSI scanners have been in space for almost a decade. However, data is unobtainable outside China. The first freely available data were from Italy's PRISMA scanner, launched in 2019. This was followed in late 2019 by Japan's HISUI instrument. Germany's EnMAP scanner was put up in 2022. And the US EMIT instrument was operated onboard the Space Station since mid-2022. PRISMA, HISUI, and EnMAP have almost identical characteristics: 30 m spatial resolution, 30 km swath width, and limited daily acquisition capacity. However, they fulfill the promise of hyperspectral data for mineral identification, if only with limited coverage. NASA is planning the first global mapping mission in 2029 with the Surface Biology and Geology mission. Its VSWIR instrument will have 185 km swath width, and acquire constant, global coverage.

Work by Abrams was done at the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.

[Keynote] CURRENT AND FUTURE HIGH-RESOLUTION THERMAL INFRARED- SATELLITE AND AIRBORNE- SENSOR SYSTEMS

Simon John HOOK[1]*, NASA/JPL (simon.j.hook@jpl.nasa.gov)

Abstract

Thermal Infrared (TIR) remote sensing has been used for a wide variety of research and applications from determining how much water farmers should put on their fields to mapping the mineralogy of exposed surfaces. TIR sensors typically acquire data between 8-12 μm in the electromagnetic spectrum. This spectral region is a relatively clear atmospheric window allowing the surface radiation to be observed together with any atmospheric attenuation and atmospheric contributions by the satellite- or airborne- sensor systems. The surface radiation consists of the surface temperature and emissivity, both of which can be extracted from the data using a variety of methods. Of particular use for mineral mapping are the emissivity data that relate to the composition of the surface. In the TIR part of the electromagnetic spectrum spectral features are related to differences in the Si-O bonding of any silicate minerals that may be present. Differences in Si-O bonding are manifest as shifts in the position of the minimum in the emissivity spectra of rocks in the TIR wavelength region. Variations in silicate mineralogy are useful for geologic mapping because they are an important criterion in classifying and interpreting igneous rocks, as well as the sedimentary and metamorphic rocks derived from them. Studies utilizing TIR data have demonstrated that it is possible to distinguish between rock types based on differences in silicate mineralogy. Greater spectral discrimination is possible the more spectral bands that are present in the TIR region. Further, high spectral resolution coupled with high spatial resolution is particularly valuable for mineral mapping where compositional differences occur over short physical distances.

Currently there are three high spatial resolution satellite TIR sensors (ASTER, ECOSTRESS and Landsat), however, only two of these (ASTER and ECOSTRESS) are multispectral having at least three TIR bands. ASTER and ECOSTRESS both have 5 thermal bands with spatial resolutions of 90 and 70 m respectively. There are also several airborne systems which may have many more spectral bands and even higher spatial resolution. Two widely used airborne sensor systems are HyTES and MASTER. HyTES has 256 spectral bands in the TIR and MASTER has 10. The spatial resolution of these systems depends on the flying height of the aircraft which is determined by aircraft capability. Both MASTER and HyTES fly on several aircraft and pixel sizes range from a few meters to less than 50 meters.

Both ASTER and ECOSTRESS are in extended mission with current end of life of 2027 and 2029 respectively. Several space agencies now have similar systems in development. These include TRISHNA, SBG and LSTM scheduled to launch in 2026, 2028 and 2030 respectively. These systems will be followed by Landsat-Next consisting of 3 spacecraft-sensor systems which together image the land surface every 5 days.

This presentation will summarize each of these systems and provide examples of how the current

systems are being used for geological studies.

A Multiscale Hyperspectral Remote Sensing Approach for Detection of Petroleum Offshore

Carlos Roberto Souza Filho[1]*, University of Campinas (beto@unicamp.br)
Rebbeca Del'Papa Scafutto[2], University of Campinas
Cristina BENTZ[3], Petrobras

Abstract

Petroleum offshore detection is a critical task for environmental monitoring and resource management. This study presents a novel multiscale hyperspectral remote sensing approach tailored for detecting petroleum slicks in offshore environments. Leveraging advancements in hyperspectral imaging technology, our approach integrates data from multiple scales, ranging from satellite to unmanned aerial vehicle (UAV) platforms, to enhance detection capabilities. At the satellite scale, we utilize high spectral resolution hyperspectral images (e.g. EnMap) to capture broad spatial coverage of offshore areas. These images are processed using advanced algorithms to identify spectral signatures indicative of petroleum presence. Additionally, we incorporate data from a field scale leak experiment using UAV platforms equipped with hyperspectral sensors to achieve finer spatial resolution and improve detection accuracy in localized areas. Key components of our approach include preprocessing of hyperspectral data to remove atmospheric and water column effects, spectral unmixing techniques to differentiate between petroleum slicks and background materials, and machine learning algorithms for automated detection and classification. We validate the effectiveness of our approach through comprehensive lab and field experiments simulating offshore environments with varying petroleum concentrations and APIs. Results demonstrate the capability of our multiscale hyperspectral remote sensing approach to accurately detect and differentiate petroleum slicks from natural phenomena and other anthropogenic sources. The proposed approach offers several advantages, including improved detection sensitivity, enhanced spatial resolution, and reduced false alarm rates compared to traditional methods. Furthermore, its scalability and adaptability make it suitable for monitoring large offshore areas and detecting petroleum slicks of varying sizes and concentrations. In conclusion, our study presents a promising multiscale hyperspectral remote sensing approach for effectively detecting petroleum offshore, with significant implications for environmental protection, oil spill response, oil exploration (seepages), and sustainable resource management in marine ecosystems.

The EnMAP hyperspectral satellite: an overview of the mission and its applications in geology and resource exploration

Saeid Asadzadeh[1]*, GFZ German Research Centre for Geosciences (saeid@gfz-potsdam.de)
Sabine Chabrillat[2], GFZ German Research Centre for Geosciences

Abstract

The Environmental Mapping and Analysis Program (EnMAP) hyperspectral satellite was successfully launched into orbit on April 1, 2022. Since the end of October 2022, it has entered the operational phase, collecting on-demand hyperspectral data globally. EnMAP is a German satellite system designed to provide high-quality hyperspectral data for environmental monitoring and sustainable management of natural resources. It covers the spectral range between 420 and 2450 nm by 224 bands, offering a spectral resolution of 8.1 nm in the visible-near infrared (VNIR) and 12.5 nm in the shortwave infrared regions (SWIR) by two individual prism-based push-broom spectrometers. It maintains a signal-to-noise ratio (SNR) higher than 250:1 at a spatial resolution of 30m. In this presentation, we aim to provide an overview of the mission, data levels, and user data access. We also aim to present some application examples of the EnMAP Level 2A orthorectified surface reflectance data in geology and raw materials exploration. These examples range from mapping the outcrops of carbonates, sulfates, and iron oxides in sedimentary basins to mapping the alteration footprints of hydrothermal systems in different geological settings, including porphyry copper deposits, volcanogenic massive sulfides, and Mississippi-valley type deposits, as well as a Rare Earth Element (REE)-bearing carbonatite body. Our presented case studies indicate that EnMAP has superior performance in mapping surface mineralogy over exposed solid earth thanks to EnMAP's high spectral resolution, accurate calibration, and high SNR. The high-quality freely available hyperspectral data offered by EnMAP can be efficiently used to identify, characterize, and map a rich number of spectrally active minerals over the earth's surface facilitating geologic studies and resource exploration in arid to semi-arid regions of the world.

Characterization of “Sale ‘e Porcu” salty pond (SPp Sardinia, Italy) suitable for CAL/VAL activities using multi sensor approach in the VNIR-TIR range: new optical satellite mission perspective

Maria Fabrizia BUONGIORNO[1]*, Istituto Nazionale di Geofisica e Vulcanologia (fabrizia.buongiorno@ingv.it)
Malvina Silvestri[2], Istituto Nazionale di Geofisica e Vulcanologia,Italy

Jan Kanuk [8], Faculty of Science Pavol Jozef Šafárik University in Košice (UPJŠ), Slovakia
Michal Gallay[9], Faculty of Science Pavol Jozef Šafárik University in Košice (UPJŠ), Slovakia

Abstract

The “Sale ‘e Porcu” (SPp) is located in the Sinis peninsula (West Sardinia), and is the largest temporary salty pond in Sardinia. It occupies a flat-bottomed interdunal depression where rainwater is collected. The basin, with a maximum depth of 1 meter and an average depth of 40 cm, is characterized by the absence of tributaries and emissaries, therefore it represents an independent basin from the other ponds present in the area. During the summer period, the strong evaporation causes the fully dry out of the SPp, presenting itself as a large expanse of salt. This characteristic makes this area an almost unique site placed at mid-latitudes in Europe, which could be suitable for Vicarious Calibration and Validation activities (CAL/VAL) for new optical satellite missions. In 2023 remote and proximal data have been collected, covering the VNIR-TIR spectral range, and are currently analysed to obtain a fully characterization of the site. This study includes satellite data with Ground Sampling Distance (GSD) ranging from 90x90 m (Landsat) up to 30 x30m (EnMAP and PRISMA) passing by about 70m of ECOSTRESS. Proximal acquisition ensures the higher GSD reached by using VNIR and TIR sensor mounted on drone and geological and mineralogical analysis. Moreover, hyperspectral thermal infrared data were acquired on the SPp site by the NASA-JPL airborne instrument HyTES in the frame of the 2023 ESA airborne campaign aimed to the characterization of a number of European test sites suitable to evaluate the performances of new optical satellite sensors. In the coming 5-6 years a large number of satellite missions equipped with sensors acquiring data in the range of SWIR-TIR, developed both at National (IRIDE constellation), European (ESA-LSTM) and International (NASA-ASI-SBG) will be deployed. These missions will permit to acquire higher temporal and spectral resolution data increasing the capabilities to monitor large area with different sampling performances. This study highlights the necessity to integrate data coming by several platforms to preliminary analyze the suitability of remote area for CAL/VAL purposes. Indeed, the logistic of the SPp, in terms of accessibility and data availability, permits to define the correct methodology to be exported in far or remote area.

Active deformation across Indo-Myanmar suture zone, NE India: Insights from integrated RS-GIS-based Geomorphic Investigations

ALEXANDER S KSHETRIMAYUM[1]*, Department of Earth Sciences, National Central University, Taoyuan -32001, Taiwan (alexkshetri83@gmail.com)
Pradeep K Goswami[2], Centre of Advanced Study, Department of Geology, Kumaun University, Nainital -263002 India
Chung-Pai Chang[3], Center for Space and Remote Sensing Research, National Central University, Taoyuan -32001, Taiwan
Wu-Lung Chang[4], Department of Earth Sciences, National Central University, Taoyuan -32001, Taiwan

Abstract

The Indo-Myanmar suture zone, situated on the eastern flank of the Indian plate is characterized by oblique convergence of the Indian plate beneath the Myanmar microplate, which is a part of the Eurasian plate. Recent geodesy-based seismotectonic investigations reveal that the prevailing movements along the region's faults and thrusts at present are predominantly strike-slip in nature, playing a crucial role in accommodating the Indo-Myanmar plate motion. However, the crustal deformation caused by active tectonic movements in the region has not generally been determined across the entire mountain ranges except for a limited studies in some areas of the central part of it. The present study is aimed at understanding the active tectonic movements and associated crustal deformations in a part of the mountain ranges adjoining the tectonic suture zone. The study includes RS-GIS-based delineation of geomorphological indicators that reveal the structures' movements and associated crustal deformation during the Quaternary period. Employing robust geomorphic analyses such as the Normalized Steepness Index (ksn) and Hypsometric Integral (HI), we endeavor to decode the active deformation pattern across the region.

Our findings, underscored by geomorphological markers including entrenched meanders, deflected streams, pronounced straight courses, sharp stream deflections, warping of stream channels, river terraces, and linear ridge features such as pressure ridges and shutter ridges, indicate a combination of active strike-slip and dip-slip movements. These observations suggest that the suture zone is experiencing oblique slip, thereby sustaining the Indo-Myanmar plate motion. Furthermore, the spatial distribution of ksn and HI values suggest distinct deformation patterns across and along the suture zone, with the severity of crustal deformation decreasing from north to south, and from the plate margin to areas farther away from it. This pattern implies variable uplift rates and differential strain accommodation across the suture zone. Such a pattern is likely driven by the interplay of N-S extension and E-W compression as the Indian plate converges beneath the Eurasian plate. Our study highlights varying deformation pattern even in a smaller part of a particular tectonic setting and demands for more directed investigations to understand the intricacies of plate converges during an orogeny.

Remote Measurement of the Earth system with EMIT Imaging Spectroscopy from the International Space Station

Robert Otis Green[1]*, NASA JPL Caltech (robert.o.green@jpl.nasa.gov)
David R Thompson[2], NASA JPL Caltech

Abstract

The NASA Earth Surface Mineral Dust Source Investigation (EMIT) imaging spectroscopy mission was launched to the International Space Station (ISS) on the 14th of July 2022. The EMIT imaging spectrometer is a first-of-its-type F/1.8 full visible to short wavelength infrared (VSWIR) Dyson instrument that incorporates decades of lessons learned, along with advanced device technologies. Since its arrival at the ISS, EMIT has measured high signal-to-noise ratio spectra covering large portions of six continents. These high-fidelity spectroscopic observations enable new science and new applications throughout the Earth system. The EMIT prime mission measurements have been used to map the mineralogy of the Earth's arid land regions and address the prime mission science objectives. In addition, EMIT imaging spectroscopy has delivered detailed measurements of localized sources of methane and carbon dioxide. More than 1000 methane plumes have been identified and made available via the NASA Land Process Distributed Active Archive Center (LP DAAC) and the US Greenhouse Gas Center. These EMIT methane products with uncertainties have been used to advance mitigation of methane emissions into the atmosphere. In 2024, EMIT has entered an extended mission phase, and the target areas for observations below the ISS are being expanded to support new science objectives spanning the disciplines of terrestrial ecology, coastal oceans and inland water, snow and ice hydrology, and geology. A new broad set of applications spanning elements of agriculture, forestry, critical minerals, water quality, wildfires, water resources, and more are anticipated to be supported as well. Looking forward, these imaging spectroscopy measurements, algorithms, science, and applications support preparatory activities for the Surface Geology and Biology Decadal Survey mission with a next-generation VSWIR imaging spectrometer that is part of NASA's Earth System Observatory.

Assessing Spatio-temporal Changes of climate variables on Diverse Crops in region of Punjab, Pakistan

Waqar YASIN[1]*, Land Information and Management System Centre of Excellence, Pakistan, Institute of Geo-Information and Earth Observation, PMAS-Arid Agriculture University Rawalpindi, Pakistan. (waqaryasin@me.com)

Abstract

Certain crops are climate sensitive in Pakistan such as rice, vegetables, cereals, spices and other grains. Rising temperature and changing rainfall is resulted in the form of shortage of water, which further leads towards the problems of food security due to low productivity especially in cropped food sector. Crop growth in Pakistan is highly dependent upon rainfall, which either fall in the form of rain or snow. Whereas high air temperature reduces the growth of shoots and in turn reduces root growth. High soil temperature is more crucial as damage to the roots is severe resulting in substantial reduction in shoot growth.This study deliberates the effect of changes in rainfall and temperature of Punjab, Pakistan on the production of five major crops viz. wheat (triticum), maize (zea mayes), cotton (gossypium), sugarcane (Saccharum officinarum) and gram (Cicer arietinum).The changes in mean temperature and rainfall from 1951 to 2015 were assessed at region level. Whereas the changes in crop growth were computed through remote sensing and crop reporting data. The variations in crop performance were compared with changes in studied climate variables (temperature and rainfall). It was found that increased in mean annual temperature decreased the crop yield. In addition, the climatic variation imparts negatively on analysed crop production data in the central and southern areas. Although exhibited a positive effect in the northern parts. It is therefore, suggested that various agriculture departments be educated regarding outcomes / conclusions of this study so that formers be trained to take necessary precautions while looking after their crops at different stages of crop cycle regarding these climatic variables i.e. temperature and rainfall.

Detection of high-geothermal-potential zones in densely vegetated areas through a combination of vegetation and mineral indices derived from hyperspectral satellite imagery

Taiki KUBO[1]*, Kyoto University (kubo.taiki.3n@kyoto-u.ac.jp)
Hiroaki Gonnokami[2], Idemitsu Kosan Co.,Ltd.

Katsuaki Koike[6], Kyoto University

Abstract

Geothermal resources are expected to be increasingly utilized due to their high capacity and sustainability as an energy source for electric power generation. Satellite imagery analysis is one of the effective methods for detecting surface geothermal manifestations in the initial stages of regional resource exploration. However, direct observation of the ground surface becomes challenging in high-potential areas for geothermal resources located in densely vegetated zones. Therefore, we endeavored to identify surface geothermal manifestations through anomalies observed in vegetation. The Patuha geothermal field in West Java, Indonesia, was selected as the study area due to the availability of abundant survey data for validation. For the case study, a single satellite image acquired by the Hyperion sensor was used. We defined a vegetation index to detect spectral features of stressed vegetation: a blue shift of the red edge and an increase in shortwave-infrared reflectance. This index, named as VIBS (Vegetation Index considering Blue shift and Shortwave infrared), proved to be suitable for detecting vegetation stress caused by soil acidification conditions resulting from ascending geothermal fluid. The validity of VIBS was demonstrated through comparison with various local geological structures and geothermal systems. Therefore, VIBS was subsequently applied to geothermal areas in Yuzawa area, Japan. This area has several geothermal power plants operate and it is predominantly covered with vegetation, similar to Patuha. The analysis of the Yuzawa area was performed by utilizing HISUI (Hyperspectral Imager Suite; Iwasaki et al., 2011) imagery. Because the HISUI data analysis process is not fully established, we conducted data preprocessing with parameter validation. The VIBS values showed a clear difference between the northern and southern regions of the target area. In southern part of the study area , high VIBS value zone distributes continuously along faults. This is consistent with the estimated location of the geothermal reservoir and the flow pattern of the geothermal fluid. In contrast, the lower VIBS values in the northern area can be attributed to differences in surface geology. This result is supported by the results of on-site geophysical and geochemical surveys.

DELINEATION OF MINERAL POTENTIAL HYDROTHERMAL ALTERATION ZONES AND FAULT ZONES USING MULTISPECTRAL ASTER AND LANDSAT 8 DATA OVER SANDUR SCHIST BELT, BELLARY DISTRICT, KARNATAKA, INDIA.

VIJAYAKUMAR MOOLA[1]*, GEOLOGICAL SURVEY OF INDIA (vijaya.moola@gsi.gov.in)
ANJU VR[2], GEOLOGICAL SURVEY OF INDIA

Abstract

Advanced Space borne Thermal Emission and Reflection Radiometer (ASTER) with 3 Bands in visible and near-infrared (VNIR) and 6 bands in shortwave-infrared (SWIR) regions makes its data useful for mapping of Ferric Iron (0.4μm,0.5μm,0.7μm & 0.87μm), Al-OH (2.2μm), Mg-OH (2.3μm) and carbonates (2.16μm, 2.35μm, & 2.55μm), thus making it more suitable for mineral exploration in geological applications. Landsat 8 satellite payload consists of two science instruments—the Operational Land Imager (OLI) and the Thermal Infrared Sensor (TIRS). It has 5bands in VNIR (0.43μm-0.88μm), 2 bands in SWIR (1.57-2.29μm) and 2 bands in thermal infrared region (10.6-12.51μm).

Sandur Schist Belt of eastern Dharwar craton in Bellary District in Karnataka has been taken up for identifying mineral potential areas through processing of multispectral ASTER and Landsat data. Under the present study, hydrothermal alteration minerals such as talc-chlorite (band ratio: (6+9)/(7+8)) and carbonate (band ratio: (7+9)/8) were mapped using Band Ratios, Relative Band Depth (RBD), Matched Filtering, constrained energy minimization (CEM) and Minimum Noise Fraction (MNF) mapping methods from ASTER reflectance data (AST_07_00301142004053445 & AST_07_00301142004053453) acquired on 2004-14-01, by removing vegetation and water by preparing NDVI and NDWI and band thresholding using ENVI software. A new relative band depth, (B1+B4)/B3+2(B4+B6)/B5 in the Landsat OLI data was arrived based on the known mineral occurrence of hematite mineral in the schist belt. Lineaments/ faults were identified using Landsat 8 OLI data, which was acquired on 2020.22.03 (path/row: 145/049)

Two mineral promising areas for gold & base metal, 1. Joga-Vaddu (20 sq km), 2. Lingadahalli (30sq km) were identified, from alteration zone mapping of chlorite and carbonate from ASTER data and lineaments (faults) inferred from satellite imagery (Landsat data) by integrating them with geochemical distribution of MgO, mineral occurrences, structure, lithology and field validations, favourable for mineralisation in the study area. Talc-chlorite alteration zone was identified between Lingadahalli and Shantappa Camp areas from ASTER data, and faults were delineated near Joga from Landsat data.

Ore petrographic studies have indicated the presence of pyrite, pyrrhotite, chalcopyrite and arsenopyrite along quartz-carbonate veins in metabasalt from Joga area. Gold values up to 550 ppb were found in limontised quartz vein in fault zone near Joga. Near Lingadahalli, grey/smoky quartz veins have got up to 115ppm of copper values.

The study has revealed a positive correlation of multispectral hydrothermal alteration zones &

lineaments with the field evidences and mineralization and has resulted in targeting mineral potential zones.

Research on Vegetation Geochemical Anomalies in Uranium Mining Areas Based on Hyperspectral Remote Sensing and Vegetation Spectral Analysis

Yongfei CHE[1]*, .National key Laboratory of Remote Sensing Information and Image Analysis Technology, Beijing Research Institute of Uranium Geology (cheyongfei@163.com)
Minglin ZHANG[2], China Nuclear Geology
Fawang YE[3], National key Laboratory of Remote Sensing Information and Image Analysis Technology, Beijing Research Institute of Uranium Geology

Abstract

Using hyperspectral remote sensing and vegetation spectral analysis technology can extract geochemical anomaly information of plants in uranium mining areas. This paper combines knowledge from multiple disciplines such as remote sensing, botany, plant geochemistry, and petrology to systematically explore the natural landscape and vegetation communities in typical uranium mining areas and non-uranium mining areas. Through hyperspectral technology analysis of common plant spectral characteristics in mining areas and non-mining areas, sensitive feature bands are identified, and the indicative elements of plant geochemical prospecting in uranium mining areas are determined using correlation analysis and cluster analysis. The study found that plants in uranium mining areas are generally enriched in Mo, Th, and U, and there are differences in the enrichment of different elements in different organs. Through the contrast coefficient and barrier coefficient of vegetation element content, Eulalia japonica and Rhus chinensis were selected as effective indicative vegetation, with indicative elements of U and Mo. Finally, combining field spectral data, GF-5 hyperspectral image data, and vegetation geochemical anomaly data above the uranium mining area, the relationship model between vegetation spectral sensitive bands, band ratio, and indicative element content was established, and the spatial distribution characteristics of indicative elements were retrieved. The research results show that the method of extracting mineralization information of uranium deposits in vegetation-covered areas based on hyperspectral remote sensing and vegetation spectral anomalies can better reflect the spatial distribution characteristics of relevant element anomalies in the region, providing new ideas for the prediction of metal deposits in high vegetation coverage areas, and having application value and promotion significance.

Computing Sediment Grain Volumes with GIS

Tim Whiteaker[1]*, The University of Texas at Austin (whiteaker@utexas.edu)
Michael L Sweet[2], The University of Texas at Austin

Abstract

When studying sedimentary basins through a source-to-sink lens, we want to track sediment movement into the basin, measuring how it is partitioned between sedimentary environments. We are especially interested in quantifying the fraction of sediment that passes the shelf-slope break into deep water. In this presentation, we introduce a Geographic Information Systems (GIS) workflow for computing the distribution of sediment grain volumes through space and time. Driven primarily by data from well logs, the workflow not only calculates total grain volume, but also considers the partitioning between sand and mud, and deep water deposits from shallow water deposits. Part of the workflow includes using the Sclater-Christie compaction curve to account for changes in porosity with changes in depth, taking into account both depth of sediment and water depth. We exercise the workflow on a case study with Cenozoic depositional systems of the Gulf of Mexico (GOM) Basin, for which we have compiled a rich database of published well logs, seismic data, and datasets derived from publicly available sources. The workflow utilizes Esri ArcGIS desktop software including ArcMap, geoprocessing tools, and ModelBuilder. In this presentation we focus primarily on our GIS methods, and we highlight some key results from the GOM study to demonstrate the utility of the approach.

Polish Geological Cartography Platform: fostering geological map data accessibility, enhancing integration and harmonisation for informed decision making

Katarzyna JÓŹWIK[1]*, Polish Geological Institute - National Research Institute (kjoz@pgi.gov.pl)
Urszula Stępień[2], Polish Geological Institute - National Research Institute
Piotr Gałkowski[3], Polish Geological Institute - National Research Institute
Józef Mikołajków[4], Polish Geological Institute - National Research Institute

Abstract

Performing geological mapping and providing accurate knowledge about the geological structure of the country have been priority tasks for the Polish Geological Institute (PGI) for more than a century. Over the years, PGI geoscientists have compiled hundreds of different maps within the framework of domestic, regional, and international projects. Many of these maps are accessible through various national thematic applications, as well as international portals and initiatives such as OneGeology, INSPIRE, EGDI, and IQUAME.

However, based on the results of a questionnaire conducted last year among Polish stakeholders, it is often challenging for them to locate the maps they need. Some stakeholders also lack tools that would enable them to combine and analyze map data within their own systems. The Polish Geological Cartography Platform aims to address these challenges by providing a centralized access point for all geological and geology-related maps, along with an advanced map search engine and a set of specialized tools for spatial data analysis. It is also designed to become one of the fundamental tools supporting the daily duties of the Polish Geological Survey's employees. By replacing some existing internal procedures, the platform seeks to minimize the bureaucratic steps required to access different types of map data.

The platform will facilitate the integration of data from past and ongoing cartographic undertakings and distributed domain systems into a common database. It will also incorporate the results of other projects of the Polish Geological Survey related to the standardization of geological vocabularies, thus enabling further harmonization of map series as well as map data across different scales.

Lime phosphates in Senegal: characterization, modelling and predictive mapping for the development of a prospecting guide.

Abdoul Aziz NDIAYE[1]*, ENSMG - University CAD Dakar (UCAD)
(abdoulaziz.ndiaye@ucad.edu.sn)
Mamadou FALL[2], PCSTUI - University CAD Dakar (UCAD)
Mamadou GUEYE[3], ENSMG - University CAD Dakar (UCAD)

Abstract

The first paleogeographic and stratigraphic work carried out within the general framework of mining prospections in Senegal in the years 1943 to 1955 made it possible to highlight deposits and indices of lime phosphates (in the central west of Senegal at Taïba, LamLam and later in the 1980s in Matam in the North East). Since 1962, Senegal has been a producer of phosphate, to the tune of 2.5 million tons in 2021 for proven reserves of 116.5 million tons and probable reserves of 337 million tons. The mining sector, driven by phosphates and gold, plays an important role in the country's economy, producing a value of US$ 2.49 billion.

The general goal of our research work is to sustain these strategic resources for the country. The methodology thus consisted of compiling and reinterpreting data on phosphates in order to provide decision support in the form of a prospecting guide for the development of research projects or the exploitation of new deposits.

An exhaustive compilation of lime phosphate prospecting and exploitation data throughout Senegal, from 1948 to 2023, made it possible to carry out a geological, mineralogical, paleontological and geochemical characterization of the ores.

These same data, supplemented by morpho-structural elements as well as operating data from mining companies, made it possible to construct a GIS with 45 layers of information of various types (drilling points, isolines, faults and discontinuities, etc.) grouped into six categories namely (i) phosphate occurrences, (ii) lithological units, (iii) tectonic structures, (iv) stratigraphic markers, (v) facies types and (vi) multielemental geochemistry.

This GIS allowed modeling of the geometries of the deposits and the creation of a new map at 1:500,000 giving the main characteristics of the Lower Eocene, support of the stratigraphic horizon of phosphates in Senegal.

Subsequently, the combination of data from the 45 layers made it possible to produce predictive maps of potential in phosphate reserves from two approaches, first by “Regionalized PCA” (also called “Analyse Krigeante”) mapping the Phosphate Factor and second by “Directed Pixelation” of information.

The use of these predictive mapping techniques makes it possible to identify areas with potential reserves in the form of probability maps for phosphate presence. These maps will allow either mining companies to optimize their exploration strategy, or the State of Senegal to better guide its mining policy for this very important strategic mineral, in particular by defining promotional zones as authorized by the 2016 Mining Code.

Boosting Europe's Energy Transition: The Pivotal Contribution of a Geological Service for Europe in Delivering FAIR Subsurface Data and Knowledge for Informed Policy and Industrial Decision-Making

Francesco Pizzocolo[1], TNO - Geological Survey of the Netherlands
Julie Alison HOLLIS[2], EuroGeoSurveys
Patrick Wall[3]*, EuroGeoSurveys (Patrick.Wall@eurogeosurveys.org)

Abstract

The world's evolving energy needs demand accurate geoscientific data, information, and knowledge to achieve the energy transition, environmental management, and sustainable development. The Geological Service for Europe (GSEU) project is a strategic initiative funded by the EU, with a mission to provide comprehensive geoscientific data, information, and knowledge harmonized at European scale. The project addresses key challenges associated with the energy transition in the fields of groundwater, minerals, energy, coastal zone management, underlying geoscientific maps and models, and geospatial data delivery, focussing on sustainable development, regulatory improvement, social governance of the subsurface, public participation, derisking of renewable energy projects, and science-informed policy development. The ultimate project goal of establishing a permanent Geological Service for Europe is pivotal in supporting Europe's energy transition, environmental management, natural resource exploration and exploitation, and policy-making.

The transnational nature of geology necessitates collaboration, standardization, and a shared vision. Aligned with the European Commission's vision for a climate-neutral economy, the GSEU project emphasizes the key role of the subsurface in Green Deal and NetZero goals and vital resource exploration and management. Leveraging the network and data of the National Geological Surveys and EuroGeoSurveys – a not-for-profit association representing 37 geological surveys of Europe – GSEU is establishing joint services supporting energy and climate transitions.

Specifically, the GSEU project will deliver:

• pan-European harmonized data services
• an International Centre of Excellence for Sustainable Resource Management
• the European Geological Data Infrastructure and
• a strengthened network of national geological survey organizations and connections with the European Commission and other stakeholders.

These data, information, and knowledge services have the potential to inform:

• Current economy and market dynamics in European Renewables: Assessing geological

characteristics for renewable projects.
• Barriers and improvements to regulatory frameworks: Providing geological insights for effective regulations.
• Social Governance of the subsurface: Fostering transparency and public engagement in decision-making.
• Just Energy Transition and the Green New Deal: Considering socio-economic implications and equity.
• Technical projects with focus on public participation: Advising policymakers on impactful projects.
• Policy developments: Offering valuable lessons from geosciences to accelerate the adoption of renewable energy technologies.

The five-year GSEU project is a stepping stone towards establishing a permanent Geological Service for Europe, providing an ongoing bridge between the geological survey and broader geoscience expert community and policymakers. Our ambition for a permanent Geological Service for Europe is to offer a centralized platform for up-to-date geoscientific data, information, and knowledge harmonized at European scale, building on the existing European Geological Data Infrastructure (EGDI), and linked to national-level data and expertise. Through provision of current geological data, information, and knowledge, and collaborative initiatives, the Geological Service for Europe will allow effective, efficient geoscience-informed decision-making in renewable energy development, contributing to strategic decision-making, responsible subsurface management, public participation, and policy development. The future Geological Service for Europe stands as a cornerstone in ensuring a sustainable and just energy future for Europe.

On the issue of developing a methodology for compiling a map for assessing the anisotropy of the natural stress state of dispersed soil massifs

Violetta SHANINA[1]*, Lomonosov Moscow State University (violettav@inbox.ru)
Vladimir MATVEEV[2], Geotechnical Graduate Lab

Abstract

The goal is to develop a methodology for drawing up a map for assessing the anisotropy of the natural stress state of dispersed soil masses, which allows one to obtain a spatial representation of the stress distribution at a given depth from the earth's surface. It is recommended to set the depth corresponding to the most frequently selected depths of the foundations of structures with a high level of responsibility, for example, 5, 10 or 15 m. The difficulty of drawing up a map for large areas consists, as a rule, in the insufficiency of factual material. To describe and calculate parameters, a grouping of soils of the same type, having the same genesis, similar lithological composition and condition, is proposed. The methodology is being developed using the example of soils in the Moscow region. The source material is a field description of soils, as well as the results of laboratory and field studies. The parameters required to construct a map are assessed primarily using empirical formulas, due to the paucity of direct definitions. Formulas are used that are widely used and have high accuracy and stability. In the Moscow region, clay deposits in the upper part of the section belong to the Quaternary, Cretaceous, Jurassic and Carboniferous systems. Among these deposits, overconsolidated ones are often found. Natural pore pressure u is determined by interpolation. Interpolation is carried out in accordance with groundwater data. For depths below the groundwater level, pore pressure is determined by the formula u=γ_w (z-z_0). Pre-compaction stress can be determined by direct methods in key areas according to GOST R 58326-2018, as well as by indirect field methods, for example, by static sounding using an empirical formula. Based on the collected stock data and statistical analysis, it was revealed that the lateral pressure coefficient of cohesive soils does not depend significantly on the lithological composition, condition and genesis, and the age of the deposits and the value of the effective vertical stress are of decisive importance. For Holocene normally compacted soils in the Moscow region, as well as for Quaternary overconsolidated soils with over 200 kPa, vertical stresses predominantly exceed horizontal ones. For Quaternary sediments in the range from 100 to 150 kPa, Mesozoic - from 100 to 350 kPa, the stress state is predominantly isotropic. Overconsolidated Quaternary and Mesozoic sediments at shallow depths (vertical effective stress of 50 kPa or less) are characterized by inversion of principal stresses, horizontal stresses exceed vertical ones. The map for assessing the anisotropy of the natural stress state of dispersed soils shows areas with different lateral pressure coefficients, isolines corresponding to the effective household vertical and horizontal stress, as well as additional information, such as the overconsolidation coefficient. A map for assessing the anisotropy of the natural stress state of dispersed soil masses allows one to obtain a spatial representation of the stress distribution at a given depth from the earth's surface, which contributes to the safety of the construction of underground structures.

[Keynote] Bathy-morphological mapping for geohazard assessment

Francesco Latino CHIOCCI[1]*, Sapienza, University of Rome (francesco.chiocci@uniroma1.it)

Abstract

The mapping of the seabed has been a fundamental pursuit in scientific research, dating back to the earliest scientific explorations.

Technological advancements, such as the availability of steel ropes in the 1800s, the introduction of the first echosounders in the early 1900s, utilization of satellite data in the late 1900s, and the development of multibeam echosounders in the present century, have continually expanded our reconstruction of the ocean depths.

Various methodologies are currently used by researchers for seafloor mapping, utilizing light (visible and hyperspectral) for shallow waters and seismic energy (sonar) for deeper seabed. In the latter case, the use of autonomous or remotely-operated vehicles acquiring data in close proximity to the seabed has substantially increased survey efficiency and resolution.

The rapid technological progress, leading to the generation of terabytes or petabytes of data annually, necessitates a concerted effort to standardize and homogenize interpretations, facilitating the production of cartographic products applicable beyond the domain of scientific research.

While subaerial mapping has long addressed these needs for habitat, land use, infrastructure, seismic, volcanic, and hydrogeological risk maps, the marine domain, aside from bathymetric and nautical charts, faces challenges with diverse research groups and end-users adhering to different standards. Lack of standards also hinders the land-to-sea continuity, an important goal for trans-domain mapping of geological features.

Building upon geohazard feature mapping experiences, however applicable to various thematic cartography types, this presentation aims to explore different facets ranging from data acquisition, processing, management, interpretation, to cartographic representation. In Europe, numerous projects, including Mareano in Norway, Infomar in Ireland, Magic in Italy, have contributed to original geohazard maps, while the European Emodnet project serves as a reference for harmonizing existing maps.

The initial unavoidable step involves determining the final scale of representation and the cartography's subject. Despite the apparently obvious nature of these considerations, the resolution of data, ground truthing, interpretative ambiguities, and cartographic representation are intricately interconnected. Misalignments in these aspects can compromise the final product's quality and result in resource wastage. Although multi-scale cartography is often advocated for accommodating diverse-scale products, careful consideration is required for the integration, even conceptually, of data at varying spatial scales.

The crucial involvement of end-users from the outset in defining interpretation and cartographic representation criteria cannot be underestimated. Different users possess specific needs and requirements, and accounting for these from the beginning enhances the final product's quality when it has to be utilized for different purposes.

Finally, a paramount consideration is entrusting the interpretation of mapping data to research groups with expertise in their respective geographical areas. Seafloor mapping tools are inherently limited to morphological expressions of seafloor features, and certain non-homogeneous information (e.g., seismics, sampling, dating) may be essential for accurate interpretation, necessitating the competence in the interpreter's understanding of the area.

Abstract

The Geological Survey of Italy – ISPRA, in collaboration with several Italian universities and research institutes, is realizing an update concerning submerged areas of the Structural Model of Italy. The work is carried on in the frame of the European Marine Observation and Data Network (EMODnet) Geology Project.

EMODnet is a long-term marine data initiative funded by the European Union. It provides easy and free access to marine data, metadata and data products and webservices spanning seven broad disciplinary themes (lots): bathymetry, geology, physics, chemistry, biology, seabed habitats and human activities. EMODnet Geology provides full areal coverage of all European regional seas producing maps at a 1:100,000 scale or finer, but also at coarser scales (1:250,000 and 1:1,000,000) to ensure maximum areal coverage. The geology data compiled in the frame of the project are available through the EMODnet Central Portal: https://emodnet.ec.europa.eu/en and include sea-bed substrate, sediment accumulation and erosion rates, Quaternary and pre-Quaternary lithology and age, geomorphological features, coastal behaviour, geological events and probabilities, minerals and submerged landscapes.

The Geological Survey of Italy – ISPRA coordinates the “Geological events and probabilities”

work package concerning submarine landslides, earthquakes, volcanic centres, tsunamis, fluid emissions and Quaternary tectonics. In order to provide a comprehensive and updated product for the Italian contribution to EMODnet Geology, cooperation among marine geology researchers from universities and research institutes has been promoted. Data gathered during this work allowed to realize a structural geology database for the entire Italian submerged territory. Information has been conveyed into a printed map at 1:1,250,000 scale representing an update for submerged areas of the Structural Model of Italy.

The map reports tectonic elements, rocky outcrops, seamounts and earthquake epicenters in Italian seas as revealed by the marine geological researches carried out during the last thirty years that have benefited from the contribution of relevant technological innovations in the field of marine geological surveys (multibeam, sub-bottom profiler, high penetration seismic surveys). The map contains structural data from original surveys as well as data from scientific literature or derived from strategic national research programmes, properly integrated and validated in order to create a harmonized dataset.

Structural and volcanic elements, classified according to the EMODnet terminology (INSPIRE compliant), are characterized by geometric, kinematic and chronological parameters. They are complemented by additional information on heat flow, crustal thickness and thickness of the Plio-Quaternary deposits. The map aims to present in a synthetic but exhaustive way the structural setting of Italian seas, a key region in the geologically very active Mediterranean Sea which is dominated by the geodynamic process of convergence and collision between the European and African plates.

The map provides indications concerning the migration over time and space of the tectonic events, the features that have contributed mostly to the current structure of the Italian seafloor and, among these, those that may originate geohazards. The map represents a solid base for more detailed studies of seismotectonics and applied geology, for territorial management and spatial planning as well as for scientific dissemination.

Thematic mapping, potential and interactions

Roland Erich OBERHAENSLI[1]*, Potsdam University (roob@geo.uni-potsdam.de)

Abstract

Its the prime property of any map to show data related to a theme. That is why the first known geologic map reports a goldmine in Egypt.
All along data were putt on geographic maps for retracing. Then geologic and tectonic maps were used as such, but also as base maps to put mineralogic or palaeontologic facts in a static manner. It took quite an effort during last century to produce maps related to dynamic phenomena such as landslides, mass movements or hydrology pointing to potential hazard. Similarly the presentation of data related to metamorphism, changed from reporting mineral assemblages to depicting P,T - data accordingly to a facies grid. Such a facies grid is related to geodynamic processes by the concept of thermodynamic calculations of P and T, pseudogetherms and the plate tectonic paradigm. Each geodynamic setting produces its typical sequence of metamorphic facies. When compared to a tectonic maps, where basically tectonic style and transport directions are reported the metamorphic data can add substantially. Especially when gaps in metamorphic conditions occur within a single tectonic unit, then revisions are needed. This was the case for the metamorphic map of the Alps, where co-operation with tectonists lead to a tectonic recompilation published on the same map. Other interactions of metamorphic mapping with paleogeographic maps, which globally base on stratigraphic and sedimentologic data, can led to spatial constraints. A good example of this are the two map sets of the MEBE as well as the DARIUS programs, both reated to reconstruct the Tethyan realm in the Eastern Mediterranean realm. The observation of high pressure relics and the inferred associated subduction processes, especially depth for the formation of eclogites led to implement additional oceanic curst and constrained minimal width of the oceanic basins. Including geophysical data might further enhance the potential of interaction and lead to new insights and interpretation of the geodynamic past.

Towards an integrated and harmonized geological data model for Europe

Esther HINTERSBERGER[1]*, Geosphere Austria, Dep. of Geological Mapping
(esther.hintersberger@geosphere.at)
Hans-Georg Krenmayr[2], Geosphere Austria
Christine Hörfarter[3], Geosphere Austria
Martin Schiegl[4], Geosphere Austria

Abstract

The initiative of the European Geological Survey Organizations towards a Geological Service for Europe (GSEU project) includes an advancement of the joint infrastructure for various geological data (EGDI). A basic necessity to gather such complex geoscientific data from different partner organizations from all over Europe is a common framework comprising metadata for existing maps and 3D models, an extended multiscale geological data model, and hierarchical and well-defined scientific vocabularies for various topics. Work package 6 of the GSEU initiative is responsible for creating this common framework with special focus on the seamless integration of all parts in order to provide well-structured and easy access to science-based geological information on Europe's subsurface.

This presentation is focused is on scientific vocabularies - developed in a controlled manner according to the principles of Linked Data technology, taking into account the W3C approved SKOS-RDF standard - and the advantages they provide. These vocabularies not only provide definitions for terms in use (and therefore already help better understand the presented data), but also allow storing unstructured information such as geographic description, detailed investigation history, debated theories, etc. In addition, the implementation of Linked Data technology creates a semantic knowledge network beyond the actual database by integrating links to other existing database and information resources, e.g. Wikipedia (DBpedia) and other online controlled vocabularies. Such, let's call them "semantic vocabularies", are also helpful managing transregional or transnational information and data with respect to different languages and across scales. These vocabularies can also build bridges between 2D and 3D visualizations. The implementation of the semantic vocabularies into the EDGI data infrastructure helps to do the step from mere digital data presentation to the construction of a knowledge platform.

As a showcase for the usage of Linked Data vocabularies, we show two examples: Semantic vocabularies have been already implemented in the HIKE European fault database (developed in the GeoERA project, the predecessor of GSEU project), especially regarding the hierarchical nomenclature of faults, semantic harmonization across national (and language) borders, and the linkage between fault geometries at different scales. At Geosphere Austria, the implementation of the Linked Data technology has been widely used for the semantic harmonization of geological units.

Geological Map of South America in the twenty–first century

Jorge GÓMEZ TAPIAS[1]*, Servicio Geológico Colombiano (mapageo@sgc.gov.co)
Nohora Emma MONTES RAMÍREZ[2], Servicio Geológico Colombiano
Carlos SCHOBBENHAUS[3], Geological Survey of Brazil
Daniela MATEUS–ZABALA[4], Servicio Geológico Colombiano

Abstract

The Geological Map of South America (GMSA) at a scale of 1:5 000 000 depicts the recent advancements in geological mapping across South America. Information from national geological maps of various countries and regional maps was aggregated and standardized at the 1:5 000 000 scale and subsequently was enriched with geochronological data from indexed journals.

The construction of the GMSA involved eight workshops convened to discuss and define its features. The main workshop took place in Villa de Leyva, Colombia, and included the participation of delegates from multiple countries. During this workshop, the official geological cartography from each South American country was obtained, and agreements were reached to create, revise, and endorse the final map. Subsequent workshops involved groups overseeing the GMSA at the Colombian Geological Survey and the Geological Survey of Brazil, who compiled and integrated the map. The GMSA comprises layers of chronostratigraphic units, faults, folds, basaltic dikes, intrusive and alkaline volcanic rocks, carbonatites, high–pressure metamorphic rocks, impact craters, kimberlites, and volcanoes.

A methodology for integrating geological information from each country was followed as follows. First, a new code was generated for each chronostratigraphic unit according to the proposed legend, using digital layers provided by the geological survey of each country; second, the symbology and colors representative of rock type and ages were created; and third, a map with coded units was prepared at a scale of 1:5 000 000.

The GMSA was printed at a scale of 1:3 000 000 with the new codification to facilitate generalization and manual linking of units. Subsequently, the GMSA was scanned and georeferenced to generalize the geological units, faults, and folds at a scale of 1:5 000 000. Despite the small–scale of the GMSA, the chronostratigraphic units, faults, and folds on the map were adjusted with the aid of shaded relief images (SRTM from NASA) to enhance the agreement between relief and mapped geological units. Harmonization of geology between countries was then carried out. Notably, updates to the GMSA were conducted taking into account data published in indexed journals.

The GMSA is available free in several formats including ArcGIS, PDF, TIFF, ArcGIS web map service, ArcGIS Online, Google Earth, and 3D. The creation of 3D models was accomplished

using Blender 3D software, allowing for schematic representation through objects, elements, shadows, and textures added to an initial 3D surface generated with a DEM (GEBCO). Once rendered, the resulting work yields a 3D image with a 90–meter SRTM resolution.

Spatial relationships between gold deposits, crustal structures, and geophysical fields using GIS and statistical analysis in Central Kyzylkumes, Uzbekistan

Bakhtier NURTAEV[1]*, Institute of geology and geophysics (nurtaev@ingeo.uz)
Oksana TSAY[2], Institute of geology and geophysics

Abstract

The westernmost region of Tien Shan, located in Uzbekistan, is renowned for its world-class ore deposits, which make it one of the wealthiest gold and copper provinces in Eurasia. However, the unique nature of these deposits is still not fully understood. To expand mineral resources, it is necessary to identify deposits that are hidden at a certain depth. Identifying the criteria for searching for these world-class deposits in the Tien Shan belt is a significant geological problem that is of great interest to both academic science and the mining industry.

We have chosen to study the Kyzylkum gold province, which is located in Central Kyzylkum and spans an area of approximately 165,000 km2. In this region, more than two dozen gold and silver deposits have been explored, and over 500 ore occurrences have been discovered. Although most of the mineralization has been found on the surface, there are indications of ore deposits in deeper layers. To identify new large deposits, we need to focus on three regional-scale phenomena that highlight the unique location of the Kyzylkum gold mining region in the Tien Shan belt. These phenomena are morphological features, anomalies of geophysical fields, and mega-scale structures. By examining these phenomena, we can gain a better understanding of the geological basis and uniqueness of this region.

GIS technologies and statistical analysis were utilized in an attempt to develop a methodology for predicting the metal content of a local territory. The research aimed to forecast the mineralization of a gold-bearing territory through data acquisition, data management, and geothematic mapping representation. This process involved conducting a spatial analysis of the geological structure to create a set of features and identify the typical features of mineralization localization.

A database containing geological and geophysical information on geology, geophysical anomalies, mineral deposits, ring structures, fault, and lineament structures has been created in the ArcGIS environment. We have categorized the digitized cartographic information into 4 blocks: geophysics, geology, tectonics, and mineral deposits, presented separately in layers with qualitative and quantitative data (polygonal, linear, and point objects). By using methods of spatial-statistical analysis of heterogeneous cartographic-geological information, we were able to assess the spatial distribution of geological objects and gold mineralization in the study area. As a result, we carried out a spatial analysis of the conditions that localize gold deposits and established their connection with structural, geological, and geophysical characteristics. The work carried out demonstrated the effectiveness of the methods used in large-scale metallogenic studies.

Hassan Kheyrollahi[6], Geological Survey of Iran, Tehran, Iran
Roghiyeh Mosavi[7], Geological Survey of Iran, Tehran, Iran

Abstract

Bazman exploration block is located at the southeastern end of the Urumieh-Dokhtar Cenozoic volcanic arc, which is the result of subduction of the Neotethys oceanic crust under the Cimmerian blocks. Based on geological evidence, this structural zone, as a part of the magmatic arc of the continental-oceanic margin, can be a suitable environment for the formation of deposit types such as porphyry Cu-Mo-Au, epithermal Au, and skarns associated with intrusive bodies. Considering the geodynamic environment, the geological data, high-resolution airborne geophysical data, geochemical data and remote sensing data have been used to prepare information layers and interpret them for prospecting the areas with high potential for porphyry Cu-Mo-Au and epithermal Au mineralization. Mapping the faults, igneous intrusive bodies as heat and fluid sources, suitable host rocks and locating the mineralization indices were the geological information extracted from the geological maps. Magnetic structures, hidden intrusive bodies, potassium alteration zones, demagnetized zones related alteration zones are information layers extracted from high-resolution geophysical data. Mapping the phyllic, argillic, advanced argillic, chloritic, propylitic alteration zones by Aster and Sentinel-1 data are the remote sensing layers. Stream sediment and heavy mineral samples in the area were analyzed for up to 33 elements and identification of different heavy mineral groups, and the geochemical anomaly maps were provided for the elements. The integration of layers in the GIS environment and using the methods of fuzzy integration, index overlap and hierarchical analysis process (AHP) has identified 35 promising areas with an approximate area of 915 square kilometers for more detail follow-up.

The geochronological database of Colombia: Review and new geological perspectives for this sector of the Americas

Daniela MATEUS ZABALA[1]*, Servicio Geológico Colombiano (dmateusz@unal.edu.co)
Nohora Emma MONTES RAMÍREZ[2], Servicio Geológico Colombiano
Jorge GÓMEZ TAPIAS[3], Servicio Geológico Colombiano
Eliana MARÍN RINCÓN[4], Servicio Geológico Colombiano

Abstract

The Geological Map of Colombia (MGC) 2023 is the most recent edition of the geological map of this South American country. Its updating is a missionary function of the Colombian Geological Survey, which publishes periodic versions according to the progress of national mapping and new geochronological data. The map presents chronostratigraphic units grouped according to the age and lithology of the surface materials. For age, the International Chronostratigraphic Chart 2022 was used as a reference. For lithological classification, the rocks and deposits were differentiated according to their formation environment, composition, or metamorphic grade.

Additionally to the Map, the latest update of Colombian mapping includes the geochronological database of Colombia that was created with the country's geochronological ages published in indexed journals until March 2022. This database contains ca. 35000 ages obtained from U–Pb, U–Th–He, Lu–Hf, Ar–Ar, Re–Os, U–Th–Sm, K–Ar, Sm–Nd, Rb–Sr, 14C, and traces of fission isotopic systems. In addition to the identification of each sample, the database presents the stratigraphic unit to which it belongs, the dated mineral, the number of dated grains, measurements and isotopic ratios, errors, and type of errors, published coordinates, cathodoluminescence (characteristics of zircons and dating location), and the interpretation of the data with information such as age, type of age, quality control of dating, observations, discussion, etc.

This database made it possible to update the age of the chronostratigraphic units on the national map and, therefore, separate or group units mapped in the previous edition of the map as a single one. This compilation work raises new questions and confronts the most accepted hypotheses about the formation of the Colombian territory. Also, the timing of main tectonic events that occurred on the western and northern margins of South America since the Proterozoic made the growth of the subcontinent possible.

One of the most relevant updates of the 2023 edition is the demarcation in the MGC of the late Paleozoic magmatic and metamorphic record. Thanks to the advance in detailed geological mapping and the combination with new petrological, geochemical, and geochronological analyses, discontinuous units of the Carboniferous (ca. 333–300 Ma) and Permian (ca. 294–263 Ma) could be defined in the national territory. These crop out from the upper Guajira in the Macuira

mountain range (the Macuira Gneiss), in the north of the country, the Sierra Nevada de Santa Marta (the El Encanto Orthogneiss), and in the Central cordillera (the El Carmen Stock, the Los Guayabos and Belalcázar Gabbros, the La Plata and Ortega Granites).

Magmatic and metamorphic units from the Carboniferous–Permian had already been recognized in other localities in central–southern South America, but not to the north due to lithological similarities with the superimposed Jurassic magmatic record. The record of these Paleozoic periods is relevant at a continental level because it has been considered evidence of the Alleghanian orogen, produced on the western margin of Gondwana by the collision with Laurentia during the Pangea assemblage.

New edition of the Geological Map of Colombia at a scale of 1:1,5M

Vanessa Rey León[1]*, Servicio Geológico Colombiano (vannerey0722@hotmail.com)
Nohora Emma Montes Ramírez[2], Servicio Geológico Colombiano
Jorge Gómez Tapias[3], Servicio Geológico Colombiano
Eliana Marín Rincón[4], Servicio Geológico Colombiano
Daniela Mateus Zabala[5], Servicio Geológico Colombiano

Abstract

Since 2003, the Geological Map of Colombia research group at the Colombian Geological Survey has been updating, refining, and integrating the most recent surface geological maps of the country and data published in geoscientific indexed journals.

The new edition of the Geological Map of Colombia at a scale of 1:1500000 was created using ArcGIS 10.8.2 and ArcGIS Pro 3.0.3 and includes twelve elements. Of these, the geological maps of the continental and island Colombian areas and the legend stand out. The reverse side of the map contains the references used for updating the map.

Surface materials are represented on the map as chronostratigraphic units. These are shown with colors, numbers, and patterns based on their age and lithology. For the ages and colors, the International Chronostratigraphic Chart 2022 was used as a guide.

Rocks are represented based on their primary classification in igneous, metamorphic, and sedimentary; additionally, volcaniclastic rocks were considered as an additional type. Igneous rocks were classified by their formation environment into volcanic, subvolcanic, and plutonic; these were further subdivided by composition into ultramafic, mafic, intermediate, and felsic. Metamorphic rocks were separated by the degree of metamorphism into very low, low, medium, high grade, and high–pressure rocks, and, due to their economic relevance, marbles.

Sedimentary and volcaniclastic rocks were grouped according to their depositional environment. The first ones were classified as continental, transitional, marine, continental–transitional, continental–transitional–marine, transitional–marine, while the latter were classified as continental, marine, and continental–transitional. Finally, deposits were divided into alluvial, terrace, alluvial fan, paludal, glacial, pyroclastic, dune, swamp, and volcanoclastic.

Despite the cartographic basis consisted mainly of geological maps at scales of 1:100000, 1:50000, and 1:25000 produced by the Colombian Geological Survey, there were numerous challenges in harmonizing the contacts between chronostratigraphic units and keep the continuity of structures because they were made by different authors in different years, therefore, with diverse quality. This is why, in some cases, contacts had to be followed using geomorphology, using Colombia's shaded relief images with a spatial resolution of 30 meters.

As a significant innovation, the map includes the following layers: volcanoes —distinguishing between polygenetic and monogenetic ones—, mud volcanoes, and high–pressure and ultrahigh–pressure rocks.

For the users to have a better understanding of the geology and to reach the greatest number of queries, the map was released in GIS (ArcGIS), PDF, TIFF, PNG, and 3D format, which helps highlight tectonic features more effectively, and Google Earth, as this tool is more user–friendly and widely recognized by the general public. Furthermore, an iOS app was created to display and consult the geological map of Colombia.

Surface and subsurface geological data in Italy: state of the art of the harmonization process.

Marco PANTALONI[1]*, ISPRA (marco.pantaloni@isprambiente.it)
Maria Pia CONGI[2], ISPRA

Abstract

The Geological Survey of Italy - ISPRA serves as the authoritative entity responsible for the comprehensive collection and management of geological data at a national scale. Before the realization of the new 1:50k scale map series, the evolution of the nationwide surface geological mapping in Italy spans from 1877 to 1976, resulting in the production of 277 geological sheets 1:100k scale. This prolonged timeline mirrors the significant advancements in both geological knowledge and cartographic technologies, evident in the diverse terminology used to describe rock formations.

Conversely, information garnered from deep boreholes for oil or geothermal exploration in continental or marine environments falls under the purview of the National mining office for hydrocarbons and georesources (UNMIG-MASE). Following the expiration of industrial licenses, ISPRA has undertaken the task of collating, analysing, and digitizing this information, incorporating it into a dedicated database.

Our aim is to integrate surface (100k scale Geological map) and subsurface (deep boreholes) geological information using a standardized data model, aligning with European and international geological management systems such as OneGeology, EGDI, and EPOS.

The entire dataset from the 100k scale mapping underwent a process of semantic and partial geometric harmonization conforming with the INSPIRE and GeoSciML data models.

The INSPIRE Data Specification and the Implementing Rules are also applied through the support of UML data models developed by INSPIRE's thematic working groups. These models are available in the INSPIRE Geoportal and in the specific GIT-LAB repository.

With these tools, the Geological Survey of Italy started additional harmonization process by applying it to the dataset derived from deep boreholes. The result is an organized dataset that adheres to the GeoSciML data model.

The deep boreholes dataset includes stratigraphic, lithological, structural, and chronostratigraphic data extrapolated from about 1,100 deep wells logs, realized both onshore and offshore.

Given the complexity of the dataset, the simplest standard chosen for this purpose was GeoSciML - Lite, designed for simple map-based applications. This standard is a simplify model aligned with INSPIRE, by complying the interoperability requirements.

Deep well data are provided in Geography Markup Language (GML) format for INSPIRE validation purposes. Other OGC standard formats (e.g. gpkg) have been prepared to simplify the download and the reuse.

The result of our efforts is thematic mapping sharing using OGC standard, semantically harmonized with respect to lithostratigraphic units, chronostratigraphy, lithology, depositional

environment, texture, and layering.
The analysis of deep boreholes facilitates the correlation of stratigraphic and structural features, enabling correlation between geological horizons and the reconstruction of geologically significant surfaces.
The integration between geological map and boreholes datasets is particularly valuable for conducting stratigraphic and structural studies, assessing subsurface resources, and contributing to CO2 capture studies.
The next phases of our work plan involve geometric harmonization of geological map polygons and the integration of the deep boreholes database with newly acquired log registrations. These steps will further enhance the completeness and accuracy of our geological information integration efforts.
This work was developed by ISPRA with the contribution of the EPOS Italia - Joint Research Unit.

Lingxue Gao[10], Chengdu University of Technology

Abstract

With the ongoing evolution of unmanned aerial vehicle (UAV) technology in geology, particularly the emergence of oblique photogrammetry, a novel approach for creating high-precision 3D models of geological outcrops has been introduced. This technique offers a more abundant and detailed perspective compared to traditional orthophotography. To guarantee optimal data collection, an extensive preliminary survey of the surrounding area of the geological outcrop was conducted using satellite imagery. We selected the DJI Mavic 3 drone, equipped with a 4/3 CMOS sensor and boasting an effective resolution of 20 million pixels. The incorporation of a Hasselblad lens significantly enhances the image quality. During the photography process, we meticulously controlled critical parameters such as the overlap rate of images, flight altitude, and the angle of photography. The overlap rate was typically maintained between 60-70%, necessitating systematic photography from macroscopic to microscopic levels and the continual adjustment of the drone camera's tilt to capture intricate details of the outcrop from various angles, enabling the construction of a more detailed and comprehensive 3D model.

Our project has digitally captured and modeled over 120 notable geological outcrops across 12 countries, including China, the United Arab Emirates, Italy, France, Germany, Spain, and Namibia, etc. We have amassed over 240,000 drone photos for 3D modeling, in excess of 7,000 panoramic shots, and more than 800 video segments featuring international experts discussing outcrops, culminating in 8000GB of data. The essence of our work is rooted in precise UAV oblique photography, and through extensive experimentation, we've established a systematic approach, achieving centimeter-level resolution. In terms of further interpretation and processing of the model, we have implemented steps such as automatic stratification, discrimination of paleoflows and determination of occurrence.

Looking to the future, our goal is to further the digitalization of classical geological outcrops, field practice bases, and world geoparks. The data and models we produce are invaluable for geological

research and education, offering a more vivid and intuitive understanding of complex geological phenomena to both the academic community and the public.

Geological and Prospectivity mapping of phosphates deposits in the Senegalese sedimentary basin

Mamadou Fall[1]*, UNIVERSITE CHEIKH ANTA DIOP DE DAKAR
(mamadou48.fall@ucad.edu.sn)
Abdoul Aziz NDIAYE[2], UNIVERSITÉ CHEIKH ANTA DIOP / ENSMG
Mamadou GUEYE[3], UNIVERSITÉ CHEIKH ANTA DIOP / ENSMG

Abstract

Lime phosphate exploration work begun in 1943 *resulted in the identification of deposits in the Center West of Senegal at Taïba, LamLam and Matam in the North East as well as the discovery of indices in different points of the sedimentary basin* (*Gossas, Kolda, etc.*). *Senegal produces phosphate around* 2.5 *million tons and have proven reserves of* 116.5 *million tons and probable reserves of* 337 *million tons. The mining sector, driven by phosphates and gold, plays an important role in the country's economy, producing a value of US*$ 2.49 *billion. Consequently, significant prospecting work must be carried out to sustain the reserves. The general aim of the work is to use the geological data available to model known deposits and to develop predictive maps which will serve as decision support in the form of a Prospecting Guide. The work thus consisted of* (*i*) *compiling geological and mining data on all deposits and indices* (*a GIS was created with* 45 *layers of information of varied kinds grouped into* 6 *categories namely phosphate occurrences, lithological units, structures tectonics, stratigraphic markers, facies types and multielemental geochemistry*), (*ii*) *carry out a geological, mineralogical, paleontological and geochemical characterization of the ores*, (*iii*) *model the deposits by producing a new geological map at* 1:500,000 *giving the main characteristics of the Lower Eocene, support of the stratigraphic horizon of phosphates in Senegal and* (*iv*) *produce predictive maps from two approaches namely by the "regionalized PCA"* (*also called Analyse Krigeante*) *which maps the Phosphate Factor and "oriented pixelation" which provides probability maps of phosphate occurrences. These maps will allow either mining companies to optimize their exploration strategy, or the State of Senegal to better guide its mining policy for this very strategic mineral, in particular by defining Promotional Zones as authorized by the* 2016 *Mining Code.*

Innovative Approaches to 3D Geo-Modeling of Geological Structures: Integration of Laser Scanning and Digital Photogrammetry, case studies from Ukraine

Mariia OLIINYK[1]*, Lviv Polytechnic National University (mariia.a.oliinyk@lpnu.ua)
Ihor Bubniak[2], Lviv Polytechnic National University
Andrii Bubniak[3], Lviv Polytechnic National University
Yevhenii Shylo[4], Lviv Polytechnic National University
Anatolii Vivat[5], Lviv Polytechnic National University

Abstract

In our presentation, we explore advanced techniques of laser scanning and digital photogrammetry as key tools for creating multi-scale 3D geological models, ranging from small minerals to massive rock outcrops. We demonstrate how the integration of these technologies not only improves the accuracy and detail of the models but also ensures high reliability of the results, which is critically important for geological research.

Our presentation includes specific examples from Ukraine, where these methods have been applied to study various geological structures. We highlight their significance for understanding the geological history of the region and for practical applications in areas such as natural resource exploration, ecological planning, engineering geology, natural risk management, and the development of geotourism.

Special attention is given to the data analysis obtained through these technologies. It is crucial to understand how proper interpretation of these data can contribute to accurate reproduction of geological conditions and processes. We also discuss how these innovative methods can be applied across different geological disciplines, underscoring their versatility and effectiveness.

At the same time, we acknowledge the challenges and limitations associated with laser scanning and digital photogrammetry. Including technical and financial aspects, we discuss how these issues can impact geomodeling and what strategies can be used to overcome them.

In conclusion, we focus on the future of these technologies. Discussing potential innovations and development in the field of 3D geomodeling, we attempt to predict how these changes might affect geological science and practice. Particular attention is paid to the role of these technologies in the development of geological research in Ukraine and their impact on the international geological community.

Finally, we emphasize the significance of these advanced technologies in enhancing the level of geological science and practice, particularly in the context of geological research and development in Ukraine. We aim to show how modern geomodeling methods can open new horizons in understanding and utilizing geological resources.

Detecting Brittle Structures in Vegetated Landscapes with Sentinel-2 Data: A Case Study of Deep Geological Repository Site Assessment

Jan JELENEK[1]*, Czech Geological Survey (jan.jelenek@geology.cz)
Lucie Koucká[2], Czech Geological Survey
Barbora Kořínková[3], Czech Geological Survey

Abstract

Identifying brittle structures in Central European landscapes, often characterized by dense vegetation and agricultural modifications, presents a significant challenge. Existing methods, such as in-situ mapping and remote sensing via LiDAR or airborne geophysics, can be costly or limited by accessibility. Brittle structures, particularly those hydrologically active, pose a significant limitation for a potential Deep Geological Repository (DGR) site. This study investigates the potential of Sentinel-2 satellite imagery, a freely available multispectral dataset with high spatial resolution and frequent revisit times, for indirect detection of brittle structures through soil moisture variations at four potential DGR sites across the Czech Republic.

The analysis addresses three key challenges: (1) significant crop type variability within the study area, (2) diverse land cover types (fields, pastures, forests) and (3) variations in cloud coverage between the images. To overcome these, we employ newly developed tool, "Moi v2.0," which weights per-pixel occurrences of high moisture content based on a 9-year Sentinel-2 time series. Moi v2.0, built using Python and Google Earth Engine, facilitates efficient processing of large satellite datasets in the cloud. By leveraging weighted time series of spectral indices, the approach successfully mitigates year-to-year variations in land cover and precipitation, standardizing the spectral response across the analyzed area. The resulting map indicates the probability of high soil/vegetation moisture content at each pixel.

Our analysis revealed that, on a larger scale, spatial variability in soil moisture aligns with the location and boundaries of geological units. In particular, the contrast between impermeable clays and permeable granitic sands was clearly visible. On a smaller scale, it was possible to directly identify hydrologically active brittle structures. These were validated using morphological lineaments and existing tectonic map.

This study demonstrates the potential of freely available multispectral satellite data, like Sentinel-2, for aerial geological mapping, even in landscapes with high vegetation cover. This offers a cost-effective and accessible method for preliminary assessments in DGR site selection and other geological investigations.

Further research is needed to validate its applicability across diverse geological settings, also using new ground-truth data.

(Open)GeoSGB: State of the art of Transition to an Open Source, semi-automated, FAIR-ready Geological Spatial Data Infrastructure of the Geological Survey of Brazil

CARLOS EDUARDO MIRANDA MOTA[1]*, Geological Survey of Brazil/SGB (carlos.mota@sgb.gov.br)
Flavia Renata Ferreira[2], Geological Survey of Brazil/SGB
Alvaro Gomes Sobral Barcellos[3], Geological Survey of Brazil/SGB
Americo dos Santos Junior[4], Geological Survey of Brazil/SGB
Pietro Laba Menezes[5], Geological Survey of Brazil/SGB
Edgar Shinzato[6], Geological Survey of Brazil/SGB
Hiran Silva Dias[7], Geological Survey of Brazil/SGB

Abstract

The Geological Survey of Brazil (SGB) is under a digital transformation process. One of the pillars of this process involves speed, scalability, security and availability of data produced. Furthermore, CPRM is creating a favorable environment for the adoption of cloud-based architecture. This paper aims to present an overview of a new developed Geological Spatial Data Infrastructure for the SGB. The GeoSGB is the main source for internal mapping, infographic and dashboard applications. It will assimilate legacy services, that runs on isolated map servers, such as self hosted node of OneGeology OGC Services. The solution adopted is GeoNode 4.2, which brings together map, data services, metadata catalog and spatial database. It is free and open source software with a very active community. In addition, GeoNode has a good content management system, a rich API, and it's fully customizable. To meet data access demands, it was customized to run in Kubernetes-based environments and each mapped area produces its own geoservice, exportable to different formats, such as shapefile and geotiff. However, it became necessary a complete separation between the production and publishing environments. SGB's production pipeline is composed by internally developed data management software. Some of these systems are being modernized, with updates on business rules, frameworks and security. GIS work is carried out in ArcGIS Enterprise®, with some exceptions in QGIS and GeoServer. With this background, it should be considered as a hybrid GIS model. About database structures, a process of harmonization was necessary, mainly those produced from proprietary GIS. For legacy reasons, the proprietary structures were maintained, as long as possible to export to OGC WKT or WKB. Exported geometries are analyzed for compliance with Simple Features Standard (OGC/ISO19125). The information eligible for publication were consolidated in database views and is literally replicated to GeoSGB, by script. The metadata production for continuous databases is carried out semi-automatically – templated - in accordance with the mapping program. This is possible by integrating GeoNode's APIs with internal databases, delivering associated metadata and resources directly to the authors. The contact with (meta)data authors were managed by GeoNode. The symbolization of thematic layers involved the development of interoperable libraries, based on SVG glyphs inserted in OpenType fonts (ISO/IEC 14496-22:2007), with near

equal rendering among different multi-platform GIS software. Data and metadata pipelines were implemented using Python scripts, with specific libraries associated with GeoNode APIs. Apache Airflow manages the entire process of extracting internal bases, quality tests, structure analysis and loading on the GeoSGB database server, including being responsible for notification activities. So, GeoSGB now is a continuous development platform, with focus in increase quality in delivered data to customers. The future perspectives involve the transformation itself into research line in geotechnologies and high-performance IT services. It shoud envolve plug-in development for data management, processing and visualization including use of artificial intelligence. In operational terms, adoption of OGC APIs, data internationalization and harmonization, associated with adoption of OGC specific standards, such as GeoSciML and WaterML contributes to become SGB a global supplier of geoscientific data.

Abstract

Resources estimation and numerical simulation of coalbed methane reservoirs depend on precise 3D geological models. The various properties of coalbed methane reservoirs (such as coal thickness, buried depth, coal quality, gas content, porosity, permeability, etc.) are heterogeneous in 3D space, which affect the occurrence, migration and development of coalbed methane. Lauren is one of the critical coalbed methane–producing fields in Surat Basin, Australia. Take Lauren coalbed methane field as the experimental area, a rapid modelling method of coalbed methane reservoirs based on well logs was studied in this paper. Firstly, by analyzing and using the data of remote sensing, DEM, and well logs, the integrated geosciences structure model of the aboveground and underground was created rapidly. Then, a multi-linear regression mathematical model for interpreting properties of coalbed methane reservoir was generated based on geophysical logs and laboratory analysis data. Furthermore, the 3D geological structure model was segmented into voxels, and the 3D high-resolution property models were achieved by interpolating the log interpretation data in 3D space. The 3D high-resolution property models, such as coal quality, coal faces, porosity, permeability and gas content, can characterize the high-resolution property characteristics of coalbed methane reservoirs, which can provide decision supports for the development of coalbed methane resources.

Abstract

The subsurface of the Netherlands has been the focus for oil and gas exploration for decades. With exploration and production of hydrocarbons decreasing, the need to safeguard, consolidate and make existing data and knowledge publicly available for future use became more and more apparent. In this light the GEODE project was set up with the aim to create an easily accessible, web-based GIS environment where play-based exploration (PBE) data can be displayed and downloaded for the main hydrocarbon and potential CO2 aquifer storage (sub)plays of the Dutch subsurface. The PBE process is an industry best-practice to document and evaluate subsurface data and systematically determine the value of remaining reserves. Within the context of this project, we are extending the use of this approach from pure hydrocarbon-focused exploration to including other relevant use cases such as CO2 saline aquifer storage and hydrogen storage.

The initial components of the PBE for hydrocarbon exploration include risked assessments of the presence and quality of a source rock, reservoir, seal, and trap. Common Risk Segment Maps (CRS) were made using a traffic light system identifying areas with high, medium, and low potential. To assess the subsurface potential for saline aquifer CO2 storage, additional subsurface analyses/deliverables were needed, such as injectivity, relative storage capacity density as well as geological containment potential. The gross thickness and permeability of the aquifers were used as a proxy for CO2 injectivity in the subsurface. The relative storage capacity density was estimated using gross reservoir thickness, average porosity and reservoir depth, as well as a set of rock and fluid properties. Overpressure and fault fracture likeliness maps were included to highlight the compartmentalization of the aquifers and indicate potential containment/vertical leakage risks. Due to limitations in the available input parameters as well as the availability of field data for calibration, the current maps can only be used for qualitative screening purposes.

For the first time a combined resource atlas is built, using a coherent database of subsurface data which gives the possibility to assess and evaluate potential synergies but also to identify conflicts of use and therefore aid in the planning and decision making process for subsurface energy

projects. The PBE results for the Triassic, for example, show significant overlap in areas with historic gas production and aquifers for potential CO2 injection, suggesting possibilities in infrastructure re-use but also potential containment issues.

The Landslide Whisperer: An Intelligent and Efficient Framework for wrapped Interferogram Detection of Potential Hazards

Ruixuan Zhang[1]*, Chang'an University (rx.zhang@chd.edu.cn)
Wu Zhu[2], Chang'an University
Qian He[3], Chang'an University

Abstract

The Multi-Temporal Interferometric Synthetic Aperture Radar (MT-InSAR) technology shows significant advantages in identifying potential landslide hazards. However, the process is invariably affected by unwrapping errors and Atmospheric Phase Screen (APS), resulting in less accurate identification. Additionally, unwrapping operations incur substantial time costs, hindering real-time responsiveness. Hence, why not consider completing the identification task before unwrapping? In this work, leveraging the ISSLIDE dataset and data-driven convolutional neural networks (CNNs), we design and propose an intelligent framework for more efficiently identifying potential landslide hazards from wrapped interferograms. The framework consists of three main parts. The first part involves reprocessing the ISSLIDE dataset, where we read phase, cosphase, and sinphase in a more computer vision-oriented manner. The second part focuses on the network structure design. The model is divided into three sections: firstly, the phase, cosphase, and sinphase information is abstracted into high-dimensional semantic features through three weight-sharing, parallel encoding processes; secondly, features of the same dimension at each encoding level are fused via a feature fusion mechanism; finally, five different dimensions of the fused features are loaded into the decoder to complete the final decoding process. The third part addresses the integration of extracted results from interferograms across different time periods. We also take this opportunity to discuss "How to Train a Segmentation Network to Unearth Deformation Regions in Wrapping Interferogram with Unparalleled Precision?" This includes examining the impact of channel numbers, input methods, loss functions, and feature fusion techniques on segmentation results. Ultimately, our goal is to generalize the trained high-precision model to real-world scenarios. To validate our method, we use data from the publicly available LiCSBAS platform and conduct experiments in the lower reaches of the Jinsha River in China. The results demonstrate that our proposed intelligent framework shows promising performance in practical applications.

The f(utility) of GIS-based landslide susceptibility: a review approach

Mihai Niculiță[1]*, Alexandru Ioan Cuza University of Iași (mihai.niculita@uaic.ro)

Abstract

The landslide susceptibility approach is very used today in landslide research. While the utility of this type of approach, especially in the context of hazard-risk workflows, other uses of the methodology are problematic. To understand the evolution and the progress of the susceptibility approach we realized an intensive critical review of the literature pinpointed both the utility, but also the futility of such an approach. The utility in the context of the hazard-to-risk evaluation is clearly shown in the literature, but even in this context, very often there are issues with the landslide inventories, with the lack of the optimization criteria, and with the utility in a practical context. The literature review analyzed the papers since 1980 when the approach was born, to the present day. After 2010 the increase in the number of papers is exponential. In the review, we analyzed the typology of the papers (theoretical, applicative), the data sources (in terms of landslide inventory, DEM, landslide factors), the methodologies (geomorphological, empirical, statistical, physical), validation strategy, the complexity of the scenario, the typology of the landslide, and applicability. The results show that the majority of the literature is applicative, with the theoretical approaches in the minority, although a certain number of these theoretical studies drive the trend of number increase. After 1990 the majority of the papers rely on GIS and statistical models, and on DEM variables for factors. The typology is variate (natural, anthropic-induced, co-seismic), but very often there is a lack of analysis of mechanism type differentiation (falls, slides, and flows considered together). The validation strategy is in majority based on ROC, and only a few papers deal with multi-temporal inventories that allow robust validations. The scenario of landslide triggering and evolution is limited to point-based GIS and statistical approaches, but there is a minority of papers considering run-out modeling. The applicability is the area where there is a general lack of specific applications of the results. As a conclusion of the analysis we have synthesized the results on the criteria mentioned and we have outlined the desired directions of the study in order to improve the utility of the GIS-based landslide susceptibility.

InSAR analysis for monitoring Cultural Heritage threatened by multiple risk and anthropogenic hazards: the seaport quarter in Valparaiso (Chile) case study.

Federica Ferrigno[1], ISPRA Geological Survey of Italy
Gabriele Leoni Leoni[2], ISPRA Geological Survey of Italy
Francesco Menniti[3], ISPRA Geological Survey of Italy
Daniele SPIZZICHINO[4]*, ISPRA Geological Survey of Italy (daniele.spizzichino@isprambiente.it)

Abstract

Valparaiso is a colonial city located on central Chile's Pacific coast, of which the historic seaport district has been declared as UNESCO World Heritage Site in 2003 for its rich history, unique architecture, and remarkable landscapes. However, the area is threatened by multiple natural risks, including slope instability, seismic hazard, tsunami, and man-induced hazards such as fires and subsidence. Slope superficial instabilities are caused by the thick layer of weathered rock from the Paleozoic and Mesozoic batholit and plutons along the hill slopes and subsidence is due mainly due to the compaction of soft sediments of the recent coastal deposits.

The current work shows the application of the InSAR (Interferometric Synthetic Aperture Radar) technology able to estimate, with millimeter precision, slow and non-catastrophic morphological processes, both long-term and seasonal, triggered by a great variety of causative factors. These kind of Aanalysis allows the planning of mitigation strategies.

More in detail, a specific InSAR data processing has been performed in the UNESCO buffer area of the historic district i of Valparaíso, additionally, a direct field survey to test the InSAR results has been carried out (November 2023).

SAR images acquired from Sentinel-1 constellation (C-band radar sensor) have been processed to generate multi temporal ground displacement measurement points using an A-DInSAR method, and to analyze their spatial distribution and correlation with slope instability and historical remains damages, thus allowing to verify the evolution of recent ground deformation phenomena (from January 2020 to August 2023).

The initial results show clear deformation patterns in different areas in both descending e ascending geometry, but any cluster of moving measurement point has been detected. Only some isolated points have been identified, and the analysis of their time series suggests that the movement (ca about 3mm/y) is probably due to small and local deformation instead than medium or large slope instability phenomena over the whole investigated area.

In conclusion, the results of the Sentinel-1 data provided useful information for detecting and monitoring the potential interaction between ground displacements and structures and to define potential unstable areas over the time, detecting anomalies and accelerations of the ground displacement, offering a powerful tool for the prevention of damage to cultural heritage related to the slope instability and subsidence.

The proposed research activity was developed within implementation of the FPCUP programme.

More in detail the actions aims to promote the uptake of Copernicus data and services in Central and South America (C&SA) focusing on Natural and Anthropogenic hazard and vulnerability assessment

Multi-frequency SAR time-series analysis of ground subsidence at coastal reclaimed land in Busan

Jeong-Heon JU[1]*, Pusan National University (jh.ju@pusan.ac.kr)
Sang-Hoon Hong[2], Pusan National University

Abstract

Synthetic Aperture Radar (SAR) is a remote data acquisition method that exploits microwaves to interact with the Earth's surface, enabling the retrieval of distance and scattering characteristic information about the Earth. With technological advancements, many satellites equipped with SAR payloads with different system characteristics, such as radar wavelength, revisit period, and incidence angle, have been launched and are being operated. Multi-temporal interferometric SAR (MT-InSAR), a technique utilizing multiple observations acquired over a long period, effectively removes residual phase errors in SAR observations and enables the precise estimation of time-series ground displacement. In the golden age of spaceborne SAR, characterized by the availability of numerous SAR sensors, exploiting multi-frequency SAR imagery for MT-InSAR research is indispensable. Ground subsidence, a phenomenon where surface materials sink due to natural or anthropogenic factors, can cause significant damage to human and material resources. Continuous monitoring is necessary to manage the devastating disaster of ground subsidence, and multi-frequency spaceborne SAR offers a promising solution. In this study, we aim to observe ground subsidence occurring at coastal reclaimed land in Busan, located in the southeastern region of South Korea, using multi-frequency space-borne SAR. We utilized X-band COSMO-SkyMed, C-band Sentinel-1, and L-band ALOS-2 PALSAR-2 SAR observations acquired from 2015 to 2019, comparing and analyzing results to measure ground subsidence and its causes accurately. In each result, there were differences in coverage by frequency, but similar distributions of subsidence were observed. The average subsidence rates in the research area were -1.99 mm/year from COSMO-SkyMed, -0.64 mm/year from Sentinel-1, and -1.10 mm/year from ALOS -2. In contrast to previous multi-frequency studies aimed at extending the observation period, this study demonstrated the potential to identify suitable SAR images through comparisons between SAR images from similar periods.

Abstract

Coasts are continually evolving and remote sensing from satellites has the potential to both map and monitor coastal change at multiple scales for geohazard management. Experts in Earth Observation and end-users responsible for coastal monitoring from 5 different countries jointly developed the project Coastal Erosion from Space funded by the European Space Agency (ESA, 2020-2023) with the aim of assessing the ability of satellite derived products to detect coastal changes. This study presents the application of shorelines extracted from S1 SAR combined with S2 optical datasets, from publicly available satellite imagery, to map and capture intra-annual to inter-annual shoreline variability. This is assessed in three distinct settings areas from Ireland, Spain and the UK that represent coastal segments with different backshore environments: low-lying dunes and marsh; steep, rocky cliff; and urban environments. We have found that SAR derived shorelines consistently corresponded to positions above the high-water mark across all three sites. In a low-lying coastal setting, the annual change rate derived through SAR presents a high degree of alignment with the known reference values derived from optical satellite analysis. We further discuss the influence of the scene geometry, meteorological and oceanographic conditions, and backshore environment and provide a conceptual interpretation for the satellite-derived shorelines. The present study contributes with validation to our understanding of the poorly constrained knowledge of using shorelines derived from publicly available SAR satellite missions. It outlines a quantitative approach to automatically assess their quality with a novel automatic detection method that is transferable to shoreline evolution assessments worldwide.

Geospatial Analysis of Coastal Dynamics and Development Strategies: A Case Study of Nagapattinam District, Tamil Nadu, India

Isai RAMACHANDRAN[1]*, Post Doctoral Fellow (isairamachandran@gmail.com)
Kannan Perumal[2], Research Scholar
Babu BALAKRISHNAN[3], Research Scholar
Natarajan GOVINDARAJU[4], Research Scholar

Abstract

This research delves into coastal zone management and planning for Nagapattinam District in Tamil Nadu, South India, leveraging Geospatial technology. Through meticulous analysis of various spatial distribution thematic maps encompassing rainfall patterns, geology, geomorphology, shoreline changes, and land use/cover utilizing collateral and satellite data, critical insights have been unearthed. Notably, areas such as Vanjiyur, Nagore, and Nagappattinam stations exhibit high rainfall, contributing to flooding and sediment deposition in estuaries, as evidenced by the annual average rainfall map. Geologically, flood basin deposits dominate, covering a substantial 1608 km2 area, with direct implications for coastal dynamics. Vulnerability assessments underscore regions of fluvial origin as particularly susceptible, where saltwater intrusion imperils agricultural lands and groundwater. Shoreline analysis spanning from 1971 to 2013 highlights significant accretion primarily attributed to major cyclones, notably Cyclone Nisha in 2008 and Cyclone Thane in 2011. Detailed land use/cover mapping delineates a gradual increase in human-made aquaculture ponds and salt pans until 2008, stabilizing thereafter, alongside a steady rise in built-up areas. Moreover, strategic development sites for tourism, transport networks, ferry services, sand harvesting, and resorts have been identified, emphasizing the holistic approach towards sustainable coastal development. This comprehensive research serves as a pivotal resource for informed decision-making and proactive management of coastal resources, fostering resilience and prosperity in the region.

Multitemporal Monitoring of Landslides using Remotely Piloted Aircraft (RPA) and Structure from Motion–Multi View Stereo (SfM-MVS): Case Studies in Brazil

Camila Duelis VIANA[1]*, Universidade de São Paulo (camila.viana@usp.br)
Rebeca Durço Coelho[2], Universidade de São Paulo - Institute of Geosciences
Vivian Cristina Dias[3], Universidade de São Paulo - Institute of Energy and Environment
Lucas Pedrosa Soares[4], Spatial Analysis And Modelling Lab (SPAMLab) IEE-USP
Guilherme Pereira Bento Garcia[5], Spatial Analysis And Modelling Lab (SPAMLab) IEE-USP
Carlos Henrique Grohmann[6], Universidade de São Paulo - Institute of Energy and Environment

Abstract

Landslides are among the most frequent and destructive natural hazards, representing one of the main causes of disasters. In Brazil, mass movements are geological processes that result in the highest number of fatalities. According to data from the Institute of Technological Research of the State of São Paulo (IPT), between 1988 and 2022, these processes led to 4,146 deaths in 16 Brazilian states. Thus, the automation of landslide mapping and monitoring is crucial for a better understanding of these processes, ensuring a swift response in disaster scenarios, and enhancing landslide susceptibility models.

The development of remote sensing technologies in the last decade has led to a significant growth in the information available about the Earth's surface. Among these advances, high-resolution orbital images capable of generating Digital Elevation Models (DEMs), airborne or terrestrial Light Detection and Ranging (LiDAR), and, more recently, the application of Structure from Motion–Multi View Stereo (SfM-MVS) technique to sets of images obtained by Remotely Piloted Aircraft (RPAs) can be mentioned.

The combination of such technologies, especially RPAs and SfM-MVS, provides a low-cost solution and the possibility of greater control over the temporal and spatial scales of surveys, making it particularly valuable in the study of landslides. In Brazil the use of RPAs to study landslides is still incipient and particularly challenging considering the diversity of scenarios within the country. To illustrate these differences, we selected two study areas in São Paulo State, southeastern Brazil, and evaluated multitemporal monitoring of landslides using RPA and SfM-MVS.

The first area is located in the São Sebastião municipality, in the coastal area of the State. The region is mainly prone to shallow landslides and debris flow. The most recent disaster event was registered in February 2023, resulting in significant human and economic losses. The studied area consists of a vegetated hillslope with a shallow landslide measuring approximately 250 x 100 m. Historical satellite imagery shows that the first ruptures of the landslide occurred around 2002. We conducted fieldwork for RPA surveys in October 2019 and May 2021, 2022 and 2023.

The second area is located in the northern part of the São Paulo municipality. Unlike São Sebastião, São Paulo is highly urbanized and the fourth-most populous city in the world, posing some challenges to the use of RPAs. The study area is locally known as CEU Paz, where urban

communities have developed in steep slopes since 2004, causing recurrent small landslides.
For both areas, images were acquired by a DJI Phantom 4 Pro V2 RPA and the SfM-MVS workflow was processed in Agisoft Metashape Pro. For each area, we compared the multiple digital surface models using Geographic Information System and the point clouds using CloudCompare. The analysis revealed the suitability of the chosen method for landslide monitoring while also highlighting limitations to consider. This research demonstrates the potential of RPAs and SfM-MVS for landslide monitoring in diverse Brazilian landscapes, contributing to improved risk assessment and mitigation strategies.

Utilizing PSInSAR and Open-Source Software for Monitoring Slow-Moving Landslides: A Case Study from Southern Taiwan

Abhishek Ravindra LAKHOTE[1]*, Institute of Earth Sciences (abhi.lakhote1994@gmail.com)
Yu-Chang Chan[2], Institute of Earth Sciences
Chiao-Yin Lu[3], National Science and Technology Center for Disaster Reduction

Abstract

Slow-moving landslides pose significant threats to the stability of mountainous regions, affecting both human settlements and infrastructure. This study focuses on the southern part of Taiwan, specifically at the Hsinfa village in the vicinity of Laonong River, where slow-moving, deep-seated landslides have been identified as a significant geohazard since the 2009 Morakot Typhoon. This study presents a detailed analysis of monitoring slow-moving deep-seated landslides utilizing PSInSAR techniques, complemented by the integration of open-source software tools. Utilizing the temporal and spatial information provided by these techniques; this study aims to characterize the movement along the slope of the identified deep-seated landslides in the Laonong River region. The integration of StaMPS with ISCE environment facilitates the identification of persistent scatterers and the detection of ground deformation associated with slow-moving landslides. The datasets used for this research focused on the Sentinel 1 datasets from 2018 to 2023, which contribute to a better understanding of the dynamics of slow-moving deep-seated landslides in the southern part of Taiwan. The findings from the PSInSAR techniques provide valuable information, such as that the slope is characterized by EW (horizontal) and NS (vertical) velocity values ranging from 1.5 mm/yr to 6.5 mm/yr movement for the observed period. The results observed along the slope also corroborate the present inclinometer stations at the site-specific areas. This observation surely helps in developing early warning systems and implementing effective mitigation strategies to reduce the impact of such geohazards on local communities and infrastructure. Furthermore, the study highlights the significance of remote sensing technologies in monitoring and managing landslide-prone areas for sustainable development and risk reduction.

Fostering New Talent: Exploring Innovative Approaches in Geoscience to Meet 21st Century Societal Needs

Courtney Elaine Jermyn[1]*, ESM Foundation (c.jermyn@earthsciencematters.org)

Abstract

The escalating challenges posed by climate change, resource scarcity, and the need for skilled labour in a sustainable economy are pressing global issues that must be addressed. Earth's role is central to many of these challenges, necessitating increased societal awareness and innovative, science-driven solutions that harmonize the demands of our planet with those of its inhabitants. The commitment of UN member states to the Paris Agreement underscores the urgency of transitioning to a low carbon economy. The competition for essential metals between renewable industry scaling and technological advancements further complicates this transition. To navigate these complexities sustainably, leaders require access to comprehensive information underpinned by Earth Science expertise, which is currently at risk of depletion. Addressing the decline in Earth Science education and expertise is crucial for overcoming these obstacles and fostering a sustainable future.

As the geoscience field faces the challenge of an aging expert population, the question arises: how do we ensure the continuity of knowledge and inspire a new generation of Earth scientists? Could advancements in GIS and remote sensing be the vehicle to bridging the gap geoscience education?

Through an open discussion format, we will delve into this pressing issue, and examining the current trends experienced by geoscience professionals. During the presentation session we aim to engage the audience to collaboratively seek solutions to sustain and invigorate geoscience programs, ensuring that our understanding of the Earth remains robust to meet society's needs in the 21st century and beyond.

Landslide susceptibility assessment using Mahalanobis Distance-based class imbalance strategies: A comparison of under-sampling, over-sampling, and hybrid sampling techniques

Kounghoon NAM[1]*, Andong National University (geonamsoil@gmail.com)
Jongtae Kim[2], Nature and Tech Inc, Korea
Hojin Lee[3], Korea Water Resources Corporation, Korea
Shuai Zhang[4], Institute of Geomechanics, Chinese Academy of Geological Sciences, China
Chang-Oh Choo[5], Andong National University, Korea
Gyo-Cheol Jeong[6], Andong National University, Korea

Abstract

This research investigates the effectiveness of different resampling methods—under-sampling, over-sampling, and hybrid sampling—within the Random Forest (RF) framework for enhancing landslide susceptibility modeling in Hokkaido, Japan. The region, severely impacted by 5,625 landslides triggered by the 2018 Iburi earthquake, serves as the study site. The primary aim is to mitigate the challenges posed by class imbalance in landslide susceptibility assessment (LSA) and to refine the predictive accuracy. The study leverages multiple data sources to define conditioning factors and employs a novel strategy for selecting absence data based on Mahalanobis distance to address the issue of unlabeled samples. The RF model is utilized to compute susceptibility scores and produce LSA maps, which are assessed using the Area Under the Receiver Operating Characteristic curve (AUROC) and the Precision-Recall curve (AUPRC). These metrics facilitate the evaluation and interpretation of the model's predictive capabilities in the context of imbalanced datasets. Findings indicate that resampling methods, especially when combined in a hybrid approach and supplemented with Mahalanobis distance-based absence data selection, significantly enhance model performance and reliability in LSA. The study underscores the potential of these strategies to improve the precision and stability of machine learning models in landslide risk reduction efforts. Acknowledgment: This study was carried out with the support of R&D Program for Forest Science Technology (Project No. 2023476C10-2325-BB01) provided by Korea Forest Service(Korea Forestry Promotion Institute).

Opportunities of Advanced Remote Sensing for Rock Mass Classification on Inaccessible High Alpine Rock Slopes

Nicole OYSMUELLER[1]*, University of Natural Resources and Life Sciences in Vienna
(nicole.oysmueller@students.boku.ac.at)
Christian Zangerl [2], University of Natural Resources and Life Sciences in Vienna
Christine Fey [3], University of Natural Resources and Life Sciences in Vienna
Erik Kuschel [4], University of Natural Resources and Life Sciences in Vienna

Abstract

In order to describe and classify rock slope failures and to estimate the slope stability for an area of interest, it is important to perform several in-situ investigations with various methods. Thereby, a special focus is laid upon the structural inventory of a rock mass, as its discontinuities can provide kinematic feasibility for rock slope failure.
Investigations in areas exposed to natural hazards can be challenging to perform or generally be unfeasible due to its inaccessibility for humans.
Thus, the application of advanced remote sensing techniques may be crucial, in order to derive important rock mass parameters, such as the discontinuity network. However, the method still needs to be validated with in-situ data.
The study area 'Kühtaier Längental' with its high alpine terrain is located in the Oetztal Nappe of the Austrian Alps. Its well-exposed, fractured, metamorphic rock mass offers great potential for our investigations.
During a four-week field campaign detailed in-situ investigations were performed.
A total number of 675 discontinuities were recorded and evaluated, which led to a proper rock mass characterization of the rock slope.
The study area was additionally examined remotely both with a UAV system and a terrestrial laser scanner (TLS) from different positions, making it possible to gather a 3D terrain-model of the inaccessible areas. This provided the basis to compare the in-situ measurements with the advanced remote sensing data, derived by UAV and TLS. Furthermore, the results of the manual recording of discontinuities can be compared with the structural inventory derived from the TLS and UAV point-clouds.
In our study, we present a comparison of the data by highlighting advantages and disadvantages of the respective techniques.
As a conclusion, this study is intended to make a qualitative statement as to whether semi-automatic recordings can be suitable for engineering geology issues. In our study we demonstrate the opportunities and limitations of deriving a fracture network by advanced remote sensing in inaccessible high alpine terrains.

rock mass characterization, remote sensing, discontinuity network, high alpine rock slope

A Study on the Utilization of GNSS Data for Monitoring the Stability of the Yangsan Fault

Heeun KIM[1]*, Korea Meteorological Administration (khu0716@gmail.com)
HaSeong LEE[2], Korea Meteorological Administration
Jimin LEE[3], Korea Meteorological Administration
Sun Cheon PARK[4], Korea Meteorological Administration

Abstract

In recent times, major earthquakes, including those in Gyeongju and Pohang near the Yangsan Fault, have occurred on the Korean Peninsula, highlighting the need for monitoring studies on the ground movements around the Yangsan Fault Zone. This study utilized GNSS (Global Navigation Satellite System) observational data to conduct monitoring by analyzing the displacements and calculating strain stresses in the vicinity of the Yangsan Fault. The analysis methods employed in this study involved, firstly, analyzing the global movements of the ground around the Yangsan Fault based on the IGS (International GNSS Service) reference station. Secondly, analyzing the strain stress around the Yangsan Fault using domestic GNSS data. Data processing was carried out using the Bernese GNSS Software. The Bernese GNSS Software is a scientific, high-precision, multi-GNSS data processing software developed at the Astronomical Institute of the University of Bern (AIUB). The analysis period spanned from July 2018 to December 2023. The results indicate that the ground movements around the Yangsan Fault corresponded to the annual average of the Korean Peninsula in terms of magnitude and direction. Additionally, the stress levels around the Yangsan Fault were relatively stable compared to the period of the Tohoku Earthquake. However, continuous monitoring using GNSS is deemed necessary due to the persistent seismic activity in the region.

Keyword

GNSS, Strain Stress, Yangsan Fault, Bernese, Earthquake

Geological Risk Mapping in the Largest City in Brazil: From Paper Reports to Artificial Intelligence

Thais Feitosa TREVISANI[1]*, São Paulo City Hall - Civil Defence Coordination (thaistrevisani@gmail.com)
Camila Duelis Viana[2], Universidade de São Paulo - Institute of Geosciences
Natália Leite de Morais[3], São Paulo City Hall - Civil Defense Coordination
Caroline Gevaert[4], University of Twente - Faculty of Geoinformation Science and Earth Observation

Abstract

São Paulo ranks in the top 20 most populous cities, with over 11 million inhabitants in the municipality alone. While it is the wealthiest city in Brazil, it is also highly unequal. Approximately 26% of its inhabitants are low-income, leading to many of them living in areas prone to mass movement processes.

Although the urban expansion from the center to the periphery, with the occupation of land with lower construction aptitude and areas of protection for water sources, began in the 1930s and consolidated from the 1970s onwards, it was only in the late 1980s that geological risk areas began to be mapped, after a landslide killed 14 people, including 12 children.

Until 2015, risk mapping was carried out by hiring companies, atlarge time intervals: 1989/1990, 1996, 2002/2003, and 2009/2010. The reports and maps were produced using different mapping methods, were delivered in printed form, and were based on different cartographic bases. This resulted in discrepancies between them, making it impossible to perform spatialized comparative and quantitative analyses.

Starting in 2018, an effort began to initially organize all the mapping updates in a geographic information system (GIS), and then to digitize the risk sectorization of previous mappings in the same system. The digitization work was essentially manual, with consultation of several historical maps and reports, cartographic bases, and current high-resolution images, as well as the correction to the official datum of the country, to faithfully preserve the boundaries of the various risk sectors.

The unification of the various mappings in a GIS environment allowed for the quantitative evaluation of the spatialization and evolution of geological risk areas. Such data also allows for verifying whether the implemented risk mitigation and prevention actions for the occupation of new risk-prone areas are satisfactory, pointing out shortcomings or successes in the city's risk management.

In 2023, a new phase began, with the final goal of using artificial intelligence to help monitor the more than 480 areas at risk of geological hazards, many of them representing low-income neighborhoods. Using the GIS database, orthophotos with a resolution of up to 10 cm produced from two airborne lidar surveys (2017 and 2020), and orthomosaics produced using remotely piloted aircraft and photogrammetry, it is expected to achieve the segmentation of elements that may alter the risk classification (e.g., leaning trees, exposed soil, wooden houses), and which are

not always visible during field inspections. To this end, the Segment Anything Model (SAM), a new AI model from Meta AI that is a promptable segmentation system with zero-shot generalization to unfamiliar objects and images, without the need for additional training, will be tested. Such an automatic workflow has the potential to harmonize risk classifications and increase the ability to monitor changing risk profiles across São Paulo.

Abstract

The Taiwan main island, with 47% of its land situated above 1000 meters, has consistently experienced slopeland disasters caused by intensified typhoons and torrential rains triggered by the extreme climate. To prevent and mitigate potential landslide hazards, relevant government agencies have been proactive and dedicated to conducting large-scale landslide monitoring and analyses. After evaluating the scale of disaster-affected areas, potential risks, and preservation targets, the Agency of Rural Development and Soil and Water Conservation, Ministry of Agriculture (hereinafter referred to as the ARDSWC) has further planned a landslide activity assessment for 306 potential large-scale landslide sites this year. At the current stage, to acquire extensive ground surface deformation data, the use of the all-weather and high-resolution Interferometric synthetic aperture radar (InSAR) technique with continuous spatial coverage is essential to provide long-term and quantified information for potential large-scale landslide areas.
This project has adopted the imagery of the ALOS-2 satellite released by the Japan Aerospace Exploration Agency (JAXA) in 2014, along with the Temporarily Coherence Point InSAR (TCP-InSAR), to analyze the ground surface deformation data of potential large-scale landslide areas. In the meantime, the aerial Lidar-derived Digital Elevation Model (DEM) is utilized for geomorphometric analysis and value-added algorithms to further obtain cartographic information, such as the slope, openness, curvature, and roughness. This information can facilitate the statistical, quantitative, and image analysis of surface terrain features in potential large-scale landslide areas. In light of this, leveraging multi-variant and multi-scale observations effectively contributes to managing disaster-prone areas, thereby serving as a valuable reference for subsequent detailed planning and engineering management of slopes.

Abstract

With the rapid development of Taiwan's economy and the increasing construction of infrastructure, it is important to prevent the planning and construction of road corridors from being affected by potential hazards, which may lead to subsequent environmental loads or extreme events that may disrupt the structural stability of the transportation facilities. This project integrates multiple remote sensing techniques to interpret underlying geological structures, detect regional slow ground deformation in a larger scale, and assess rainfall and hydrological information at different scales. This project aims to analyze the potential environmental hazards in the early stages of planning and design, and provide early warning when road facilities from being subjected to the amount of cumulative deformation on the ground surface or exceeding a certain limit, which may threaten the normal operation of the transportation network or even cause major incidents. Taking the national highway as an example, several collapses on the dip slopes along the northern coast of the Keelung River and the effects of the regional structure on the Zhongliao Tunnel highlight the importance of understanding the regional geological structure, and conducting landslide activity assessment and environmental monitoring in selecting the infrastructure site and planning road corridor at the early design stage, and the subsequent environmental impact assessment. At the same time, regular deformation monitoring of infrastructure is essential for timely detection of potential safety hazards and ensuring their safe operation.

The project has accomplished the following achievements: (1) Conducting topographic metric analysis using airborne LiDAR to interpret the topography and geomorphology of the eastern sections of National Highway 7 and Provincial Highway 86 with a focus on prominent gullies and structural features (e.g., terrain slope, openness, curvature, and roughness); and further identify factors along the road corridors that potentially contribute to slope disasters. (2) Collecting and pre-processing of radar satellite images, including 66 ALOS-2 raw images spanning from 2015 to 2022; and, based on the InSAR ground surface deformation analysis results, pinpointing key road sections with significant ground surface deformation rates on National Highway 7 and Provincial Highway 86. (3) The time-series profile analysis of cumulative ground surface deformation, coupled with rainfall data, reveals that ground surface deformations in specific areas of both road

sections are influenced by typhoons, heavy rainfall, and seismic events; and the limestone segment of the Dasha Formation in the Fengshan section of National Highway 7 experiences a pronounced trend of ground surface deformation triggered by the erosive effect of rainwater. Therefore, in regions with relevant topographic and geological conditions along these two highways, a careful evaluation of hydrological and geological conditions is advised. Moreover, since Provincial Highway 86 is situated in proximity to the Longchuan Fault zone and features an exposed mud volcano, it is recommended to assess exposed mud diapirs during the eastward extension project of Provincial Highway 86 and prevent the infrastructure from being affected by mud diapirs and fault activities.

Assessing Landslide Vulnerability in Sindhudurg District, Western India: Integrating Stakeholder Perspectives and Geospatial Analysis

AMIT VIJAYKUMAR SHIRKE[1]*, Research Scholar, Department of Geology, Savitribai Phule Pune University, Pune (amitshirke2311@gmail.com)
Bhavana Umrikar[2], Professor, Department of Geology, Savitribai Phule Pune University, Pune

Abstract

Landslides pose a significant threat in the Western Deccan Volcanic Provinces, particularly in the Western Ghats region of India, where unique weathering properties, rugged terrain, heavy rainfall, and human activities converge to heighten susceptibility. This study concentrates on pinpointing landslide-prone areas within Sindhudurg district, Western India, by amalgamating stakeholder insights with geospatial analysis. A structured questionnaire was administered to 208 stakeholders, including local government officials and public representatives from various villages in the district, considering factors such as Deccan Trap typology, heavy rainfall, seismic activity, and anthropogenic influences. Statistical methodologies, encompassing mean, standard deviation, and factor analysis, were employed to extract pivotal influencing factors from stakeholder responses. Geospatial datasets, incorporating digital elevation model (DEM), slope, aspect, geology, geomorphology, road network, and drainage density, were assimilated into the analysis. The Analytic Hierarchy Process (AHP) facilitated the weighting of influential parameters, contributing to the formulation of a landslide vulnerability map. Findings unveiled that stakeholders' perceptions were shaped by a myriad of factors, including heavy precipitation, seismic events, and human interventions. This research underscores the significance of integrating stakeholder perspectives into disaster management strategies. Validation of the landslide vulnerability map was performed through alignment with stakeholders' observations of hazardous areas. The outcomes furnish valuable insights into landslide vulnerability dynamics and serve as a foundation for informing policymakers and district disaster management authorities. By prioritizing resources and deploying targeted mitigation measures, authorities can effectively mitigate the adverse impacts of landslides, promoting resilience and sustainable development. This interdisciplinary approach, blending stakeholder engagement with geospatial analysis, provides a robust framework for assessing landslide vulnerability and enhancing disaster preparedness in analogous geographical contexts.

Research on Precipitation Prediction and Geological Disaster Warning Based on Infrared Remote Sensing and Deep Learning

jingyi zhang[1]*, School Of Earth Sciences, Zhejiang University (Zjingyi@zju.edu.cn)
linshu hu[2], School Of Earth Sciences, Zhejiang University

Abstract

Precipitation is a natural phenomenon, which has great significance in human production and life. Its complex relationship with agriculture, water resources, and the overall ecological balance highlights the urgent need for accurate prediction and effective management of precipitation. This article utilizes large-scale infrared remote sensing technology to capture high-precision, near-real-time precipitation data and analyzes and processes the remote sensing data to make it more suitable for precipitation estimation. This enables a deeper study of the subtle differences in precipitation dynamics, decoding the local spatial and temporal patterns of precipitation, and revealing the complex and high-order spatial and temporal characteristics of large-scale weather systems. Through research, we can deepen our understanding of precipitation mechanisms, patterns, and evolution trends to make better decisions and strategic plans. The paper uses deep learning methods to build a precise and real-time short-term precipitation prediction model, considering three geological disasters that are greatly affected by rainfall: collapses, landslides, and debris flows. When the precipitation forecast reaches a certain threshold, disaster warnings will be issued to reduce losses of life and property and enhance the ability to predict and respond to precipitation-related challenges. By utilizing advanced remote sensing technology, we can obtain information on dynamic changes in precipitation and improve the resilience and sustainability of the human life support system.

Geological Hazard Mitigation Portal of Indonesia

Ahmad BARNES[1]*, Geological Agency (barnes.esdm@gmail.com)
Gentur Dwi Teguh Santoso[2], Geological Agency
Hery Kuswandarto[3], Geological Agency

Abstract

Located along the “Pacific Ring of Fire”, Indonesia faces high seismic, tsunami, landslide and volcanic risk. As the government-mandated agency to perform geological hazard mitigation, CVGHM has duty to do monitoring, evaluating, reporting, mapping, perform analysis and providing technical recommendations of geological hazards in Indonesia. We continuously strategizing and establishing an efficient and optimal infrastructure and data management system to improve mitigation that allow contingency planning, effective emergency preparedness, timely assessment, warning and action during crisis. Multi-hazard disaster mitigation action requires functioning disaster mitigation information systems that can provide reliable and timely data, statistics and analysis. For this reason, we created geological hazard mitigation portal, an open access interactive graphical user interface allowing users to search and download various geological hazard maps (earthquake, tsunami, landslide, volcanic), volcano geological maps and and rain-induced landslide susceptibility maps. This map can be visualize interactively based on area of interest following administrative boundary and kept up-to-date with the most recent recommendation. Given that we are also dealing with large amounts of volcano monitoring data that are complex and of various types and formats, a robust and efficient data management platform is crucial for CVGHM. We are using PostgreSQL, an open-source relational database management system emphasizing extensibility to GIS-based data type and SQL compliance. To make an efficient data archiving, we developed a system that able to automatically input low-rate processed data into the database. This system also allows data display in near real-time through web application. All of these efforts aimed for quick assessment, timely evaluation, and better decision to provide early warning to the community.

Integration of ISAR and GNSS for Monitoring the Stability of Artificial Slope: a Case Study of Lijiang, China

Yinjie CAO[1]*, Tongji University (james008@tongji.edu.cn)
Lei ZHANG[2], Tongji University

Abstract

China, with a vast territory, complex terrain, diverse climate and unique geology, frequently experiences landslides that result in heavy casualties and property losses. In southwest China, where extensive construction of highways and high-speed railways is taking place, the creation of high and steep artificial slopes has become common. However, due to the complex geological structure in southwestern areas, these artificial slopes are prone to sliding or even collapsing after one or two rainy seasons. Such occurrences not only disrupt the progress of construction projects but also pose a potential threat to the infrastructure safety operation management. Therefore, it is crucial to establish an automated real-time monitoring and warning system for various geological hazards, particularly focusing on the artificial slope sliding, which assumes paramount practical significance in guaranteeing the safe operation of infrastructure.

Nowadays, traditional methods employed for monitoring artificial slope sliding include leveling instruments, GPS ground stations, and crack meters, among others. However, these traditional methods exhibit limitations in terms of their ability to effectively monitor proven landslide points within a restricted area, resulting in low efficiency, high costs and susceptibility to external conditions. Furthermore, they fail to accurately reflect the overall deformation characteristics and trends of the sliding forms at regional scale, particularly with regard to the hidden landslides in inaccessible areas. The emergence of spaceborne synthetic aperture radar (InSAR) technology has effectively addressed the deficiency associated with traditional technologies, rapidly establishing itself as a prevalent geodetic method due to its extensive coverage, high precision, high resolution and independence from weather and lighting conditions. However, the low temporal resolution of InSAR technology remains limited, precluding the extraction of real-time surface deformation information.

In this project, we amalgamate the space-borne Interferometric Synthetic Aperture Radar (InSAR) and Global Navigation Satellite System (GNSS) technologies to monitor the stability of artificial slopes formed during the construction of Huali Highway in Yunnan Province (Huaping to Lijiang section of National Highway G4216). Initially, we employ the TCPInSAR technology to extract deformation information in Lijiang, utilizing a set of 17 PALSAR-2 images acquired between 2014 and 2019. Then we select 8 artificial slopes situated along the highway as our designated monitoring areas, where we deploy GNSS ground monitoring stations. The optimal deployment of these stations will be guided by the InSAR historical deformation census. The effectiveness and practicality of this integrated InSAR and GNSS monitoring system will be verified through this project. This integrated system has successfully found three deformation areas with more than ten times warning messages during past two years.

Multi-Sensor Remote Sensing Data and Deep Learning for Time-Series Analysis of Caldera Lake Dynamics at Mt. Changbai: Monitoring Volcanic Activity

EURU LEE[1]*, University of seoul (eurulee22@uos.ac.kr)
Ha Seong Lee[2], Korea Meteorological Administration
Ji Min Lee[3], Korea Meteorological Administration
Sun Cheon Park[4], Korea Meteorological Administration
Hyung Sup Jung[5], University of seoul

Abstract

To mitigate and minimize the damages caused by volcanic eruptions, continuous monitoring of pre-eruptive signs is essential. In the case of the active volcano Mt.Changbai, changes in the area and water level of the caldera lake, Cheonji, serve as reliable indicators of volcanic precursory phenomena (Shibata and Akita., 2001). However, due to the extensive area of caldera landscapes and the accessibility limitations in high mountain regions, satellite imagery becomes indispensable for monitoring Cheonji water body and level (KMA2022). Deep learning technologies have demonstrated superior performance in detecting changes in water body and level compared to traditional methods, robustly adapting to various conditions and environmental changes, thereby enhancing the accuracy and efficiency of volcanic monitoring. This study employs SAR-EO sensor satellite imagery alongside deep learning techniques to monitor volcanic activity at Mt. Changbai. Utilizing images captured between 2014 and 2022 during the thawing period of August to December, we developed an algorithm with an F1-score of 0.996 for estimating the water body area and level using 129 Sentinel-1 SAR images, 45 Sentinel-2 optical images, and Copernicus DEM data. The developed algorithm facilitated the analysis of multi sensor satellite time-series data on water body area and level, allowing for the assessment of seasonal effects and discrepancies between satellites. To achieve precise volcanic activity monitoring that incorporates heterogeneous satellite imagery, we acquired regional meteorological data near Mount Changbai and developed and applied an Long Short Term Memory model that corrects for time-series weather distortions and inter-satellite biases. The study did not identify any significant volcanic activity in Cheonji during the research period, aligning with the results of other studies on Mt. Changbai's volcanic activity. The consistency of our findings with other research suggests that, when used in conjunction with other Mt. Changbai volcanic activity monitoring techniques, our approach can contribute to a more

precise surveillance system for the volcano.

Assessing the Potential of Novel Remote Sensing Techniques in Landslide Monitoring and Susceptibility Mapping

Dylan GORDON[1]*, University of Pennsylvannia (dylan44514@gmail.com)

Abstract

Landslides are a major hazard that can cause significant damage to property and infrastructure. Traditional methods for identifying landslide conditions and demarcating landslide susceptibility are often time-consuming and labor-intensive. In recent years, there has been a growing interest in the use of remote sensing to improve these methods. Continuous satellite-derived data and imagery can provide a wealth of information about landslide conditions, including changes in land surface elevation, vegetation cover, and soil moisture. This information can be used to identify areas that are at risk of landslides and to track the development of landslide conditions over time. By comparing and contrasting differences between commonly used methods of continuous landslide monitoring and identification, an assessment of the results can determine the most viable and/or successful method to identify areas susceptible to landslides. The use of satellite-derived data and imagery in continuous landslide monitoring is still in its early stages, but it has the potential to revolutionize the way that landslide hazards are assessed. There is significant potential in novel remote sensing techniques in landslide monitoring and susceptibility mapping. By providing a more accurate and timely assessment of landslide hazards, recent advancements in remote sensing can help to save lives and property.

Mitigating decorrelation noises and atmospheric delays in InSAR

Jun HU[1]*, Central South University (csuhujun@csu.edu.cn)
Jihong LIU[2], Central South University
Yuqi TANG[3], Central South University

Abstract

Decorrelation noises and atmospheric delays pose significant challenges in achieving high-accuracy surface displacement measurements using Interferometric Synthetic Aperture Radar (InSAR). Decorrelation noises, which manifest randomly in both temporal and spatial domains, hinder the recovery of interferometric phases. Traditionally, optimization of interferometric phases relies on statistically homogeneous points throughout the observation period, leading to inadequate recovery of decorrelated phases and potential use of incoherent phases in optimization, consequently compromising measurement accuracy and density. To tackle this challenge, we propose incorporating a strain model to capture the spatial correlation between displacements of adjacent points. By leveraging this spatial constraint relationship, homogeneous points of target pixels can be identified on an interferogram-by-interferogram basis, effectively suppressing decorrelation noises and achieving precise interferometric phase optimization.

In contrast, atmospheric delays exhibit spatial correlation and temporal randomness. Methods to mitigate these errors typically fall into two categories: those based on external information and those using data-driven techniques. External methods rely on sources like GNSS-derived tropospheric models and meteorological data but often lack the necessary spatial resolution. Conversely, data-driven techniques directly utilize InSAR data, addressing stratified and turbulent components separately. However, this separation may lead to biased estimates due to the interdependence of these components. To overcome these challenges, we introduce DetrendInSAR, a novel data-driven method that simultaneously models and mitigates turbulent and stratified delays. Leveraging their spatiotemporal characteristics, DetrendInSAR models turbulent delays as a slowly changing spatial process and stratified delays as linearly related to local terrain height. These components are integrated into a mathematical model using a pixel-by-pixel window-based strategy, with additional constraints provided by the assumed temporally smooth displacement signals in InSAR observations.

Validation using both simulated and real SAR data demonstrates the efficacy of the proposed methods in mitigating decorrelation noises and atmospheric delays. Case studies include investigating surface displacements in the Geysers geothermal field and postseismic displacement after the 22 May 2021 Maduo earthquake in China. Results reveal the enhanced accuracy of the proposed methods in displacement measurement compared to traditional methods. The ground surface deformation in the Geysers is slowdown after the construction of two fluid injection projects in 1997 and 2003. Moreover, analysis of postseismic displacements highlights the contribution of poroelastic rebound to near-field deformation, in addition to afterslip reported in earlier studies.

High-Density and High-Temporal-Frequency Monitoring of Reservoir Landslides with InSAR based on Environmental Prior Information

Qian SUN[1]*, Hunan Normal University (sandra@hunnu.edu.cn)
Aoqing GUO[2], Central South University
Wanji ZHENG[3], Central South University

Abstract

The creep of rock and soil masses along the slopes of reservoir banks occurs due to fluctuations in water levels, leading to sudden and destructive landslides that can rapidly slide into the reservoir in just a few dozen seconds, generating huge waves and posing a significant threat to the safety of people's lives and property. Monitoring the evolution of historical surface deformation using Interferometric Synthetic Aperture Radar (InSAR) technology can predict the risk of premature instability in landslides. However, current InSAR deformation monitoring for reservoir bank landslides still faces technical barriers in terms of precision and temporal frequency. Regarding monitoring precision, factors such as steep terrain and seasonal decoherence can limit the detection of deformation characteristics within blind spots. In terms of temporal frequency, SAR satellites typically operate at relatively low orbit altitudes, resulting in limitations in InSAR deformation monitoring due to fixed revisit cycles and low temporal resolution, which cannot meet the need for continuous monitoring of geological disasters. To address these issues, we have proposed a new InSAR method that leverages the spatiotemporal characteristics of landslide deformation as prior information to effectively enhance the density and accuracy of temporal monitoring of landslide deformation in low-coherence regions. This method combines independent component analysis (ICA) with the identification of temporary coherent points. Additionally, we have developed a high-temporal frequency landslide deformation estimation method that incorporates hydrological observations, such as rainfall and reservoir water levels, as prior information, significantly improving the temporal resolution of InSAR temporal monitoring of landslides. By utilizing the characteristics of our new methods, which yield products with high spatial density and temporal frequency, we have conducted detailed high-temporal frequency deformation monitoring of the Xinpu landslide in the Three Gorges Reservoir Area. The application of our new methods has revealed previously undetected potential small-scale movement units, detected significant seasonal signals, and identified accelerated deformation triggered by the rainy season in 2020. Furthermore, our methods have increased the temporal resolution of landslide deformation monitoring along the reservoir bank to one day. Our proposed methodological framework has advanced the development of landslide deformation detection, monitoring, and disaster risk prediction, paving the way for more accurate and timely assessments of landslide hazards and the mitigation of potential risks.

Identification of lithium deposits information based on two Chinese satellites

Nannan ZHANG [1]*, Xinjiang Institute of Ecology and Geography , Chinese Academy of Sciences (znn_0802@163.com)
Li CHENG[2], Xinjiang Institute of Ecology and Geography , Chinese Academy of Sciences
Hao ZHANG[3], Xinjiang Institute of Ecology and Geography , Chinese Academy of Sciences

Abstract

Currently the worldwide development and utilization of lithium has gained significant attention, as its demand remains inflexible in both military and civilian applications. The search of lithium ore remains a critical research focus in geological prospecting, as consumption continues to rise. Remote sensing has been used for mineral and lithology identification for years, but the identification of lithium ore is still in its infancy. Using China's Gaofen-5 hyperspectral data, this study has conducted research on identifying Li-rich pegmatite in the high-altitude and high-cold West Kunlun region of Xinjiang. Additionally, the study has analyzed the spectral characteristics of Li-rich and Li-poor pegmatite in the 509 mining area of the large-scale lithium mine in China. Finally, the study has determined the identification factors of Li-rich pegmatite based on ground spectral data and the Gini coefficient. In the Gaofen-5 remote sensing image, various factors have been identified, indicating that the method has a significant impact on the identification of Li-rich pegmatite. Furthermore, the sensitive feature bands for Li-rich pegmatite identification are determined using a genetic algorithm. These bands are then combined with geological maps to distinguish between Li-rich and Li-poor pegmatite using a random forest algorithm. The classification results are evaluated based on overall classification accuracy (OA) and the kappa coefficient. The evaluation of inversion and recognition accuracy of Li-rich pegmatite on remote sensing images has been completed, with the highest recognition accuracy of Li-rich pegmatite achieving an F1-score of 0.771. This study demonstrates the effectiveness of the "genetic algorithm + Gini coefficient + random forest" approach in identifying Li-rich lithology in remote sensing images, offering a novel technology and perspective for discovering lithium deposits in alpine cutting areas.

Abstract

The "Exploration Information System" (EIS) project, funded by the European Union (EU) Horizon Europe research and innovation funding programme, aims to discover new sources of critical primary raw materials within the EU. Therefore, EIS intends to develop and utilize a unique combination of the mineral system approach and mineral predictive mapping (MPM) tools in the open-source geographic information system (GIS) software of Quantum GIS (QGIS).

Since the beginning of the EIS project in May 2022, the “EIS Toolkit” and the “QGIS EIS Plugin” have been successfully designed and developed. The “EIS Toolkit” is a Python library of functions customized for mineral prospectivity mapping (MPM) and analysis. The “QGIS EIS Plugin” consists of two parts: The “EIS Wizard” and the “EIS Processing Toolbox”. The EIS Wizard is a user interface guiding through different steps of mineral system modelling and prospectivity analysis. It provides the possibility to organize data for the different mineral system components and proxies and track the processing workflow of the prospectivity modelling. The “EIS Processing Toolbox” is the QGIS interface to the “EIS Toolkit” functions, and it can be used outside the “EIS Wizard” for building custom prospectivity analysis workflows in QGIS, for instance, with the QGIS model builder.

The beta release of the “EIS Toolkit”, dated 6th November 2023, can be found on GitHub under: https://github.com/GispoCoding/eis_toolkit. The first release will be available by the end of April 2024. The EIS QGIS Plugin can be found on GitHub under: https://github.com/GispoCoding/eis_qgis_plugin. The beta release is scheduled for April 2024, while the first release is planned for October 2024. Both software products – “EIS Toolkit” and “QGIS EIS Plugin” - are published with a free and open-source EUPL 1.2 license, which is a GPL-compatible copy left license.

Characterization of mineral systems in northern Finland using autoencoders- and self-organizing maps-based deep learning architecture.

Bijal Chudasama[1]*, Geological Survey of Finland (bijal.chudasama@gtk.fi)

Abstract

The northern Finland province is comprised of several tectonic domains and geological divisions. The geological characteristics of these regions are similar to the highly mineralized belts of Australia and Canada. For instance, the Palaeoproterozoic belts such as the Central Lapland belt and the Peräpohja belt are known to host mineral deposits of ferrous metals (Fe, Ti, V, Cr), precious metals (Au, Pd, Pt), base metals (Ni, Co, Cu), and critical metals (REE, Ta). Out of the 47 metallogenic areas identified in Finland, more than half are located within the northern Finland province comprising genetically diverse mineral deposits encompassed in different mineral systems. Studies have shown that a single geological province can host different mineral systems yielding several mineral deposit types because of the presence of shared mineral system components such as sources for metals and energy or the pathways. This feature can be attributed to the presence of a favourable geodynamic architecture, that over the history of geological evolution of the region could sustain different mineral systems through repeated reactivations.

In this study we characterize the signatures of different mineral systems existing in the metallogenic areas of northern Finland using advanced machine learning methods. Two unsupervised methods, namely, self-organizing maps and autoencoders are combined in a deep learning architecture to jointly implement representation learning and clustering of regional scale geoscientific datasets. Unsupervised machine learning methods are deployed to gain insights into the structure of the data, identifying features in latent space and subsequently, the sparsely labelled training data facilitates characterization of these features to genetically different mineralization styles and systems. Additionally, the implementation of supervised machine learning based mineral prospectivity analysis is generally constrained because of lack of sufficient training data that represent mineral deposits. Class balancing method such as SMOTE (Synthetic Minority Oversampling Technique) is used for data augmentation to generate additional feature vectors representative of mineral deposits for subsequent supervised classification and predictive mapping.

Sparse spectral unmixing applied to hyperspectral satellite imagery for accurate identification and mapping of hydrothermal alteration minerals

Masahide KISHIMOTO[1]*, Kyoto University (kishimoto.masahide.75z@st.kyoto-u.ac.jp)
Taiki Kubo[2], Kyoto university
Katuaki Koike[3], Kyoto university

Abstract

Remote sensing using Earth observation satellites has been widely applied to detect signs of metallic deposits and hydrothermally altered minerals, because it can detect them in wide areas. With many observation wavelength ranges (bands) and a large amount of information, Hyperspectral satellite imagery can identify surface materials accurately. However, not all bands of hyperspectral data are optimized for the analysis method. In this study, we apply feature selection methods used in machine learning, and propose a high-accuracy mineral content estimation method that combines sparse spectral unmixing method with band importance evaluation based on two criteria: class separability performance and linear separability performance. The proposed estimation method was verified by laboratory experiments using several hydrothermal alteration minerals and hyperspectral Hyperion and HISUI data of the Cuprite field, west Nevada, USA. The Cuprite field is a suitable site for testing the proposed method, as it has been extensively studied by geological surveys and remote sensing techniques that reveal the surface minerals, especially hydrothermal alteration minerals like alunite and kaolinite. In the analysis of laboratory experimental data, the actual and estimated contents matched well. Also, from the HISUI image taken on 1st October 2021 and Hyperion image taken on 19th September 2011 with zero cloud cover, mineral distribution maps were created by the proposed method, and a mineral distribution map that corresponded well with the geological map was obtained. Furthermore, kaolinite distribution was able to be discriminated and delineated despite similarity of the reflectance spectrum to alunite.

Spectral Geological mapping in Kuhi area, Maharashtra, with AVIRIS-NG Airborne Hyperspectral Data

Trina Vishal VYAS[1]*, Geological Survey of India (trina.royburman@gsi.gov.in)
Debjani Sarkar[2], Geological Survey of India
P. Balaji[3], Geological Survey of India

Abstract

The Advanced visible infra-red imaging spectrometer - Next Generation (AVIRIS-NG) data of many mineralized belts in India has been acquired from aerial platforms over the Indian subcontinent during October-November, 2015, January-February, 2016 and March-April 2018 under ISRO-NASA collaboration. The Kuhi area is a part of the north-western limb of the Sakoli synclinorium. The Sakoli Group of rocks are Archean to Lower Proterozoic metasedimentary sequences of chlorite-quartz-sericite schist, tourmaline schist, graphite schist, sericitic quartzite, marble, migmatites, potash feldspar porphyroblasts bearing mica schist, lepidolite bearing mica schist, phyllite, pegmatite with or without tourmaline quartz vein, milky and smoky quartz veins, silicified zone. Tourmalisation and brecciation in the schistose rock are commonly associated with greisenization. Hematitization is also associated at places with greisen zones.

For the extraction of end members, the Minimum Noise Factor images are subjected to Pixel Purity Index (PPI) module followed by the n-Dimensional Visualization technique. The spectrally purest pixels of tourmaline were identified using PPI. The n-dimensional visualization method serves as an interactive tool for multidimensional analysis and identification of spectral endmembers. To determine the greisen zone this set of end member signatures is used in the spectral feature fitting (SFF) techniques to find the most spectrally pure or spectrally unique pixels within the dataset. Tourmaline and hematite-rich areas are hence demarcated and the result indicates that the SFF algorithm is very effective in differentiating subtle spectral features and obtaining accurate mineral information.

The standard USGS mineral spectra, AVIRIS-NG image spectra, and field-lab spectra of samples collected from muscovite schist, greisen zone, ferruginous alterations areas in quartz, azurite-malachite staining have been compared and the diagnostic spectral characteristics confirm the presence of these rocks, minerals and zone.

Abstract

The concept of the Digital Twin of Russia's Mineral Resources implements the transition from the accumulation of static data to the creation of a dynamic, constantly updated multidimensional model of Russia's mineral resources based on the integration of information flows obtained during geological exploration, regional geological study of mineral resources and scientific studies. The combination of technical solutions and resources of the Digital Twin will provide analysis and modelling of geology, identification of new patterns, their verification and refinement in virtual space.

The technology of the Digital Twin of Russia's Mineral Resources provides

- Automated process of integration, updating, processing and spatial analysis of results of geological studies at various scales of geological mapping, creation of a unified geological mapping model of the country;
- Dynamic integration of up-to-date data from state information systems of licensing and exploration, accounting systems of mineral deposits, promising areas and licensing;
- Use of structured digital data arrays for complex processing and interpretation of geological information, assessment of exploitability of geological features and settings, prediction and exploration of mineral deposits;
- Creation of a reliable and up-to-date information base for management decisions in geological exploration, development of the mineral resource base and its use at the federal and regional levels.

The Digital Twin resource developed at the Karpinsky Institute includes more than 130,000 maps, 200,000 natural mineral and man-made features, 2.1 million primary data, as well as tens of thousands of geochronological determinations and reference geological features.

The technologies of the Digital Twin of Russia's Mineral Resources have been developed on the basis of standard software and hardware solutions and can be used for arranging digital geological information by various geological surveys and national geological institutes.

[Keynote] Assessment of Machine Learning Techniques for Prospectivity Modeling and Vectoring of IOCG Mineralizations

Carlos Roberto Souza Filho[1]*, University of Campinas (beto@unicamp.br)
Elias PRADO[2], University of Campinas / Geological Survey of Brazil

Abstract

The progression of mineral exploration, with an emphasis on bolstering mineral resource availability while mitigating environmental ramifications, is integral for fostering a robust and sustainable socio-economic development within society. The current era witnesses a rapid surge in mineral extraction and consumption owing to escalating human populations, heightened economic activity, and the shift towards new technologies. Addressing this mounting demand necessitates the mineral industry to tackle significant challenges such as discovering new mineral resources, optimizing production efficiency and safety, and minimizing the environmental impacts of mining activities. Promising solutions to these challenges are found in the adoption of artificial intelligence techniques, big data analysis, and other Industry 4.0 technologies.

Here, we introduce innovative approaches to mineral exploration targeting, specifically focusing on the application of cutting-edge machine learning algorithms for mineral prospectivity mapping and ore grade estimation utilizing spectral data. These methodologies are exemplified through the exploration of Iron-Oxide Copper Gold (IOCG) deposits, which are reservoirs of economically vital commodities like copper (Cu) and rare earth elements (REEs), currently experiencing high and escalating demand.

The methodologies developed herein encompass two primary stages of mineral exploration: the identification of new mineralized zones and the extraction of known deposits. Given the pioneering nature of these methodologies, the essence of this work revolves around various facets including data processing, algorithm optimization, model architecture, and hyperparameter tuning of machine learning algorithms. Specific details regarding the mineral prospectivity mapping approach and ore grading estimation are also explained.

Machine learning techniques were tailored to process geological and geophysical data from the Carajás mineral province in Brazil, with the aim of modeling the prospectivity of IOCG mineral deposits in the region. The results demonstrate that the synthetic minority oversampling technique, utilized for dataset balancing, markedly enhances the performance of machine learning algorithms for mineral prospectivity mapping. These models, developed employing machine learning algorithms, exhibit superior classification and spatial performance compared to traditional data-driven methods such as the weight of evidence approach. Hence, these methodologies are poised to become prominent in the field in the forthcoming years.

Additionally, a novel approach is introduced where deep learning algorithms are employed to forecast Cu grades at the Olympic Dam deposit in Australia, utilizing hyperspectral data. The outcomes indicate that this approach holds promise for application in automation systems for identifying mineralized zones, enabling selective mining. This has the potential to reduce costs

and environmental impacts while enhancing the efficiency of mining operations.
The findings of these studies indicate that machine learning techniques surpass traditional methods used for prospectivity modeling and vectoring of IOCG mineralizations. These developed methodologies can seamlessly be applied to explore other mineral deposits. Furthermore, the techniques proposed in this study, integrating Industry 4.0 technologies into the mining industry, contribute to a solid and sustainable development of mineral exploration.

Enhancing Mineral Prospectivity Mapping for Cu-Pb-Zn in Faraj Abad, Qom, Iran: A Comprehensive Integration of Geology, Geochemistry, and Remote Sensing Data Using Fuzzy Analytical Hierarchy Process Models.

Kamyar KESHAVARZ[1]*, Shahid Beheshti University of Tehran (kamyar.ksh@gmail.com)
Aida Mohebi[2], Geology Survey of Iran

Abstract

Faraj-Abad is an area of about 600 square kilometers in Qom, Iran. The Urmia-Dokhtar volcanic belt passes through this region, leaving mineral deposits comprising metals such as copper, lead, zinc, iron, and manganese dating back to the Eocene. The exploration trend of the area was initially established through the application of exploratory modeling within a Geographic Information System (GIS) framework. This approach leveraged geological, geochemical, aerial geophysics, and remote sensing data, spanning multiple scales, to effectively analyze the region. In this regard, each of the aforementioned data sets underwent a unique processing methodology. Geological maps were used to determine lithological units and faults, while ASTER and ETM satellite images were used for the same purpose. Satellite imagery was also useful in locating alteration zones. Additionally, drainage sediment data and heavy mineral data were used to identify geochemical anomaly locations at various scales.

Within the Faraj-Abad region, two distinct types of copper mineralization can be found. The first type is referred to as porphyric, and it is exemplified by the Narbaghi mines. The second type is known as epigenetic polymetallic mineralization, where copper is commonly associated with lead and zinc. The Kuh-Pang Mine serves as an example of this second type of mineralization. Iron in this region is present in two forms: hematite accompanied by manganese of the oxalate type, and magnetite associated with ultramafic bodies.

In this exploratory modeling, all the aforementioned factors were thoroughly examined and evaluated using the fuzzy Analytic Hierarchy Process (AHP) methodology. Based on these evaluations, various data sets were assessed and valued. Consequently, mineral potential maps were prepared for each factor. Additionally, the areas with potential mineralization underwent field visits and geological sampling. Ultimately, a total of 45 geochemical samples were collected from these areas and subjected to analysis using the ICP-MASS method. The mineralized regions were then presented in the form of maps and tables, providing a comprehensive overview of their mineralization potential.

Identification of High-grade Ni Laterite Ores Using Hyperspectral Imaging and Deep Learning

Koichi FURUKAWA[1]*, Hokkaido University (furukawa.koichi.m5@elms.hokudai.ac.jp)
Natsuo Okada[2], Hokkaido University
Ryosuke Kikuchi[3], Hokkaido University
Yoko Ohtomo[4], Hokkaido University
Tubasa Otake[5], Hokkaido University
Youhei Kawamura[6], Hokkaido University

Abstract

Nickel (Ni) laterite deposits account for ~60% of the world Ni ore supply. They form by chemical weathering of ultramafic rocks, consisting of multiple weathered layers such as laterite and saprolite. Although Ni grades in the ores are generally higher in the saprolite than in laterite layers, they tend to be heterogeneous depending on various geological and geographical factors, which makes efficient mining and processing difficult. This study aimed at using visible-light to near infra-red range (450 – 950 nm) hyperspectral (HS) imaging to classify Ni ores (e.g., laterite and saprolite ores from bedrocks) as well as the Ni grades (low (<1.8 wt% Ni), medium (1.8~3.0 wt% Ni), high (>3.0 wt% Ni)) at the site. While the visible-light range has an advantage on the cost, it is usually more difficult to distinguish the constituting minerals than when an infra-red region is used. Therefore, we also employed machine learning, particularly Convolutional Neural Network (CNN), aiming at rapid and automatic classification by letting the Al model learn from many training input data. The study focused on Ni laterite deposits in the Sulawesi and Halmahera Islands in Indonesia. Indonesia has the largest Ni ore reserve in the world formed by intensive chemical weathering under tropical climatic conditions. We compared rock chip and pulverized samples as training data to investigate the effect of sample forms on the quality of classification. The obtained HS data from the laterite and saprolite ores as well as the bedrocks from different mines in Sulawesi and Halmahera Islands showed peculiar peak shapes depending on the weathering layer. Nevertheless, there appears to be no difference among variable Ni grade samples. A comparison of the sample forms demonstrates that training both forms yielded better results. The Al model successfully classified different weathering layers (i.e., laterite and saprolite layers) from the bedrocks with high accuracy (79 – 100%) even with untrained test samples. However, the classification of Ni grades in the saprolite layer samples was found to be more difficult, and their accuracy was variable (5.3 – 99%). This is likely due to variations in major chemical and mineralogical compositions of the saprolite samples rather than the Ni grade, which would make the Ni grade difficult to reflect in the HS data. Further improvement of the Al model such as pre-screening based on the bedrock type or Ni host mineral will be needed for the more accurate classification of Ni grade.

Advancing Mineral Resource Prediction through Distributed Cloud Computing and Remote Sensing: A Case Study in Namibia

Tianyi LI[1]*, Zhejiang University (lity@zju.edu.cn)
Linshu Hu[2], Zhejiang University

Abstract

Mineral resources, as a vital material foundation for human societal development, involve the scientific analysis and assessment of the location and potential of industrially valuable minerals within the Earth's crust. Typically, mineral deposits exhibit distinct alteration zone distributions, including widespread occurrences of hydroxyl minerals, carbonate minerals, and iron oxides, which become more prominent under long-term weathering effects. Utilizing remote sensing technology, particularly through the analysis of remote sensing data from the visible to the shortwave infrared spectrum, effectively extracts this alteration information. In recent years, significant advances in cloud computing technology have made it feasible to process large-scale, continental remote sensing data. By shifting mineral resource prediction work from traditional single-machine operations to a cloud environment, we can scale up data processing and more efficiently apply complex and precise prediction models, thereby enhancing the accuracy and efficiency of predictions. In this study, we selected Namibia as a case study area, employing distributed cloud computing technology for continental-scale surface erosion index analysis. We developed a remote sensing image processing workflow based on parallel computing theory and utilized the powerful computational capabilities of a cloud spatiotemporal database to compute and analyze vast amounts of remote sensing data, ensuring high scalability of the system. Through in-depth analysis of Namibia's entire ASTER remote sensing imagery, we successfully identified potential mineralization areas and analyzed their distribution characteristics. This research provides crucial reference material for local mineral resource management, development, and utilization, and also demonstrates the feasibility and advantages of distributed cloud computing in the field of remote sensing image processing, offering a concrete example of such technology applied in this domain.

Hydrothermal Alteration Mapping using Remote Sensing and GIS in parts of North Purulia Shear Zone (NPSZ), Purulia District, West Bengal, India

Anirudh CHAKRABORTY[1]*, University of Mumbai (anirudhchakraborty@gmail.com)

Abstract

According to Sarkar et al. (1998), the North Purulia Shear Zone (NPSZ) is a significant brittle-ductile shear zone with an E-W to ENE-WSW strike. It starts more west of Kotshila, travels via Sindri, Chas Road, Tetuldih, and Dubrajpur, and ends in the east by defining the northern edge of the Osthosite Massif. This shear zone has not been thoroughly investigated or defined. This shear zone roughly delineates the northern boundary of anorthosite rock, separating it from the surrounding high-grade rocks. It runs well within the Chotanagpur Gneissic Complex (CGC) rocks on a regional scale. The CGC's anorthosite-granulite rocks are undergoing shear deformation along the NPSZ, resulting in the production of mylonite fabrics. Along with some pegmatites, the lithological assemblage includes the following rocks: syenite, enderbite, anorthosite, amphibolites, khondalite, quartzite, biotite gneiss, calcsilicate granulite, basic granulite, etc. Objectives of the present study is to use the widely regarded ASTER data to distinguish the litho units and map the alteration zones from their host rocks, as prospective potential locations for mining important minerals can be identified and also to study the structural lineaments of the study area using remote sensing. The results were field validated. Remote sensing methods such as False Color Composites, Band Ratios, Principal Component Analysis and Spectral Classification proved useful in detecting alteration zones for potential mineral deposits.

Evolution of a Sand Spit in Ujeon Tidal Flat at Sinangun, Jeollanamdo, Korea's West Coast

Junho Lee[1]*, Marine Domain & Security Research Department, Korea Institute of Ocean Science & Technology (leejh@kiost.ac.kr)
Huigyeong Ryu[2], Marine Domain & Security Research Department, Korea Institute of Ocean Science & Technology
Hoi-Soo Jung[3], Marine Domain & Security Research Department, Korea Institute of Ocean Science & Technology
Joo-Hyung Ryu[4], Korea Ocean Satellite Center, Korea Institute of Ocean Science & Technology

Abstract

Jeungdo Island, a unique and valuable location, is home to the Ujeon tidal flat. This island has been recognized and protected for its exceptional environmental importance. It was designated a UNESCO (United Nations Educational, Scientific and Cultural Organization) convention concerning the protection of the world cultural and natural heritage in 2021, a Ramsar Wetland in 2011, and a Wetland Protection Area in 2010. However, the intertidal zones along the West Coast, including our study area, have experienced significant environmental changes due to human activities such as the construction of fish farms and large tidal embankments for reclamation projects. The Taepyeong salt farm, the largest salt field in South Korea, was also established on Jeungdo Island in 1953. The Ujeon tidal flat, a significant part of Jeungdo Island's ecosystem, now features a sand spit that stretches about 800 m in a north-south direction. Our research indicates that this sand spit has formed and grown as a direct result of the construction of the Taepyeong salt farm. This development, coupled with the spit's formation, has led to a profound change in the sedimentary environment of the Ujeon tidal flat In this study, we present a model of these sedimentary environment changes and further predict the potential closure of the Ujeon tidal flat highlighting the urgent need for action. This study delves into the long-term effects of human activities on tidal environment processes, shedding light on a crucial aspect of coastal conservation. It significantly contributes to our understanding of the effects of human activities on coastal sedimentary environments, providing vital information for the development of effective management and conservation strategies for coastal areas, including the Ujeon tidal flat. Its findings are not just academic, but also practical, offering a roadmap for sustainable coastal development.

Guided sampling method of diffusion model for cloud area restoration from tidal flat satellite images

Donguk LEE[1]*, Korea Institute of Ocean Science & Technology (ldu3833@kiost.ac.kr)
Hyeong-Tae JOU[2], Korea Institute of Ocean Science & Technology
Geun-Ho KWAK[3], Korea Institute of Ocean Science & Technology
Jingyo LEE[4], Korea Institute of Ocean Science & Technology
Joo-hyung RYU[5], Korea Institute of Ocean Science & Technology

Abstract

With recent advances in the Earth observation technology, satellite imagery is being used in a wide variety of applications, but satellite observations are often hampered by clouds. To address this, various methods have been developed to remove cloud regions from images.

Early methods used only neighborhood information and were simple to apply, but difficult to apply to complex terrain. Later methods were proposed that utilized both temporal and spatial information, and were able to successfully restore complex areas using previous acquisitions. However, because tidal flats change rapidly with the tides, selecting prior information to use for restoration is much more difficult than on land.

In this study, we applied a restoration method using a diffusion model to automatically restore cloud regions without the need for prior selection. Diffusion models store image characteristics in the form of distributions, and images can be generated from the distributions. Since the characteristics of all acquired images are included in the distribution, it is possible to generate images of any desired shape as long as the image characteristics are provided.

To restore clouds in the tidal flats satellite image, we used images of cloudless areas. It was considered that images of cloudless areas have information about the tides themselves, and it was possible to generate an image from the distribution that best fits the tides in the image. To this end, we proposed a gradient-based guided sampling method to restore the cloud-covered areas without any prior selection of information.

The restoration results were validated by qualitative and quantitative analysis using synthetic data. The qualitative analysis confirmed that the clouds were successfully restored, and the quantitative analysis confirmed that the range of pixel values in the generated image was reasonable. In addition, the validity of the restored images was indirectly verified by comparing the land-water boundaries extracted from the satellite images with those extracted from the high-resolution DEM.

This method allowed us to restore the cloud-covered area by providing only the surrounding information without any prior selection process, which is expected to contribute to the development of automated systems for real-time monitoring of tidal flats and as training material for artificial intelligence models. In addition, as a direct application example, it is expected to reduce the time required to generate satellite-based tidal flat topographic maps using restored images.

Performance comparison of waterline based topographical mapping of tidal flats with different spatial interpolation methods

Jingyo LEE[1]*, Korea Institute of Ocean Science and Technology(KIOST) (jingyo@kiost.ac.kr)
Keunyong KIM[2], Korea Institute of Ocean Science and Technology(KIOST)
Geun-Ho KWAK[3], Korea Institute of Ocean Science and Technology(KIOST)
Yeongjae JANG[4], Korea Institute of Ocean Science and Technology(KIOST)
Joo-Hyung RYU[5], Korea Institute of Ocean Science and Technology(KIOST)

Abstract

Tidal flats are highly sensitive to change due to repeated erosion and deposition caused by tidal energy and seasonal factors. Recent emphasis on the ecological value of tidal flats has led to the need for precise tidal flat topographic maps as a basis for tidal flats ecosystem protection and restoration. Because tidal flats are inaccessible due to the tidal cycle, remote sensing data that can be surveyed periodically using non-accessible methods are often utilized. Satellite-based waterline method is one of the most common methods used to map tidal flats using remote sensing data. To ensure high performance, it is important to collect imagery at different tide levels. However, remote sensing data is limited by clouds and weather conditions, and it is difficult to acquire images evenly at different tides due to tidal cycles and acquisition cycles. To solve this problem, spatial interpolation has been applied to improve the accuracy of tidal flats topographic maps produced by the waterline method. However, no study has analyzed the effect of the mean tide interval on the spatial interpolation of tidal flat topographic maps, considering the availability of images. In this study, considering the limitations of the above-mentioned existing studies, a case study was conducted on the Hwangdo tidal flats in Taean, Chungnam, using a total of 21 Landsat-8, 9 and Sentinel-2A/B images. In order to improve the accuracy of tidal flat topographic maps, spatial interpolation methods such as TIN, IDW, Spline, and Kriging were compared, and the average tide intervals of the acquired images were comprehensively compared. The results of the case study showed that the spatial interpolation method actually decreased in performance as the tide interval increased, compared to the conventional waterline based tidal flat topography, but outperformed the denser tide interval. Based on these interpolated results, it was possible to significantly improve the accuracy of tidal flat topography by utilizing a minimum number of images, and can provide guidelines for applying interpolation to tidal mudflat topography in cases where a large number of images are difficult to acquire.

Airborne Sensor system for monitoring Tidal Flat

Hyunsoo Hur[1]*, Geostory (caebc44@gmail.com)
MinYoung KIM[2], Geostory
Kahyeon KIM[3], Geostory
HYEYOUNG JEONG[4], Geostory

Abstract

Tidal flat is challenging area to survey for both land based survey method and shipborne based survey method. Development of Tidal flat survey system is essential to monitor tidal flat thoroughly and accurately. Thus, multi purpose integration sensing system based on Airborne Bathymetry LiDAR will be used for capturing tidal flat. Multi sensor integration system is consisted with ABL and Hyperspectral sensor and Digital camera. Each sensor maximizes performance through mutual complementation.

General Topography LiDAR firing near infrared Laser to survey land area. However, Airborne Bathymetry LiDAR uses more powerful visual wavelength of green laser that penetrate water surface and we can get the sea bottom data. With this technology. We can survey land side and waterside simultaneously. This Characteristic is Key feature for capturing Tidal flat. Airborne Bathymetry LiDAR is best for surveying shallow water as well. It took only about 10% of time to survey shallow water than shipborne survey.

Hyperspectral sensor is another important component of the Multi sensing integration system. Hyperspectral imagery which captured with Airborne Bathymetry LiDAR simultaneously can improve Turbid water penetration ability as well as tidal flat environment monitoring.

In this research project we are planning to build multi sensing integration system and collecting tidal flat elevation data and environmental data using Airborne Bathymetry LiDAR and Hyperspectral sensor.

Abstract

This research explores the Hwangdo tidal flat, a significant intertidal zone within Cheonsu Bay, Taean-gun, Chungcheongnam-do, along Korea's western shoreline. The area's unique topography, characterized by water channels, sandbars, small islands, and tidal flats, is situated in a semi-enclosed bay on the eastern perimeter. Data collection involved tide gauge readings from Hwangdo Bridge and ellipsoid height determinations via a real-time kinematics global positioning system (RTK-GPS). A digital elevation model (DEM) was also developed from processed Matrice 300 drone imagery. The study also examined geochemical sediment attributes and tidal flat exposure times influenced by environmental conditions. Sediment samples (n = 107), collected from October 25 to 28, 2022 were used to classify sediment particles according to Folk and Ward (1957). Sedimentary facies ranged from coarse sand (sand : mud ratio = 9 : 1) to sandy silt (sZ) followed by muddy sand (mS) and slightly gravelly sandy mud ((g)sM). The investigation into total organic carbon (TOC) was informed by particle-size analysis. Tidal height variations recorded at Hwangdo Bridge, with a significant mean change of ~7.53 m (minimum: –3.86 m, maximum: +3.67 m), underscored the dynamic nature of the tidal flat. Based on the Boryeong's sea level measurement tide data in 2022, the tidal area in the drone images ranged from 6.360 square meters (0.006 square kilometers) at DEM +4.0 to 4,841,100 square meters (4.8410 square kilometers) at DEM –4.0 m, indicating an increase in the tidal-flat area according to the tidal level of up to ~800-fold. The daily average exposure time was 9.0 h (minimum: 1.5 h, maximum: 17.9 h). Multivariate analysis, incorporating exposure durations and geochemical data, delineated four distinct zones: upper, middle, and lower intertidal areas, alongside regions enriched in organic matter. Spatial analysis revealed that sediment composition shifts, attributed to community dynamics, predominantly influence the environmental makeup of the Hwangdo tidal flat. This study's findings articulate the complex interplay of marine environmental characteristics across the tidal flats, with sedimentary transitions, more so than exposure duration, marking the variances across different zones as a trend poised to persist.

Land Subsidence Observation using InSAR Time-Series Analysis of Bangkok and Samut Prakan, Thailand

Raisa Najma Najma Sakina[1]*, Kangwon National University (raisaarifinn@kangwon.ac.kr)
Wahyu Luqmanul Hakim[2], Kangwon National University
Muhammad Fulki Fadhillah[3], Kangwon National University
Chang-Wook Lee[4], Kangwon National University

Abstract

Climate change has become a critical issue due to its impact particularly on coastal cities. Bangkok is such a coastal city already facing the impact of climate change, notably the rise of sea level leading to flooding and posing a danger situation of submerging land in Bangkok Area. This situation is intensified by the land subsidence phenomenon caused by excessive groundwater extraction causing damage to buildings. This study provides a time-series analysis using Synthetic Aperture Radar (SAR) undertaken for Bangkok and Samut Prakan, both of which are part of Bangkok Metropolitan Region (BMR) that located on coastal area in Thailand, aimed at constructing the susceptibility map. In this study, 183 SAR data obtained from Sentinel-1 radar satellite in ascending direction were used ranging from 2017 to January 2024 which can be show the current situation of the subsidence of Bangkok through time-series analysis. The result of time-series measurements in this study were compared with the GPS data measurements to obtain the correlation between time-series InSAR deformation map and ground data measurements. According to the result, the land subsidence in Bangkok and Samut Prakan occurred mostly along the Chao Praya River, which has a geological composition that prone to land subsidence. Another cause of land subsidence in Bangkok and Samut Prakan is over-exploitation groundwater in the urban areas. The susceptibility map then can be generated for future research, enabling the identification of the additional locations susceptible in order to anticipate the risk of land subsidence in the future.

Identification of slope failure by random forest using topographic characteristics changes

Mitsunori UEDA[1]*, Osaka Metropolitan University (so22000t@st.omu.ac.jp)
Tatsuya NEMOTO[2], Osaka Metropolitan University
Venkatesh RAGHAVAN[3], Osaka Metropolitan University

Abstract

Slope failure is one of the events of erosion and sedimentation. This event is a phenomenon in which rocks are weathered due to physical and chemical processes and the weakened slopes slide down due to rainfall, earthquakes, melting of snow and volcanic eruption. Therefore, generation of slope failure inventory map is extremely important for solving geologically related problems such as land development, disaster prevention planning, and environmental conservation. Also, to understand the slope failure morphology and structure, it is necessary to clearly classify between the erosion area which is the sliding area, and the sedimentation area which is the moving body. Therefore, in this study, slope failures were identified using a distribution map of slope failures (head scarp and main body) caused by heavy rain. Random Forest (RF), a machine learning method, was used to recognize slope failures, and the importance of features was also investigated. Topographical data were collected from aerial LiDAR survey and aerial photographs for data before and after the slope failure. The topographical data used the slope angle and slope direction of the terrain, the topological classification, and the terrain convergence index. We used Change Vector Analysis (CVA) to investigate changes due to erosion and sedimentation. CVA is a vector representation of changes between two time periods. You can investigate changes over time by plotting two input variables for two periods on the x-axis and y-axis, respectively, and calculating the changes between the data as the magnitude and direction of the vector. Here, we analyzed changes in slope angle and various topographical parameters using data before and after the slope failure. The y-axis is the slope angle and the x-axis is the other terrain features. The aerial photographs were used as learning data by calculating the Vegetation Index (VI). VI used the Modified Photochemical Reflectance Index (MPRI) calculated from red band and green band of the photographs.

As a result, the magnitude of CVA tended to be suitable for separating slope failure and non-slope failure and the direction of CVA tended to be suitable for separating scarp and main body within slope failure areas. The topographical features that contribute to learn were the slope angle, vector magnitude of CVA and MPRI. Also, the identification failure areas by RF were in good agreement with the slope failure distribution map. the extraction accuracy exceeded 0.8 per pixel within the slope failure area. By using topographic features and their changes, it has become possible to identify slope failures by dividing them into head scarp and main body. In particular, head scarp tended to be clearly extracted. However, the range of sediment movement along the area of erosion that occurred in the river downstream of the collapsed area was misidentified. In addition, parts of the slope that were not affected by the event were also interpreted as Slope failures, in

reality they were non slope failure areas. In future, it will be necessary to build a highly accurate model that can only extract collapsed areas.

Integrating InSAR Time-Series Machine Learning Optimized and Susceptibility Assessment for Monitoring Land Subsidence in the Iron Mining Site Musan

Muhammad Fulki Fulki Fadhillah[1]*, Kangwon National University (fulkifadhillah@kangwon.ac.kr)
Raisa Najma Sakina[2], Kangwon National University
Chang Wook Lee[3], Kangwon National University

Abstract

The combined use of interferometric Synthetic Aperture Radar (SAR) and disaster susceptibility mapping has become an important approach to identifying, understanding, and managing disaster risk in mining areas. Interferometric SAR (InSAR) is a monitoring method that utilizes SAR satellite imagery and interferometric principles to produce information about changes in the earth's surface. Notably, the progression of the InSAR time-series technique has advanced to encompass the utilization of artificial intelligence algorithms, thereby enhancing data processing capabilities and ensuring the retention of critical information amidst extensive datasets.

On the other hand, disaster susceptibility mapping utilizes spatial and attribute data combined with InSAR time series results to determine the susceptibility of an area to various types of natural disasters and disasters caused by human activities. The synergy between remote sensing data and spatial information presents a valuable framework for assessing disaster susceptibility within mining sites.

This research explores how a combination of InSAR technology and disaster susceptibility mapping can improve the understanding of disaster risk in Musan mining areas. By integrating InSAR-derived data from the Sentinel-1 C-band SAR satellite, which provided insights into land deformation conditions in the study area. Then, the disaster susceptibility analyses can delineate environmental change patterns and evaluate potential disaster risks, including landslides, land subsidence, and infrastructure collapse.

The research results show that the use of machine learning algorithms can provide an optimization impact on the final results of time-series data on mining sites. Furthermore, the disaster susceptibility mapping model, facilitated by machine learning algorithms, has yielded a ROC value exceeding 0.8, indicative of robust performance. This integrated approach facilitates risk mitigation planning, informed decision-making, and the formulation of adaptation strategies to curtail disaster ramifications within mining precincts. Moreover, the combination of InSAR technology and disaster susceptibility mapping fosters sustainable development, bolstering disaster risk management endeavors and upholding environmental conditions within mining areas.

NSDI Implementation at the Ministry of Mines and Energy in Namibia

FREDDY MUYAMBA[1]*, GEOLOGICAL SURVEY OF NAMIBIA
(Freddy.Muyamba@mme.gov.na)
Paulina Pokolo[2], GEOLOGICAL SURVEY OF NAMIBIA

Abstract

The National Spatial Data Infrastructure (NSDI) is a framework that aids the management, use, sharing, and integration of spatial data and related services in Namibia. This is the policies, standards, technologies and institutional arrangements that enable an easy access and utilization of spatial information by the various stakeholders, which includes government agencies, private sector organisations, and the public.

The NSDI implementation at the Ministry of Mines and Energy (MME) in Namibia is a major advancement in improving the management, accessibility, and utilisation of spatial information in the country's mining and energy industries. This effort is in line with worldwide patterns in utilising spatial data for making informed decisions, managing resources sustainably, and promoting economic growth.

The main objectives of implementing NSDI at MME are to: Create a centralised and standardised repository for spatial data. Facilitate interoperability among various spatial datasets, enabling seamless data sharing and integration within MME. Provision of current, up-to-date, and easily accessible spatial information for effective and efficient decision-making in planning and management of resources. Strengthen and enhance collaboration with relevant stakeholders being other government agencies, private sector entities, and research institutions in an all-inclusive geospatial ecosystem.

The NSDI implementation at MME involves a phased approach, encompassing the following key elements: Data Standardisation: Development and uptake of standardised data formats, metadata, and quality assurance to ensure consistency and reliability within the spatial datasets. Infrastructure Development: Establishing a robust and secure spatial data infrastructure to host, manage, and disseminate spatial information efficiently. Capacity Development: Providing training sessions to prepare MME employees with the essential skills for managing, analysing, and using spatial data. Inter-Agency Collaboration - This is to be done through collaboration with other government departments, non-governmental agencies and even the private sector to create a network of shared spatial resources and expertise. Public Outreach: Public outreach programs to create awareness among the public on the benefits of NSDI implementation and mobilising communities to ensure responsible use of spatial data.

Expected Outputs: The implementation of NSDI at MME is expected to result in the following outputs: Improved access to current and accurate spatial data, efficient and cost-effective data sharing and management practices, standardised datasets, Strengthened capacity for spatial data analysis and utilisation. Boost collaboration and data sharing among relevant stakeholders in the country.

Conclusion: The implementation of the NSDI in the Ministry of Mines and Energy in Namibia represents a nation-driven strategic initiative that aims at harnessing the power of spatial data to underpin sustainable development. It seeks to position MME as a leading ministry in leveraging spatial information by adopting a comprehensive approach that includes development of infrastructure, capacity building, and collaboration through standardised data use in the mining and energy sectors.

New opportunities with Earth Science data platforms in Europe: fostering next-generation cross-domain research and decision-making

Marc URVOIS[1]*, BRGM - French Geological Survey (m.urvois@brgm.fr)
Matthew HARRISON[2], UK Environmental Data Service
Christelle LOISELET[3], BRGM - French Geological Survey
Jørgen TULSTRUP[4], GEUS - Geological Survey of Denmark and Greenland
Carmela FREDA[5], EPOS ERIC, European Plate Observing System European Research Infrastructure Consortium

Abstract

European-level data is co-created by research communities and National Geological Survey Organisations (NGSOs), and there has been a focus on creating platforms to enable open access. Here we will argue that there is also an opportunity and duty for these groups to contribute to the overall governance surrounding geoscience data and information at a global scale. This is through ensuring geoscience data is discoverable and reusable in recognised formats for onward analysis, validation and research (the FAIR principles). Also that a European geoscience voice and perspective is recognised and listened to in the development of geoscience standards beyond the boundaries of the European Continent.

As a result of a decade of design and implementation, two major and complementary geoscientific data platforms are now online making available harmonised and quality-controlled subsurface data to support both research and policy-making. The European Plate Observing System (EPOS, www.epos-eu.org) brings together national research infrastructures across 26 countries in Europe. The delivery framework of this unique Solid Earth Research Infrastructure currently includes more than 260 data and product services from ten domain-specific communities accessible through the metadata-driven web-enabled EPOS Data Portal. The contents proposed by these thematic services cover a wide range of geoscience disciplines (e.g., seismology, geodesy, geology and remote sensing).

The geological information and modelling data services are exposed to EPOS by the European Geological Data Infrastructure (EGDI, www.europe-geology.eu). Through the collaboration of 37 European NGSOs, EuroGeoSurveys established the EGDI as the framework to capitalise and disseminate project results as well as national and pan-European inventories. A wealth of more than 800 datasets cover a broad spectrum of geoscientific areas relevant to policy such as groundwater, geohazards, minerals, coastal zone management, carbon and hydrogen potential.

This actual connection between these two platforms brings to life the operational level of interoperability standards and best practices for the benefit of the end-users: researchers, citizens and policy-makers. The synergy of contents at their fingertips fosters the analytical possibilities to produce added-value information and knowledge. EPOS and EGDI are timely, taking advantage of the maturity of the necessary standards defined by OGC, IUGS-CGI and INSPIRE. The FAIRness of the numerous data sets exposed by the platforms is constantly being improved, and now part of the Open Science and national and international research framework programs.

One of the initial ambitions of these pan-European platforms has been successfully achieved, which was to federate high-quality data and information produced by research centres and national survey organisations. This supply-driven process providing robust infrastructures and rich contents now evolves towards a demand-driven approach. Awareness and training sessions are organised to further develop the confidence of a wide range of users in using EPOS and EGDI, create advanced product services to generate next-generation research and decision-making.

International geoscience terminology management and governance

Mark Rattenbury[1]*, GNS Science, New Zealand (m.rattenbury@gns.cri.nz)

Abstract

International terminology standards are important for communication of geoscience information across borders and between countries, particularly for addressing multinational and global issues such as climate change, resilience to natural hazards and sustainable resource extraction.

The Commission for the Management and Application of Geoscience Information (CGI), an International Union of Geological Sciences (IUGS) commission, develops, manages and publishes geoscience data models and vocabularies, amongst other standards. CGI's Geoscience Terminology Working Group has members drawn from most continents and regions, and their collaboration results in agreed, published geoscience vocabularies that are used internationally. To date these vocabularies have been developed to support the GeoSciML and EarthResourceML data models but their application has been wider.

CGI as an IUGS commission has both a unique position and an opportunity around governance of global geoscience terminology standards. Through its enduring status, CGI is not bound by finite and funding-constrained projects. Projects can accelerate terminology standards development but sustaining these standards after project cessation can be difficult and this is where CGI can assist.

CGI has predominantly managed and governed standards it has developed or co-developed. The opportunity for CGI going forward is to take more of a leadership role across IUGS as well as internationally-focussed societies and agencies in assisting to host, manage and/or promote their terminology standards. With growing expectations of FAIR Principles adherence across the global geoscience community, CGI can help enable their implementation by providing a platform for enduring, authorised, geoscience information standards and services.

A Framework for Smart Geological Mapping Using Data and Knowledge Hybrid-drivenFAIR

Yongzhi WANG[1]*, Jilin University, China (iamwangyongzhi@126.com)
Yuhao DONG[2], Jilin University, China
Yangchun LI[3], Development Research Center of China Geological Survey, Beijing, China
Dongjie ZHAO[4], Development Research Center of China Geological Survey, Beijing, China

Abstract

Traditional geological mapping is mainly conducted by geoinformatics experts using GIS software under the instruction of geoscientists. This professional work still has few disadvantages such as (1) *geoscientists lead the work while information experts can't finish the task on their own*, (2) *most of works are repeated and time-consuming*, (3) *many complex processes and manual actions affect data quality of the final map. Thus, cut-edging technologies are utilized to solve these problems and result in new methodology for geological map compilation and in which big data, cloud computing, artificial intelligence are widely used. Geologic mapping work mainly includes data management, data preprocessing, generalization, symbolization & rendering and output. So, this paper proposes a new data and knowledge hybrid-driven methodology for geological map compilation in vector format semi-automatically. The novel geological data generalization mechanism for compilation concentrates on the knowledge of geologists. It aims to deal with various geologic features and corresponding property values using both data-driven and knowledge-driven method. Geologists retrieve the geological knowledge of the region in research from related unstructured geologic reports and saves them into a structured database. The geologic knowledge data includes original and final status attributes of geological body such as strata, geological era, importance, etc. The data-driven approach promotes geologic data transferring from raw data to target map data after some procedures. Of course, it would follow predefined rules and inherit property data from the specific scale digital geological survey databases or perform other vector data processing. The knowledge-driven method employs geologists' knowledge and GIS analysis and even AI algorithms to drive the generalization of different geological features in all areas or interests respectively. For example, during geological map compilation from large-scale to small-scale, geological bodies can be generalized by some generalization operations such as dissolve, elimination, simplification, smoothness, exaggeration, various merged methods, and so on. Although the method names are similar as GIS algorithms, they are all customarily*

developed based on geologists' knowledge and GIS architecture, changed geometry shapes and property values of geologic bodies, lines, or points simultaneously. In addition, the upperscript and subscript, color and legend of geologic features can be performed automatically based on geological knowledge and mapping rules. This framework integrates types of data, mapping model, geologic knowledge, intelligent algorithms together, uses knowledge as core driving force to complete compilation task supported by generalization in interactions with back-end algorithms. The proposed framework powers geologist's knowledge to update spatial data and property data separately or integratedly. It needs geologist's less time, fewer repeated works, and it works much quicker and easier with higher quality than before. Now, it has been developed and used in several national and regional geological mapping projects in China.Results show that it is a new powerful tool to help geologists in the compilation work.

Geoscience Information in the 2020s

Leonard Harvey Thorleifson[1]*, University of Minnesota (thorleif@umn.edu)

Abstract

Geoscientists deliver research, which is conceptual, mapping, which is spatial, monitoring, which is temporal, and dynamic modeling, which assembles the foregoing, to guide management. Current international geoscience information arrangements are meant to accelerate research, and serve the needs of society regarding energy, engineering, hazards, minerals, and water. To better serve global society, we must optimize adoption of standards, and commit to FAIR principles for publications and databases – findable, accessible, interoperable, and reusable. Publications are being made accessible to machine methods. Concurrently, authoritative, ideally-jurisdiction-wide, indefinitely-updated, evergreen databases are being built, as observations in part assembled through data sharing and appropriate crowdsourcing, and as inferences increasingly as fully categorized, machine-readable, multi-resolution seamless 3D geological mapping that is coordinated with other mapping. To access and utilize information, there are increasing roles for methods such as large language models and knowledge graphs, and appropriate roles for artificial intelligence and machine learning. Modeling, in some cases indefinitely sustained with iterations, inputs, and outputs and thus a digital twin, is permitting gradually increasing implementation such as jurisdiction-wide groundwater modeling and management to ensure sustainability, and other applications such as managing the energy transition and optimizing sourcing of materials. International coordination of earth science information is facilitated by broader mechanisms such as the Committee on Data (CODATA) of the International Science Council (ISC), standards organization such as Open Geospatial Consortium (OGC), the International Union of Geological Sciences (IUGS) Commission for the Management and Application of Geoscience Information (CGI), influential initiatives such as Deep-time Digital Earth (DDE), and highly active partners.

EarthResourceML 3.0

Michael Graham SEXTON[1]*, Geoscience Australia (michael.sexton@ga.gov.au)
Jouni Vuollo[2], Geological Survey of Finland (retired)
Oliver Raymond[3], Geoscience Australia (retired)
Daniel Cassard[4], Bureau de Recherches Géologiques et Minières (retired)
Ernst Schetselaar[5], Natural Resources Canada
Mark Rattenbury[6], GNS Science
Ursula Michael[7], Department for Energy and Mining

Abstract

EarthResourceML (https://earthresourceml.org/) is the international logical data model and data standard for mineral occurrences, mines, and mineral resources. The release of EarthResourceML (ERML) 3.0 represents the first significant update to the standard since 2018. ERML 3.0 makes the transition to Open Geospatial Consortium (OGC) standard GeoSciML 4.1 (http://geosciml.org/) as its foundation. The standard undergoes a major revision to the Earth Resource and Mineral Occurrence feature types and their related features, enabling future extension of the model to incorporate other earth resources unrelated to mining and minerals. A new Mine Status type defines the time-series data for the lifecycle of a mine from feasibility through to operation and closure. The reporting of reserves and resources is now collected under a single Ore Measure Observation feature type. New feature types for Processing Plants and Processing Activities capture downstream mineral processes related to refining and smelting. The Mining Waste Measure data type is extended to include new attributes which better describe the composition, size, and mineral commodities for tonnages and volumes of mining waste. Mining Waste features are related to Processing Plants to capture waste outputs such as slag and fly-ash. Simplified features containing the minimum set of necessary attributes for simple map-based applications and basic data exchange are defined in ERML Lite 2.0.1 for Mineral Occurrences, Commodity Resources, Mines, Mining Activities, Processing Plants and Mining Waste. Simple Knowledge Organisation System (SKOS) vocabularies (https://cgi.vocabs.ga.gov.au/vocab/) for the new ERML 3.0 types are provided by the Commission for the Management and Application of Geoscience Information (CGI) Geoscience Terminology Working Group (GTWG). These include the new vocabulary for the deposit classification naming system developed by the Critical Minerals Mapping Initiative (CMMI), collaboration between Geoscience Australia (GA), the Geological Survey of Canada (GSC) and the United States Geological Survey (USGS). These extensions to ERML provide a sustainable data framework for important areas of modern research, including critical minerals and environmental, social, and governance (ESG) decision-making.

Building a Digital Framework for Europe's Geology: GSEU and the Significance of Data Modelling and Vocabularies

Kristine E.C. ASCH[1]*, Federal Institute for Geosciences and Natural Resources (BGR)
(Kristine.Asch@bgr.de)
Hans-Georg Krenmayr[2], GeoSphere Austria
Kris Kris Piessens[3], Royal Belgian Institute of Natural Sciences - Geological Survey of Belgium,
Zoltán Németh Nemeth[4], State Geological Institute of Dionýz Štú
Cécile Le Guern[5], Bureau de recherches géologiques et minières - BRGM

Abstract

Amongst the objectives of the GSEU project is the provision of harmonized data and information. Such data are needed to coordinate and ensure sufficient and sustainable provision of natural resources, efficient use of the subsurface, sustainable management of our landscape and the protection of the environment. They all have in common that they need to rely on, and to work with, basic geological data representations, such as digital map data sets and 3D models. A comprehensive and flexible (e.g. regarding scale) digital framework, able to take up these data sets and models is therefore a central objective of GSEU.

In this context, the development of a commonly agreed data model is necessary for the compilation of interoperable, harmonised, multiscale geolscientific data sets in 2D and 3D. It will be based on the Structural Framework (developed within the GeoConnect[3]d-project) but also on standards developed by OneGeologyEurope, INSPIRE, HIKE or at national level.
Scientific vocabularies and hierarchic nomenclatures are being improved or newly created to be used for the following geoscientific thematic map layers (spatial data):

- lithology – essential to describe the geological subsurface;
- anthropogenic deposits – an actual theme, important to describe human impact on the subsurface;
- lithotectonic units – tectonic structures and geological units, important for understanding regionally significant rock frequences and structures, their evolution and their potential to contain mineral reserves.

As a testbed for the data model and newly created vocabularies, the 1 : 5 Million International Geological Map of Europe and Adjacent Areas (IGME 5000) will be be used which is the only existing, harmonized, pan-European geological map data set.

REASSESSMENT OF DETAILED LITHOLOGICAL MAPPING USING A MACHINE LEARNING ALGORITHM: A CASE STUDY ON THE BOA VISTA SHOSHONITIC STOCK IN NORTHEASTERN BRAZIL

Mariana Izabel Tomaz de LIMA[1]*, Federal University of Rio Grande do Norte (UFRN) (marianalima506@gmail.com)
Frederico Castro Jobim VILALVA[2], Federal University of Rio Grande do Norte (UFRN)

Abstract

Contemporary approaches to "visual" integration for geological mapping from geophysics are notoriously challenging, often influenced by user assumptions and characterised by significant time demands. The use of a supervised machine learning method, such as Random Forest, applied to airborne geophysical datasets, emerges as a viable alternative for the rapid generation of interpretative maps. These maps can then be submitted for validation through geological mapping, resulting in more efficient and reliable processes. The geophysical and geological data used, which is widely available at an adequate resolution, is provided by the Geological Survey of Brazil. The use of this data made it possible to carry out a predictive lithological analysis for the Boa Vista Shoshonitic Stock and for the region's crystalline basement, represented by the Caicó Complex. This process made it possible to identify areas that need to be revised for a more precise refinement of the lithologies in the field. After selecting the areas for reassessment, detailed lithological mapping was carried out, resulting in a more precise distinction of the lithological contacts and rock formations present. Based on the most recent geological data, which was described in detail in the field, a new predictive lithology analysis was carried out for the Stock. Of the 10400 samples available, 322 were selected as training samples for the random forest algorithm to predict the desired area. These training points had associated geological and geophysical information, which was incorporated into the ArcGIS software. This analysis resulted in a compatibility rate of 86.9 percent. However, it is important to emphasise that some factors may contribute to this percentage of incompatibility. One of these factors could be the discovery of new correlations between geological and geophysical data, which could be exploited to improve the current geological map. In the context of the Boa Vista Stock, the predicted lithological analysis revealed a notable decrease in the presence of other lithologies within the crystalline basement. Due to the diversity of the lithological unit in question and its similar characteristics to the lithologies of other units, it is possible that some sites were mistakenly interpreted as belonging to the Caicó Complex. A new correlation identified in the first lithological forecast was confirmed during field exploration, with the rocks of the Caicó Complex being affected by the Stock thermal halo, undergoing a process of migmatization. In addition, it was observed that the intrusive body itself did not show major geometric changes. This conclusion was supported by the body's geophysical response and confirmed during field exploration. Using the new predictive lithological map of the region, an updated geological map was drawn up, incorporating the corrections derived from field exploration and identifying specific areas for detailing the facies

found in the Stock. The lithological forecast emerges as a crucial tool not only for improving existing lithological maps, but also as an essential starting point for mapping regions lacking in lithological information due to the lack of significant outcrops.

Serverless Computing Powered Efficient Remote Sensing Image Processing: A Case Study on Potential Sand Source Identification in the Yarlung Zangbo River Middle Reaches

Qing LAN[1]*, School of Earth Sciences, Zhejiang University (lanqing@zju.edu.cn)
Linshu HU[2], School of Earth Sciences, Zhejiang University
Sensen WU[3], School of Earth Sciences, Zhejiang University
Zhenhong DU[4], School of Earth Sciences, Zhejiang University

Abstract

Currently, remote sensing image processing faces the ever-growing challenge of big data tasks, and cloud computing provides a viable solution for efficient processing of these massive datasets. However, traditional cloud computing solutions still encounter challenges in resource provisioning, scheduling, and scalability. In this context, serverless computing architecture has emerged as a new paradigm for delivering cloud services, allowing users to upload only the functional code and delegate the underlying server management tasks to service providers. This opens up new possibilities for remote sensing image processing. This study, using the potential sand source identification in the middle reaches of the Yarlung Zangbo River as a case, aims to explore the integration of serverless computing architecture with traditional remote sensing data processing while investigating potential changes in sand sources in the research area. Therefore, we constructed a remote sensing image analysis tool based on a cloud computing platform, utilizing serverless technology to endow it with high scalability. We efficiently analyzed 30 years of remote sensing images of the middle reaches of the Yarlung Zangbo River, extracting potential sand sources and studying their change patterns. This research provides essential references for local sand control and ecological conservation. Simultaneously, the study demonstrates the feasibility and advantages of serverless computing in the application of remote sensing image processing, offering a practical example for its implementation in the field.

Enhancing Environmental Understanding with Spatio-Temporal Knowledge Activation in Large Language Models

Xinhua FAN[1]*, Zhejiang University (fanxhgis@zju.edu.cn)
Zhenhong Du[2], Zhejiang University

Abstract

This paper proposes a methodology for activating spatio-temporal knowledge within large language models to enhance understanding of environmental phenomena. We extract scene knowledge and derive spatio-temporal rules from remote sensing data, integrating them into large language models for improved analysis. Our methodology combines remote sensing image processing with natural language processing techniques. Initially, we preprocess remote sensing images to extract meaningful features representing various environmental phenomena, capturing spatial patterns and temporal variations. These features are then encoded and embedded for ingestion by the large language model, allowing it to capture rich spatio-temporal information. Within the large model, algorithms are developed to extract scene knowledge by identifying and classifying environmental entities and their relationships based on the encoded features. Spatio-temporal rules are derived to discover patterns and trends in the temporal evolution and spatial distribution of these entities. Integrating spatio-temporal knowledge into the large model enables it to generate more accurate insights about environmental phenomena, potentially enhancing environmental monitoring, analysis, and decision-making processes. This paper contributes to the emerging field of integrating remote sensing and large language models for environmental studies, demonstrating the feasibility and effectiveness of leveraging spatio-temporal knowledge from remote sensing data within large models to enhance understanding of complex environmental systems.

Unraveling Seismic Patterns: A Deep Dive into Earthquake Sequences and Swarms in Northeastern Algeria through a Dual Method Approach

Sofiane Taki-Eddine Rahmani[1]*, CRAAG (sofianerah1@outlook.fr)
Issam Abacha[2], CRAAG
Oualid Boulahia[3], CRAAG
El-Mahdi Tikhamarine[4], UFAS 1
Khaled Roubeche[5], CRAAG

Abstract

In nature, there are two main types of seismic sequences: the first involves mainshocks followed by aftershocks, exhibiting a temporal decay in line with the Omori-Utsu law, typically with the mainshock initiating the sequence. The second type consists of earthquake swarms, deviating from Omori-type decay, where events of significant magnitude often occur in the middle or towards the end of the sequence. In the northeastern region of Algeria, seismic sequences often involve more than two main earthquakes, featuring both temporal and spatial migrations (Rahmani et al., 2023; Abacha et al., 2022; Boulahia et al., 2021). Clarifying and categorizing these sequences is crucial for understanding the triggering mechanisms governing this seismicity.

In the current study, two methodologies were employed. Firstly, we determined spatio-temporal ETAS model parameters for the entire region, incorporating a bootstrap approach to assess uncertainties. Subsequently, using these parameters, the region was divided into grid cells of dimensions 0.2 x 0.2, and transformed time was calculated in each grid cell. Finally, the '1σ criterion' introduced by Nishikawa et al. in 2017 was applied. A total of 21 clusters were identified, encompassing 312 swarm events.

For the second method, skewness and kurtosis of the moment release time series (Mesimeri et al., 2019) were computed for each cluster after identification using the CURATE method ((Jacobs et al., 2013). In total, 621 events exhibited swarm-like behavior. The two swarm catalogs were merged, as both techniques are independent of each other. In all, 762 events were accepted as swarm after applying additional criteria, such as ensuring the difference between the largest event and the second largest event in each cluster is less than 1. From this catalog, interpretations were made based on the tectonic setting of the region and the geological area to understand the factors responsible for these earthquake swarms.

Estimation of earthquake hazard parameters of delineated sources of the Shillong Plateau, Northeast India and adjoining regions

MOHD SHAHABUDDIN[1]*, Indian Institute of Technology Kharagpur India (mohdshahabuddin@iitkgp.ac.in)
William Kumar Mohanty[2], Indian Institute of Technology Kharagpur
Eleftheria E. Papadimitriou[3], Geophysics Department, Aristotle University of Thessaloniki, GR 541 24 Thessaloniki, Greece

Abstract

The Shillong plateau is one of the most seismically active regions of world and it experienced many major to great earthquakes in the past. Earthquake hazard parameters such as seismicity rate (λ), b value and maximum magnitude (Mmax) from the G-R relationship are the essential input for the seismic hazard assessment. The seismicity rate or the mean return periods of earthquakes with magnitudes greater than or equal to a given threshold value are considered for the evaluation of the seismicity of the region. We have estimated the earthquake hazard parameters namely Gutenberg–Richter b-value, beta (β=b*ln(10)=2.303*b), Maximum magnitude (Mmax), and earthquake mean activity rate (λ) of the twenty one seismic zones delineated based on spatial distribution and level of seismicity, seismotectonic properties, historical earthquakes, focal mechanisms and geology of the region. Earthquake catalogue compiled in the present study is used for these estimations. We applied Kijko Sellevoll Bayes technique (Kijko, 2004) to assess the essential earthquake hazard parameters for each seismic zone. Return period versus magnitude, annual probability of exceedance versus magnitude, Hazard curves have been made for each seismic zone. It is observed that λ, b value and Mmax range from 0.355 to 2.816, 0.86 to 1.50, and 5.67 to 9.21, respectively.

Bekoa Ateba[4], Institute of Geological and Mining Research

Abstract

Mount Cameroon is an active volcano rising to almost 4100 m above the sea level on Cameroon south-western coast on the Gulf of Guinea. Over the past century,it has experienced 7 major volcanic eruptions, the most recent of which occurred in 1999 and 2000. Its volcanic eruptions are usually preceded by major seismic crisis, with seismicity rising from an average of 30 events in the quiescent period to over 100 events per month as an eruption approaches. At the end of the year 2010, over a period of almost 3 months, we witnessed an increase in seismicity, with a peak of just under 200 events reached in September,yet no eruption followed. In order to better understand the physical phenomena behind this crisis, we therefore proposed to use a seismological statistical approach, in this case the non stationary ETAS model and the analysis of magnitude distribution to characterize this seismicity. The b value, considered as one of the important parameters representing the nature of earthquake occurrence and characterizing the state of stress in the crust was found to be high. The background rate, obtained from the inversion of non-stationary ETAS parameters, reveals a slow transient deformation with gradual onset. The computation of the forcing rate show so far that almost 55 % of the seismicity is due to an external process like fluid extrusion.

A regional insight on the tectonic and geometric configuration of the Bengal Basin for hosting predicted mega earthquakes

MIR FAZLUL KARIM[1]*, Geological Survey of Bangladesh (Formerly) / Presently Retired/ Address - 700 Massachusetts Avenue, Boxborough, MA 01719, USA (geologist.karim@gmail.com)
Daya Shanker[2], Department of Earthquake Engineering, IIT, Roorkee-247667, Uttarakhand, India

Abstract

Bangladesh is tectonically active and experiences often moderate to significant damage during earthquakes. Due to rapid socioeconomic and infrastructure development it is essential for a rational understanding of seismic risks factors for engineering design and hazard management in this region. Bangladesh occupies a major part of Bengal Basin, folded hills of Indo-Burma Range (IBR), a broadly N-S trending arcuate fold-thrust, close to the Indo-Burmese subducting plate boundary. This plate-boundary is an arch part and extends southward to the Andaman-Nicobar Island arc. The geological and tectonic setting of the region is extraordinarily complicated due to a juxtaposition of multiple tectonic plate margins. The Bengal Basin is covered by extensive sediment thickness of 10 - 17 km. It is formed during the separation of Antarctica from India in the early Cretaceous. Shillong plateau is over thrusting the Bengal Basin from the north, thereby depressing the Sylhet Basin. The Bengal Basin has experienced two massive earthquakes in the past (1923, M7.0, and 1918 M7.1). In recent geoscientific research based on hypothetical simulation models Steckler et al. (2016) suggested that the Indo-Burmese subduction slabs are locked, and Bangladesh is likely to host mega-earthquakes of magnitude Mw 8.2-9 soon. The prediction is highly conjectural due to lack of sufficient geological evidence. Therefore, for a thorough understanding and reliability of the prediction we investigated the geometry and stress field of the subduction zone. It is found that a stress value of the order of 30–40 MPa is estimated in the Bengal basin, Meghalaya region, and some parts of the Burmese region and Himalayan region. Based on detailed scrutinization of regional and local field geology, magnetic, gravitational anomaly maps and subsurface data published by the Geological Survey of Bangladesh we postulated the tectonic and geometric configuration of Bangladesh. Further, we did not find any megathrust structure to host any mega earthquake in the Bengal Basin.

Recent Earthquakes along the Ogcheon Fold Belt in the Korean Peninsula

Won-Young KIM[1]*, Columbia University (wykim@ldeo.columbia.edu)
Minseong Seo[2], School of Earth and Environmental Sciences, Seoul National University, Seoul, Republic of Korea.
Jun Yong Park[3], School of Earth and Environmental Sciences, Seoul National University, Seoul, Republic of Korea
YoungHee Kim[4], School of Earth and Environmental Sciences, Seoul National University, Seoul, Republic of Korea

Abstract

The tectonic map of the Korean Peninsula, published in 2019 by the Korea Institute of Geoscience and Mineral Resources (KIGAM), revised the extent of several tectonic provinces in the Korean Peninsula. Notably, the Imjingang belt in the central Korean Peninsula has been extended to include the western edge of the Precambrian Gyeonggi Massif and down to the Ogcheon fold belt (OBF) and is named the Hongseong-Imjingang belt (Permian collisional and accretionary feature). Another prominent tectonic province, the Ogcheon fold belt, a ~60 km wide and about 450 km long geologic unit that runs diagonally from southwest to northeast in the middle of the southern Korean Peninsula, had its northern border moved by about 30 km to the south. The newly defined northern and southern boundaries of the Ogcheon fold belt show a remarkable correlation with recent significant earthquakes (magnitude > 3.5) in the southern Korean Peninsula. The focal mechanisms of these earthquakes are predominantly east-west trending strike-slip faulting – nearly perpendicular to the OFB boundaries. In the framework of plate tectonics, OFB is thought to be produced by the collisions of the North China-Korea block and the South China block with the proto-Korean Peninsula.

Recent earthquakes in and around the Korean Peninsula since 1996 suggest that 1) the boundaries of the tectonic provinces may act as the zone of weakness that accommodates the occurrence of earthquakes. 2) seismogenic faults, however, appear to be stray faults trending perpendicular to the boundary faults of the tectonic provinces. These may be typical seismogenesis in stable continental regions. We will show important examples to support these arguments.

Abstract

This study investigates the eastern North China Craton (ENC), Korean Peninsula, and Bohai and Yellow Seas. These areas are located in the convergence region of ancient Asian Ocean, Tethys Ocean, and Pacific Ocean, collectively constituting the eastern Sino-Korean Craton (SKC). The areas currently undergo a significant craton destruction process. However, the precise boundaries of major geological units and their stress conditions are still inadequately understood. A velocity tomography of the entire eastern Sino-Korean Craton (SKC) demands refinement, particularly at the China-South Korea border, where the resolution is relatively poor due to the absence of collaborative works based on seismic data from both Chinese and South Korean stations.

The study integrates a comprehensive dataset, combining 87,260 earthquakes recorded at 680 Chinese seismic stations since 2008 and 5,400 earthquakes recorded at 483 South Korean seismic stations since 2017. A joint inversion method, VELEST, is employed to determine 1D minimum velocity models and hypocenters, then the events location are further refined by using the double difference method, HYPODD. All the seismic events are relocated, and the 1D minimum velocity models are improved. Different regions with diverse geological backgrounds undergo separate relocation procedures. The P and S arrival times for events in the South Korean region are determined through both the machine learning method, PHASENET and the manual picking process. The machine learning model has been trained to adapt to the Korean dataset, and the picking capacity appears to have improved after transfer learning. The arrival times of events located in the Bohai Sea and Yellow Sea regions, recorded by South Korean stations, are manually picked. Subsequently, the TOMODD tomography method is employed to image the P-wave and S-wave velocity structures for events with magnitudes of ML 2 or higher.

The seismic rays, with their cross-coverage extending over the Yellow Sea and Bohai Sea, enhance the tomography resolution of the boundary regions between mainland China and South Korea. The inverted models reveal the P and S wave velocity structures of the eastern SKC, featuring pronounced anomalies and low-velocity layers intricately connected to the ongoing craton destruction process. This research contributes new insights into the tectonic evolution and seismic activity of this dynamic region.

The 2022 Goesan earthquake of the moment magnitude 3.8 along the buried fault in the central Korean Peninsula

Hobin LIM[1]*, Korea Institute of Geoscience and Mineral Resources (HBL@kigam.re.kr)
Chang Soo Cho[2], Korea Institute of Geoscience and Mineral Resources
Minkyung Son[3], Korea Institute of Geoscience and Mineral Resources

Abstract

On October 28, 2022, a moment magnitude (Mw) 3.8 earthquake occurred in Goesan, South Korea, typically characterized as a stable continental region. Herein, we analyze 42 earthquakes, including the Mw 3.8 earthquake, the largest foreshock (Mw 3.3), which preceded the mainshock by 17 s, and the largest aftershock (Mw 2.9). The primary aim of this study is to identify interactions among the seismic events. To this end, we utilized the permanent seismic networks with the closest station at 8.3 km from the epicenter, and the temporary network deployed eight hours after the mainshock's occurrence. Relocation results delineate that the mainshock occurred at the southeastern tip of the hypocenter distribution of three foreshocks, trending west-northwest–east-southeast. The aftershocks form an overall spatially diffused seismic pattern that propagates toward both ends of the inferred lineament in the downdip direction. The rupture directivity of the mainshock, along with waveform similarity across the mainshock and foreshocks, confirms the inferred geometry, corresponding well with the focal mechanisms of the mainshock and the largest foreshock. We demonstrate that the change in Coulomb failure stress (ΔCFS) by the largest foreshock was positive where the mainshock occurred and that the mainshock generated ΔCFS capable of triggering the propagation of the aftershocks.

Resolving rupture properties of small earthquakes in the southern Korean Peninsula using direct and reflected phases

Min-Seong SEO[1]*, Seoul National University (36wnfgodfkd@snu.ac.kr)
Sangwoo HAN[2], Seoul National University
Won-Young KIM[3], Lamont-Doherty Earth Observatory
YoungHee KIM[4], Seoul National University

Abstract

While finite-fault earthquake source inversions have become a standard method for studying the kinematics of earthquake ruptures, detailing small earthquake (usually magnitude < 4) ruptures still remains challenging due to limited resolution. This limitation is pronounced in stable continental regions (SCRs), such as the Korean Peninsula, where the infrequent occurrence of moderate-to-large earthquakes impedes routine analysis and hinders a comprehensive understanding of earthquake rupture processes. This study, therefore, undertakes a systematic analysis of 28 small earthquakes (ML 2.0 – 4.1) in the southern Korean Peninsula (SKP) since 2019, taking advantage of a dense seismic network deployed in the past decade. Employing nearby smaller events as empirical Green's functions, we retrieve relative source time functions (RSTFs) of target earthquakes using direct P and S phases from stations within 100 km of the epicenter. We further obtain RSTFs from P and S phases down-going from the source and arrive as reflected from Moho, which ensures the acquisition of source pulses with up- and down-going takeoff angles. The diverse takeoff angles in the RSTFs are pivotal for resolving the vertical component of rupture propagation, which has often been overlooked in previous studies due to the absence of close-in stations. By utilizing a Bayesian framework to model RSTF durations with a simple line source model, we successfully invert for key rupture parameters — direction, length, velocity, and degree of asymmetry — thereby facilitating robust quantification of uncertainty and trade-offs between parameters.

Our results demonstrate that approximately 85% of the analyzed events can be effectively modeled using the line source model. We find that the rupture direction can be reliably inverted, thus defining the actual fault plane. Remarkably, the majority (~70%) of the events reveal asymmetric rupture propagation with varying degrees of asymmetry, while only ~15% exhibit nearly symmetrical rupture. The strategic use of Moho-reflection phase RSTFs is indeed effective in substantially reducing parameter uncertainties by tightly constraining the vertical component of rupture. Additionally, our findings reveal a positive correlation between rupture length and magnitude, aligning with the previously suggested scaling relationship for SCR earthquakes. Furthermore, well-resolved rupture velocities range from 0.56 to 0.94 times the shear wave velocity (VS), encompassing the range reported for large crustal earthquakes (0.7 – 0.9VS).

Constraints on crustal seismic properties of the southern Korean Peninsula using Virtual Deep Seismic Sounding

Young Oh SON[1]*, Seoul National University (sonofson@snu.ac.kr)
YoungHee KIM[2], Seoul National University
Chunquan YU[3], Southern University of Science and Technology

Abstract

The southern Korean Peninsula (SKP) preserves complex history of geologic processes in the Northeast Asia including Permian–Triassic collision between North China Craton (NCC) and South China Craton (SCC), as well as the formation of the island arcs of Japan in the Neogene. Traces of these events are manifested by series of tectonic units trending NE–SW to NNE–SSW, such as Yeongnam Massif and Gyeongsang Basin in SE of SKP, Gyeonggi Massif in NW, and Okcheon Belt in between. Knowledge of the average P-wave velocity (Vp), thickness (H) and P-to-S velocity ratio (κ) of the SKP crust can provide key information on its composition, isostasy, and state of thermal interaction with the upper mantle. In this study, we constrain these properties of the continental crust of the SKP by performing a joint analysis of Virtual Deep Seismic Sounding (VDSS) and P-wave receiver function (PRF). For VDSS, we inverted for H and Vp by fitting traveltimes and phases of direct S and SsPmp recorded by 192 stations (107 broadband seismometers and 154 accelerometers) in SKP. Inherent large amplitude of SsPmp, along with removal of source-side scattering effects via deconvolution of S-type waves separated by particle motion analysis, facilitates robust waveform fitting.

Estimates of Vp and H range within ∼6.0–6.7 km/s and ∼23–34 km, respectively, whereas values of κ, computed from differential arrivals of direct and multiple P-to-s conversions in the PRF combined with Vp and H from VDSS, lie mostly within ∼1.66–1.82. Independent calculation of H and κ from H–κ stacking fed by variable Vp from VDSS shows similar trend overall, supporting the validity of our results. Comparison of crustal constituents inferred from obtained Vp and κ with those from the rock samples indicates abundance of typical metamorphic rocks and granites, with composition transiting from felsic to intermediate as it goes southeast. Vp over 6.4 km/s in the southern province of Yeongnam Massif and Gyeongsang Basin might reflect magmatic underplating in the Cretaceous, induced by the subduction of Izanagi Plate. Similar value in the southwestern portion of Okcheon Belt seems to be the result of rifting between Precambrian massifs in the Paleozoic. Shallow Moho (∼23–25 km) along the eastern coast shows evidence for the opening of the East Sea of Korea (Sea of Japan). Vp in the Yeongnam Massif and Gyeongsang Basin shows similarity to NCC, while those are significantly lower in the Gyeonggi Massif at similar latitudes. This discrepancy, together with lower κ in the Gyeonggi Massif, implies its possible origin linked to SCC.

Focal Mechanism Solutions and Crustal Stress Field around the Korean Peninsula

Dong geon KIM[1]*, Yonsei University (kdg3290@yonsei.ac.kr)
Junhyung LEE[2], Yonsei University
Tae-Kyung HONG[3], Yonsei University

Abstract

The Korean Peninsula is located in the eastern margin of the Eurasian plate surrounded by the Okhotsk, Pacific, and Philippine Sea plates. The crustal stress field is mainly influenced by the regional tectonics. We collect the focal mechanism solutions of 473 earthquakes around the Korean Peninsula. We also determine the focal mechanism solutions of additional 93 regional earthquakes using a long-period waveform inversion and P phase polarity analysis. The strike-slip earthquakes are dominant in the region around the Korean Peninsula. Reverse faulting earthquakes occur in the western East sea (Sea of Japan). Normal faulting earthquakes are observed in the central Yellow Sea. We investigate the regional crustal stress field in the continental margin around the Korean Peninsula and Japanese islands. The regional stress field was inferred from the focal mechanism solutions of 13334 regional earthquakes using a damped stress inversion technique. We present a detailed stress map. The dominant compressional stress is directed ENE-WSW around the Korean Peninsula, NW-SE in the central Japanese islands, and N-S around the northern Nankai trough. The dominant compression direction changes between the Korean Peninsula and Japanese islands. The lateral variation in stress field may be due to the relative motions of surrounding plates. The stress field may provide information on potential earthquake mechanisms and vulnerability of faults in local regions.

Fault complexity revealed by focal mechanisms of small earthquakes in Gyeongju, South Korea: effective use of S-wave polarizations retrieved from the high-density seismic array

Sangwoo HAN[1]*, Seoul National University (sangw876@snu.ac.kr)
YoungHee KIM[2], Seoul National University

Abstract

The southeastern part of Korean Peninsula is the most seismically active after the 2016 Mw 5.5 Gyeongju earthquake. This earthquake sequence involves foreshocks, mainshock, and aftershocks which appear to occur on multiple segments of the Naenam fault. We here investigate detailed fault structures with the focal mechanisms of small earthquakes recorded by the 200 broadband seismic stations that cover a 50 km by 50 km zone of the earthquake sequence.

We developed a method that utilizes S-wave polarizations to increase the accuracy of focal mechanism solutions of small earthquakes (ML<3). S waves recorded within epicentral distance of 13 km were used to exclude non-linear particle motions due to free-surface interactions at incidence angle greater than critical angle of S-to-P conversion. Through rigorous synthetic tests, we assessed focal mechanisms using three different datasets: P-wave first-motion polarities, S/P amplitude ratios, and S-wave polarization directions, with varying levels of measurement errors. Results indicate that utilizing the S-wave polarization directions with correction of S-wave splitting effectively reduces the minimum required number of stations. Considering realistic noise levels for a ML 2.6 event, the solution could be derived with only two stations with mean error of 15° in the 3-D rotation angles. Lastly, we applied our method to determine focal mechanisms of small earthquakes that occurred within the network since 2019 in Gyeongju. We obtained ~90% strike-slip and ~10% reverse faulting mechanisms having spatially different distributions depending on their focal depths. We also found that reverse faulting mechanisms are mostly concentrated at shallower depths. Our analysis results suggest that the location of earthquakes can be improved by using seismic waveforms rotated to the direction of S-wave polarization constrained by the focal mechanism.

Do Subducted Seamounts Act as Weak Asperities?

Sungho LEE[1]*, KIGAM (slee29@memphis.edu)
Eunseo Choi[2], University of Memphis
Christopher H. Scholz[3], Columbia University

Abstract

The additional work of ploughing makes seamounts more resistant to subduction and more strongly coupled than smoother areas. Yet there is a school that believes that seamounts have weak coupling and slip aseismically. This idea is primarily based on the claim that a seamount being subducted in the southern Japan Trench behaves this way. The key element in this assertion is that large M~7 earthquakes that abut the leading edge of the seamount require that the seamount be aseismically sliding to initiate them. More recent observations which were found by ocean-bottom seismometers deployed in the southern Japan Trench show instead that the surrounding region is aseismically sliding while the seamount acts as a stationary buttress. Here we re-examine this case and model it with both weak and strong asperity assumptions. Our modeling results show that only a strong asperity model can produce this type of earthquake. Strong asperities also rupture the seamount in great earthquakes with long recurrence times. This provides the previously unknown source for a series of great tsunami earthquakes that have occurred along the southern Japan Trench, the most recent being the 1677 M8.3–8.6 Enpo Boso-oki tsunami earthquake. The ‘weak asperity’ hypothesis is thus found to be false in this foundational example.

Crustal Structure in the Southeastern Korean Peninsula Using a Receiver Function Analysis

Jeongin Lee[1]*, Yonsei University (jeongin6422@yonsei.ac.kr)
Tae-Kyung Hong[2], Yonsei University
Seongjun Park[3], Yonsei University
Junhyung Lee[4], Yonsei University
Byeongwoo Kim[5], Yonsei University

Abstract

The southeastern Korean Peninsula (Yeongnam region) is a region with a population of 12 million and 19 nuclear power plants in operation. Recent moderate-size earthquakes, including the 2016.9.12 ML5.8 Gyeongju earthquake and the 2017.11.15 ML5.4 Pohang earthquake, occurred in the southeastern Korean Peninsula. Small to moderate-size earthquakes (≥ ML 3.0) constantly occur in the region. The southeastern Korean Peninsula is composed of two geological provinces of Yeongnam Massif and the Gyeongsang Basin. In the Gyeongsang Basin, complicated fault structures developed by tectonic processes during the Miocene. High-resolution crustal structures may provide information on tectonic processes and seismic hazard potentials. We investigate the crustal structures of the southeastern Korean Peninsula using a receiver function analysis. We collect seismic records in 182 stations for 138 teleseismic events with magnitudes of ≥ MW 6.0 and distances of 30°–90° since 2019. We calculate the receiver functions and shear-wave velocity models using a time-domain iterative deconvolution method and iterative least-squares inversion method. The shear wave velocity distribution is generally consistent with geological features. Low velocities are observed in the Cenozoic sedimentary region in the east of the study area. The crustal thickness and VP/VS ratio are estimated using an H-K staking analysis. The Moho depths range mostly from 28 to 34 km, becoming shallower on the east coast of the peninsula. The western study area, corresponding to the Yeongnam Massif, presents a crustal thickness greater than 34 km. The VP/VS ratios vary between 1.68 and 1.86, with higher values around the coast and fault zones.

Comprehensive Earthquake Parameter Determination using the AI and Bayesian Inference Techniques: Case Study on the Southeastern Korean Peninsula

Jongwon Han[1]*, Korea Institute of Geoscience and Mineral Resources (jongwony@korea.ac.kr)
Seongryong Kim[2], Dept. of Earth and Environmental Sciences, Korea University
Dabeen Heo[3], Division of Earth Environmental System Science, Pukyong National University
Tae-Seob Kang[4], Division of Earth Environmental System Science, Pukyong National University
Dong-Hoon Sheen[5], Dept. of Geological Environment, Chonnam National University

Abstract

To investigate the seismic source characteristics and the safety of nuclear power plants (NPPs) due to ML5.8 Gyeongju earthquake, 200 broadband seismic stations (Gyeongju Hi-density Broadband Seismic Network) were deployed over a 60 * 60 km area centered around the epicenter. During the investigation, signs of various seismogenic faults developing in the study area were discovered, and it was confirmed that several faults exhibit complex segmentation. When seismogenic faults are segmented, it is necessary to analyze the 3D structure of the faults and the possibility of rupture propagation. Securing an earthquake catalog with statistical completeness down to the lowest possible magnitude earthquakes is essential in this process. In this study, deep learning (DL) based techniques were used to build a comprehensive earthquake catalog more efficiently with the massive amount of dataset. Training models were optimized for the research area using fine-tuning and transfer learning techniques, and as a result, microearthquake catalog with better statistical completeness than previous studies were suggested. Additionally, various earthquake parameters such as phase picking, association, signal discrimination, and event declustering were provided through DL (or machine learning) based analysis. Focal mechanisms were automatically determined using a DL based P-wave polarity determination model, and the spatiotemporal background stress distribution in the research area was elucidated using a Bayesian inference-based stress inversion algorithm. The earthquake distribution derived from this study was used to confirm various 3D fault structures and secure segments of seismogenic faults. Furthermore, the potential for fault rupture and propagation was analyzed through the derived stress field distribution. The results of this study are expected to be utilized in assessing the safety of NPPs, including estimating the maximum potential earthquakes at seismic sources, the characteristics of seismic attenuation between sources and NPPs, and calculating the maximum ground motions at NPPs.

Utilization of Regional Lg Wave in Precise Epicentral Relocation and Source Characterization of Two 2021 Earthquake Sequences in Gunsan Basin, Yellow Sea

JUN YONG PARK[1]*, Seoul National University (zip1900@snu.ac.kr)
YoungHee Kim[2], Seoul National University
Won-Young Kim[3], Lamont-Doherty Earth Observatory, Columbia University
Xuzhang Shen[4], Sun Yat-sen University

Abstract

The Yellow Sea encompasses the tectonic boundary of China Blocks and the Korean Peninsula. Despite its regional importance, seismogenic faults and ruptures remain insufficiently investigated due to the lack of close-in stations and station coverage. In this study, we examined seismogenic faults and distinct rupture processes of two intraplate earthquake sequences using Lg-wave observations in the Gunsan Basin, situated in the middle of the Yellow Sea, characterized by low seismicity.

The first sequence initiated with a Mw 4.7 event on January 18, 2021, followed by five aftershocks until March 9, 2021. The second sequence began with a Mw 4.2 event on December 3, 2021, accompanied by two aftershocks within 13 hours. Focal mechanisms of the mainshocks indicate strike-slip faulting along steeply dipping nodal planes striking NW (~305º) and SW (~215º) at a depth of 10 km. While the focal mechanisms are similar to other events in the Yellow Sea, the fault planes of these events have been rarely investigated. Furthermore, event location uncertainty in the sequences hinders the definition of fault planes due to weak Pn/Sn signals despite the alignment of the two mainshocks in the NW-SE direction. We utilized Lg waves, characterized by strong amplitude and travel through the continental crust beneath the Yellow Sea with a group velocity centered at 3.3 km/s, to relocate epicenters of aftershocks.

Epicentral relocation was determined through differential travel times (Δt) measurements using the Lg-wave cross-correlation technique. The measured Δt exhibited sinusoidal features against azimuth, even in event pairs of different sequences and small events. Consequently, both earthquake sequences exhibited an NW-SE trend fault along one of the nodal planes of the focal mechanism. Additionally, we investigated rupture processes using the Lg-wave source spectrum, revealing distinct rupture processes between the two mainshocks. The Mw 4.7 event displayed bi-lateral or circular rupture, while the Mw 4.2 event exhibited a uni-lateral rupture strongly directed to the SE, supporting the epicentral relocation of aftershocks. Our results indicate that the stress field in the Gunsan Basin is similar to the overall Yellow Sea, governed by the same tectonic sources. This also suggests the possibility of defining fault and rupture directions of other events in the Yellow Sea for future studies.

[Keynote] Lithosphere structure from comparative tomographic study: Implications for deformation mechanisms of the Tibetan Plateau

Xiaodong SONG[1]*, Peking University (xdsong@pku.edu.cn)
Xuezheng Zhang[2], Peking University
Jincheng Ma[3], Peking University
Xuewei Bao[4], Zhejiang University
Jiangtao Li[5], Wuhan University

Abstract

Several geodynamic models have been proposed for the deformation and growth of Tibetan Plateau (TP) without consensus, including continuum, rigid block, and channel flow models. In the meanwhile, numerous models of the lithosphere structure of the TP have been developed over the decades with different methods and datasets in various studies. These models show apparent discrepancies as well as consistencies. In this study, we compare these models and synthesize robust model features to explore the deformation mechanisms. The results show complex but distinct features in the crustal thickness and the velocity and anisotropy of the crust and the uppermost mantle. The results suggest a lithospheric-scale deformation of continuous shortening as well as localized faulting, which is affected by the strength of the lithosphere blocks of the TP. The thickened mantle lithosphere can be removed, which facilitates the formation of middle-lower crustal low-velocity zone and flow. However, such flow is likely a consequence of the deformation rather than a driving force for the outward growth of the TP. We propose an episodic growth model for the TP, in which heterogeneous crustal thickening was a primary driver at the early stage and the weakened middle-lower crust flowed locally at a later stage.

Jin-Han REE[7], Korea University

Abstract

The southeastern Korean Peninsula (SeKP) is known as one of the most seismically active regions in South Korea. The previous studies suggested that the SeKP experienced complex tectonic processes influenced by the subduction of the paleo-Pacific plate in the Cretaceous and the East Sea (Japan Sea) opening in the Cenozoic. The Gyeongju Hi-density Broadband Seismic Network (GHBSN) deployed in an area of 50 km by 50 km consists of 200 broadband stations that densely cover the region where aftershocks of the 2016 moment magnitude 5.5 Gyeongju earthquake occurred. The GHBSN covers two major fault systems such as the Yangsan Fault (YSF) and the Ulsan Fault (USF) from west to east, encompassing the Gyeongsang basin to the west and the Miocene basin to the east with respect the Yeonil tectonic line situated in close proximity to the USF. We calculated the receiver functions (RFs) using 647 teleseismic events in distance of 30°–90° in 2018–2023 to retrieve detailed crustal structure and seismic properties.

As the first-order crustal structure obtained by two different stacking methods, the Moho is deepest in the west (33.5 ± 0.35 km) and shallowest in the east (25.6 ± 0.42 km). Rather than gradual change in Moho depth, we find two step-like changes beneath the YSF with its vertical offset of ~6 km and the USF with ~3 km offset, which could be related to the formation of extensional basin in SeKP. The P-to-S wave velocity ratio (Vp/Vs) for the crust as a good proxy for rock types is estimated as 1.817. Slightly higher Vp/Vs estimate, exceeding 1.8 in the eastern side of the USF and the western side of the YSF, could be affected by mafic crustal composition related to Cretaceous to Cenozoic magmatic activities. The P-to-S converted phase at Moho (Pms) of the radial and tangential RFs shows systematic backazimuthal phase shift, indicating the presence of seismic anisotropy in terms of fast symmetric axis (FSA) and delay time (DT). Overall trend of the FSA shows the clockwise rotation from west to east. In the west of the YSF, the azimuth of the FSA is ~325°; it becomes ~355° between the YSF and USF and > 30° in the east of the USF. Lastly, the average DT is 0.32 s, which corresponds to the degree of anisotropy of ~4%. Our crustal anisotropy measurements suggest that the crust might have experienced sufficient deformation attributed to the east sea opening in the Cenozoic.

The intricate fault interactions: source parameter estimation of the 2017 Pohang, Korea, earthquake and its aftershocks

Minkyung SON[1]*, KIGAM (kersti@kigam.re.kr)
Esteban J Chaves[2], OVSICORI-UNA
Chang Soo Cho[3], KIGAM

Abstract

In 2017, the Korean Peninsula experienced its second-largest recorded earthquake, a moderate-magnitude (M 5.4) event near fluid injection sites in Pohang. We analyzed the waveforms of this earthquake and seven aftershocks to elucidate their occurrence and subsequent triggering mechanisms. An empirical Green's function approach provided apparent source time functions and stress drop estimates, isolating the effects attributed to earthquake source characteristics from the influence of propagated waves through the Earth. Our findings revealed that the mainshock ruptured in multiple stages along a central segment of the fault system, contrasting with the relatively simpler processes observed in most aftershocks. Notably, one aftershock, occurring within the mainshock slip zone, also exhibited multi-stage patterns, and its hypocenter coincided with a potential fault jog of the mainshock segment. Stress drop estimates indicated that aftershocks occurring outside the mainshock slip zone released higher stresses than those within. Particularly, the aftershock at the shallowest depth released the highest stress, following the upward-progressing aftershock sequence. We posit that the mainshock swept out much of the stress accumulated within its slip zone, prompting the upward migration of aftershocks and stress buildup along the fault system edges. Furthermore, we observed that the migration head corresponded to a fluid diffusion curve, suggesting a fault-valve mechanism. Stress transfer along the upper part of the northern fault segment, connected to the mainshock fault at depth, could have caused the highest stress-drop event at the top. Our investigation, highlighting the intricate interplay of earthquakes, may improve seismic hazard assessment and mitigation strategies by further understanding earthquake genesis.

Seismic Properties of Upper-mantle 410- and 660-km Discontinuities Beneath the Korean Peninsula Using P-wave Receiver Functions

Juhyung LEE[1]*, Seoul National University (juhyung@snu.ac.kr)
Hyunsun KANG[2], University of Florida
YoungHee KIM[3], Seoul National University

Abstract

Fundamental questions relevant to the mantle transition zone concern the nature of phase transition, distribution of chemical heterogeneities, temperature gradient, as well as degree and extent of hydration and melting. One particularly important question is how the slab stagnation may be influenced by hydration or/and basalt enrichment in the mantle transition zone. To help answer these questions, we aim to retrieve upper mantle seismic discontinuity properties, such as the shear-wave velocity contrast, the density contrast, the transition sharpness and the gradient using high-quality receiver functions (RFs) using dense seismic data in South Korea, which is located in the immediate vicinity of the stagnant slab near northeast China.

We retrieve P-to-S converted phases from the 410- and 660-km discontinuities as well as their reverberated phases, as these phases are sensitive to the shear-wave velocity contrast and density contrast across the discontinuities. Nearly 20-year data (2003-2022) recorded by 151 broadband stations are used to compute the RFs; we further stack the RFs in a distance interval of 0.5° in order to enhance RF amplitudes of the converted phases. We plan to conduct amplitude analysis of direct converted waves and multiples from the 410- and 660-km seismic discontinuities to detail seismic properties of the mantle transition zone and to discuss the role of slab stagnation in the deep mantle structure.

Constraining crustal composition of the continental China by three-dimensional Vp/Vs model

Guifang ZHANG[1]*, University of Science and Technology of China (guifangz@mail.ustc.edu.cn)
Haijiang zhang[2], University of Science and Technology of China
Guifang Zhang[3], University of Science and Technology of China
Hailiang Xin[4], Geophysical Exploration Center, CEA, China

Abstract

The ratio (Vp/Vs or k) between seismic compressional wave velocity (Vp) and shear wave velocity (Vs) is directly related to Poisson's ratio. In the continental crust of the continental China, Vp and Vs models have been obtained using an improved method of joint inversion of body wave and surface wave data. However, the Vp/Vs ratio model directly derived from these models may contain some artifacts due to an inherent inconsistency between the resolution and uncertainty of the models. In this study, a high-resolution three-dimensional Vp/Vs model is directly inverted based on body wave arrival time data collected from the regional seismic network in continental China during the period from 2008 to 2018. Following Fang et al. (2019), Vp/Vs is directly determined by P and S arrival times by constructing sensitivity of S arrival times with respect to Vp/Vs. Resolution analysis reveals that the spatial resolution of the obtained Vp/Vs model is approximately 1.5° across most regions of mainland China, reaching depths of up to 150 km. Overall, the Vp/Vs anomalies of the upper crust correlate well with surface geological features. With the Vp/Vs model, we can further estimate the SiO_2 content of the crystalline crust because it is related to Vp/Vs ratio. The spatial distribution of SiO_2 content as a whole shows a strong correlation with major geological provinces, offering new insights into the composition and evolution of the continental China.

Intraplate lithospheric structures near plate margins: comparison between northeast India (Eastern Himalayan Syntaxis) and southern Korean Peninsula

ABHISHEK KUNDU[1]*, Yonsei University (kunduabhishek@yonsei.ac.kr)
Tae-Kyong Hong[2], Yonsei University
Devajit Hazarika[3], Wadia Institute of Himalayan Geology
Jeongin Lee[4], Yonsei University
Seongjun Park[5], Yonsei University

Abstract

Lithospheric structures near plate boundaries are highly deformed by tectonic activities. Various signatures and byproducts are imprinted in the lithosphere that provide valuable information on tectonic evolution in the plate margins. We investigate the intraplate lithospheric structures of India and the Korean Peninsula using a receiver function analysis. The lithospheric structures beneath the Eastern Himalayan Syntaxis (EHS) at the northeast corner of the indenting Indian Plate (i.e. Lohit Valley and Siang Window) have been studied using the P-wave receiver function (PRF) analysis of teleseismic earthquakes. The three-component waveforms recorded by broadband seismological networks have been utilized in this study for PRF analysis. We present fresh insights into the lithospheric features using the common conversion point (CCP) stacking and 1-D velocity models generated through the inversion of PRFs. The signature of the Main Himalayan Thrust (MHT) or dècollement which separates the underthrusting Indian plate from the Himalayan wedge above, is observed at a depth of around ~22–26 km beneath the Lohit Valley. The signature of MHT is not prominent beneath the Siang Window. The absence of the prominent MHT beneath the Siang Window can be attributed to the large-scale crustal deformation due to window formation and antiform folding. The crustal and intra-crustal structures along with the lithospheric deformation patterns at the eastern part of the Eurasian plate in the Korean peninsula will also be investigated utilizing the concept of CCP stacking and 1-D inverted velocity models using PRFs. The seismic velocity characteristics of the Precambrian massif blocks along with the intervening fold-thrust belts and basins of the Korean peninsula will be studied using high-resolution subsurface imaging and different passive seismological experiments which can provide some new important information regarding the geodynamic evolution of the Korean peninsula. The comparative study on the lithospheric configurations and deformation patterns carried out at the eastern parts of the Indian (EHS) and Eurasian (Korean peninsula) plates can reveal some interesting facts about global tectonics.

Deploying a Temporary Seismic Network for the 2022 Goesan Earthquake Sequence and its Integration with the Deep Learning Model EQTransformer

EunJin LEE[1]*, Pusan National University (eunjinlee@pusan.ac.kr)
Yu Jin Sohn[2], Pusan National University, Department of Geological Science, Busan, South Korea
Su young Kang[3], Institute of Geologic Hazard & Industrial Resources, Pusan National University, Department of Geological Science, Busan, South Korea
Hyeong-Tae Jou[4], Korea Institute of Ocean Science and Technology, Busan, Republic of Korea
Kwang-Hee Kim[5], Pusan National University, Department of Geological Science, Busan, South Korea

Abstract

In the morning on October 28, 2022, the Goesan region in Korea experienced a light earthquake with a ML 4.1 mainshock with a preceding ML 3.5 foreshock. Responding to the seismic activity and considering azimuthal coverage with nearby stations, PNUGL (Pusan National University Geophysics Laboratory) deployed nine temporary seismic stations within an 8 km radius of the main earthquake epicenter and operated them for the next 7 months until May 31, 2023. The temporary seismic network comprised one broadband seismometer and eight short-period seismometers. We detected 386 events by manual inspection. In the first 13 days of the aftershock monitoring, 330 events were detected. Most aftershocks following the Goesan earthquake were recorded in the period. The number of aftershocks per day decreases over time. Event locations were determined using the earthquake location program, HYPOELLIPSE, and the double-difference method, HypoDD. The distribution of relocated aftershock epicenters aligned along the fault trace at the surface, with hypocenters predominantly located at depths of 12 to 15 km. We utilized the P-wave polarities of microseismic events and the mainshock to derive a representative composite focal mechanism solution. We observe the effects of ambient noise on earthquake detection by examining Power Spectral Density (PSD) Probability Density Functions (PDF) at each temporary seismic station. Comparing the mode PSD value of GE09 (most noisy station) with that of GE03 (most quiet station) revealed a difference of approximately 20 dB at 0.1 ~ 2s period bands, suggesting varying observation conditions. The thickness of soft sedimentary layer also affects ambient noise levels and signal-to-noise ratios. We also applied the Deep Learning model EQTransformer (EQT) for simultaneous detections of events and phase pickings. Four models were used to compare and observe differences and improvements in predictions. A model, trained exclusively with earthquake data from the study area and non-earthquake signals, demonstrated improved prediction accuracy for P- and S-waves compared to results using the EQT original model.

Upper crustal azimuthal anisotropy and seismogenic tectonics of the Hefei segment of the Tan-Lu fault zone from ambient noise tomography

LI CHENG[1]*, Anhui University of Science and Technology (licheng@aust.edu.cn)

Abstract

The Tan-Lu fault zone is a large NNE-trending fault zone, which has a significant effect on the development and earthquake disaster prevention of eastern China. Aiming at the upper crustal azimuthal anisotropy structure and seismogenic tectonics in the Hefei segment of this fault, we collected continuous ambient noise phase velocity dispersion data of fundamental mode Rayleigh waves from ~400 temporal seismographs in the area about 80 km×70 km along the fault zone. The period band of the dispersion data is 0.5~10 s. We inverted for the upper crustal 3-D shear velocity model with azimuthal anisotropy from surface to 10 km depth by using a direct 3-D azimuthal anisotropy inversion method. The inversion result shows the spatial distribution characteristics of the tectonic units in the upper crust. Meanwhile, the evolution of Tan-Lu fault and its conjugated fault systems can be inferred from the anisotropy model. Especially, the faults that kept active from early and middle Pleistocene, control the anisotropic characteristic of the upper crustal structure in this area. The direction of fast axes anisotropy near the fault zone area in the upper crust is consistent with the direction of the faults which kept active from early and middle Pleistocene. While for the region far away from the fault zone, the direction of fast axes is consistent with the direction of regional principal stress caused by plate movement. Combined with the azimuthal anisotropy models in the deep crust and uppermost mantle from Pn wave and surface wave, the different anisotropic patterns caused by the Tan-Lu fault zone and its conjugated fault system nearby are shown in upper crust and lower crust. Furthermore, by using the double-difference method, we relocated the Lujiang earthquake series, which contain 32 earthquakes with the depth shallow than 10 km. The result shows these earthquakes are mainly located in the transition zone between high and low velocities. Together with the tectonic characteristics from azimuthal anisotropy results, we constructed a seismogenic model for these upper crustal earthquakes in this area.

Determination of moment magnitude of earthquakes in the Korean Peninsula from 2017 to 2022.

Yoontaek HONG[1]*, Chonnam National University (ythong@jnu.ac.kr)
Dong-Hoon Sheen[2], Chonnam National University

Abstract

The accurate determination of earthquake magnitudes is crucial for seismic hazard assessments. In South Korea, a local magnitude scale using the peak amplitude of S waves has been proposed (Sheen et al., 2018). However, at the time of the previous study, there were a limited number of observations within 50 km of the epicenter. Therefore, it is difficult to consistently determine the magnitude of small earthquakes that are observed only at short distances, using the previous scaling relationship. Additionally, the local magnitude scale underestimated for small earthquakes due to the limitations of the Wood-Anderson response (Hanks and Boore, 1984). In contrast, the moment magnitude is proportional to the seismic moment, which quantifies the energy of an earthquake in physical units. In this study, we determined the moment magnitude of earthquakes in and around South Korea, occurring from 2017 to 2022. For this, we collected seismograms within 100 km of the hypocenter of 647 earthquakes ($M \geq 2.0$). We adopted the source spectrum approach for moment magnitude determination, and the source spectrum was calculated for the S-wave using the multitaper method to avoid spectral leakage. To reduce the impact of outliers, we selected the spectrum with a signal-to-noise ratio greater than 3.0. For source parameter estimation, we employed MCMC (Markov chain Monte Carlo) to fit the Brune source model (1970). It is expected that the moment magnitudes of earthquakes in the peninsula determined in this study can be used for seismic hazard assessment.

Recent seismicity in the Haenam and Suncheon regions using template matching method

Bohyun KIM[1]*, Chonnam National University (kbobo41@naver.com)
Dong-Hoon Sheen[2], Chonnam National University

Abstract

According to the Korea Meteorological Administration, 48 microearthquakes occurred persistently in the Suncheon region of southwestern Korea over the years from 2009 to 2024. However, 76 earthquakes occurred in the Haenam region in southwestern Korea, apart from 98 Km from Suncheon, between April 26, 2020, and June 11, 2020, and few earthquakes have occurred intermittently, suggesting a distinct seismic pattern from Suncheon. Previous studies on Haenam (Son et al., 2021; Han et al., 2021; Hong et al., 2021) and Suncheon (Kwak et al., 2022) have shown that microearthquakes in both areas have occurred more frequently than cataloged by the KMA. However, these studies only utilized data up to 2020, leaving us unaware of the detailed seismic activity in both areas beyond that period. This study applies the template matching (TM) method to detect recent microearthquakes in both areas. TM is a detection method based on the idea that colocated earthquakes with the same focal mechanism have similar waveforms. We performed TM on data from both regions for the period up to 31 May 2023. For Haenam, we used 77 template events reported by the KMA and detected 1340 earthquakes, of which 1273 were not cataloged. Most of the earthquakes occurred between April 25 and May 8, 2020, with only 68 earthquakes occurring intermittently in several years after this period. For Suncheon, using 28 cataloged events resulted in the detection of 753 earthquakes, of which 723 had been undetected. In contrast to the Haenam region, we found that all the 753 earthquakes detected in the Suncheon region were evenly distributed over the entire period. Based on these results, we generated a catalog that is completeness guaranteed even at the low cutoff magnitude, so using this catalog we were able to calculate b-values as 0.77±0.02 for Haenam and 1.01±0.06 for Suncheon. Furthermore, we analyzed several quantitative factors proposed by Bachura et al. (2021) and determined whether the earthquakes in the two regions were earthquake sequence or swarm. We found that they were more likely to be earthquake sequence. To investigate the spatiotemporal distribution of earthquakes in both regions, we relocate earthquakes in the catalog with high correlation coefficients using hypoDD, which is based on a double-difference relocation algorithm.

Determination Focal Depth of the 2014 ML 5.1 Offshore Gyeongyeolbi Island Earthquake Using Depth Phase

Hyeonjun LEE[1]*, CHONNAM NATIONAL UNIVERSITY (hyunj@jnu.ac.kr)
Dong-Hoon Sheen[2], CHONNAM NATIONAL UNIVERSITY

Abstract

The focal depth is an important factor in analyzing the overall cause and process of earthquake occurrence, and therefore, accurately determining the focal depth is crucial. Since a routine earthquake location method is based on the arrival times of the seismic phases, the number of data and the distribution of the stations are critical. Determining the focal depth requires additional constraints than determining the epicenter, and in particular, the acquisition of near-field S-waves is crucial for constraining the focal depth (Gomberg et al.,1990). However, regional earthquakes are challenging because of the difficulty of acquiring near-field S-waves and the relatively small amount of data available, leading to large uncertainties in the results. Determination of the focal depth of offshore earthquakes is under the same conditions. Seismic stations are usually installed on land, making it difficult to obtain near-field observations for offshore earthquakes. The focal depths of offshore earthquakes usually show large variations. (up to 17 km depth deviation). As an alternative, depth phase, which can be observed in seismograms, was used in this study. It is reported that the regional depth phase (sPg, sPmP, sPn) and its reference phase can well constrain the focal depth (Ma, 2010). To identify these depth phases, after extracting the depth phase from the seismograms, we compared the shape and arrival time of the propagable depth phase obtained through waveform modeling. This allowed us to use the differential time between the depth phase and the reference phase with depth to constrain the focal depth. In the Yellow Sea, small- to moderate-sized earthquakes have been occurring continuously, and it is analyzed that they have a significant variation in their focal depth. In particular, numerous earthquakes have occurred around Gyeongreolbi Island in the Yellow Sea in the past, but their focal depths have large uncertainties. The reason for this is that the seismic network is sparse in the area, and the epicentral distance to the nearest station is about 100 km, making it difficult to determine the focal depth. Therefore, in this study, we aimed to increase the understanding of the seismicity in the Yellow Sea by determining the focal depth the magnitude 5.1 (ML) Offshore Gyeongnyeolbi Island earthquake that occurred on 31 March 2014 using depth phase.

Introduction to Research using the Unified Model for Subsurface Fault and Velocity Structure in the Korean Peninsula

Kyungmin MIN[1]*, Korea Meteorological Administration (mkmzx@korea.kr)
Mikyoung CHOI[2], Korea Meteorological Administration
Yeongjae CHOI[3], Korea Meteorological Administration
Ah-Hyun BYUN[4], Korea Meteorological Administration
Eun-young JO[5], Korea Meteorological Administration
Sun-Cheon PARK[6], Korea Meteorological Administration

Abstract

The Korea Meteorological Administration (KMA) is conducting a project to develop a unified model of 3-D subsurface fault and velocity structure in the Korean Peninsula to determine the causes of earthquakes and improve the accuracy of earthquake information. This project, targeting the Korean Peninsula and its surrounding seas, involved research conducted in the Seoul metropolitan region and the Youngnam region from 2018 to 2021. As a result, we have developed initial models of subsurface fault and velocity structure. We are various research are being conducted to utilize and apply this initial model. First, we apply the DD-RT procedure, which uses cross-correlation and double-difference methods, to rapidly relocate new earthquakes in the Seoul metropolitan region and the Youngnam region. The DD base catalog is computed from a simultaneous relocation of all events, involving the cross-correlation of waveforms between each event and all neighboring events within select regions. The new events are relocated relative to a selected number of reference events in the DD catalog. Secondly, the hypocenter determination system was established using the initial 3D velocity structure model(Ver.1). We utilize the nonlinloc program that can apply the 3D velocity structure model for the hypocenter and construct a system to determine the hypocenter through the Antelope database. Finally, we are conducting research on accurately calculating 3D elastic wave propagation using the spectral-element method implemented in the SPECFEM3D Cartesian software package.

Analysis of the three earthquakes with moment magnitudes greater than 4 in the Gunsan Basin, Yellow Sea, Korea, 2021

Miji KIM[1]*, Korea institute of Geoscience and mineral resources (miji61759@gmail.com)
Minkyung SON[2], Korea Institute of Geoscience and Mineral Resources
Chang Soo CHO[3], Korea Institute of Geoscience and Mineral Resources
Tae-Seob KANG[4], Pukyong National University

Abstract

Three earthquakes, with magnitudes exceeding 4, occurred in the far sea of the Yellow Sea on January 18, August 21, and December 3 (UTC), respectively, according to the Korea Meteorological Administration (KMA). The academic annual report of earthquakes from the Korea Institute of Geoscience and Mineral Resources (KIGAM) indicates that the epicenters of the January and December earthquakes were located on the eastern highlands of the Gunsan Basin, near the Haema Platform. We relocated these two nearby earthquakes based on the fact that depth differences in nearby hypocenters affect travel time differences for Pn phases rather than Pg phases. The seismic stations located along the coast of the Yellow Sea, including station RCN in the Shandong, China, region, enabled us to approximate the vertical slowness of the Pg to zero. Furthermore, we estimated corner frequencies, rupture radii, and stress drops of the three earthquakes by approximating S-wave displacement spectra of the three earthquakes to the Brune's source model. The time-domain moment tensor inversion also provided moment magnitudes along with variance reduction values, searching the best solution with varying hypocenter depths. The relocation results showed that the difference in focal depths among the two nearby earthquakes was 1.9 km, and the epicenter of the December earthquake was located 3.3 km southeast from the epicenter of the January earthquake. The corner frequencies estimated from the curve fitting to the Brune's model were 2.5 Hz and 3.0 Hz for the January and December earthquakes respectively. Assuming an S-wave velocity of 3.5 km/s, the estimated corner frequencies yield the rupture areas of 520 m and 440 m, respectively. The rupture areas of the two nearby earthquakes do not overlap on the map for the relocated hypocenters. The moment magnitudes are 4.6, 4.1, and 4.1 for the January, August, and December earthquakes, respectively, and the direction of maximum compressive stress is ENE-WSW for all three earthquakes. This direction corresponds to the current compressive stress environment on the Korean Peninsula and its surrounding sea, which is known as the ENE-WSW to E-W.

[Keynote] What determined the Rupture Extent of the 2023 Mw7.8 Kahramanmaraş Earthquake

Ali Ozgun KONCA[1]*, Bogazici University (ozgun.konca@boun.edu.tr)
Hayrullah Karabulut[2], Bogazici University
Yasemin Korkusuz Ozturk[3], Bogazici University
Sezim Ezgi Guvercin[4], University of Southern California

Abstract

2023 Eastern Turkey earthquakes were the largest earthquakes experienced during the instrumental period. Mw7.8 ruptured 350 km portion of the 600 km long East Anatolian Fault (EAF). The second Mw7.6 earthquake ruptured 9 hours later northwest of the first earthquake along the Çardak fault, which is another E-W trending left-lateral fault. The 2023 Mw7.8 is a remarkable earthquake due to its implications about seismic cycle, interesting sequence of foreshocks and rupture dynamics. Based on paleoseismogical studies and fault slip-rate on the fault the 2023 Mw7.8 earthquake cannot be explained by the last seismic cycle and implies that to understand these earthquakes multiple seismic cycles must be considered. We also study the foreshock sequence of the Mw7.8 earthquake and show that there was increasing seismic activity in the vicinity of the epicenter which started about 6 months before the mainshock. Finally we study what determined the slip distribution of this earthquake and whether the rupture would have propagated in a similar way had it started on the EAF rather than Narli fault. In that regard, we first calculate dynamic rupture models that mimic the Mw7.8 earthquke. Then we change the rupture initiation point to the main fault. We show that with a similar rupture initiation patch the earthquake might not have propagated bilaterally if it had started on the main fault. The results indicate that dynamic stresses which cannot be predicted from static stress are a very important factor in determining the rupture extent of these large earthquakes.

[Keynote] The East Anatolian Fault System: An Overview on Active Tectonic Setting of the February 6, 2023, Kahramanmaraş Earthquake Sequence, Türkiye

OMER EMRE[1]*, Fugro Sial (o.emre@fugro.com)
TAMER Y. DUMAN[2], Fugro Sial

Abstract

The East Anatolian Fault (EAF) is a complex continental transform fault system in the Eastern Mediterranean, accommodating westward extrusion of the Anatolian block along with the North Anatolian fault. On February 6, 2023, two large earthquakes, Mw 7.8, and Mw 7.6 occurred on the EAF system nine hours apart, resulting in multi-segment surface ruptures spanning a total of 517km. The ruptures largely followed the previously mapped Holocene fault traces but also triggered previously unmapped fault splays. Available data on the fault characteristics along the entire EAF provided valuable insights understanding the nature of the multi-segment rupturing and fault interactions in the earthquakes.

The EAF consists of a 580 km-long main strand extending between Karlıova and Amik triple junctions, and the northern strand as known the Sürgü-Misis fault system bifurcating from the main strand. The 160 km-long southwestern section of the main strand overlaps with Dead Sea Fault (DSF). The main strand is divided into seven fault segments, ranging in length from 31 to 112 km, separated from each other by releasing and restraining jogs. The eastern part of the northern strand comprises the Sürgü and Çardak faults, and the Nurhak fault complexity, which is a fault junction on a regional scale between the Çardak, Sürgü, Malatya, and Doğanşehir faults.

The slip rate decreases from northeast to southwest along the main strand, with approximately 10 mm/year on the Karlıova-Çelikhan section, decreasing to 5.6-7 mm/year on the Erkenek and Pazarcık segments, and further to 4-4.5 mm/year on the Amanos segment. The change in the slip rate west of the Çelikhan reveal slip partitioning between the main and the northern strand, as well as between the Amanos segment and DSF. The estimated slip rate of 2-3 mm/year on the Çardak fault suggests a slip partitioning ratio of approximately 1/3 with the main strand.

Historical earthquakes along the EAF have resulted in surface rupturing in the 19th and 20th centuries. Recurrence intervals of 350-400 years have been suggested for the Palu segment, and 510 years have elapsed since the 1513 earthquake on the Pazarcık segment. The timing of the last event on the Pütürge segment was unknown. Historical records indicate large earthquakes in AD 521 and AD 1893 on the Amanos and Erkenek segments, respectively. The Pütürge, Pazarcık, and Amanos fault segments, along with the northern strand, were considered seismic gaps of the EAF system prior to the 2020 Doğanyol earthquake. The 2020 earthquake of Mw:6.8 originated from the Pütürge seismic gap. 2023 earthquakes ruptured the fault segments in these seismic gaps and the Erkenek segment. Additionally, the Narlı segment of the DSF and Doğanşehir faults, and previously unmapped two fault splays involved in the rupturing. Thus, the entire main strand of

the EAF have been ruptured in the last two centuries except for the Gökdere bend. However, we infer that the earthquake potential of Sürgü fault and the westerly fault segments of the northern strand has been increased due to stress loading onto them by the 2023 earthquake sequence.

[Keynote] The earthquake deformation cycle along the East Anatolian Fault deduced from space geodesy; implications for rupture propagation and arrest

Ziyadin CAKIR[1]*, Istanbul Technical University (ziyadin.cakir@itu.edu.tr)
Semih Ergintav[2], Bogazici University, Kandilli Observatory
Ugur Dogan[3], Yildiz Technical University

Abstract

The initiation of ruptures in large and major continental strike-slip earthquakes typically occurs near the lower part of the seismogenic crust, propagating both upward and laterally until encountering geometric or mechanical obstacles that impede further propagation. Historically, the existence of fault creep has been considered one of these potential mechanical barriers. However, the challenge lies in experimentally identifying the parameters controlling rupture arrest due to the absence of significant earthquakes on well-monitored creeping strike-slip faults during the instrumental period. This difficulty arises from the rarity of creeping faults with a well-constrained geodetic history displaying hybrid creep and seismic rupture. Moreover, major earthquakes have not occurred near these locations in recent decades.

Utilizing Envisat and Sentinel-1 SAR data along with GPS measurements, we have meticulously mapped the inter-, co-, and post-seismic velocity fields along the East Anatolian Fault (EAF), where the January 24, 2020 Mw6.8 Elazig and the February 6, 2023 Mw7.8 Kahramanmaras earthquakes occurred. Our study unveils a key observation—the coseismic rupture of a substantial strike-slip earthquake being halted by shallow creep during the January 24, 2020 Mw6.8 Elazig and February 6, 2023 Kahramanmaras earthquakes in Turkey. Contrary to conventional earthquake scaling laws and to the surprise of many, no surface rupture was evident in the field fallowing the former earthquake. This absence is attributed to the fault exhibiting creeping behavior from the surface to shallow depths before the earthquake, as discerned from Envisat and Sentinel-1 data. The rupture, abruptly arrested by the shallow creep, subsequently propagated aseismically upward as afterslip following the earthquake. Similarly, the eastward progression of the rupture during the February 6, 2023 Mw7.8 Kahramanmaras earthquake was impeded by a creeping section on the EAF, creating a gap of approximately 20 km long between the two earthquakes that is also currently exhibiting afterslip. Geology along the EAF suggests that creep is most likely promoted by the presence of minerals with low friction within the ophiolitic and metamorphic rocks along the fault zone. This study highlights the significant finding that creeping faults can halt earthquakes, even if the creeping is partial and limited to shallow depths, thereby holding crucial implications for seismic hazard analyses.

AYKUT AKGUN[7], The Disaster and Emergency Management Presidency of Türkiye
HASAN SOZBILIR[8], Dokuz Eylul University, Izmir, Turkiye

Abstract

The devastating Mw7.7 and Mw7.6 earthquakes that struck eastern Türkiye on February 6, 2023, prompted a rapid establishment of an earthquake clearinghouse at AFAD (The Disaster and Emergency Management Presidency of Türkiye) in Ankara. Within a week, AFAD and TUBITAK (The Scientific and Technological Research Council of Türkiye) coordinated efforts to mobilize reconnaissance teams, funded by TUBITAK and comprised of approximately 577 researchers from 61 universities across Türkiye. Collaborating under the umbrella of the earthquake clearinghouse in Ankara, AFAD and TUBITAK teams worked together to rapidly pull the field observations from reconnaissance teams. Additionally, the Earthquake Engineering Research Institute (EERI) contributed invaluable tools and forms, including the EERI mobile application and field forms, to bolster reconnaissance efforts. Following thorough evaluation of available resources, a decision was swiftly reached to utilize ESRI-ArcGIS Enterprise mobile application over the EERI's application. This choice was mainly based on ArcGIS Enterprise's seamless integration with AFAD's IT policy and the comprehensive technical and software support provided by ESRI- Türkiye.

The collected reconnaissance data, which encompassed crucial information on liquefaction, landslides, surface rupture, and structural damage, was promptly archived, transferred to the AFAD server, and disseminated to national agencies and ministries of Türkiye. This effort contributed to the rapid formulation of recovery plans and provided supportive information for the selection of new settlement sites in the affected region. Despite its establishment following the Kahramanmaras, eastern Türkiye, earthquakes, the first earthquake clearinghouse of Türkiye proved to be highly effective, serving as a central hub for international reconnaissance teams. Moving forward, the AFAD Earthquake Clearinghouse will continue to play a pivotal role, facilitating collaboration among stakeholders and leveraging archived data for further research and investigations. This concerted effort will not only enhance recovery efforts but also strengthen earthquake mitigation plans and preparedness for future potential devastating earthquakes in Türkiye.

Aykut AKGUN[4], The Disaster and Emergency Management Presidency of Türkiye, Ankara, Türkiye

Abstract

Türkiye, located in a seismic hotspot, faces recurrent seismic challenges, with earthquakes holding a central position in disaster and emergency management. Boasting the largest earthquake monitoring network in Europe, The Disaster and Emergency Management Presidency of Türkiye (AFAD) Earthquake Department records approximately 22,000 earthquakes annually through its 1,187 seismic stations as of 2024. On February 6, 2023, Eastern Anatolia experienced the devastating impact of the Mw7.7 and Mw7.6 earthquakes. The aftermath prompted an immediate state of emergency in Kahramanmaraş, extending its reach to Hatay, Gaziantep, Malatya, Diyarbakır, Kilis, Şanlıurfa, Adıyaman, Osmaniye, Adana, and Elazığ. This disaster zone expanded further to include Bingöl, Kayseri, Mardin, Tunceli, Niğde, and Batman. Official reports document a staggering toll of 53,537 lives lost, 107,204 individuals injured, and 38,901 buildings collapsing. This earthquake catastrophe highlighted the paramount importance of effective earthquake risk management, with a distinct emphasis on emergency response and recovery strategies. The enacted National Earthquake Strategy and Action Plan (UDSEP-2023) in 2011 aimed to establish a prepared and resilient society capable of reducing seismic risks. This collaborative initiative, involving public, private, and academic sectors, executed 80 distinct actions focused on mitigating earthquake risks, particularly emphasizing emergency response and recovery.

In the aftermath of the February 6, 2023, earthquakes, the AFAD Earthquake and Risk Reduction General Directorate conducted comprehensive seismological studies and field observations, well-documented efforts aimed at reducing potential damages from future seismic events. These efforts also elucidate the instrumental role of robust emergency response and recovery strategies following such catastrophic events, with a focus on preparedness and collaboration in mitigating the impact of earthquakes on communities and infrastructure.

Abstract

On February 6, 2023, at 04:17 local time, four fault segments (Narlı, Erkenek, Pazarcık, Amanos segments) on the southern branch of the Eastern Anatolian Fault (EAF) ruptured within 78 seconds, causing a 300 km long surface rupture. Approximately nine hours after this Mw7.8 main shock, two fault segments (Çardak and Doğanşehir segments) on the northern branch of the EAF ruptured within 60 seconds, creating a 150 km long surface rupture. Fieldwork began within a day after the earthquakes, spanning a two-month period. Meticulous observations were conducted along the surface ruptures, capturing damages inflicted on both natural landscapes and human-made structures using drone footage.

While fieldwork in the earthquake area was ongoing, another earthquake occurred on February 20, at 20:04 local time, centered in Defne (Antakya). In this Mw6.4 earthquake, the northern segment of the Antakya Fault was ruptured. In the earthquake region, where aftershocks exceeded 100,000, over 53,000 lives were lost, and thousands of buildings were destroyed or damaged. Our findings indicate that the leading factors influencing the loss of life and property can be classified into seven key categories: (1) construction on active faults, (2) construction on ground susceptible to liquefaction, (3) construction along lake shores, (4) construction along rivers, (5) flawed project design, (6) substandard workmanship, and (7) utilization of inappropriate materials in building construction.

Our observations on surface ruptures revealed that a significant portion of the February 6 earthquakes exploited pre-existing surface fractures. In the first Mw7.8 earthquake, a lateral

displacement of 7.3 meters was identified, followed by a lateral displacement of 6.3 meters in the subsequent Mw7.6 earthquake, and a vertical displacement of 20 cm in the third Mw6.4 event. Various deformations were observed on structures along the surface rupture. Particularly in regions with observed surface fractures and liquefaction hazards, high damage levels were noted. In areas distanced from the surface rupture, the dynamic behavior of the ground became prominent, and a notable degree of damage was observed.

The extent of destruction and damage is much higher, especially in buildings constructed before 1999. Additionally, even modern buildings constructed in compliance with the latest earthquake regulations suffered destruction or damage. Evaluating the interplay between ground conditions, building structures, and active faults, it has been ascertained that irrespective of the ground type and the inventory of buildings and structures, a specific degree of deformation occurs along the surface fracture, resulting in a consequential loss of life and property. Hence, it is crucial to control or avoid construction on active faults with the potential to produce devastating earthquakes in the near future.

The Role of Stress Transfer in Earthquake Nucleation and Inhibition in the 2023 Kahramanmaraş, Türkiye, Earthquake Sequence

Shinji TODA[1]*, Tohoku University (toda@irides.tohoku.ac.jp)
Ross S Stein[2], Temblor Inc.

Abstract

We here explore the interaction of large earthquakes on the East Anatolian Fault Zone, site of four M≥6.8 earthquakes since 2020 and then forecast the subsequent one-year aftershocks. Regarding the 2023 Kahramanmaraş sequence, we find that the 2023 M 7.8 Pazarcık shock promoted the subsequent nine-hour later M 7.7 Elbistan quake, largely through unclamping of the epicentral patch of the future rupture. Unclamping effect on upcoming rupture plane is also reported in other earthquakes such as the 1987 Superstition Hills, 1997 Kagoshima, and 2019 Ridgecrest sequences, so this may be common. The M 7.7 Elbistan earthquake, in turn, is calculated to have reduced the shear stress on the central Pazarcık rupture, producing a decrease in the aftershock rate along that section of the rupture. However, the M 7.7 event ruptured through a Çardak Fault section on which the shear stress was decreased by the M 7.8 rupture, and so rupture propagation was not halted by the static stress decrease. The 2020 M 6.8 Elazığ earthquake, located beyond the northeast tip of the M 7.8 Pazarcık rupture, locally dropped the stress by ~10 bars. The 2023 M 7.8 quake then increased the stress there by 1-2 bar, leaving a net stress drop, resulting in exceptional seismic dormancy in the 2023 Pazarcık aftershocks. This seismic hole is also explained by the Monte Carlo time sequence simulation of earthquake nucleation incorporating rate/state friction. We find that many lobes of calculated stress increase caused by the M 6.8-7.8 earthquakes during the period of 2020-2023 are sites of aftershocks, and we calculate 5-10 faults in several locations off the ruptures brought closer to failure. The earthquakes also cast broad stress shadows in which most faults were brought farther from failure, and we observe the beginnings of seismicity rate decreases in some of the deepest stress shadows. Some 42 M≥5 aftershocks have struck since the M 7.8 mainshock. But based on these Coulomb interactions and on the rapid Kahramanmaraş aftershock decay, we forecast only about 1-2 M≥5 earthquakes during the 12-month period beginning 1 March 2024, which is fortunately quite low.

Stress perturbation induced by precedent earthquakes and its implications for the 2023 Kahramanmaras earthquake sequence

Junhyung LEE[1]*, Yonsei University (aqualung@yonsei.ac.kr)
Tae-Kyung Hong[2], Yonsei University

Abstract

The 6 February 2023 Mw7.8 Pazarcik and Mw7.5 Elbistan earthquakes (Kahramanmaras earthquake sequence) occurred in southern Turkey near the northern border of Syria. The 2023 Kahramanmaras earthquake sequence occurred in the East Anatolian Fault zone, located in a region known for active seismicity. Stress perturbation in the fault zone plays an important role in the occurrence of earthquakes. Understanding the stress changes in the fault zone is crucial for mitigation of seismic hazards. We investigate the influence of stress perturbation caused by precedent large earthquakes in the East Anatolian Fault zone, where the earthquake sequence occurred. The static stress perturbation is assessed by stacking the induced Coulomb stress changes by the large earthquakes. The Coulomb stress changes are calculated for 64 earthquakes with magnitudes greater than or equal to 6.0 since 1900 when the instrumental earthquake monitoring began. The cumulative Coulomb stress changes vary between -218 and 123 bar around the East Anatolian fault zone. The negative cumulative Coulomb stress changes were generally dominant, suggesting that loaded stresses were released after large earthquakes. We observe laterally heterogeneous stress fields with stress contrasts of tens to hundreds of bars along the East Anatolian Fault zone. The Kahramanmaras earthquake sequence occurred in regions with large lateral gradients in cumulative Coulomb stress changes by precedent large earthquakes. This observation suggests that lateral heterogeneity in static stress fields may induce large earthquakes. Heterogeneity in the stress field may play an important role in nucleation of large earthquakes.

Abstract

Continental transform faults create broad zones of deformation with multiple strike-slip faults, making it challenging to determine earthquake recurrence intervals due to geometric complexities and variable slip. Collecting datasets related to history of surface faulting and slip distribution to understand spatial and temporal seismic behavior of these faults is crucial yet challenging. The February, 6, 2023 Mw 7.8 Pazarcık (Kahramanmaraş) Earthquake triggered a 300-kilometer-long, multi-segment failure along the East Anatolian Fault Zone (EAFZ), presenting another challenge to this phenomenon. Prior to this large earthquake, our focus was on the seismically silent Pazarcık segment of the EAF, aiming to understand its role on the earthquake cycle of EAF. Due to limited paleoseismological dat along the EAF compared to the North Anatolian Fault (NAF), we initiated a project employing both subaqueous and on-land paleoseismology techniques to assess earthquake recurrence along the Pazarcık segment comprehensively. The Gölbaşı basin, the second-largest basin along the EAF, includes three shallow lakes, with Gölbaşı Lake serving as a segment boundary between Pazarcık and Erkenek segments. In September 2022, we collected sediment gravity cores from Gölbaşı and Azaplı Lakes and excavated a 17-m-long, 2.7-m-deep trench along the Gölbaşı basin section of the Pazarcık segment. The Çelik-1 trench revealed a fault zone with four branches, showing diverse infills and divergent sediment packages on the southeast and northwest sections of the fault zone, indicative of the strike-slip character of the fault. Four months later, the Çelik Trench was offset by ~5.3 m during the 2023 Mw 7.8 earthquake. This event enabled us to evaluate both the penultimate large earthquake and the recent surface rupture along the

Pazarcık segment. Physical and geochemical analyses of the gravity cores provided evidence of earthquake-triggered sediment deposits. Pb-210 and Cs-137 dating results from sediment cores, indicate that these seismic deposits are associated with historical earthquakes in AD 1513 and AD 1114, as well as other events dating back to 1498 BP and 2168 BP. Following the Mw 7.8 earthquake, we obtained new sediment cores and excavated two new trenches, with findings to be compared with the observations of previous field campaign.

The surface rupture of the 2023 earthquake along the Pazarcık segment spans 85 km, with max. sinistral slip of ~7 m. Slip decreases towards the Karaburun and Gölbaşı sections, reaching around 1.2 m. Near Gölbaşı lake, Near Gölbaşı lake and its town, where the most severe destruction occurred due to intense liquefaction and wide lateral spreading, the deformation zone widens, and slip decreases to less than 1 m. Gölbaşı lake serves as the junction between Pazarcık and Erkenek segments. In the Ozan section of the Erkenek segment, slip increases again to a maximum of 3.5 m. A notable feature in this area is the 10 km-long surface rupture with an average slip of 2 m along an unmapped fault branching off north-east from Pazarcık segment towards Yaylacık village.

The overall characteristics of the surface rupture, along with our ongoing multi-proxy paleoseismology project, offer insights into fault behavior and earthquake recurrence along the EAF.

The 2023 Kahramanmaraş, Tu¨rkiye, earthquake doublet as the most powerful continental earthquake doublet: magnitudes, rupture process, triggering mechanism, and aftershocks

Xiaodong SONG[1]*, Peking University (xdsong@pku.edu.cn)
Yue Han[2], Peking University
Zengxi Ge[3], Peking University
Yijian Zhou[4], University of California, Riverside

Abstract

The 2023 Kahramanmaraş, Tu¨rkiye, earthquake doublet, which caused massive damages and casualties, has attracted wide attention and intense studies. Here we report our studies on the doublet magnitudes (Jiang XY et al., Earthq. Sci., 2023), rupture process and triggering mechanism (Ren CM et al., Science, 2024), and aftershocks (Ding HY et al., Earthq. Sci., 2023) in collaborative efforts. The magnitudes and the relative sizes of the two events are essential information for scientific research and public awareness. There are obvious discrepancies among the results that have been reported. We applied a recently developed long-period coda moment magnitude method with minimum influence from Earth structure and source complexities. The moment magnitudes were determined to be about 7.9 and 7.8 for the two events, respectively, which appear the largest continental earthquake doublet ever recorded. The first mainshock, which matches the largest recorded earthquakes in the Turkish history, is slightly larger than the second one by 0.11±0.035 in magnitude or by 0.04 to 0.18 at 95% confidence level.

To investigate the rupture process over multiple fault segments, we performed a comprehensive analysis of local seismic and geodetic data and determined supershear ruptures on the initial branch and the Pazarcık and Erkenek segments and subshear ruptures on the Amanos segment of event 1. The bilateral rupture of event 2 also presents distinct sub- and supershear velocities. The dynamic stress of the branch fault rupture triggered the Pazarcık segment initial rupture at a point 9 kilometers west of the junction of these two faults, boosting the supershear rupture of the Pazarcık segment of the main fault. The geometry and prestress level of multiple segments controlled the rupture behaviors and influenced the ground shaking intensity.

We also built a high-resolution early aftershock catalog using a workflow that sequentially performs phase picking, association, location, and matched filter (PALM) for continuous data, containing 29,519 well-located events in the two mainshocks rupture region during 2023-02-01–2023-02-28. From the catalog, the Eastern Anatolian Fault (EAF) that generated Event 1 is overall near-vertical, whereas complexities are revealed in a small-scale, such as subparallel subfaults, unmapped branches, and stepovers. The seismicity on EAF is shallow (<15 km) and concentrated in depth distribution, indicating a clear lock-creep transition. In contrast, the Su¨gu¨

Fault (SF) that is responsible for Event 2 is shovel-shaped for the nucleation segment and has overall lower dip angles (~40°–80°). Aftershocks on the SF distribute in a broad range of depth, extending down to ~35 km. A clear complementary pattern between the distributions of aftershocks and coseismic slips was found for both events. Two voids of aftershocks on the central Seg P of Event 1 and the western portion of Event 2 (Fig. 2C), which seems related to supershear rupture behavior. No immediate foreshocks within ~5 days preceding Event 1, and no seismic activity on the SF before Event 2.

[Keynote] Rupture Geometry and Segmentation associated with the 6 February 2023 Pazarcık (Mw 7.8) and Elbistan (Mw 7.6) Earthquakes: East Anatolian Fault, Southeastern Türkiye

Tamer Y. DUMAN[1]*, Fugro Sial (t.duman@fugro.com)
Omer Emre[2], Fugro Sial

Abstract

On February 6, 2023, two large earthquakes with magnitudes of Mw 7.8 and 7.6 occurred on the East Anatolian Fault (EAF), causing 54k fatalities and an economic loss of over 100 billion USD. Both earthquakes occurred in previously identified seismic gaps within the EAF zone and collectively resulted in 517-km-long surface ruptures. Nearly all the ruptures followed the mapped Holocene fault trace. The first earthquake, Pazarcık, originated from the southwestern half of the main strand of the EAF at the junction with the northernmost tip of the Dead Sea Fault (DSF). Nine hours later, the second earthquake, Elbistan, occurred on the Misis-Sürgü Fault, forming the northern strand of the EAF.

The Pazarcık earthquake resulted in a 302-km-long rupture along the main strand of the EAF, spanning between the Yarpuzlu double bend to the northeast and the Amik triple junction to the southwest. During this event, Erkenek (62-km), Pazarcık (82-km), and Amanos (112-km) fault segments entirely ruptured, separated by releasing step-overs. Additionally, a 40-km-long section of the Narlı fault at the northernmost tip of the DSF and a 15-km-long western part of the Tut fault were also included in the rupturing. While a maximum slip of 7.1m was observed in the Pazarcık segment, the highest and average slip values successively decreased in the Pazarcık, Erkenek, and Amanos segments. This variable slip was assessed based on the slip rate and the elapsed time since the penultimate event on each segment. The epicenter's location suggests that the event was initiated on the Narlı fault. We speculate that initial dynamic stress loading during the event triggered the Pazarcık segment on the main strand of the EAF, which experienced a high-stress state due to the long-term elapsed time since the penultimate events. Subsequently, the rupturing propagated bilaterally on the Pazarcık segment and transferred to the Erkenek and Amanos segments.

The Elbistan earthquake was likely triggered by the Pazarcık earthquake. This event nucleated at the eastern tip of the Çardak fault, which is connected to the Nurhak fault complex. The rupturing propagated bilaterally towards the west and east. In the east, the rupture was directed toward the Doğanşehir fault zone through the Kapıdere double bend, instead of the Sürgü fault. In the west, a previously unmapped north-east-striking Sisne fault with a 20-km-length was included in the rupturing. The surface rupture of the Elbistan earthquake is 142-km-long, with a maximum slip of 8.2m. The rupture passed through the Nurhak complex but terminated in the Göksun releasing

bend. The maximum and average slip on the Doğanşehir fault is half of that on the Çardak fault. Despite having a smaller magnitude than the initial event, the Elbistan earthquake caused greater maximum and average slips on the Çardak fault compared to the Pazarcık earthquake. We consider that this difference is attributed to a longer elapsed time.

Abstract

A catastrophic earthquake with magnitude Mw 7.8 and followed by a series of triggered earthquakes occurred on the East Anatolian Fault Zone (EAFZ), on the 6th of February 2023. The earthquake caused severe damage to 11 cities in eastern Turkey and settlements in northern Syria, killing more than 50.000 people. Surface rupture mapping and slip measurements was initiated immediately after the earthquake and continued until the end of March 2023.

In addition to ground observations, HGM-KURE orthophoto and MTA-UAV images were used in surface rupture mapping and slip measurements. The amount of displacement was measured at a total of 410 points on the 6 February 2023 Pazarcık (Kahramanmaraş) earthquake surface rupture. In contrast to previous studies, a total of 375 km of surface rupture was mapped in this study.

According to the field studies, Yarpuzlu restraining double bend and Erkenek, Pazarcık and Amanos segments of EAFZ have been ruptured during this earthquake. In addition, Tetirlik, Serinyol, Kazkeli faults and Gölbaşı splay fault, which were identified for the first time in this study, also ruptured during this earthquake. Although no surface rupture occurred on the fault south of the Tetirlik segment during the earthquake, the distribution of aftershocks points out that also this fault may have ruptured at depth. The maximum displacement associated with this event was measured as 7.2 ± 1 m on the Pazarcık Segment of the EAFZ.

The most important geological causes of loss of life and structural damage were determined as earthquake magnitude, duration, focal depth, directivity of earthquake waves, soil-related liquefaction, lateral spreading and ground amplification effects, and construction on faults.

The 2023 Pazarcık earthquake showed that the EAFZ can also produce multi-segment surface faulting like the North Anatolian Fault Zone (NAFZ). The EAFZ is one of the most active transform fault zones in the eastern Mediterranean region. This earthquake sequence may have transferred stress to faults kinematically linked to the EAFZ, such as unbroken segments of the northern strand of EAFZ, northern segments of DSFZ, western segments of Southeast Anatolian Thrust Zone, Yedisu Segment of NAFZ, Kahramanmaraş Fault Zone, Engizek Fault Zone and Malatya Fault.

Abstract

The second main shock, the Ekinözü Earthquake (Mw 7.6) of the February 6, 2023, Kahramanmaraş earthquake sequence, nucleated on the eastern tip of the Çardak fault, on the northern strand of the East Anatolian Fault Zone (EAFZ). The earthquake produced a 167-km-long surface rupture on the Çardak fault segment of the northern strand of the EAFZ and the Doğanşehir Fault Zone (DFZ), which is connected to the northern strand at the Nurhak fault complexity west of the Sürgü fault. Following the main shocks, fieldwork and drone surveys were conducted to map the surface rupture in detail and document the slip measurements. Our observations revealed that the easternmost section of the surface rupture associated with the Ekinözü earthquake was directed onto the DFZ east of Nurhak fault complexity. Left lateral strike-slip surface faulting, 44 km long, extended on the DFZ, generally trending N50°E. The rupture locally displays normal and reverse components, depending on step-overs and bends in fault geometry. The DFZ surface rupture consists of two distinct sections: the main body of the rupture zone between the Sürgü fault to the south and Işıklı village to the north, and the Eskiköy splay. Approximately 39 km long, the main body of the rupture, extending in the N50°E direction, comprises small-and-large scale subsections in a right-stepping pattern in general. Observed

maximum and average slips on the main body of the rupture zone were 1.96±0.20 m and about 1.00 m, respectively. A 5 km long left lateral strike-slip Eskiköy splay extends conjugate to the main body of the rupture zone. Although a short splay bifurcates from the main body of the rupture zone, the amounts of the maximum and average slips were measured to be larger than those of the main body of the rupture zone, with 2.18±0.20 m and 1.11 m, respectively. The splay rupture, with a strike of N70°W, has a north-dipping reverse component characterized by a 1.80 m vertical offset. The southern section of the surface ruptures nearly followed the previously mapped Doğanşehir Fault Zone; however, there is not any Holocene fault previously mapped in the north of Doğanşehir. There are no clear geomorphic manifestations indicating Holocene activity of the fault, except for a lineament along this section of the surface rupture. However, aftershocks clustered along the northern continuation of the Doğanşehir fault zone towards Malatya city. We infer that the heavy damage in Malatya city might have been related to the directivity of the rupture propagation along the DFZ. We also infer that the second shock of the Kahramanmaraş earthquake sequence transferred stress onto the Malatya fault that had not ruptured for ~2550 years with a recurrence interval of 2275±605 years according to literature.

Rupture Propagation Paths and Probabilities Considering Fault Continuity and Geometry in the 2023 Kahramanmaraş, Türkiye Earthquake

Yuki HARA[1]*, Tohoku University (yhara@irides.tohoku.ac.jp)
Shinji TODA[2], Tohoku University

Abstract

In the assessment of the activity of large-scale faults, considerations at segmented levels defined based on geometry and paleoseismic history are typically conducted. While occurrence of multi-segment rupture led to broader and more extensive damage, there are cases where only a part of that segments is ruptured (e.g., Okada et al., 2015). Therefore, probabilistic assessment for fault rupture propagation is necessary.

Initiation, termination, and propagation of the rupture are significantly influenced by the fault geometry such as bends and steps. For instance, Wesnousky (2008) suggested that fault rupture consistently ceased at fault step of 5 km or more in strike-slip faults. On the other hand, at fault step from 1 to 4 km, fault rupture ceased in 33-50% of cases, indicating a non-binary relationship with 5 km as a threshold. Recently, Biasi and Wesnousky (2021) proposed a method for predicting total rupture lengths based on empirical propagation probabilities at steps and bends (Biasi and Wesnousky, 2016; 2017). However, there have been no examples conducting the validation of these methods for the recent large-scale fault ruptures.

In this study, we developed an objective method using QGIS and Python to semi-automatically measure the fault geometry and extract rupture paths, and then applied the empirical rupture propagation probabilities reported by Biasi and Wesnousky (2021). Furthermore, to validate the method, we applied our code to the detailed active fault data (Emre et al., 2018) and surface rupture trace (Reitman et al., 2023) in the 2023 Kahramanmaraş, Türkiye earthquake. We assigned the rupture initiation point on the intersection of East Anatolian Fault with the Narlı Fault, and calculated rupture propagation probabilities to the northeast and southwest.

Initially, we discretized fault lines into 5-km-long and calculated rupture propagation probability. As a result, unrealistic probabilities, below 10^-5%, were obtained at active fault trace corresponding to the endpoints of the 2023 earthquake rupture. Considering the global frequency of long surface rupturing earthquake exceeding Mw7.8 (Five earthquakes since 2000), this result may lead significant underestimation of the probabilities. The potential flaw is attributed to the automatic definitions of bends or steps every 5 km even in relatively linear sections. Therefore, we approximated the fault traces by extracting points of change in strike using the Douglas-Peucker algorithm. Additionally, we obtained at most ~200 rupture paths from the initiation point to northern or southern end, and then calculated complementary probabilities of any of these paths enabling to pass through. As a result, probabilities exceeding 0.01% were obtained at the fault trace to the termination of the 2023 rupture, although it is necessary to appropriately evaluate a single parameter, tolerance, of the Douglas-Peucker algorithm, as increasing tolerance leads to increasing probability. In comparison with the Gutenberg-Richter (GR) distribution obtained from

earthquake databases (AFAD) from 1990 to 2020, the probability of Mw≥7.8 earthquake occurrences fall below the rate from the GR law. However, the probability gain for Mw≤7 events exceeding the GR law is up to about tenfold.

Preliminary Study on Surface Rupture Displacement Analysis of the 2023 Kahramanmaraş(Turkey) Earthquake Using High-Resolution Optical KOMPSAT-3(A) Satellite

Chaehyeon CHOI[1]*, Active Tectonics Research Center, Geologic Hazards Division, Korea Institute of Geoscience and Mineral Resources (cjc6918@gmail.com)
Jin-Hyuck CHOI[2], Active Tectonics Research Center, Geologic Hazards Division, Korea Institute of Geoscience and Mineral Resources

Abstract

A high-resolution map of the coseismic surface ruptures provide an opportunity to understand relations between tectonic faults and earthquake characteristics. Along the surface rupture of the 2023 Kahramanmaraş (Turkey) Earthquake, we have acquired imagery from the Earth observation satellites KOMPSAT (Korean Multi-purpose Satellite) 3 (launched in 2013) and 3A (launched in 2015), operated by the Korea Aerospace Research Institute (KARI). The panchromatic band's Ground Sampling Distance (GSD) of these satellites is approximately 0.7 meters, boasting high resolution alongside WorldView and Pleiades satellites. We perform Optical Image Correlation (OIC) using images acquired by KOMPSAT-3(A) both before and after the earthquake, focusing on two specific areas: 1) the Hatay Airport area, which experienced surface rupture due to the Pazarcık Earthquake (Mw 7.8) along the East Anatolian Fault, and 2) the epicenter area of the Elbistan Earthquake (Mw 7.6). Digital Surface Models (DSMs) were produced from images captured under stereo conditions, and each image was orthorectified using DSMs. These pre-processed optical images were then used to calculate the horizontal displacement field using the MicMac. MicMac, along with COSI-Corr, is the software extensively used for earthquake displacement analysis, providing the tool of mutually matching optical images taken before and after the earthquake. We intend to interpret the three-dimensional movement of faults and discuss distributed deformation (such as off-fault deformation) that are difficult to quantify through field observations.

Advanced seismic imaging of subsurface structures using wavelet-based decoupled wavefields on small aperture dense arrays

Hongfeng YANG[1]*, The Chinese University of Hong Kong (hyang@cuhk.edu.hk)
Jia Zhang[2], Shenzhen Research Institute, The Chinese University of Hong Kong

Abstract

Imaging subsurface structure holds important implications for underground space development, resource exploration, seismic hazard assessment, and so on. In recent years dense seismic arrays have been widely used in various environment, enabling high-resolution images of the subsurface structure. However, small-scale subsurface heterogeneities may cause strong scattering on waveform recordings at dense arrays, posing challenges in a reliable investigation of crustal structure using waveform tomography. To overcome, we develop a wavelet-based method to separate the teleseismic P wave and local scattered wave. We apply our technique in the waveforms recorded by two small-aperture dense across-fault arrays in Binchuan, northwestern Yunnan, China. The resulting common-conversion-point (CCP) images of decomposed tele-P wave receiver functions (RFs) depict a flat Moho at ~52 km in depth and a remarkable middle crust interface at a depth of ~30 km. Besides, seismic imaging using the decomposed local waves illustrate clear shallow low velocity zones (LVZs) beneath the Chenghai Fault (CHF), , which extend to ∼1.5 km in depth beneath the southern segment of the CHF, indicating complicate sediment distribution under the combined impact of regional east–west crustal extension and clockwise rotation of microblocks. Our results demonstrate the wave decomposition method can effectively separate different wave segments, enabling utilization of small-aperture temporary arrays to reveal reliable, high-resolution crustal structure.

Subsurface structure imaging robustness enhancement with multiple processing methods on a dense seismic array

Lanbo Liu[1]*, Pusan National University (lanboliu77@gmail.com)
Kwanghee Kim[2], Pusan National University

Abstract

Dense seismic array technique has been widely used in both natural earthquake seismology and exploration seismics. One of our research topics is using dense seismic array to image geological and tectonic structures in the depth range up to several hundred meters from the surface. Imaging subsurface structures in this depth range must face a number of challenges. The most significant one is that shallow subsurface usually contains significant lateral variation, caused by both natural processes such as buried sand channels, heterogeneous and undulating weathering layers etc., and man-made artificial objects such as buried infrastructures and pipelines, especially in highly developed urban areas. In this talk we focus on subsurface structure imaging robustness in this depth range by examining the impact of a number of factors. For using passive seismic sources originated from ambient noise, these factors include station spacing, array aperture, frequency range, noise type and spatial distribution, observation duration etc. For using active sources generated by man-made ground impacts, the factors include source energy level, source impulse width, level of background noise, ground condition, data processing methods etc. We will illustrate our viewpoints with numerical simulation and validate them using real-world examples. Field practice suggests that by the combination of both passive and active seismic data and analyses we may significantly enhance image robustness of the reconstructed subsurface targets.

Abstract

The Critical Zone (CZ) is the "living skin" of our planet, extending from the bottom of the water table to the top of the tree canopy. Processes occurring in the CZ are subject to a complex and dynamic interplay between soil structure, temperature, pressure, precipitation, and water content. Geophysical methods can be used to image the subsurface portion of the CZ but typically offer a point-in-time snapshot view which does not constrain changes over time. The development of ambient noise seismology allows us to exploit continuous recordings of the seismic wavefield to detect small changes in seismic velocity over time, which may be indicative of changes in the subsurface. In December 2022, in partnership with Stryde, we deployed a "large-N" array consisting of ~1600 seismic nodes at spacings between 5m and 10m for one month at a site in Dumfries, southwest Scotland. The site was chosen as it hosts a Critical Zone observatory, recording real-time data on soil moisture and temperature along with other meteorological data. Ambient noise recordings from this array are cross-correlated to retrieve the Green's function. We perform coda-wave interferometry to detect velocity changes across the array are able to observe relative seismic velocity changes of < 1% at a temporal resolution of 30 minutes. The time series of relative velocity variation are compared with measurements of soil moisture and temperature to establish relationships and correlations between changes in seismic velocity and environmental factors, and constrain the extent to which external hydrological factors influence seismic velocities. Our study shows the strongest correlations are with soil moisture content ($r \sim 0.6$-0.7). Heavy rainfall events leading to soil saturation temporarily disrupt the correlation trend, which then recovers as water content returns to field capacity. The correlations between velocity and soil moisture are negative, with velocity decreasing as water content increases. We attribute this to a change in the properties of the soil, whereby the density increases with added water content but the shear modulus remains the same. Other environmental factors such as soil temperature show a weaker correlation with soil moisture; however, the relationship between various factors is complex and cannot be considered in isolation. This study shows the potential benefits of newly-

developed nodal seismometer technology in the emerging field of Critical Zone seismology.

Unravelling crust-to-upper-mantle structures around the central Korean Peninsula using combined tomographic analyses

SEONGJUN PARK[1]*, Yonsei University (seongjunpark@yonsei.ac.kr)
TAE-KYUNG HONG[2], Yonsei University

Abstract

Public concern on potential seismic hazards has arisen due to recent successive major earthquakes in the Korean Peninsula. The subsurface structures may provide information on the seismic and tectonic nature, which is crucial for seismic hazard mitigation. The central Korean Peninsula is composed of complex geological structures that were formed by a series of tectonic events. We investigate the seismic velocity structures of the lithosphere in the region using the ambient noise tomography and earthquake-based Eikonal tomography based on dense seismic networks consisting of 529 stations. Interstation Green's functions for 31,532 station pairs are calculated from crosscorrelation of one-year-long noise records in 2022. We determine the Rayleigh-wave group velocities at periods of 1-15 s from the Green's functions. Additionally, we analyze the Rayleigh waves from 337 MW 5.5-8.1 global earthquakes in 2018-2022, determining Rayleigh-wave phase velocities at periods of 20-80 s using the Eikonal tomographic inversion. The integration of the two tomographic analyses enables us to examine the Rayleigh-wave dispersion curves over a wide period range of 1 to 80 s. We finally determine a 3-D shear-wave velocity model up to a depth of 200 km from the Rayleigh-wave velocities using a linearized iterative inversion with the Markov-chain Monte-Carlo technique. The shear-wave velocities generally increase with depth, presenting high lateral variations. The shear-wave velocities illuminate geological and tectonic structures that may be associated with present and paleotectonic activities. The observations may contribute to understanding seismic and tectonic processes in the region.

Abstract
We evaluated the crustal and upper mantle lithospheric structure down to 160 km depth across the Upper Indus Basin (UIB) and its neighboring area through inversion of surface waves (Rayleigh and Love waves) group velocities for periods ranging between 5 and 120 s using broadband seismograms of fifty eight regional earthquakes recorded at 60 seismological stations located in the southern neighborhood of UIB. The study region is further divided into western (A), central (B), and eastern (C) clusters as per ray paths coverage. The observed group velocities are then inverted by Genetic Algorithm (GA) to obtain the lithospheric velocity structure along each of the three cluster wave paths. The crustal thickness decreases westward with the maximum thickness of 59.8 km (Cluster A) in the eastern part, 59.5 km (Cluster B) in central UIB, and 56.1 km (Cluster C) in the western part. The average structure (UIB) has also been obtained through inversion and the estimated average crustal thickness is 65.3 km. The crustal thickness estimated along clusters A and B is thicker in comparison to crustal thickness observed along cluster C, which may indicate the subduction of Indian plate under the Eurasian plate. This study reveals the presence of a Low Velocity Zone ~128 km beneath each wave path cluster, characterized by a shear wave velocity (Vs) of around 4.67 km/s.

Lateral variation of the Mantle Transition Zone Beneath Southern Tibet inferred from receiver function analysis

YiBin WU[1]*, INSTITUTE OF GEOLOGY AND GEOPHYSICSCAS
(wuyibin21@mail.iggcas.ac.cn)
Xiaobo Tian[2], INSTITUTE OF GEOLOGY AND GEOPHYSICSCAS

Abstract

The subduction of the Indian plate beneath southern Tibet plays a vital role in the evolution of the Tibetan Plateau. Previous studies suggest that the Indian lithospheric slab has torn into sections with different subduction angles and the high-angle Indian lithospheric slab is more likely subducting into the deep mantle. However, the locations of these slab sections and the depth extent of the subduction Indian plate remain controversial. Here, we used newly collected data from a linear array in southern Tibet to study the structure of the mantle transition zone (MTZ) by adopting the receiver function methods. Our results show there is an MTZ thickening region that is approximately 15 km thicker than the global average beneath the east of the Lhasa terrane, the thickened MTZ correlates well with high P-wave velocity anomalies in the MTZ. We interpret the thickened MTZ beneath the plateau as evidence of the presence of a cold Indian slab. An obvious low-velocity layer (LVL) atop the MTZ is also observed, indicating the MTZ is hydrous, the average estimated value for water content in MTZ is +0.5wt%. We suggest the subducted Indian plate has subducted to the MTZ and disturbed the hydrous MTZ, the hydrous upwelling further weakened the overlying lithosphere and promoted continental rifting.

Pn-wave receiver function method

LiangYu ZHANG[1]*, State Key Laboratory of Lithospheric Evolution,Insitute of Geology and Geophysics, Chinese Academy of Science (zhang_ly06033@163.com)
XiaoBo TIAN[2], State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

Receiver function (RF) method is the most widely adopted method for imaging crustal structure using teleseismic data. However, through attenuation during long-distance propagation, high-frequency components are scarce in teleseismic waveforms, resulting in low resolution of RF. Although regional earthquakes are always considered very complex, containing multiple seismic phases, they do contain more high-frequency components because of their short epicentral distances. Thus to improve the resolution of crustal structure study and to derive more detailed shallow crustal structures, we propose the Pn-wave receiver function method. Among those variable regional seismic phases, Pn-wave can be approximately considered as a plane wave in the crust beneath seismic stations, and interference from other phases can be avoided at epicentral distance of 5-15°. After choosing an appropriate time window to exclude interferences of other regional seismic phases, and rotating three-component of waveform record to polarization direction of P wave and S wave, Pn-wave RFs (PnRFs) can be calculated by deconvolving S wave component with P wave component. PnRFs calculated from both numerical synthetic data and observational data at broadband seismic stations show that all converted waves present in PnRFs at the predicted time according to the theory of plane wave, and the amplitudes of converted wave in PnRFs are 2-3 times larger than those in teleseismic RFs, because of larger incident angle of Pn-wave in the crust. PnRFs calculated from observational data of a dense nodal array (DNA) clearly show not only the converted wave from Moho, but also the converted wave from crustal interface which is too weak to be observed in tele-RFs due to the fact that Pn-wave has larger incident angle and higher frequency than that of teleseismic P-wave. Cooperating with DNA observation, the Pn-wave receiver function method has potential to image crustal structure with high-resolution closing to the deep seismic reflection method.

Kwang-Hee KIM[6], Pusan National University
Jin-Han REE[7], Korea University

Abstract

We probe fine crustal seismic structure and properties from radial and tangential receiver functions (R-RFs and T-RFs, respectively) using two teleseismic earthquakes recorded by a linear dense geophone array, called the Naenam Fault Array (NFA), during a month. The NFA was deployed subperpendicular to the NNE–SSW striking Naenam fault and Yangsan fault (YSF) over the ~15 km distance. The Naenam fault is causative fault of the 2016 moment magnitude 5.5 Gyeongju earthquake in southeastern Korea.

We retrieve the isotropic and anisotropic subsurface structure based on the forward modeling of the R- and T-RFs, respectively. First, the R-RFs show clear P-to-S converted phases of the Moho (Pms) at 3.6 s and its first multiple (PpPms) at 12 s, indicating the depth of Moho at ~28 km. Additionally, we observe lateral (west-east) variation in positive amplitudes before the Pms, indicating the presence of a mid-crustal discontinuity at depths of ~12-13 km. In the west of the YSF, we observe a dip of ~10°, shallowing towards the east. An abrupt change in its depth from 12 km to 8 km is observed near the YSF. In the east of YSF, its depth ranges from ~8 km to 4 km.

Second, the T-RFs show polarity changes in their amplitudes before and after the Pms, indicating the presence of seismic anisotropy in the lower crust and lithospheric mantle. Although constraining parameters of anisotropy is challenging with only two usable events in one-month period, our analysis results show a fast symmetric axis azimuth of 100±20° and a plunge of <10°. Our observations require the presence of seismic anisotropy ~4% in the lower crust and ~8% in the lithospheric mantle.

The Seismogenic Processes of Main Faults in Sichuan-Yunnan Based on Time-varying Repeating Event Waveforms

Boyang WANG[1]*, University of Chinese Academy of Sciences (wangboyang21@mails.ucas.ac.cn)
Yuanze ZHOU[2], University of Chinese Academy of Sciences

Abstract

The Sichuan-Yunnan region is located at the southeast edge of the Tibetan Plateau, with intense crustal tectonic activity, high rates of crustal deformation, large deformation volumes, and the development of a large number of faults, making it one of the regions with the highest frequency of strong earthquakes and the most serious disasters in mainland China. Small and medium-sized earthquakes occur frequently in this region, and the distribution of seismic stations/arrays is dense, thus accumulating a large amount of high-quality seismic waveform data. The NE-oriented Zhaotong-Ludian fault zone, located in the eastern section of the Sichuan-Yunnan border, is an active tectonic zone with a relatively low level of seismic research. Since the Ms 6.5 earthquake occurred in Ludian on August 3, 2014, the Zhaotong-Ludian fault zone has gradually received attention from active tectonic researchers. The aim of this study is to investigate the seismic activity in this region in depth using the method of repeating earthquakes. We collected and organized the three-component continuous seismic data recorded by the Zhaotong station network in Yunnan from 2018 to 2021; identified seismic events from the seismic records using the PALM program; and localized the seismic events by Hypoinverse and Hypodd to determine the seismic source location and depth of the seismic events. In total, we obtained 105 seismic events. These seismic events are distributed in the range of 27°~27.5°N, 103.5°~104.1°E, and the magnitude is about ML 1.5. Based on the waveform similarity and source parameter similarity criteria, we identified three groups of repeating earthquakes, each containing two seismic events. By analyzing the waveforms of these three groups of repeating earthquakes, we can obtain important information about the pregnant earthquake of the Zhaotong-Ludian rupture as well as the fault activity; together with the local precipitation data, we can further analyze the effect of precipitation on the velocity structure of seismic waves. Through an analysis of the correlation between precipitation and seismicity, we can better understand the influencing factors of seismic wave propagation mechanism and provide geophysical data support for earthquake early warning and disaster prevention and mitigation. The results of this study are of great significance for a deeper understanding of the mechanism of seismicity in the

Sichuan-Yunnan region, for predicting seismic risk, and for providing a scientific basis for earthquake early warning and disaster prevention and mitigation.

The Characteristics of Regional Seismicity before the 2008 Mw 7.9 Wenchuan Earthquake

Xinzhong YIN[1]*, Institute of Geology CEA (yinxinzhong@ies.ac.cn)
Jiuhui Chen[2], Institute of Geology CEA

Abstract

The 12 May 2008 Mw 7.9 Wenchuan earthquake occurred on the Longmenshan Fault (LMSF) zone, the eastern margin of the Tibetan Plateau, in Sichuan province, China. This earthquake is the largest intra-plate high-angle thrust earthquake recorded by digital seismometers. Field observations revealed that the primary rupture was along the LMSF extending up to ~330km long. The results of geological and geodetic studies indicate that no obvious anomalies were found in the epicentral area before the Wenchuan earthquake. The temporary Western Sichuan Seismic Array (WSSA, 297 broadband stations; 10–30 km spacing; operational from 2006–2009) covered the central and southern part of the LMSF. We use the neural network and REAL method to pick and associate the Pg/Sg phase respectively. Then, we use the NonLinLoc and the double-difference relocation method to relocate all the events before the Wenchuan mainshock.

Our preliminary results can be summarized as follows: 1Regional seismicity is mainly distributed along the Xianshuihe fault, Longriba fault, Miyaluo fault and Xiaoyudong fault, coinciding with secondary plates boundaries; 2) Seismic activity relatively intensified along the Xiaoyudong fault before the Wenchuan mainshock; 3) Based on these observations, we speculate that long-term reginal tectonic movement led to the stress accumulation around the mainshock zone, possibly serving as the regional dynamic mechanism triggering to the the Wenchuan earthquake.

Characterizing the shallow subsurface of the Bukpyeong Basin, Korea, by the HVSR method

SU YOUNG KANG[1]*, Pusan National University (sukang@pusan.ac.kr)
Kwang-Hee Kim[2], Pusan National University
Hee-Cheol Kang[3], Pusan National University
Young-Cheol Lee[4], Pusan National University

Abstract

We present a dense seismic observation approach to characterize the shallow subsurface of the Bukpyeong Basin in Korea, employing the Horizontal-to-Vertical Spectral Ratio (HVSR) technique on ambient noise data. Situated in Donghae, Gangwon Province, Korea, the study area experienced an unusual series of micro-earthquakes in May 2023. Our hypothesis posits that faults reactivated during this seismic sequence played an important role in the formation of the Miocene Bukpyeong Basin. The basin is marked by several significant fault zones, including the Osipcheon fault and inferred basin boundary faults. Using a three-component seismometer, we conducted background noise observations at 149 sites in and around the basin. The HVSR method calculates resonance frequencies by spectrally dividing the vertical component of ambient noise from the horizontal components. The resulting data is directly linked to the depth of major impedance contrasts between bedrock and the overlying sediment beneath the observation site. The basin model proposed in this study is constructed based on 149 resonance frequencies, ranging from 0.87 Hz to 55.8 Hz. The model reveals lower resonance frequencies in the central part of the Bukpyeong Basin, suggesting a thick sedimentary cover. To validate our findings, we compared HVSR results with Bouguer Gravity anomaly (BA) data and depth measurements to bedrock available from the Geotechnical Information Database System. By integrating HVSR results, BA data, and geotechnical observations, we identify potential fault locations for further investigation. This comprehensive approach enhances our understanding of the subsurface dynamics of the Bukpyeong Basin and provides valuable insights into the geological processes and fault activity in the region.

Fragmented Plates in Sumatra-Andaman Subduction Zone Revealed by Distinct Mantle Anisotropic Directions

BHASKARARAO ILLA[1]*, Tata Institute of Fundamental Research (bhaskar.illa1992@gmail.com)
PRAKASH KUMAR[2], CSIR-National Geophysical Research Institute

Abstract

Mega-thrust subduction zones are tectonic plate boundaries where one tectonic plate is being forced beneath another, known for producing some of the most powerful earthquakes in history. Understanding the structural heterogeneity at a regional scale in the mega-thrust subduction zone is crucial for deciphering the rupture dynamics that control earthquake generation. The rupture dynamics of earthquakes in the Andaman-Sumatra region are primarily hindered due to the lack of velocity and anisotropy information at the lithospheric level. To map lithospheric velocity and anisotropy in the mega-thrust subduction zone of Andaman-Sumatra, we generated compression wave (Pn) tomography by inverting 41,354 Pn arrivals from 5,725 regional events recorded at 316 stations. Our findings reveal a significant variation in velocity and fast polarization directions (FPDs) across the entire study region, which could be an essential factor for earthquake nucleation. The intriguing observation is the abrupt change in fast polarization directions from the Andaman to Sumatra and Sumatra to Java regions along the arc. We suggest that there exist well-defined plate boundaries between Indian-Capricorn rather than the diffused one as thought earlier. The nature of plate boundaries significantly influences stress accumulation and release, impacting the occurrence and characteristics of earthquakes in the region. Our observation is also supported by the lower spreading rate and higher crustal age in the Andaman region compared to the north Sumatra region. We further argue that the mega events of 2004 and 2005 occurred along the Indian-Capricorn plate boundary. Our results also indicate the presence of low Pn velocity anomalies in the west of the Andaman Sea, suggesting the existence of a magma reservoir pouring out lava through the steep and torn subducted Indian oceanic slab.

Seongryong Kim[3], Professor
Junkee Rhie[4], Professor
Tae-Seob Kang[5], Professor

Abstract

Ambient noise tomography (ANT), extracting empirical Green's functions by cross-correlation of noise records, has been a prevalent method to constrain a shear wave velocity distribution beneath the surface. The method does not require earthquakes or explosions, which makes itself applicable anywhere receivers have been installed and cost-effective. Usually, ANT has been conducted in a 3–10 s period range, in which a major noise source is the most energetic, so broadband data is needed. Although many recent studies have shown that high-frequency ANT can work for tens of kilometer areas with any type of receiver, it is still challenging to measure dispersion curves in high frequency, especially in the case of sedimentary basin regions due to their complex structure. Thus, in this study, we tested parameters for achieving high-frequency ANT with a short-period array while employing ANT to the Santa Clara Valley, which is a sedimentary basin area in the San Francisco Bay region, bearing 2 Tertiary basins covered by Quaternary alluviums up to 500 m. As a result of the test, it is found that long-period energy recorded by short-period instruments should be eliminated to calculate empirical Green's functions stably. Also, the relationship between Gaussian alpha and interstation distances for frequency-time analysis is determined as 50 for 60 km, 25 for 30 km, and 12.5 for 10 km to obtain dispersion curves in 0.7–7 s. In resulting shear wave velocity models, two low velocity anomalies are found. The location of the anomalies corresponds to 2 Tertiary basins of the study area, and their basement is reaching to 2.5–3 km, which is consistent with the previous models. Therefore, it shows that high-frequency ANT can succeed in imaging sedimentary basin regions with careful processing.

Deep Learning-driven ambient noise surface wave dispersion data selection along linear array

Yan WANG[1]*, University of Science and Technology of China (wy57@mail.ustc.edu.cn)
HaiJiang Zhang[2], University of Science and Technology of China

Abstract

Passive seismic surface wave tomography utilizes ambient noise data to first obtain surface wave dispersion data, and then derives the subsurface velocity structure through inversion. Passive seismic surface wave tomography based on linear seismic array acquisition has now been widely used due to its efficiency in deployment. However, due to the temporal and spatial variations of high-frequency noise sources that are useful for imaging near-surface structure, the surface wave dispersion curves extracted from ambient noise may not be reliable, thereby affecting the tomography imaging.

To improve the quality of surface wave dispersion data along linear arrays, in general the acquisition time is increased. However, simply superimposing all time-lapse data cannot remove the interference of noise sources located in non-steady regions. To eliminate the interference of non-steady noise sources, we propose a data screening and superposition method based on deep learning. First, we trained a ResNet-50 deep learning network by actual dispersion data manually selected from a real dataset. Then we use the trained ResNet-50 deep learning network to evaluate and screen the quality of different time-lapse dispersion data. Lastly, we only superimpose the data segments judged as high-quality dispersion data. We have applied the developed dispersion data screening and superposition technique to a real linear array dataset. This not only significantly improves the signal-to-noise ratio of the dispersion spectrum, but also greatly reduces data processing time.

Extraction of body waves from seismic ambient noise recorded by a dense seismic array at the Zhangbaling segment of Tanlu Fault Zone, China

Mingze Du[1]*, University of Science and Technology of China (d17752@hotmail.com)
Ji Gao[2], University of Science and Technology of China
Haijiang Zhang[3], University of Science and Technology of China

Abstract

The Tanlu Fault (TLF), the largest strike-slip fault in eastern China, exhibits significant segmentations in both structural characteristics and seismic activity. The Jiashan-Feidong segment of TLF, situated between the Sulu and Dabie orogenic belts, is particularly complex due to the presence of the Zhangbaling uplift and Hefei basin on its eastern and western flanks, respectively. This complexity extends to both structural and sedimentary features, thus a detailed velocity model is needed.

In recent years, ambient noise tomography has been widely used to determine the Vs model by extracting seismic surface waves from ambient noise. However, surface waves are mainly sensitive to the Vs structure and also have limited depth resolutions. In comparison, body waves can provide complementary information to the surface waves. In this study, we have developed a procedure to extract body waves from ambient noise recorded on a dense seismic array and applied it to elucidate the upper crustal structure of the Zhangbaling segment of TLF by utilizing direct P waves extracted from ambient noise by a dense array comprising 192 receivers spaced at a minimum interval of 5 km.

Our analysis procedure includes two primary components: body wave extraction and travel time tomography. Firstly, we employ the Wavelet Phase Cross-Correlation (WPCC) technique to obtain robust cross-correlation functions of receiver pairs. Subsequently, we subdue the Rayleigh wave component by summing the imaginary parts of the ZR and RZ components of the cross-spectrum tensor for each receiver pair. Additionally, a selection filter is applied to isolate time segments exhibiting relatively high Signal-to-Noise Ratios (SNRs) indicative of potential direct P wave arrivals. Furthermore, we utilize the Adaptive Covariance Filter (ACF) to enhance the coherent signal and suppress incoherent noise within each trace, resulting in the extraction of clear direct P wave signals from all available receiver pairs.

Utilizing the extracted P wave signals, we further perform 3-D travel time tomography to estimate P wave velocities in the study area. Our results demonstrate the feasibility of reconstructing not only surface waves but also body waves from ambient noise. This further illustrates the usefulness of dense seismic array to study the detailed velocity structure at different scales.

YoungHee Kim[7], School of Earth and Environmental Sciences, Seoul National University

Abstract

Crust contains deformation by not only faults but the microcracks which are easily aligned to either the structural features or the stress regime, causing the velocity difference on the same raypath. This phenomenon is easily observed by the shear waves, called shear wave splitting. To investigate the shear wave splitting of the southeastern Korean peninsula, we analyzed the data recorded on the Gyeongju Hi-density Broadband Seismic Network using the eigenvalue method. The method measures two parameters, the fast polarization and the delay time, which enhance the linearity of the particle motion of the shear waves. We applied constraints on the observed measurements to restrict undesired measurements, the incidence angle, the error of the parameters, the analytical difference between the fast polarization and the initial polarization, and the grading system. We obtained 4611 reliable parameter pairs, concentrated mainly on the 2016 Gyeongju sequence and the eastern Ulsan Fault (USF). The distribution of the total measurements has the right-skewed distribution of the delay time and the elliptical rose diagram of the fast polarization. The two regions have similar patterns on the delay time, concentrated on the low values. The fast polarizations, however, showed different aspects as the 2016 Gyeongju sequence has NNE-SSW dominant ellipse shaped rose diagram and the eastern USF has ENE-WSW dominant one. The delay time tomography resulted in high anisotropy on the eastern USF and on the 2016 Gyeongju sequence. Also, two linearly aligned high anisotropy are observed on the western Yangsan Fault (YSF). These heightened regions might be related to some geological features, such as the slip tendency on the eastern USF and the 2016 Gyeongju sequence itself. Spatially averaged fast polarization depicted a complex pattern, two to three representative directions, with the dominant NE-SW. Various directions on the small region could indicate the complex influence of miscellaneous factors on the seismic anisotropy of the crust. The NE-SW and E-W trends on the eastern USF seem to be related to the structural features and stress, respectively. The fast polarizations aligned to the Yangsan Fault (YSF) along it indicate the influence of the YSF on the seismic anisotropy, indicating the structural anisotropy is dominant along the YSF. The NE-SW trends with low values on the delay time tomography might be related to the crustal stress on the shallow depth. Additionally, a strong yet unknown mechanical relationship was noted between the slip tendency (slip susceptibility) and the seismic anisotropy. Such discoveries suggest the crust

beneath the network reflects deformation influenced by various crustal features.

Investigation on the Influence of Non-uniform Noise Source Distribution on Ambient Noise Imaging Effectiveness

Fei HUANG[1]*, University of Chinese Academy of Sciences(UCAS)
(huangfei22@mails.ucas.ac.cn)
Yuan ze Zhou[2], University of Chinese Academy of Sciences(UCAS)

Abstract

Ambient noise imaging techniques represent significant advances in 21st-century seismology. These methods derive Green's functions of subsurface structures by utilizing cross-correlation functions from arbitrary pairs of seismic stations. Due to independence from both natural and artificial seismic sources, as well as the capability to provide continuous data, ambient noise techniques have initiated a seismic revolution. These innovative methods find extensive applications in studying underground velocity structures, anisotropy, medium attenuation characteristics, and monitoring shallow subsurface velocity changes. However, the theoretical foundation of ambient noise methods typically assumes a uniform distribution of noise sources, which differs from the non-uniform and time-varying nature of real-world noise sources. Such disparities between theoretical assumptions and real-world conditions may lead to inaccuracies in research outcomes, especially in studies involving the monitoring of shallow subsurface velocity changes, where the influence of noise source distribution is notable. Although numerous scholars have acknowledged the significance of noise source distribution in reconstructing Green's functions, previous research has predominantly focused on theoretical aspects, neglecting to assess the impact of noise source distribution in conjunction with specific empirical studies. Additionally, the potential consequences of incomplete noise field scattering on frequency components and its impact on research outcomes have been overlooked. In this contribution, we quantitatively analyze how the spatial distribution of noise sources and non-uniform frequency distributions affect cross-correlation results. Employing practical studies on shallow subsurface velocity changes as examples, we evaluate the impact of noise sources on velocity change results, analyze, discuss, and seek potential improvement methods. Through this study, we aim to establish a reliable evaluation criterion for ambient noise imaging outcomes and promote the application of ambient noise methods in practical seismic studies.

Short and long-term behavioral characteristics of the Eupcheon Fault in the southeastern part of the Korean Peninsula

Sung-il CHO[1]*, Korea Hydro & Nuclear Power Company (chosi4476@khnp.co.kr)
Jeong-seon Park[2], Korea Hydro & Nuclear Power Company
Sae-woon Choi[3], Korea Hydro & Nuclear Power Company
Donghee Park[4], Korea Hydro & Nuclear Power Company
Jae-woong Ryu[5], Korea Hydro & Nuclear Power Company

Abstract

In order to confirm the seismic safety around nuclear power plant sites, the geological characteristics must be investigated before constructing the plant. The Eupcheon Fault, located near the Wolsong Nuclear Power Plant in Korea, has a history of at least two fault movements during the Quaternary period. The Korea Hydro & Nuclear Power Corporation installed the Eupcheon Fault Monitoring System (EFMS) and has been operating it to confirm the behavioral characteristics since 2012. The EFMS includes a borehole strainmeter to observe changes in underground stress, a creepmeter and GPS (Global Positioning System) to monitor fault displacement, as well as a seismometer to detect seismic waves. All measured data were adjusted for external factors such as earth tide, temperature, atmosphere, and artificial noise to ensure reliability. In this study, changes in underground stress and fault displacement were analyzed using observed data from both short- and long-term periods. According to the borehole strainmeter, the current stress direction predominantly aligns with ENE-WSW in the Gyeongsang Basin in Korea. The temporary abnormal stress from the nearby earthquake events was observed, but its long-term accumulation was not confirmed. As analyzed results from the GPS data, there have been no abnormal changes in fault displacement. A micro-displacement of 0.0047 mm was measured by the creepmeter during the 2016 Gyeongju earthquake (Mw 5.8). But it is attributed to the micro-vibration of the earthquake rather than fault behavior. The results of this study show that the Eupcheon fault is relatively stable and not impacted by earthquakes occurring nearby. The study also confirmed the excellent effectiveness of fault monitoring systems in analyzing the fault stability against earthquakes.

Ground Motion Models for South Korea using the Hybrid Empirical Method and NGA-West2 Empirical Ground Motion Models

Seonjeong PARK[1]*, Korea Institute of Nuclear Safety (sjpark@kins.re.kr)

Abstract

Ground motion models (GMMs) play a crucial role in both deterministic and probabilistic seismic hazard assessments. Developing empirical GMMs is impractical in areas like South Korea with scarce strong earthquake records, leading to the use of alternative methods such as stochastic simulations. Thus far, all GMMs developed for South Korea have employed stochastic methods.

In this study, GMMs are developed for South Korea using the hybrid empirical method (HEM) which was suggested by Campbell (2003). Western United States (WUS) is selected as a host region so that five empirical ground motion prediction equations (GMPEs) developed by the Pacific Earthquake Engineering Research Center for the Next Generation Attenuation-West2 (NGA-West2) project are used as GMMs for the host region.

The high-frequency spectral attenuation parameter, kappa, is one of the most important seismological parameters utilized in the simulation. Therefore, kappa is estimated in this study for the accelerometer observatories operating throughout South Korea.

Derived GMMs are for magnitudes from 5.0 to 7.5 and rupture distances from 10 to 500 km. Median GMMs are provided with aleatory standard deviations. Predictive GMMs are compared with observed ground motions from the available earthquake records for moment magnitudes 5.0 and 5.5. The notable advantages of the GMMs developed in this study are as follows: The implementation of HEM complement the limitations inherent in stochastic simulations such as near-source ground motion saturation effects. The seismological parameters utilized in ground motion simulations for the target region are obtained from recent research or practically estimated values using abundant acceleration data. The aleatory standard deviations are defined for use in Probabilistic Seismic Hazard Analysis (PSHA).

Investigation of Directional Variability of Earthquake Ground Motion of South Korea for Nuclear Seismic Safety Assessment

JEONGGON HA[1]*, Korea Atomic Energy Research Institute (jgha@kaeri.re.kr)
INKIL CHOI[2], Korea Atomic Energy Research Institute
MINKYU KIM[3], Korea Atomic Energy Research Institute

Abstract

This study investigates the directional variability of earthquake ground motion in South Korea, leveraging recorded data from the 2016 Gyeongju and 2017 Pohang earthquakes. Through the analysis of over 1,200 seismic recordings from the Korean seismic observation network and a comparison with the NGA-WEST dataset from the United States, this research assesses the characteristics of variability in horizontal bidirectional responses and the vertical/horizontal (V/H) ratio of earthquake ground motion in South Korea.

The first part of the study explores the variability of horizontal bidirectional responses, which is crucial for determining structural responses to earthquakes in seismic fragility assessment. It reveals differences in the maximum and minimum directions of ground motion response, as well as component-to-component variability in South Korea. Additionally, the study compares the differences in directional variabilities between the South Korean and United States databases by frequency.

Subsequently, the research investigates the V/H ratio in South Korea, which is essential for defining the vertical spectrum shape to determine the seismic behavior of structures. The V/H ratio by frequency was compared between the South Korean and United States databases. Furthermore, using a previously empirically presented formula for the V/H ratio, the study compares it with the V/H ratio measured at a Korean nuclear power plant.

By the comprehensive analysis of both bidirectional variability and V/H ratios using the recorded earthquake motions in South Korea, this study is expected to provide a fundamental understanding for improving the seismic evaluation method of nuclear power plants.

Hybrid Empirical Ground Motion Predictions for the southern Korean Peninsula

Sae-Woon CHOI[1]*, Central Research Institute of Korea Hydro & Nuclear Power Co., LTD (choisewoon@khnp.co.kr)
Dong-hee Park[2], Central Research Institute of Korea Hydro & Nuclear Power Co., LTD

Abstract

Due to the lack of observation records of earthquakes of magnitude 5.0 or higher, there are limitations in developing ground motion prediction equations (GMPEs) for the Korean Peninsula using empirical methods. In this study, GMPEs hybrid empirical method(HEM) was used to develop a GMPE for the southern region of the Korean Peninsula. HEM is a method that provides strong ground motions for the region(target region) with insufficient strong ground motion data, using empirical GMPEs developed for a region(host region) with abundant strong ground motion records and adjustment factors based on stochastic simulations. Five NGA-West GMPEs developed for the western United States were selected as the empirical GMPEs for the host region. To calculate the adjustment factors, strong ground motions were generated by stochastic simulation for the western United States and the Korean Peninsula. Seismological parameters studied for the host region and target region were used for input variables applied to the stochastic model. The shear wave velocity of 2,500 m/s and kappa of 0.006s are applied to the site conditions of the target area. Adjustment factors are calculated for frequencies from 0.1 Hz to 50 Hz, moment magnitudes from 3.0 to 8.0, and rupture distances up to 1,000 km. We compared the ground motions generated from the developed GMPE in this study to ground motion data recorded in the Korean Peninsula. The comparison with the previously developed GMPEs for the Korean Peninsula was also conducted.

Procedure for the determination of Safe Shutdown Earthquake ground motion for nuclear power plants

Sinae HAN[1]*, KEPCO-ENC (ssinaehan@kepco-enc.com)
Jechan PARK[2], KEPCO-ENC
Hyun-Mi RHEE[3], KHNP
Hyun Jae YOO[4], Pukyoung National University
Seong-Bin YIM[5], KEPCO-ENC
Joohyeon YI[6], KEPCO-ENC

Abstract

The procedure for determining Safe Shutdown Earthquake(SSE), the earthquake which produces the maximum vibratory ground motion for which certain structures, systems, and components are designed to remain functional, is performed in accordance with Korean regulatory guidelines and 10 CFR Part 100 Appendix A. In order to determine seismic design of nuclear power plants, SSE decision must be made in advance, which is a very important procedure. The procedure for determination of SSE can be divided in to two part, a deterministic seismic hazard analysis using seismic source and attenuation characteristics and verifying suitability by conducting a stochastic simulations and probabilistic seismic hazard analysis.

The hazards of ground motion and faults associated with seismic events and geological phenomena must be investigated according to regulatory siting criteria for nuclear power plants and provided. The geological and seismological data provided in this way are used to determine SSE. In particular, seismological data collected through historical earthquake data, instrumental earthquake data, and site specific instrumental data should be combined with geological information to form a seismo-tectonic province. The maximum ground motion value that can occur at the site is calculated through a deterministic method using the ground motion prediction equation, which refer to the attenuation characteristics, and the previously obtained seismo-tectonic province. note that earthquake occurring point at each province must be determined. SSE is determined by adding margin to the calculated largest ground motion value at the site. Once SSE is decided, Standard design response spectrum is scaled for the SSE value to determine Design Ground Response Spectrum(DGRS) at the site.

An earthquake safety assessment is performed to verify the suitability of determined SSE and DGRS, if there is a linear earthquake source such as faults that meet the criteria to be considered in design in the vicinity of the site, stochastic finite-fault simulations is performed to confirm whether impacts to those sources exceed DGRS and SSE. Moreover, probabilistic seismic hazard analysis is executed to calculate the mean value of the annual exceedance probability for the SSE from hazard curve. if the mean value of annual exceedance probability exceeds reference values presented in regulations, the SSE is adjusted upward to prevent it.

[Keynote] Physics-based Ground Motion Prediction for Advanced Seismic Hazard Assessment: Potentials and Challenges

Seok Goo SONG[1]*, Korea Institute of Geoscience and Mineral Resources (KIGAM)
(sgsong@kigam.re.kr)
Eunjin PARK[2], Korea Institute of Geoscience and Mineral Resources (KIGAM)

Abstract

Ground motion prediction is a core element in seismic hazard assessment. However, it is still a challenging task to develop accurate and reliable ground motion prediction methods for future destructive earthquakes. Traditionally two approaches have been intensively studied in the community. One is to construct empirical Ground Motion Prediction Equations (GMPEs), the other is to adopt stochastic ground motion simulation schemes. The former often suffers from the deficiency of recorded data, especially in the near-source region for large events. The latter is also limited in many applications because only single component and single phase ground motions are simulated. Recently researchers have paid more attention to physics-based ground motion prediction approaches, by adopting either dynamic or pseudo-dynamic earthquake modeling methods. Since 3-component and full phase ground motions are required for dynamic structural response analysis in the Performance-Based Earthquake Engineering (PBEE), it is important to develop accurate and reliable physics-based ground motion simulation methods to generate 3-component and full phase ground motions. In this presentation, we briefly overview the potentials and challenges of the pseudo-dynamic source modeling method with 1-point and 2-point statistics of earthquake source parameters, which is one of the physics-based ground motion simulation methods recently developed. In the framework of pseudo-dynamic ground motion simulation with 1-point and 2-point statistics, we may be able to deal with both the epistemic and the aleatory uncertainty of physics-based ground motion predictions efficiently. Although there are still many challenges to overcome, we believe that physics-based ground motion prediction should be future directions for advanced seismic hazard assessment.

Preliminary evaluation of fault activity around the southeastern part of the Korean Peninsula using probabilistic approach on seismogenic potential of a fault

Sung-il CHO[1]*, Korea Hydro & Nuclear Power Company (chosi4476@khnp.co.kr)
Sae-woon Choi[2], Korea Hydro & Nuclear Power Company
Donghee Park[3], Korea Hydro & Nuclear Power Company
Sehyeon Gwon[4], Korea Hydro & Nuclear Power Company

Abstract

One of the main issues related to the seismic source for Probabilistic Seismic Hazard Analysis(PSHA) is the fault activity associated with assessing the earthquake-induced possibility from a specific fault. The US NRC (1999) suggested a probabilistic appoach on seismogenic potential of a fault that considers the spatial association between the fault and the earthquake point, the crustal extent of faults, the relationship between fault slip and tectonic stress regime, and reactivation events of the faults. In this study, we preliminarily evaluated the probabilistic seismogenic potential of active faults around the southeastern part of the Korean Peninsula using the modifed US NRC method by ourselves, which incorporates geomorphological characteristics, fault movement history, and fault origin into the assessment framework. The probability of spatial association can be assessed as 0.1 to 0.2, but this requires consideration of a few earthquake frequency and the extensive reverse fault plane. In case of a fault movement history, the probability is 1.0 because the latest fault movement occurred within 100,000 years. However, it is possible to apply various probabilities considering the recurrence inteval from 260 to 22,000 years of faults. The probability of the crustal extent and reactivation events of faults can be evaluated to be close to 1.0, considering the epicenter depth from 8 to 15 km and has multiple events of fault movement. As analysis results of geomorphological characteristics, various probabilities can be applied depending on whether there is Quaternary displacement or not.

These results can be contribute to a reasonable evaluation by incorporating the probabilistic activity as seismic sources when we conduct Probabilistic Seismic Hazard Analysis. However, in order to assess the probability of fault activity, detailed investigations should be conducted in advance to obtain results with a high confidence level.

Using logic-tree approach, reduction of uncertainty in fault source characterization for probabilistic seismic hazard analysis in South Korea

Sehyeon GWON[1]*, Korea Hydro & Nuclear Power Co., LTD. Central Research Institude (sehyeon.gwon81@gmail.com)
Sae-Woon Choi[2], Korea Hydro & Nuclear Power Co., LTD. Central Research Institude
Sung-il Cho[3], Korea Hydro & Nuclear Power Co., LTD. Central Research Institude
Donghee Park[4], Korea Hydro & Nuclear Power Co., LTD. Central Research Institude

Abstract

Probabilistic seismic hazard analysis (PSHA) is a methodology that calculates the probability of various earthquake shaking levels in a given time window. PSHA produces an estimated annual exceedance probability and provides essential information for design-basis development and safety evaluation criteria for major infrastructure projects. The Korean peninsula is located in a stable intraplate region with low seismicity and long return periods of large earthquakes. Although many Quaternary faults are reported in South Korea, fault source models are challenging to establish in PSHA, generally in the Korean peninsula, due to the significant epistemic uncertainty of fault characteristics. This study introduces examples of fault source characterization in the stable intraplate regions, including central and eastern United States (CEUS), Australia, and the Republic of South Africa, mainly focusing on logic-tree approaches. PSHA conducted in seismotectonic analogs of stable intraplate regions suggests the logic trees can be applied to incorporate considerable uncertainties in the fault source characterization associated with potential future earthquakes. In addition, we discuss the approaches to capture epistemic uncertainty considered in a seismic source characterization, including (1) alternative seismic source model and (2) alternative source parameterization. Finally, we propose an example of a fault source model using logic tree approaches that might apply to reducing the uncertainties for PSHA in South Korea.

The Study on the Seismic Source Parameters of Major Earthquakes in 2023

Hyun-Me RHEE[1]*, Korea Hydro & Nuclear Power Co., LTD (rheehm17@khnp.co.kr)

Abstract

The earthquake of magnitude 4.0 has occurred at Gyeongju region on the November 30, 2023. It was the largest earthquake that occurred on the Korean Peninsula in 2023. This earthquake occurred about 21 km away from the epicenter of the 9.12 earthquake in 2016. There are common opinions that it was occurred by different mechanism with the 9.12 earthquake in 2016. So we have been interesting in this event, and analyzed the seismic source parameters to understand the seismic characteristic.

The method of Jo and Baag (2001) which was based on the S-wave spectrum analysis by suggested Snoke (1987) and Andrews (1986) is adopted. The moment magnitude, corner frequency, seismic moment, and stress drop are measured from the seismograms. We used a vector sum of spectra of the 3 components. It was set out by Noh et al. (2003), and has been used in the previous study. In the previous study, self-similarity has been breakdown under moment magnitude 4.0 and the stress drop of the earthquakes over magnitude 4.0 has shown the similar stress drop of about 61.0 bar. The stress drop of the 9.12 earthquake shows more larger than other earthquakes, but the earthquake in 2023 has analyzed more smaller then other earthquakes even considering the self-similarity breakdown. The average stress drop measured from the records which are recorded at borehole station of the KMA within 150 km of the epicenter is about 20 bar.

Shallow earthquakes in stable continental regions and implications for probabilistic seismic hazard analysis in SE Korea

Sehyeon GWON[1]*, Korea Hydro & Nuclear Power Co., LTD. Central Research Institude (sehyeon.gwon81@gmail.com)
Sae-Woon Choi[2], Korea Hydro & Nuclear Power Co., LTD. Central Research Institude
Donghee Park[3], Korea Hydro & Nuclear Power Co., LTD. Central Research Institude

Abstract

In probabilistic seismic hazard analysis (PSHA), future earthquakes are generally characterized by the location, geometry, and faulting types of the through-going structure in the seismogenic crust and the associated potential maximum earthquake magnitudes over long recurrence intervals. The uncertainty in the spatiotemporal distribution of stable continental region (SCR) earthquakes is a significant issue for the reliability of PSHA, although multidiscipline data, including paleoseismic, geomorphic, and remote sensing investigations, provide essential information for fault source characterization. The observations of surface ruptures and strong ground motions associated with low-magnitude (≒ Mw 5.0) shallow earthquakes in the global analogs of SCRs demonstrate that the importance of considering the potentials of earthquakes at a very shallow depth (7km <), even in ~3 km, is necessary in terms of PSHA. In the present study, we describe several issues related to SCR earthquakes for PSHA and discuss the mode of shallow earthquakes and possible mechanisms of their seismogenesis with examples of damaging earthquakes. Recent studies of SCR earthquakes show that these very shallow earthquakes emerged as a source of exceptional ground acceleration near the causative fault and likely unexpected hazards in SCRs. In addition, the distribution and depth of the rupture area can reflect variable geological conditions, tectonic force or anthropogenic contribution, and preexisting geological structure. These observations suggest that the fault-scaling relations relating surface measurements (length and displacement) to earthquake magnitude estimations, which were routinely used for PSHA, should be carefully used. Paleoseismic investigations have revealed surface rupture earthquakes in SE Korea. It is necessary to identify and characterize the causative geological structures in subsurface and the associated earthquake potentials. In the future, geological and geophysical analyses should characterize the distribution of the geological units, the tectonic history, and the seismogenic potential of the fault source for PSHA in SE Korea.

Development of Earthquake Ground Motion Database in Korea

Sang-hyun Lee[1]*, Seoul National University (hiuni3@snu.ac.kr)
Junkee Rhie[2], Seoul National University

Abstract

The earthquake ground motion data plays a fundamental role as an important resource in seismic hazard analysis. The significance of seismic hazard assessment in South Korea was highlighted following consecutive earthquakes with magnitudes over 5 in 2016 and 2017. In this study, we developed a standardized database of earthquake ground motion in Korea by expanding the previous seismic motion database with additional data and refined data processing procedures. The database construction followed the methodology of the NGA-East Database from the Pacific Earthquake Engineering Research Center, adapted to South Korea's context. It includes comprehensive lists of earthquakes, observatories, observed accelerations, and seismic motion measurements from 2003 to 2022, focusing on earthquakes above local magnitude 3.0. The list of earthquakes is based on an authoritative public list from the Korea Meteorological Administration. Moment magnitudes were determined from various sources, including the annual report of the Korea Institute of Geoscience and Mineral Resources. The observatory list is derived from the National Earthquake Comprehensive Information System, incorporating site characteristics like VS30. Seismic motion data were meticulously collected and processed to obtain seismic motion measurements and Fourier amplitude spectra. The ground motion measurements of peak ground acceleration and Pseudo-Spectral Acceleration are calculated using the RotD50 method. The earthquake ground motion database is a significant resource for future earthquake research and seismic hazard analysis, expected to greatly contribute to the field.

The high frequency spectral decay in seismic station near nuclear power plant using S wave autopicking.

Arim HAN[1]*, KHNP (arimh0523@khnp.co.kr)
Sae Woon Choi[2], KHNP
Dong Hee Park[3], KHNP

Abstract

It is important to evaluate the site characteristics of each seismic station because the site effect significant impact on amplitude and frequency components of seismic waves depending on the site characteristics such as the velocity structure and density of the near-surface layer of the site.
Among the research methods to identify site characteristics, there is a method using the high frequency spectral decay parameter (κappa). Kappa was related to shallow velocity structure of the site and is an important input variable for ground motion simulation and seismic hazard analysis.
In this study, the site characteristics of a seismic station install near a nuclear power plant were analyzed through the analysis of the high frequency spectral decay (kappa) of seismic waves. Earthquakes that occurred after 2017 with 2.0 or higher magnitude in a radius of 150 km from the site were selected through signal-to-noise ratio, and S wave was autopicked using the envelope function. We calculated Kr using the extracted S wave, and then kappa was derived through regression analysis. In this study, the κR required to obtain kappa was calculated by two methods. First, κR was derived for each seismic data recorded at each seismic station, and then we calculated one kR by stacking all seismic data recorded at each seismic station. And then we derived kappa using regression analysis. Using this, we classified the seismic station level and compared them with previous research results.

Application of High-Dimensional Visualization Techniques for the development of Ground Motion Characterization Model for the Korean Peninsula

Sae-Woon CHOI[1]*, Central Research Institute of Korea Hydro & Nuclear Power Co., LTD
(choisewoon@khnp.co.kr)
Dong-hee Park[2], Central Research Institute of Korea Hydro & Nuclear Power Co., LTD

Abstract

One of the important aspects of developing a ground motion characterization (GMC) model for probabilistic seismic hazard analysis (PSHA) is quantifying epistemic uncertainty. A simple method is to select developed ground motion models (GMMs) and assign weights to it. However, since each GMM does not have same uncertainty for all frequencies, distances, and magnitudes, the simple method has limitations in capturing the center, body and range of epistemic uncertainties in GMMs. Therefore, it is necessary to individually evaluate a distribution of ground motion for each magnitude and distance. A useful method in this case is the High-Dimensional Visualization Technique. In this study, we used Sammon map, one of the High-Dimensional Visualization Techniques, to develop a ground motion characterization model for the Korean Peninsula. First, the GMMs developed for the Korean Peninsula was selected as the seed GMMs. Both of GMMs based on stochastic methods and empirical methods were included. After defining the ground motion space for magnitudes from 4.0 to 8.0 and distances from 1km to 1,000km, parameters such as mean and covariance matrix to create a continuous distribution of GMM were calculated. 5,000 GMMs were sampled using these parameters and a Sammon map was created. During this process, physically non-plausible sampled GMMs were rejected. The ground motion space of the Sammon map was divided into a total of 17 cells, and a representative GMM for each cell was derived. To derive the final GMC, the weight for the representative GMM was determined using the number of sampled GMMs included in each cell.

Fault investigation through geomorphic analysis

Su-Ho JEONG[1]*, Structural Engineering Department, Korea Hydro & Nuclear Power (jsh.1212@khnp.co.kr)
Sambit Prasanajit NAIK[2], Active Fault and Earthquake Hazard Mitigation Research Institute, Pukyong National University
Young-Seog KIM[3], Department of Earth and Environmental Sciences, Pukyong National University

Abstract

Site investigation is essential to confirm the geological safety of nuclear facilities. Site survey is conducted to examine vatious impacts such as surface faulting, ground motion, sliding, etc. Among them, direct investigation of faults is especially important as it allows obtaining information such as slip-rate and recurrence interval, which is crucial for confirming geological safety. These pieces of information hold significant importance as they can be utilized as fundamental data for deterministic and/or probabilistic seismic hazard analysis.

To conduct a fault investigation, we need to locate the fault. In the case of the Korean Peninsula, the frequency of large magnitude earthquakes and fault slip-rate are low, and the original topography has been significantly altered due to high-density development, posing limitations on fault tracing. To overcome these limitations, we carried out geomorphic anaylsis(lineament extraction, analysis of geomorphic indices and Quaternary landforms classification) using vintage aerial photographs.

As a result of the investigation, a new fault was discovered in the Cheongun-dong area of Gyeongju City, and it was named 'Cheongun Fault' after the name of the area. Stratigraphic evidences recorded in trench sections indicate that the Cheongun Fault has been active at least three times since the Quaternary period. Additionally, based on the 14C and OSL age dating results, the lastest movement period and slip-rate of Cheongun Fault are estimated to be 37±4ka~4.2±0.4ka and around 0.02mm/yr respectively.

Geological and Geotechnical Characterizations in the Arabian Gulf Coast

Yongwoo NOH[1]*, KEPCO E&C (major7700@naver.com)
Joohyeon YI[2], KEPCO E&C
Sungbin YIM[3], KEPCO E&C
Kyunghan SEO[4], KEPCO E&C

Abstract

The Arabian Plate is located in the Middle East of Asia and separated from Africa approximately 25 million years ago, resulting in the closure of the subducting Tethys sea in the northeast. The rifting of Africa and Arabia opened the Red Sea as well as the Gulf of Aden, bordering the plate on the southwest and southern sides respectively.

The Arabian Gulf is a foreland basin to the Zagros Fold and Thrust Belt (ZFTB), and is located within the tectonically stable craton of the Arabian Plate. The geology of the Arabian Gulf area has been substantially influenced by the deposition of marine sediments associated with numerous sea level changes during relatively recent geological time.

The geology of the Arabian Gulf coast area is characterized by flat-lying sedimentary rocks of predominantly the Miocene Shuweihat and Dam formations and the Eocene Dammam Formation, capped by clastic alluvial and colluvial sediments from the Arabian Shield known as the Baynunah and Hofuf formations. The Quaternary surficial sands are locally underlain by a thin, stiff clay layer that represents the completely weathered mudstone of the Shuweihat Formation.

All rock layers beneath the overburden soils are primarily carbonate dolomitic mudstone, siltstone, sandstone and gypsum. Gypsum beds are interspersed within the Shuweihat and Dam Formations, but represent a small percentage of rock and are confined within thicker beds of mudstone and sandstone. It is reported that the typical adverse effects of gypsum are subsidence due to dissolution and heave due to expansion. The subsurface is divided into engineering layers with distinct physical properties.

In this study, geological setting, main stratigraphic units, typical geotechnical profile, and engineering properties of the Arabian Gulf coast area are presented through field investigation and literature studies.

Yasmina Rouchiche[5], Centre de Recherche en Astronomie Astrophysique et Géophysique CRAAG
Amal Sebai[6], Centre de Recherche en Astronomie Astrophysique et Géophysique CRAAG

Abstract

The study presents the conception and development of a comprehensive numeric and interactive database dedicated to cataloguing historical earthquakes. Understanding the historical seismic activity of a region is crucial for assessing current and future seismic hazards. The database will be an update of the Earthquake Catalogue for Eastern Algeria (ECEA) (Harbi et al., 2010) by determining the location, intensity magnitude MI, and focal depth of historical earthquakes by using the macroseismic data available in the Algerian Homogenized Macroseismic Database (AMD), compiled and published by (Harbi et al., 2015) (https://users.ictp.it/~naget/PUBLICATIONS/resources/AMD.pdf).

The interactive nature of the database allows users to explore and analyse earthquake data dynamically. Users can access a wealth of information, such as the time, location, magnitude, and depth of each earthquake, providing a detailed historical perspective on seismic events. Additionally, the database incorporates advanced visualization tools, enabling users to generate maps, charts, and graphs to better comprehend the spatial and temporal distribution of earthquakes.

The database's user-friendly interface makes it accessible to a wide range of users, including researchers, policymakers, and the public. By promoting transparency and collaboration, the database serves as a valuable resource for advancing our understanding of historical earthquakes and enhancing earthquake resilience in Algeria

In conclusion, the numeric and interactive database represents a significant step forward in consolidating and presenting historical earthquake data. Its multidimensional approach provides a comprehensive tool for researchers to navigate and interpret seismic information effectively, ultimately contributing to the advancement of earthquake research and for assessing current and future seismic hazards.

Role of the Main Himalayan Thrust in generating earthquakes in the Himalaya

Devajit Hazarika[1]*, Wadia Institute of Himalayan Geology, Dehradun
(devajithazarika@gmail.com)
Monika Wadhawan[2], National Centre for Seismology, Ministry of Earth Sciences, New Delhi, India
Somak Hajra[3], Department of Physics, University of Alberta, Edmonton, T6G2M8, Canada
Naresh Kumar[4], Wadia Institute of Himalayan Geology, Dehradun

Abstract

The strain energy originated due to the India-Asia collision largely accumulates in the detachment plain or the Main Himalayan Thrust (MHT) that separates the downgoing Indian plate from the overriding Himalayan wedge. The MHT produced several major and great earthquakes in the Himalaya. Several researchers reported the presence of a ramp structure in the MHT in the Himalaya which is responsible for generating earthquakes. Thus, to understand the geometry of the MHT at depth and its relationship with seismicity, we carried out passive seismological studies in different segments across the Himalaya. Here, we present the passive seismological experiment carried out across two segments of the Himalaya i.e. Satluj and Kali River Valley of the NW Himalaya based on receiver function (RF) analysis.

The RF imaging in the Satluj valley suggests a gentle dipping nature of MHT from south to north between the Sub and Higher Himalaya in contrast to the ramp structure in the Garhwal, Kumaon, and Nepal Himalayas, while the ramp structure is identified further north beyond the South Tibetan Detachment. The depth of the MHT varies from ~16 to 27 km across the Sub, Lesser, and Higher Himalaya, and it increases to ~38 km beneath the Tethyan Himalaya forming a ramp. The crustal thickness varies within the range of ~44-62 km. The change in the location of the MHT ramp can be attributed to the effect of underthrusting Delhi-Hardwar Ridge, a transverse structure to the Himalayan arc. Conspicuously, no strong or large earthquake is observed during 1964–2023 in this segment of the Himalayan Seismic Belt suggesting a ramp-seismicity linkage.

On the other hand, the RF image along the Kali River Valley of Kumaon Himalaya shows a ramp (∼20◦) structure on the MHT beneath the Chiplakot Crystalline Belt (CCB) that facilitates the exhumation of the CCB. A cluster of seismicity coincides with the location of the ramp structure. The presence of steep dipping imbricate faults inferred from focal mechanism solutions suggests a Duplex structure in the CCB. The crust is observed to be thinner (~38-42 km) compared to other parts of NW Himalaya. The study reveals a low-velocity zone (LVZ) with a high Poisson's ratio (σ ∼0.28–0.30) at lower crustal depth beneath the CCB suggesting the presence of fluid/partial melt. Both experiments emphasize the effect of the ramp structure of the MHT in the generation of earthquakes in the Himalaya.

Imaging the Aegean crustal structure using P and S phase travel times

Pratul RANJAN[1]*, CSIR-National Geophysical Research Institute (NGRI), Hyderabad, India (pratulranjan@ngri.res.in)
Konstantinos I. Konstantinou[2], National Central University, Taiwan
Prakash Kumar[3], CSIR-National Geophysical Research Institute (NGRI)

Abstract

We performed P and S wave velocity tomography of the Aegean crust using travel-times of 2,135,625 P arrivals and 1,095,515 S arrivals from 178,676 earthquakes recorded across 324 stations. Several resolution and robustness tests helped discern areas with good resolution, where results can be considered reliable. These areas include the gulf of Corinth and the Kefalonia Transform Zone, active volcanoes and the regions along the fore-arc. From the tomography results and the final earthquake locations, the structural variations in the Aegean crust, possible fluid induced seismicity, porosity beneath active volcanoes, as well as the structures near the source zones of large earthquakes have been analyzed. The results show that the Aegean crust-mantle boundary exists as a transition zone and the crust is composed of three main lithological units: extremely low velocity sediments, low velocity silicic units, and high velocity metamorphic units. The porosity modeling indicates Santorini may have the highest melt-fraction out of all the volcanoes in the Aegean, which agrees with the high rate of volcanism at this volcano. Source zones of several large earthquakes (Mw > 6) indicate high Vp/Vs, which suggests an important role played by fluids in their nucleation. The 3D model thus obtained will help in the accurate relocation of crustal seismicity as well as detailed study of source zones of future large earthquakes. This study will also help in the assessment of seismic hazard in the region.

Automatic earthquake detection using open source software

Nomin-Erdene ERDENETSOGT[1]*, Institute of Astronomy and Geophysics of Mongolian Academy of Sciences (nominerdene@iag.ac.mn)
Gylfi Pall Hersir[2], GRO-GTP

Abstract

Earthquake location is the first step in seismological studies. Many countries have their own seismological monitoring center. They monitor earthquake activity and help with related warnings in their respective countries. One of the important elements in monitoring earthquake activity is locating earthquakes accurately. Operators usually work around the clock to locate earthquakes and create a database of events. It is hard work that requires a lot of manpower and time. Recently, due to the development of technology, it became possible to automatically detect and locate earthquakes. Automatically detecting earthquakes helps to reduce the workload of operators and research can consequently start earlier. Many algorithms have been developed in terms of detecting and locating earthquakes. One such algorithm is QuakeMigrate. QuakeMigrate is a Python package for automatic earthquake detection and location system (Hudson, 2019). This package scans coherent seismic phase arrivals across a network of instruments using a stacking algorithm and waveform migration. Through this paper the QuakeMigrate tested for the first time at Icelandic and Mongolian database by processing a real seismic data acquired at each country. The test was done by reliance a simple processing flow and the application was successful. Pick errors were around 0.08 to 1 s. The depth distribution was between 2 and 15 km which was reasonable compared to the seismicity of the area.

Ambient noise levels and their effects on the Pohang Community Seismograph Network (PCSN), South Korea

Yujin Sohn[1]*, Department of Geological Science, Pusan National University (yujinsohn@pusan.ac.kr)
Kwang-Hee Kim[2], Department of Geological Science, Pusan National University, Busan, Republic of Korea
Tae-Seob Kang[3], Division of Earth Environmental System Science, Pukyong National University, Busan, Republic of Korea

Abstract

A seismograph not only captures signals from earthquakes but also records background noises simultaneously. The data quality of a seismograph network, thus, is highly influenced by ambient noise which exhibits variations influenced by factors including, but not limited to, cultural activities, weather conditions, spatiotemporal changes, and installation depths. These fluctuations in ambient noise levels have a direct impact on the earthquake detection capabilities of the seismograph network. This study analyzes ambient noise variations within the Pohang Community Seismograph Network (PCSN), a dedicated seismograph network to monitor continued seismicity since the 2017 MW 5.5 Pohang earthquake. The earthquake was the most damaging in Korea since the initiation of instrumental seismic recording in 1905. At least one person was killed and 134 injured, and ~1,700 people stayed at emergency shelters. Notice that the source area never experienced significant earthquakes in the historical and instrumental seismic observation period. Although the number of earthquakes and their magnitudes are steadily decreasing, ongoing small and shallow seismicity has been a major concern to the local community and government. Utilizing data from twenty broadband seismometers on the surface and two sensors in a downhole array (one at 2.5 m depth and the other at 500 m depth below the surface), we have assessed variations in the power spectral density (PSD) and their implications. We categorized stations in rural, urban, and coastal areas and discussed results across four different period ranges: very short-period (less than 0.02 seconds), short-period (0.02-1 seconds), long-period (1-10 seconds), and very long-period (more than 10 seconds). In the very short-period range, noise from weather conditions, such as precipitation, occasionally elevates background noise levels on surface seismometers. Our results also indicated the rainfall events did not impact the ambient noise level at 500 m depth. From 0.02 to 1 second, cultural noise generated by human activities is predominant, with noise levels ranking higher in coastal areas, followed by urban and rural areas. Notably, in the period range crucial for monitoring microearthquakes (0.07-0.2 seconds), urban areas exhibit significantly higher noise levels (14-48 dB) compared to coastal or rural areas. In the period range of 1-10 seconds, a peak in probability density functions (PDF) is noticeable, which is

known as a secondary microseism or double-frequency peak in global noise observations. Noise levels increased across all seismometers as typhoon Hinnamnor approached in early September 2022, and reached a peak when the typhoon passed the Pohang region. After the typhoon passed the region, the PSD began to decrease and stabilize. Last not the least, in the very long-period range, horizontal components are noisier than the vertical component by 20-40 dB, attributed to the effects of ground tilt. Recently compiled PCSN earthquake catalog also demonstrates the effect of background noise on the earthquake detection capability. During nighttime and daytime, the number of detected earthquakes under the magnitude of completeness (Mc = 0.34) was 53 and 5 events, respectively. These findings underscore the importance of considering background noise levels and strategic deployment locations for effective microearthquake observation in the Pohang region.

IMPLICATIONS ON THE PALEOSEISMICITY IN THE PRECAMBRIAN INTRACRATONIC BASINS: CASE STUDY OF THE BALTIC SEDIMENTARY BASIN

Jurga LAZAUSKIENĖ[1]*, Vilnius University (jurga.lazauskiene@chgf.vu.lt)
Albertas Bitinas[2], Nature Research Centre
Gražina Skridlaite[3], Nature Research Centre

Abstract

The central part of Baltic sedimentary basin is characterized by rather seismic activity, still, several tens (~ 40) of historical earthquakes of small scale with intensities of VI-VII points (MSK-64 scale) are described and instrumentally recorded (magnitudes up to M-5) in the region and adjacent territories since year 1303 (Pačėsa et al., 2005). Historical seismic activity in the central part of Baltic sedimentary basin is significantly lower comparing with seismicity of Fennoscandian shield. High seismic activity of Fennoscandian shield and adjacent Baltic Sea territories during the Late Glacial and Holocene (last 13 000 years) is well documented by numerous paleoseismic investigations and corresponding publications. The earthquakes coused landslides in glacial till, seismically-induced soft sediment deformation structures, “seismites”, are common in trench exposures in the vicinity of the faults in northern Sweden and even with tsunami events reported in the Baltic Sea (Bitinas et al., 2021).

The resent studies of soft-sediment deformation structures central part of Baltic sedimentary basin demonstrated that their formation also could have been caused by liquefaction of sediments possibly triggered by palaeo-earthquakes; thus, they could be identified as seismites.

A distribution of seismic activity in the central part of Baltic sedimentary basin could be attributed to several factors, predominantly related to the lithospheric geodynamic processes and variations of rheological properties of lithosphere within the study area. The seismic activity has an irregular distribution – the northern part of the region is more seismically active than the southern one, but still is higher to compare with more inland cratonic areas. It is difficult to associate single earthquakes with some certain faults unambiguously due to significant errors of location of seismic events and location of faults. Moreover, not all the earthquakes in the central part of Baltic sedimentary basin are related to fault zones. An identification of the seismogenic faults is also rather complicated due to the small scale of tectonic structures in the intracratonic area.

A part of seismites could be attributed to the seismic events triggered by glacio-isostatic adjustment of the lithosphere during the Last (Weishselian) glacial advance. The detailed overview of soft-sediment deformation structures of possibly seismic origin discovered in the several sites of Estonia, Latvia, Lithuania, Belarus and Kaliningrad District of Russia is presented. A number of the geological structures early interpreted as cryoturbations, glaciotectonic features or so-called water-escape structures, clearly shows all the characteristics of the liquefaction-inducted sediment deformations. Such a structures have been distinguished and described in a number of localities in Estonia, Latvia, Lithuania and Belarus (Bitinas et.al, 2021). Majority of

these seismites were formed during the Late Glacial and Holocene times, and several of them are related to Middle Pleistocene, Eemian Interglacial and Early Weichselian strata.

Vector Autocorrelation and Cross Correlation for Resolution Improvement of Apparent Source Time Function

Ying-Ju Lai[1], Institute of Earth Sciences, Academia Sinica
Wu-Cheng Chi[2]*, Institute of Earth Sciences, Academia Sinica (chigeophysics@gmail.com)

Abstract

To understand spatial distribution of the crustal dislocation (earthquake source), we use seismic waveforms to study a moving source and the associated Doppler shift. Such a Doppler effect at some sites may be affected by site (observatory) effect, instrument filters, radiation patterns, and path effects. Therefore, apparent (relative) source time function which reduces these effects from mainshock seismogram is conducted by deconvolution by an aftershock. In order to study the rupture process of the mainshock, we used the aftershock as an empirical Green's function, which has been done by many excellent previous works. However, the derived apparent source time functions sometime are strongly affected by the picked starting time of the P waves. For our new approach, the mainshock data are automatically picked by the vector autocorrelation function of three-dimensional ground motions. Through the self-similarity (e.g. vector autocorrelation>0.34) and the cross similarity (e.g. vector cross correlation>0.95). We found that the uncertainty of apparent source time is suppressed so we can get better resolution of the rupture dimension. We have tested this new code using an example of Mw5.66 thrust and Mw4.62 aftershock. Even the empirical Green's function is replaced by farther and smaller aftershocks, the results are still very robust. The self-similarity and the cross similarity can be automatically processed and might help empirical Green's function research.

Estimation of seismic source parameters and high-frequency attenuation characteristic (Kappa) using microearthquake data in the southeastern Korean Peninsula

BYEONG SEOK AHN[1]*, Pukyong National University (11196abs@gmail.com)
TAE-SEOB KANG[2], Pukyong National University
DABEEN HEO[3], Pukyong National University
HYUN JAE YOO[4], Pukyong National University

Abstract

We investigated the relationship between seismic source parameters (seismic moment, corner frequency, and stress drop) using source spectrum analysis of microearthquakes. We utilized S-wave data from approximately 5,300 microearthquakes detected by a seismic network installed in the Pohang region in the southeastern Korean Peninsula. S-wave arrival times manually picked were used to extract the S-wave domain, followed by baseline correction and instrument response removal. Finally, transverse components calculated from the two horizontal components were utilized in the analysis. After obtaining observed spectra through the Fast Fourier Transform, de-noised spectra with pre-event noise amplitudes removed were used for source spectrum calculation. An averaged source spectrum, calculated from source spectra at each station, was employed for source parameter estimation. Stress drop was found to be proportional to seismic moment at low seismic moments (~1014 N-m), contrary to the commonly known fact that stress drop is regionally specific regardless of magnitudes. Additionally, we estimated the high-frequency attenuation characteristics (Kappa) using two methods: source spectrum fitting and measurement of high-frequency slopes of acceleration spectra. Then, we reevaluated the source parameters after correcting for the site attenuation effects of source spectra by using Kappa estimates. By examining changes in the distribution pattern of the source parameters from the corrected observation spectra, we investigated the effects of applying Kappa on source parameter estimation for microearthquakes.

Seismic Noise in the Deep Underground Seismic Laboratory (JSTB): Influences from Mining Activity, Typhoons, and Precipitation

Do Woon KIM[1]*, Standards Certification Division, Korea Meteorological Institute (rlaehdns77@gmail.com)
Kwang Hee KIM[2], Department of Geological Science, Pusan National University, Busan 46241, Republic of Korea

Abstract

Yemilab is an underground laboratory situated within the active mining operations of Sinyemi Mining, located in Sindong-up, Jeongseon-gun, Gangwon Province, South Korea. Since July 2021, the Korea Meteorological Administration (KMA) has established and operated the "Jeongseon Special Observation Station (JSTB)" within the Yemilab, dedicated to earthquake observation, research, and comprehensive seismic instrument tests. The station has been integrated into the Korea National Seismograph Network (KNSN) operated by KMA. Operating at a depth exceeding 600 meters below the surface, JSTB stands out as one of the deepest stations within the KNSN. Understanding ambient noise is crucial for assessing frequency-dependent noise levels and ensuring data quality for seismic stations. Given the variable noise sources from nearby mining and blasting activities, it becomes imperative to characterize and comprehend the background noise levels for reliable seismic signal analysis. This study employs the Probability Density Function (PDF) method developed by McNamara and Buland (2004) to analyze the background noise at JSTB. Comparisons with neighboring seismic observation stations shed light on the distinctive characteristics of this deep observation station. Daily and weekly Power Spectral Density (PSD) Probability Density Functions (PDFs) effectively highlight elevated noise levels attributable to mining activities. In contrast, when compared with PSDPDFs from nearby seismic observations, the study reveals comparable effects of typhoons on seismic noise levels among stations. Interestingly, the impact of precipitation on background noise levels at JSTB is found to be minimal.

Determining Hypocenter of recent earthquakes in South Korea using the 3D velocity structure model and Antelope DB

Yeongjae CHOI[1]*, Korea Meteorological Administration(KMA) (yeongjaee1@gmail.com)
Kyungmin Min[2], Korea Meteorological Administration(KMA)
Mikyung Choi[3], Korea Meteorological Administration(KMA)
Eunyoung Jo[4], Korea Meteorological Administration(KMA)
Sun-Cheon Park[5], Korea Meteorological Administration(KMA)

Abstract

The Korea Meteorological Administration (KMA) performs real-time earthquake monitoring and earthquake analysis using Antelope software. For estimating a hypocenter and developing the accuracy of earthquake information, it is significant to analysis the complicated seismic waveforms. The seismic propagation is affected by the medium, so the velocity structure model reflected these effect is utilized. When analyzing a hypocenter, the 1D velocity model considers only vertical change, but the 3D velocity model contemplates spatial change, not only vertical change but also horizontal change. The 3D velocity model has more regional and geological properties than the 1D velocity model, so the accuracy of the hypocenter determination is improved. The 3D velocity model is one of the results of the subsurface fault and velocity structure model project and construct to use three different surface velocity model set using ambient noise. This study utilizes NonLinLoc program that can apply the 3D velocity model and constructs a system to determine the hypocenter through Antelope Database. In this study, the earthquakes around the southern Korean Peninsula are selected with the magnitude greater than 2.0 from January, 2022 to November, 2023. The accuracy of hypocenter result using 3D velocity model is investigated through the uncertainty, and the hypocenter result using 3D velocity model is compared with the result using 1D velocity model. The difference in hypocenter is greater in the sea than in the inland. The earthquake occurred in the inland does not show significant change in epicenter, but difference in depth. It provides that the 3D velocity model has more information spatially and is more constraint than 1D velocity model. However, the earthquake occurred in the sea shows differences in both depth and epicenter. Since the uncertainty of various hypocenter determination factor for sea earthquakes exists, such as station gap, additional research is requisite to improve the result.

A Study on Earthquake Detection and Intensity Analysis Using High-Density MEMS Observation Network

EUNA PARK[1]*, Korea Meteorological Administration(KMA) (eunapark@korea.kr)
Hye-Won Lee[2], Korea Meteorological Administration(KMA)
Eui-Hong Hwang[3], Korea Meteorological Administration(KMA)
Sun-Cheon Park[4], Korea Meteorological Administration(KMA)

Abstract

Earthquake early warning(EEW) uses the difference in propagation velocity between P waves and S waves to determine the occurrence of an earthquake with P waves detected at each station. It informs the occurrence of an earthquake before the S wave, which causes damage by large shaking, arrives. The Korea Meteorological Administration(KMA) has been operating the nationwide EEW service since 2015. The best way to shorten the warning time is to increase the density of the seismic observation network. Currently, the national earthquake observation network in Korea is very dense and at an excellent level worldwide, but a denser seismic observation network has been established to give better earthquake information to the people. Since the existing fixed observation network has limitations in that the expansion cost is high and maintenance is difficult, a low-cost MEMS(Micro-Electro Mechanical Systems) sensor with a built-in accelerometer has been newly designed. A high-density seismic observation network using the MEMS sensor has been established and is being operated for research. As of February 2024, the MEMS observation network is about 5200 sensors. The earthquake detection of the MEMS observation network uses only the MEMS observation network alone and is carried out in real time. It normally determines the occurrence of an earthquake (inland earthquakes of magnitude 3.5 or greater and sea earthquakes of 4.0 or greater) that correspond to the earthquake breaking news among the earthquake notification criteria of the KMA, and determines the occurrence of an earthquake several seconds faster than the analysis of the EEW system. It is also possible to calculate detailed intensity information using MEMS sensors. The PGA(peak ground acceleration) is observed to be higher than the seismometer due to the influence of the structure because the MEMS sensor is basically installed on the wall of the building and is installed at a height of more than one floor. The PGA by observed MEMS sensors and seismometers installed at the same location were compared for the appropriate intensity combination of MEMS sensors and seismometers. In addition, we intend to prepare an optimal intensity combination plan by comparing the PGA observed on the seismometer and the PGA observed on the MEMS sensor that applied the transfer function to correct the surface amplification effect of the borehole station.

Case study on maximum seismic amplitude estimation for high-rise structures

Keun-Joo SEO[1]*, Korea Meteorological Administration (kjseo214@gmail.com)
Eui-Hong Hwang[2], Korea Meteorological Administration
Hye-Won Lee[3], Korea Meteorological Administration
Sun-Cheon Park[4], Korea Meteorological Administration

Abstract

Estimating maximum seismic amplitude is crucial for predicting earthquake damage and preparing appropriate responses. In South Korea, seismic intensity, utilized in earthquake alerts, is calculated based on the maximum ground motion. However, most individuals experience earthquake vibrations within buildings, where the structure's characteristics such as building shape, height, and construction material amplify ground vibrations. To estimate maximum amplitude experienced within structures during earthquakes, a method that utilizes ground motion data is essential. For this purpose, we employed the multi-degree-of-freedom (mDOF) model, which accounts for the nonlinear behavior of structures based on their height. This model is divided into elastic and inelastic components and was utilized to estimate amplitude ratios in upper levels of structures through simulations using various input seismic ground motions. The results of these analyses were compiled into tables presenting averages and standard deviations, thus termed as the detailed method. To validate the results of our model, seismic records were collected from accelerometers installed both at ground level and upper parts of high-rise structures. Collected data from the Ministry of the Interior and Safety (MOIS) in South Korea were gathered for domestic seismic events, primarily consisting of mid-sized earthquakes and focused on government buildings over 9 stories. To enhance the diversity of verification data, seismic information on earthquakes of varying magnitudes and structural heights was collected from international databases such as CESMD and BRI. Validation of the detailed method results revealed a significant alignment with actual amplification ratios across most datasets. However, inconsistencies were observed in cases where small earthquakes resulted in reduced seismic amplitude in the upper parts of buildings, indicating a need for further refinement. Despite these challenges, the detailed method demonstrated suitability for estimating maximum amplitude in high-rise structures during significant earthquakes. Nonetheless, future research endeavors aim to establish criteria for applying the estimation methods, particularly concerning seismic amplitude of ground motions, through comprehensive case studies.

Surface-to-borehole Site Correction: Assessing the suitability of transfer function

JeongYoon OH[1]*, Korea Meteorological Administration (ovita17@korea.kr)
Hye-Won Lee[2], Korea Meteorological Administration
Keun-Joo Seo[3], Korea Meteorological Administration
Eui-Hong Hwang[4], Korea Meteorological Administration
Sun-Cheon Park[5], Korea Meteorological Administration

Abstract

During an earthquake, the ground motion experienced by people on the surface or inside buildings results from a convolution of the earthquake source, path effect, and site effect. Even in areas situated at an equal distance from the earthquake's epicenter, ground motion may vary depending on the characteristics of the area. Therefore, it is necessary to understand the geological characteristics of the station site and to analyze the effect of site-specific conditions on seismic data.

Most of the seismic stations operated by the Korea Meteorological Administration are installed in bedrock, minimizing the impact of background noise and advantageous for earthquake detection. However, because these stations do not consider the site effect from installation depth to the surface, the ground motion of earthquakes recorded by the downhole stations is lower than those recorded by surface stations. Therefore, in order to accurately estimate the intensity of an earthquake as felt by people, prior research on correcting the borehole record based on surface observations is necessary.

The Korea Meteorological Administration applies the amplification coefficient presented in Borcherdt (1994) to correct the observed amplitude in borehole seismometers to the surface level. However, since this amplification coefficient was developed for the western United States, it may not accurately represent the regional characteristics of the Korean Peninsula. Furthermore, as proposed by Lai et al. (2022), a method has been suggested for correcting borehole earthquake data using the amplitude ratio between borehole and surface. Nevertheless, seismic data collection is challenging due to infrequent earthquakes on the Korean Peninsula and the most seismic stations are borehole-type. Accordingly, a correction technique has been developed through a transfer function, which applies background noise recorded simultaneously between borehole and surface installations by temporarily placing a seismometer on the surface (Lim and Ahn, 2023).

In this study, the transfer function method was applied to approximately one hundred borehole seismic stations, and the geological information from these borehole seismic stations was classified based on the soil classification provided by the Ministry of the Interior and Safety. Using the method proposed by Lai et al. (2022), we compared four types of seismic data: raw borehole data, borehole data corrected by applying the transfer function and site amplification model, data from a temporary surface seismometer that operated from November 2023. Additionally, station-specific averages were calculated based on the comparison results of the seismic data. Moreover, site characteristics, including bedrock depth and soil shear wave velocity,

were estimated at each borehole seismic station site.

Research on the identification of micro-seismic events in the Kangping area of Liaoning province based on random forest.

Zihao LI [1]*, Liaoning Earthquake Agency (772004380@qq.com)

Abstract

Efficient and accurate identification of earthquake occurrences is crucial for earthquake prediction and safeguarding lives and property. Presently, earthquake distinction heavily relies on manual interpretation, necessitating the development of more effective technical approaches to enhance identification accuracy. This research selected 634 Kangping mine earthquake incidents and 942 non-mine earthquake incidents in the Kangping region based on the nationwide unified catalog database. The seismic characteristics, including waveforms and spectra, were extracted to develop the Kangping mine earthquake random forest classification model (RFC). Upon training the model with optimal parameters (n_estimators=407, max_features=7), the prediction accuracy achieved 0.761954262 (Precision=0.743243243, Recall=0.949500263, F1_score=0.833805774). Subsequently, the trained RFC model was employed to differentiate and classify seismic waveform data collected by 8 stations in Liaoning Kangping and surrounding regions from 2014 to 2023 over a decade, identifying 783 previously missed microseismic events, six times the count recorded in the seismic network center's catalog. The identified missed earthquakes were precisely located, examined, and validated, exhibiting a correlation of 0.8532 with the mine earthquake incidents cataloged in the nationwide unified catalog database template. The technical approach introduced in this study effectively filters out manually misidentified mine earthquake occurrences, boosts the identification precision of mine seismic events, and offers a solid data foundation for investigating earthquake activity and seismic monitoring.

Sang-Jun Lee[6], Department of Earth Science Education, Korea National University of Education
Jan Dettmer[7], Department of Geoscience, University of Calgary

Abstract

Determining the accurate hypocenter of an earthquake is important for identifying and understanding the geological structures that caused seismic events. For this purpose, methods such as hypoDD, which analyzes the correlation between event pairs to determine their relative hypocenters, are widely used. However, determining the relative hypocenters is influenced by various factors, such as the parameters for inversion and differential time data and type of phases. We conducted a parameter tuning experiment for the double-difference relocation method to determine the relative hypocenters using the earthquakes that occurred in the Kiskatinaw area of northeastern British Columbia, Canada. The seismic activity in the Kiskatinaw area has significantly increased due to fluid injection for the development of unconventional resources since the early 2000s. We constructed an initial earthquake catalog of the Kiskatinaw area for 2020 using seismic data from the EON-ROSE and GSC-BCOGC seismic networks. We simplified the 1-D velocity model provided by the BC Energy Regulator based on the geological stratigraphy of the Kiskatinaw area and utilized it to determine the hypocenters. We detected events using an automatic algorithm based on the short-term-average to long-term-average ratio (STA/LTA) and kurtosis method. Then, we refined the phase arrival times through visual inspection and determined absolute hypocenters of the detected events using the Hypoinverse location algorithm. We used the hypoDD algorithm to relocate the relative hypocenters of the initial event catalog. To minutely refine the relative hypocenters, we tried to optimize the parameters for inversion and those for differential time data and type of phases. The parameters of clustering did not significantly influence the location determination, whereas parameters for the inversion affected the number of earthquakes and hypocenters. Using both P and S phases for relocation can better constrain the hypocenter than using either one. Cross-correlation analysis of waveforms is also more effective in determining relative location than using phase-picking results. By considering these factors in the input information, we can expect more concentrated relative location results at the depth where the fluid injection is most active for most events. However, the variation in these input parameters did not significantly affect the relative locations in this study. Instead, modifying the weighting parameters had a greater impact on the results. This occurrence can be explained by the accuracy of the input data utilized in this study rather than being a general characteristic of all

relative location studies. In other words, this study highlights the high accuracy of the phase-picking results obtained through preliminary analysis. This finding suggests that when using phase-picking data with verified sufficient accuracy, optimizing the weighting parameters used in a relative location study is more important than optimizing the parameters related to the input data themselves.

Tracking Typhoon Hinnamnor (2022) using microseism recorded at CTBTO seismic array

Yunah KIM[1]*, Chonnam National University (kyuna@jnu.ac.kr)
Dong-Hoon Sheen[2], Chonnam National University

Abstract

Typhoons in the ocean create ocean waves, and the energy of the ocean waves generates microseisms. Secondary microseism (SM) or double frequency microseism is known to be generated by nonlinear interaction between opposite ocean waves with similar wavenumbers (Longuet-Higgins, 1950), and SM generated by typhoons can be categorized into three classes according to their generation mechanism (Ardhuin et al., 2012). The source region of SMs generated by typhoons changes with the movement of the typhoon. Therefore, SMs can be used to track the path of the typhoon. In this study, we tracked the path of Typhoon Hinnamnor which developed in the Pacific Ocean from August 27 to September 06, 2022, using microseisms. SMs generated by Typhoon Hinnamnor were observed at coastal and island seismic stations near the typhoon's track, as well as at the Comprehensive Nuclear-Test-Ban Treaty Organization (CTBTO) seismic arrays in Asia and Australia, which are far from the track. We investigated the variations in the power spectral density of SMs and compared them to significant wave heights from Wave Watch III. The back azimuth of SM was obtained from frequency-wavenumber analysis of CTBTO seismic arrays (PETK, SONM, USRK, KSRS, MJAR, LZDM, CMAR, WRA) in the frequency band of 0.1 - 0.5 Hz, where the spectral energy of the SM was clearly visible, which was used to track the source region of the SM using a triangulation method. Then we compared the estimated source region of the SM with the best track of Typhoon Hinnamnor provided by the Joint Typhoon Warning Center (JTWC).

Estimating Moment Magnitudes of Certain South Korean Macroseismic Events

SUNGSU KIM[1]*, KEPCO International Nuclear Graduate School (suya917@naver.com)
Yee Eric[2], KEPCO International Nuclear Graduate School

Abstract

The Korean peninsula is one of the few regions in the world that has a written record of macroseismic events since the beginning of the first millennium. These events were compiled by the Korea Meteorological Administration and released as a publication log. Surprisingly, for a somewhat seismically stable region, the records show there have been several large magnitude earthquakes throughout the past two millennia. To better understand, and perhaps, constrain the seismicity in the region, an estimate of earthquake magnitudes from the macroseismic events as published the Korea Meteorological Administration would be needed. These magnitudes are estimated by comparing the macroseismic events to more modern instrument recorded earthquake events. These modern events have been locally recorded by the Korea Meteorological Administration as well as other international seismological agencies such as the Global Centroid Moment Tensor project. Preliminary results suggest that several older macroseismic events in the southern portion of the Korean peninsula displayed intensity measures larger than those exhibited by the more recent M 5.5 events, i.e. the 2016 Gyeongju and 2017 Pohang earthquakes. This would mark these earthquakes as events with magnitudes larger than M 5.5. Additionally, other factors being constant, this suggests the region is capable of producing events larger than M 5.5.

Seismicity in the South Korean Region Across Two Millennia

SEUNGHEE YUN[1]*, Kepco International Nuclear Graduate School (yshjjjj@gmail.com)
YEE ERIC[2], Kepco International Nuclear Graduate School

Abstract

The seismic events in South Korea have sparked concerns about the region's seismicity, prompting a closer examination of historical earthquake data. Continued research and monitoring are essential for improving understanding and preparedness for seismic risks in the area. Due to important infrastructure, such as nuclear power plants and radioactive waste storage facilities, two specific events, the 2016 M5.5 Gyeongju and 2017 M5.5 Pohang earthquakes, have forced many to question the seismicity of the Korean peninsula. This is because prior to these events, few earthquakes with magnitude greater than M5.0 were recorded in South Korea. However, the time period of recorded events can be extended to get a better picture of the seismicity along the Korean peninsula. The Korea Meteorological Administration compiled a list of macroseismic events from 2 A.D. to 1904, and published the results as a log. This underutilized data source is combined with events from 1900 to present as recorded by the Korea Meteorological Administration, International Seismological Center, and Global Centroid Moment Tensor project to extend the earthquake catalog for South Korea. When evaluating this compiled data set via the Gutenberg-Richter law, we observe a difference in seismicity within South Korea. Results imply slightly higher levels of seismicity before 1900 and thus an overall increase in seismicity parameters considering two millennia.

Comparing Acceleration and Velocity Horizontal-To-Vertical Spectral Ratios at South Korean Sites

Youngtaek HONG[1]*, KEPCO International Nuclear Graduate School (KINGS)
(hyt730@naver.com)
Yee Eric[2], Kepco International Graduate School

Abstract

The shear wave velocity of the upper 30 m of earth materials is a common parameter in understanding site-specific properties. This parameter is used in a variety of earthquake risk and seismological studies. One approach used to help estimate the shear wave velocity is the Horizontal-To-Vertical Spectral Ratio method. This method compares the ratio of vertical and horizontal response spectra to response spectra frequency. If there is a peak frequency, it is used to estimate a shear wave velocity for the site-specific materials. Typically, acceleration response spectra is used in this method. However, sometimes a peak cannot be identified and there is some curiosity as to whether using velocity response spectra may be a better as it would imply a velocity-to-velocity comparison. Site and ground motion data are obtained from the Korea Institute of Geoscience and Mineral Resources. Results show that there is a lack of local site-specific shear wave velocity data. Nonetheless, of the sites with both shear wave velocity and ground motion data, there did not appear to be a significant difference when acceleration or velocity response spectra were applied for a majority of the sites. An interesting observation was that for sites with similar shear wave velocities, the actual value of the Horizontal-To-Vertical Spectral Ratios were not the same in an absolute sense, but did produce peaks at similar frequencies.

Comparing South Korean Earthquakes to Next Generation Attenuation West Ground Motion Models

Jungho KIM[1]*, KEPCO International Nuclear Graduate School (wbforever012@naver.com)
Yee Eric[2], KEPCO International Nuclear Graduate School

Abstract

For Seismic and earthquake risk studies, there have been few robust ground motion models dedicated to the South Korean peninsula. However, there have been many ground motion models developed around the world throughout the years. Some of the relatively more robust ground motion models have come from the Next Generation Attenuation West program at the Pacific Earthquake Engineering Research Center in the U.S.A. These ground motion models estimated ground motion shaking by correlating intensity measures to variables such as earthquake magnitude, distance, faulting mechanism, mean shear wave velocity in the upper 30m, as well as several others depending on the model developers. The ground motion models from the first rendition were released in 2008 and have proven to be slightly unique over time. These ground motion models estimated intensity measures using the geometric mean from the rotation of two horizontal axes, which fell out of favor due to specific calculation and directionality issues. The current method relies on rotation of one horizontal axis. An investigation on the performance of the 2008 versions of the ground motion models from the Next Generation Attenuation West program is made by analyzing the residuals from several recent South Koreans of moderate magnitude. Results suggest significant variation at close and far distances, but surprisingly acceptable performance at moderate distances. However, results also showed the differences between modern estimations of intensity measures from the original 2008 suite to be more than expected. These suggest that although the ground motion models from the 2008 version of the Next Generation Attenuation West program can be applicable to South Korea even though the base tectonic regime is different.

Comparing Peak Frequency to Shear Wave Velocity Models in South Korea

Joohwan CHA[1]*, KEPCO International Nuclear Graduate School (cha480@naver.com)
Yee Eric[2], KEPCO International Nuclear Graduate School

Abstract

To better understand subsurface material properties, a variety of physical testing and analysis techniques have been developed over the years. One such technique involves relating the mean shear wave velocity of the earth materials in the upper 30 m to a site-specific peak frequency. If not directly measured, these peak frequencies can be estimated using a horizontal-to-vertical spectral ratio method. The horizontal-to-vertical spectral ratio is typically calculated as the ratio of the vertical response spectra to the horizontal response spectra. Response spectra are derived from ground motions at the site. For this study, horizontal-to-vertical spectral ratios are estimated using several South Korean earthquake ground motions recorded by the Korea Institute of Geoscience and Mineral Resources. Along with the spectral ratio derived peak frequencies, the corresponding field measured shallow shear wave velocities are compiled to form a dataset for comparison. This dataset is compared to several methods developed for global use. Results show that there is a lack of local site-specific shear wave velocity data overall. There are also difficulties in identifying a peak frequency in several sites using these Horizontal-To-Vertical Spectral Ratio models and even when working the results are scattered. Additionally the global model did not perform as well, but a model based on central and eastern North America did well.

New insights of seismicity and stress pattern from the dense temporary deployment network in Anker, Kunene Region, Namibia

Bufelo Lushetile[1]*, Geological Survey of Namibia (Bufelo.Lushetile@mme.gov.na)
Azangi Mangongolo[2], GEO4D Consultancy

Abstract

The monitoring of seismic activity in the Anker settlement was initiated in May 2018 after the Anker community reported an increase of seismic events in the area. Between the months of March and May 2018, five (5) significant earthquake events were recorded on the National Seismological Network in the Kunene Region with local magnitudes (ML) ranging from 4.0 to 4.6 ML. This write-up provides an update based on the continued processing and analysis of data from the temporary seismic stations deployed around Anker settlement. The temporal seismic stations were deployed for a period of one year from November 2021 to December 2022. The Deep Learning method was used as huge amount of data was acquired. The Deep Learning successfully picked P and S wave arrivals that were used for subsequent processing for location and moment tensors. Picks having probability higher than 0.6 to mimic the model were used. 27603 earthquakes from Ml 0 to 4.6 were located, with depth ranging from 0 to 22 km. The epicentres were aligned in an NNW-SSE direction which is the prolongation like of the eastern part of the Kaoko Belt. Few epicentres were aligned along the NE-SW direction which is believed to be associated with the Northern Damara Belt. The biggest epicentral cluster is located in Anker along a structural line. In the vicinity of Anker, three major structural lines can also be identified: two faults and magnetic lineament. 5047 moment tensors were obtained: 1061 of normal faulting type, 998 of strike slip right lateral type, 903 of strike slip left lateral type, 935 of thrust/reverse type, and the rest was of oblique normal or reverse type. Results of the focal mechanism showed NNW-SSE direction of the principal stresses as well as Thrust and Strike Slip faulting types surrounding Normal faulting type. This means, the area has a complex stress regime characterised by extensions compensated by a small amount of compression in the middle. The NNW-SSE extension regime coincides with the NNW-SSE trending of the Kaoko Belt. The reverse/thrust regime expresses the N-S horizontal contraction.

Stratigraphic Analysis of Regressive Erosion in the Upper Coca River Basin: Insights from Seismic Imaging and Field Data

Isabel Cristina Garcia[1], Universidad Regional Amazónica Ikiam
Christian Wladimir ROMERO CÓNDOR[2]*, INSTITUTO DE INVESTIGACIÓN GEOLÓGICO Y ENERGÉTICO (criscescz@gmail.com)
Jóse Sebastían Araujo[3], Universidad Regional Amazónica Ikiam

Abstract

The phenomenon of regressive erosion in the upper basin of the Coca River was characterized by rapid erosion velocity and a high rate of undercutting. Previous researchers have studied this phenomenon from morphological and hydrological aspects; however, sedimentological and stratigraphic parameters still need to be reported. The main objective of this research is to analyze the geometry of the depocenter of the Coca River Basin from tomographic images and stratigraphic sections (field data). We use seismic data from RENSIG. We used INSIGHT software for the tomography results for the P-wave velocity model in two models of 50° and 0°.
From this perspective, this research applies a combination of seismic and stratigraphic techniques to establish the geometry of the paleo-basin, relative thicknesses, and the geographical position of the depocenter. Seismic images reveal that the basin exhibits a regular elongated concave geometry, elongated in the NE-SW direction. The thickness of the basin fill sequences averages 800 m. Field data indicate that the fill consists of five first-order sequences, including lava flows and pyroclastic deposits linked to the construction history of the El Reventador volcano, as well as fluvial-lacustrine deposits associated with the fluvial dynamics of the Coca River. The thickness of the sequences, observed through morphological field observations and measured in seismic images, suggests that the depocenter of the basin is located northeast of San Luis. The development of sub-vertical slopes on the flanks of the Coca River, attributed to fluvial erosion, is directly related to the lithology and thickness of the depocenter.

Focal mechanisms of earthquakes in the Korean Peninsula based on P-wave first-motion polarity determination using deep learning

Ah-Hyun BYUN[1]*, Korea Meteorological Administration (ahyun0809@korea.kr)
Mikyung CHOI[2], Korea Meteorological Administration
Kyungmin MIN[3], Korea Meteorological Administration
Eunyoung JO[4], Korea Meteorological Administration
Sun-Cheon PARK[5], Korea Meteorological Administration

Abstract

The focal mechanism of earthquakes is usually obtained by using P wave first-motion polarities. In order to accurately determine the focal mechanism of an earthquake, sufficient numbers of reliable P-wave first-motion polarities are required. Recently, deep learning techniques that can learn inherent features in the data have been widely used in various fields, and various studies based on deep learning techniques are also being proposed in the field of seismology. Deep learning techniques for identifying P-wave first-motion polarity are also being introduced. In this study, we developed a procedure that can automatically determine the focal mechanism of earthquakes using a deep learning model for P-wave first-motion polarity identification trained using global and local seismic data.

Deep neural network models were trained using data from the Southern California region and local earthquake data from South Korea. The Southern California data is the same data used in Ross et al. (2018), which consists of about 2.5 million local earthquake data and P-wave first-motion polarity information. P-wave first-motion polarities of local data was manually identified from seismograms of earthquakes of magnitude 2.0 or greater that occurred in the Korean peninsula between 2017 and 2020, and a total number of local training data was about 30,000. In this study, the VGG16 model structure was tested, and the neural networks were configured to identify P-wave first-motion polarity using 2.56-second-long vertical component earthquake waveform as the input. A base trained model was obtained using the Southern California dataset and improved by fine-tuning with relatively small amount of local dataset.

The performance of the trained neural network model was evaluated using global and local earthquake data that were not used in the training. The performance of the base trained model was measured to have an average precision of about 96 % and that of the fine-tuned model was improved to an average precision of 98 %. For Japanese earthquake data, the fine-tuned model performed with a very high precision of about 99%.

We are currently testing the applicability of the P-wave first-motion polarity identification model developed in this study to earthquakes of occurring on the Korean Peninsula.

Mehmet Safa ARSLAN[5], Istanbul University-Cerrahpasa, Geophysical Engineering Department, Büyükçekmece, Istanbul

Abstract

Rupture zones of active faults in the near-surface are studied widely for engineering purposes, and for paleoseismic studies to reveal parameters of past events and to provide more precise future hazard estimations. Detection of rupture zones presents a challenge when they are buried and become invisible from the surface. Geophysics provides numerous methods to image near-surface structures in detail. Among these, Electrical Resistivity Tomography (ERT) and VLF-R methods are applied to image the subsurface by the means of electrical resistivity. Models representing the subsurface resistivity distribution are recovered by the interpretation of collected data using a mathematical algorithm called "inversion".

Fluid distribution is known to be one of the major factors affecting the electrical resistivity structure in the subsurface causing significant anomalies in ERT and VLF-R measurements. Faults often interact with the fluids by acting as conduits or barriers, revealing themselves as strong conductors for the first case or causing fluid accumulations at one side for the latter. Horizontal and vertical movements caused by the fault slip also shifts geological units with different fluid contents.

We investigated the buried surface rupture of the 17 August 1999 (Mw = 7.4) earthquake on the North Anatolian Fault using ERT and VLF-R methods comparatively and in a complementary way to determine the location of the rupture and to test a new regularization scheme to improve VLF-R inversion results. The recovered resistivity models of the subsurface using both methods reveals the now buried rupture of the NAFZ and suggests that the non-permeable clayey fills in the rupture are causing the fault to act as a barrier accumulating meteorological waters in the north.

Detection of buried faults: a case study at the north end of the Miryang Fault, southeastern Korean Peninsula

Lanbo Liu[1]*, Pusan National University (lanboliu77@gmail.com)
Fei Peng[2], China Earthquake Administration
Su Young Kang[3], Pusan National University
Young-cheol Lee[4], Pusan National University
Kwanghee Kim[5], Pusan National University

Abstract

We present the results of a seismic investigation aimed to characterize the structure of shallow formation stratigraphy across an area believed to be in the vicinity of the north tip of the Miryang Fault in the Geoncheon Valley, Gyeongju City, Republic of Korea. The Miryang Fault is a major branch of the Yangsan Fault system in the Gyeongsang Basin, southeastern Korean Peninsula. Despite local earthquake records showing scattered micro-seismicity along the surface expression of the fault, other geophysical and geological information are relatively rare. The location of the Geoncheon Valley is tectonically critical: it is on the borderline that separates a major part of the Gyeongsang Basin into two sub basins: the Miryang Basin (formed by late Cretaceous Yucheon Group) to the south and the Euiseong Basin (formed by the early Cretaceous Hayang group) to the north. Consequently, this special tectonic setting poses the following questions: First, is the Miryang Fault terminated in the Geoncheon Valley? Second, if the fault is terminated in the valley, what is the type of tip damage zones of the right- lateral strike-slip Miryang Fault?

The surface expression of the Miryang Fault in this area is difficult to define due to surface morphology of highly cultivated rice lands. Integrated seismic exploration is an effective solution to locate subsurface structures where surface geomorphological evidence is inconclusive to define fault structures. On a 1200-m long linear profile we deployed a dense array using 3-component seismic sensors and acquired both passive and active seismic data. The passive seismic data acquisition lasted about 12 days. At the end of the deployment period directly before withdrawing the array, an active survey using sledgehammer source. The integrated seismic profile displays significant segmentation of the texture of the seismic image, the sediment-bedrock interface is between several meters to a bit greater than 20 meters with a general trend of dipping to the southeast. The preliminary seismic results suggest that it is likely the Miryang fault is terminated inside the Geoncheon Valley, with a high likelihood of horsetail splay type of tip damage zone. We will validate this preliminary recognition with more geophysical data acquisition and analysis including ERT and gravity surveys.

Structural characterization of intracratonic strike-slip faults in the southern Oridos Basin

Yunwen GUAN[1]*, NorthWest University(China) (gynw_6@163.com)

Abstract

In the southern Ordos Basin, China, a series of small-scale strike-slip faults have been observed, with their scale differing by several orders of magnitude from the plate-boundary strike-slip faults. This paper analyzes the geometric and kinematic characteristics of the intracratonic strike-slip faults in the southern Ordos Basin, based on high-accuracy 3D seismic data. The formation and evolution are deeply discussed through geological and structural settings. The results obtained by this study show that the small-scale strike-slip faults in the research area have undergone multiple stages of tectonic evolution, exhibiting complex structural features. Braided, horsetail, feather, flower structures and Riedel within Riedel Structures are observed, with differential activation observed in plan view and cross-section view, respectively. This fully demonstrates that the control exerted by tectonic stress direction and the angle between pre-existing faults on fault movement varies.In addition, the extension and lateral linkage growth pattern of intracratonic strike-slip faults are also evident in this region. The terminations of strike-slip faults typically arc outward, gradually connecting with other fault terminations as they expand, resulting in a gradual decrease in fault spacing. This research enhances understanding of the development characteristics of intracratonic strike-slip faults and enriches the development patterns and mechanisms of strike-slip faults in intraplate structural transition zones of small blocks and multi-cycle basins.

GPR detection of buried paleo-channel through unconsolidated layer and characterization of the channel fill

Takao KOBAYASHI[1]*, Korea Institute of Geoscience and Mineral Resources (tak@kigam.re.kr)
Changwan Sun[2], Geological science, KIGAM School, University of Science and Technology
Jin-Hyuch Choi[3], Korea Institute of Geoscience and Mineral Resources

Abstract

Observation of surface terrain around an active fault helps to better understand the nature of the fault. Stream channel is one of surface terrain features that provides valuable information regarding fault.

We conducted Ground Penetrating Radar (GPR) survey over a fault which is a part of Yang-san fault system, South Korea, for a purpose of defining the paleo-surface around the target fault, and detected a paleo-channel buried under an unconsolidated layer.

A 2-D (multiple-line) GPR survey was conducted to obtain 3D information of subsurface structure. The survey area was as wide as 10 m X 20 m. The survey line interval was 0.5 m whereas the measurement point interval was 0.5 m.

GPR measurement was done with 40 MHz antennas. All the measurement data were processed to produce a 3-D instantaneous power grid data set. We studied the data through visual inspection to define paleo-horizon, and found paleo-channel signals.

The paleo-channel appeared to have an oval shape in the GPR instantaneous power vertical cross section image, and showed a band-like shape on a horizontal slice image, implying a flow area, at a depth of ~1 m (assuming relative permittivity of 16). Ground truth trench work found the U-shape of the paleo-channel gouging on the paleo-surface, hence confirmed the GPR survey result.

Furthermore, we conducted a real scale Finite Difference Time Domain (FD-TD) simulation to examine if there is any influence of the filling material of the paleo-channel on the GPR image appearance. This examination led to an interesting result that the relative permittivity difference of the filling material and the paleo-surface material result in difference of instantaneous power signals of the two media materials: If paleo-channel fill has a larger permittivity than that of the paleo-surface material, the paleo-channel signal instantaneous power is smaller than that of the paleo-surface, and vice-versa. The result implies that the paleo-channel fill of this study has smaller permittivity than that of the paleo-surface material. The smaller permittivity is due to typically large porosity of the filling material. This was confirmed by the observation of the trench cross section of the paleo-channel.

Buried Geomorphic Signatures of Paleo-Earthquakes Detected by 3D GPR survey and Trench Analysis: A Case Study of the Yangsan Fault, South Korea

Changwan SUN[1]*, Geological science, KIGAM School, University of Science and Technology (csun@kigam.re.kr)
Jin-Hyuck Choi[2], Geological science, KIGAM School, University of Science and Technology / Active Tectonics Research Center, Geologic Hazards Division, Korea Institute of Geoscience and Mineral Resources
Takao Kobayashi [3], Active Tectonics Research Center, Geologic Hazards Division, Korea Institute of Geoscience and Mineral Resources
Yire Choi[4], Active Tectonics Research Center, Geologic Hazards Division, Korea Institute of Geoscience and Mineral Resources

Abstract

Near-surface geophysical techniques have been used as important tools in paleo-seismological research. Particularly, in the intraplate regions, they are able to uncover the records of the surface faulting buried by the unconsolidated sedimentary deposit. This study conducts three-dimensional Ground Penetrating Radar (GPR) survey coupled with the multiple-trench surveys to investigate geomorphic features which are related to paleo-earthquakes of the Yangsan Fault, S. Korea, that is located in an intracontinental setting. The research site is the Miho area, of which a previous study had reported geologic records of paleo-seismological event. We conducted GPR surveys in an area of 20 m x 20 m over a fault with using 40 MHz unshielded antennas and acquired 21 GPR profile data of 20 m long parallel to the fault. Additionally, we conducted trench works for a purpose of "ground truthing": 4 trenches intersecting the fault and 6 trenches being parallel to the fault were excavated in an area of 20 m x 30 m that covers the GPR survey area. Three-dimensional GPR results revealed different slopes of unconformities parallel to the fault on its both sides. The findings from a series of trenches represented that the local slope of the unconformity parallel to the fault had sudden variation, and that their stratigraphic and geochronological assessment facilitated how the sag pond and the colluvial wedge behaved during the earthquake event. Such geomorphic indicators are interpreted as results of along-strike variations in the vertical separation on the right-lateral earthquake surface rupture. This case study shows how valuable it is to analyze the geomorphic features related to paleo-earthquakes through three-dimensional geophysical exploration of GPR with multiple trenches.

Geophysical investigation using ERT and MASW surveys at the Quaternary faults along the Yangsan fault system, SE Korea

Hwanwoo SEO[1]*, Ulsan National Institute of Science and Technology (UNIST)
(hwanwooseo@unist.ac.kr)
Jeong-Ryul CHOI[2], Chungnam Nationa University
Seung-Sep KIM[3], Chungnam Nationa University
Byungmin KIM[4], Ulsan National Institute of Science and Technology

Abstract

This study aims to assess the reliability of the results obtained from the two geophysical surveys (Electrical resistivity tomography (ERT) and multi-channel analysis of surface waves (MASW)) in areas where the Quaternary faults have been observed. Furthermore, we evaluate the applicability of the two surveys for fault detection. We conduct the ERT and MASW surveys at the five sites (Site 1: Bogyeongsa area in Pohang; Site 2: Manseok-ri 64 in Pohang; Site 3: Nangsu-ri 184-2 in Pohang; Site 4: Nangsu-ri 113 in Pohang; Site 5: Bangi-ri 65-2 in Ulsan) along the Yangsan fault system in southeastern Korean Peninsula. Through these non-invasive surveys, we estimate the electrical resistivity and shear wave velocity of the subsurface and identify zones with relatively low resistivity and shear wave velocity at each site. These anomaly zones might be attributed to a fault anomaly or fracture zone. We also compare the thickness of the Quaternary sediments as determined from the boring test and the MASW survey, and they are consistent with each other. Based on the results of the geophysical surveys and trench excavations, we provide comprehensive analyses up to a depth of approximately 25 m. This study demonstrates the usefulness of the ERT and MASW surveys for fault detection by identifying anomaly zones and suggests their applicability for tracing faults in urban areas where trench excavation is challenging.

3D Imaging of Fault Fracture Zones using Electrical Resistivity Survey

Samgyu PARK[1]*, Korea Institute of Geoscience and Mineral Resources (samgyu@kigam.re.kr)
Jin-Hyuck Choi[2], Korea Institute of Geoscience and Mineral Resources
Youngbeom Cheon[3], Korea Institute of Geoscience and Mineral Resources

Abstract

During the active fault investigation process, trench surveys are vital for conducting paleoseismological research. Since most trench survey sites are buried with unconsolidated sediments, geophysical exploration technology is used to select suitable locations. In Korea, 2D electrical resistivity surveys are commonly employed for this purpose. Because the ground resistivity is influenced by various factors such as rock type, porosity, weathering, water saturation, pore water conductivity, and clay contents, fault fracture zones typically show lower resistivity compared to their surroundings. In this study, a 3D electrical resistivity survey was conducted in the field to visualize a fault zone characterized by linear geological structures, and its effectiveness was evaluated. The survey site includes a Quaternary fault located south of the Yangsan Fault and a granite-based fault positioned northeast of the Gongju Fault, both previously confirmed as active faults through trench surveys. To create a 3D image of the fault fracture zone, a rectangular area with horizontal and vertical lengths of 27 m was established. Fourteen survey lines were set at 2 m intervals horizontally, while eight survey lines were positioned at 4 m intervals vertically. The electrode array used a dipole-dipole configuration, with field data collected at an electrode spacing of 1 m and a survey line length of 27 m. The DC_3DPRO inversion program developed by KIGAM was employed to calculate the 3D resistivity model using the field-acquired data. Upon comparing the block diagram of the 3D resistivity distribution and depth-specific slices with the trench logs, it was observed that the ground resistivity accurately represented the geological characteristics of the fault zone. This facilitated a comprehensive understanding of the spatially geological structure, including the fault fracture zone.

Utilizing Electrical Resistivity Method to Characterize Buried Faults in Suhari, Hong-Cheon, South

Jeong-Ryul CHOI[1]*, Chungnam National University (ddolbong@cnu.ac.kr)
Seung-Sep Kim[2], Chungnam National University
Youngboem Cheon[3], Korea institute of Geoscience and Mineral Resources

Abstract

Prior to 2017, South Korea lacked a systematic, government-level investigation of Quaternary active faults. However, following the consecutive occurrences of the 2016 Gyeong-ju and 2017 Pohang earthquakes, the urgency for research on the distribution and activity of Quaternary faults on the Korean Peninsula became apparent, triggering proactive research endeavors. Such investigations aim to evaluate seismic disasters and risks, crucial for identifying high-risk areas and ensuring the safety of critical infrastructure. Employing interdisciplinary methods including remote sensing, geophysical exploration, and trench investigation, researchers aim to delineate Quaternary faults. Trench investigation plays a pivotal role in confirming fault cross-sections obscured by unconsolidated sediment layers, crucial for understanding seismic activity timing along fault planes. However, relying solely on this point-based survey method presents limitations in determining the spatial connectivity of buried faults. To overcome uncertainties in tracing the extension of buried faults, near-surface geophysical exploration techniques such as electrical resistivity tomography (ERT) prove invaluable. ERT effectively images geological structures and faulted strata by reflecting fundamental physical properties of the rock matrix. Particularly in regions characterized by fault fracture zones or weathered strata, ERT reveals low electrical resistivity values attributed to increased clay minerals and water content resulting from weathering and fracturing processes. In this study, ERT was employed around a fault identified through trench investigation in the Suhari area of Hongcheon, Gangwon-do, to trace the extension of the buried fault. Post-processing and correction of collected ERT data generated detailed images of underground structures, revealing anomalous patterns associated with faults near the trench site. The trench investigation conclusively verified the fault's presence, discerned through sharp transitions between high and low resistivity values in ERT sections. Furthermore, the alignment of low resistivity anomalies in the southern study area followed a north-northeast direction, whereas those in the northern area exhibited a north-northwest alignment. 3D inversion results corroborated the fault's orientation predominantly aligning with the north-northeast direction, characterized by a distinct lineament of low resistivity. Integrating the trench survey's identified fault direction with ERT results confirmed the efficacy of this method in imaging buried faults and tracing their extensions.

Peering Through Sediments: Ground-Penetrating Radar Mapping of the Yangsan Fault

Hak Min LEE[1]*, Chungnam National University (hakmin2379@cnu.ac.kr)
Seung-Sep Kim[2], Chungnam National University
Jeong-Ryul Choi[3], Chungnam National University

Abstract

Traditional fault characterization methods involve a combination of survey techniques to provide comprehensive insights into fault structures and zones. Typically, the initial phase employs airborne LiDAR surveys to detect fault lineaments. Subsequently, trench surveys or boreholes are deployed to validate assumptions, often supported by isotopic dating of obtained samples near fault zones. Geophysical methods, such as Ground-Penetrating Radar (GPR), are pivotal for subsurface imaging, offering high-resolution data acquisition. In this study, we applied the GPR method to image unconsolidated sediment structures within the Yangsan fault area. Utilizing the PulseEKKO Pro GPR system with a 50 MHz antenna frequency ensured adequate penetration depth. To optimize signal quality, the UltraReceiver augmented recordings to enhance the signal-to-noise ratio. Accurate positioning was achieved through RTK GPS system integration, enhancing data reliability. Notably, GPR data often suffer from attenuation and noise interference. To mitigate these issues, we employed an f-k filter alongside de-wow, band-pass, and background subtraction filters for comprehensive post-processing. Characteristic GPR signals indicative of fault structures, such as discontinuities in radargrams resembling displaced strata, were consistently observed along the Yangsan Fault. Additionally, these discontinuities were noted proximal to river terraces, highlighting landforms affected by fault movement. Low amplitudes and chaotic reflection signals further suggested historical subsurface strata movements. To bolster interpretive confidence, Electrical Resistivity Tomography (ERT) data were concurrently collected along survey lines. Remarkably, anomalous zones delineating fault planes were consistently identified in both datasets, augmenting interpretive robustness. In conclusion, our findings underscore the efficacy of the GPR method in fault movement tracing, facilitated by effective noise suppression through the f-k filtering method. This integrated approach not only enhances understanding of subsurface fault dynamics but also underscores the importance of multi-physics data fusion for comprehensive fault characterization.

Understanding the subsurface structure of Bukpyeong Basin through 2-D electrical resistivity survey

WooHyun Kim[1]*, Pusan National University (1030banana@pusan.ac.kr)
Hanjin CHOE[2], Pusan National University
Kwang-Hee KIM[3], Pusan National University

Abstract

The Bukpyeong Basin, located in southeastern Gangwon Province, South Korea, is a sedimentary basin formed in the late Miocene. A May 2023 earthquake (M4.5) off the east coast of Donghae-si highlighted the potential for natural disasters in this area. To understand the subsurface structure of the basin and its surrounding tectonic environment, we conducted various ground geophysical surveys. We compared 2-D electrical resistivity tomography (ERT) and Horizontal Vertical Spectral Ratio Analysis (HVSR) to investigate the consistency between the two datasets and estimate the thickness variations of the unconsolidated sediments in the basin. The results showed similar depth variations in both datasets. The northern ERT image revealed a thicker sedimentary section at the hanging wall bordering the fault line, indicating a normal fault structure. In contrast, the southern ERT image displayed a shallower sediment layer, suggesting a reverse fault structure. By analyzing the ERT images, we delineated a possible fault line trending NW-SE. The HVSR results corroborated this interpretation, with thicker sediments deposited northeast of the fault line and thinner sediments on the southwest side. This suggests a higher stress environment in the southern part of the hanging wall compared to the north, potentially causing the rotation of the tectonic block. The formation of a reverse fault and basin evolution likely resulted from compressional forces and sedimentation, possibly indicative of a piggyback basin. However, due to limited data, additional geophysical surveys are necessary. This study aimed to improve our understanding of the Bukpyeong Basin's subsurface structure, which can provide valuable insights into the mechanisms of earthquakes and related hazards in the surrounding area.

A top-down control on upper crustal inheritance on the south-eastern Tibetan Plateau

Kun ZHANG[1]*, Chinese Academy of Geological Sciences (zhangkun1010@163.com)

Abstract

Mantle tectonics, such as asthenospheric upwelling, usually controls subsequent fluid formation and migration from deep to shallow levels in the lower lithosphere and promotes rock failure and deformation, especially in southeastern Tibetan Plateau. Some models have proposed that lithospheric shearing and lower-crustal flow have controlled the crustal deformation in the Cenozoic. However, crustal rotation models show less possibility of a channel flow and relate the crustal deformation to the remote effect of India-Asia collision. Based on the concept whereby the fluid migration location defines the structural inheritance, we aim to relate crustal processes to mantle tectonics using fluids revealed by a new dense magnetotelluric (MT) array across the Ailao Shan-Red River belt with high quality, investigating above hypotheses. The 3D resistivity model of the study area reveals notable variations in the electrical property throughout the lithosphere. The lithosphere is interpreted to have been divided into two horizontal systems by a fluid diffusion layer at the bottom of upper crust, indicating a transition zone. In the lower lithosphere, two prominent near-vertical conductive regions are revealed and determined as consistent with the Dian-Qiong (DQ) suture and Song Da (SD) belt. These resistivity lows, which have spread at the bottom of upper crust, are inferred due to partial melting of deep lithosphere and reworking of the paleo sutures (DQ and SD) in the Late Cenozoic, because surface potassic magmatism in our study region was enabled by partial melting in the lower lithosphere. Therefore, fluid migration is considered to generate a transition zone featured by low-viscosity conductivity, which is inferred feeding by aqueous and melt fluids originating from the two channels and diffusing at depths from 15-20 km. Rather than the channel flow, this fluid migration process sensitively reflected in our model relates the mantle tectonics to crustal rotation by providing rheological conditions. We, hence, propose an inherited structure model featured by vertical mantle tectonic and upper-crustal translation-rotation that may occur before the major strike-slip event. The lithospheric transition zone could have provided convenience to induce the entirely upper crustal translation-rotation. The upper crust may move southwards and rotate clockwise, with respect to the lower part of the lithosphere, which is consistent with the surface geological and petrological observations to the north of our study region. Moreover, this transition-rotation process may have occurred within the time interval between potassic magmatism and strike-slip of the RRF (34-31 Ma), constrained by the geochronology results and duration estimation of shear zone by electrical model and energy equation. This translation-rotation process is inherited from the underlying mantle processes and may further be remotely affected by the upper crustal movement of the Tibetan Plateau, conforming with the mechanism interpretation of crustal rotation observed to the north of our study region. Furthermore, the crustal translation-rotation may also control the inherited strike-slip event in our study region.

[Keynote] Pacific Array: an observational effort to find a link between the deep mantle process and surface features of the Pacific Basin

Hisashi UTADA[1]*, Earthquake Research Institute, University of Tokyo (utada@eri.u-tokyo.ac.jp)

Abstract

There is an apparent contrast between the eastern and western parts of the Pacific basin. For example, the eastern part exhibits a systematic deepening of seafloor depth depending on the age that can be explained by a simple cooling of the oceanic lithosphere, while the seafloor depth of the western part is almost independent on age. The bathymetric variation is smooth in the eastern part, while a lot of sea mounts and LIPs are distributed in the western part. Although such contrasting features were known since long time ago, the mechanism is still a matter of controversy. A well-known plate cooling model explains the flattening of the old seafloor such as we see in the western Pacific, in which development of small-scale convection below older lithosphere is regarded as one of the most plausible mechanisms. If we accept such a scenario, it means that seafloor flattening has nothing to do with the topographic contrast because volcanism in the western Pacific is an ancient event. Volcanism that created seamounts and Lips was active when the lithosphere was young, and ceased 90~100 Myr ago. The seafloor is flat in the western Pacific owing to extra heating below the currently old lithosphere. Are these two asymmetric features really independent? There is a general consensus that knowledge on deep mantle structure (the lithosphere-asthenosphere system: LAS) is one of the key issues to solve this kind of problem. Global seismic tomography is a powerful tool toward this goal but contains a limitation on the spatial resolution due to relatively sparse separation of existing observatories. Some years ago, we proposed a new concept (Kawakatsu and Utada, 2018) of an array study of seafloor observations (array of arrays) to overcome this limitation, and the first attempt is on-going in the Pacific Ocean called the Pacific Array. This is an international effort to which different groups from Korea, US, Taiwan and Japan are contributing. The entire array is not complete yet but is supposed to consist of a number of independent seafloor arrays of ocean bottom seismic and electromagnetic observations. Each seafloor observation array which is normally deployed for 1-2 years with 10-20 sites can reveal the lateral heterogeneity of sub-array scale, which contributes to understand the mantle dynamics locally. In addition, a properly distributed array of such arrays (10-20 sites/array, 10-20 arrays/entire basin) will provide accurate information on the basin-scale lateral heterogeneity in the oceanic lithosphere asthenosphere that may relates with surface features such as the east-west contrast. This presentation reviews some of recent efforts and major scientific outcomes during the past decade or so.

Lithosphere thermal structure of Greenland and Antarctica: Implications for the ice sheets dynamics –

Irina M. ARTEMIEVA[1]*, SinoProbe Lab, China; GEOMAR, Germany (iartemieva@gmail.com)

Abstract

I present results of geophysical modeling of lithosphere thermal structure, lithosphere thickness and compositional heterogeneity in Greenland, North Atlantic region and Antarctica. For Greenland, the results indicate that mantle thermal anomaly around the Iceland hotspot is too weak to be resolved by seismic methods, while its hotspot track can be seen in the reduced lithosphere thickness across Greenland. The cratonic part of Greenland preserves a typical thick cold cratonic lithosphere, except for the NW-ES trending area, possibly modified by the passage of the Iceland hotspot. Thermal structure and lithosphere thickness variations imply that the Greenland icesheet melts primarily from the above, with the major melting anomaly located outside of the ice sheet.

For Antarctica, the results on the compiled crustal thickness, and newly calculated lithosphere thickness, thermal structure and mantle density anomalies demonstrate that West Antarctica lithosphere does not have continental characteristics, but instead represents a series of back-arc basins, therefore reducing the size of the Antarctica continent by 30%. The cratonic part of East Antarctica shows strong magmatic reworking, with significant lithosphere thinning below several regions. In contrast to Greenland, the Antarctica icesheet melting is associated with a strong mantle melting anomaly (characterized by a thin, hot and very low-density lithosphere) located below the ice sheet, in particular below West Antarctica and parts of the East Antarctica craton, in an overall agreement with GOCE-based models on the icesheet dynamics. The results imply that the Antarctica icesheet melts by lubricated sliding, promoted by basal melting of the icesheet.

Pandey O.P[6], CSIR-National Geophysical Research Institute

Abstract

The Capricorn micro-plate is a prominent tectonic block located between the Indian and Australian plates. We evaluate the kinematics of this microplate relative to adjacently located tectonic plates using GPS data to understand the plate tectonic processes and deformation/strain pattern in the Indian Ocean. The lengths of baseline are computed from the DGAR GPS site, placed at the northern fringe of the Capricorn plate and adjacently positioned other GPS sites over the different geotectonic plates. The study suggests a relative convergent tectonics between Capricorn and southern tip of India at a rate of 1 mm/yr. In comparison, a clear convergence at a high rate of 18 mm/yr is seen between the Capricorn and Sunda plates. Such a high convergence rate, if persists, would considerably shrink the wide diffusive boundary that exists today between the Capricorn and Sunda blocks. Similarly, the baseline length change between Capricorn and Australia indicate a shortening at a rate of about 10 mm/yr, which is in good agreement with earlier findings with a diffusive convergent boundary inferred between Capricorn and Australia. A complex rate of change in baseline length is also noticed between Capricorn and two different sites inside the African plate. The DGAR-ZAMB station pair shows divergence between the two plates at a rate of 9 mm/yr, while the DGAR-SUTH (southern margin of Africa) pair shows convergence between the plates at a rate of about 4 mm/yr. The observed divergence between the Capricorn and the Rovuma microplate can be explained by the presence of Comoros hotspot in the Somalian plate which is centered between north Madagascar and Rovuma plate and causing deformation due to magmatic extrusion led internal rifting (or spreading) below the Comores Islands and its surrounding regions. Consequently, a broad deformation zone is being formed east of Rovuma plate due to internal rifting of the Somalian plate that covers the northern part of Madagascar and northernmost part of the Lwandle plate.

Geodynamic implications of small plume-driven weakening of the continental lithosphere

Ritabrata Dasgupta[1]*, Department of Earth System Sciences, Yonsei University, 50 Yonsei-ro, Seodaemun-gu, Seoul 03722, Republic of Korea (rdasgupta@yonsei.ac.kr)
Changyeol Lee[2], Department of Earth System Sciences, Yonsei University, 50 Yonsei-ro, Seodaemun-gu, Seoul 03722, Republic of Korea

Abstract

Mantle plumes are integral geodynamic components of Earth and other terrestrial planets (e.g., Mars and Venus) that transport primordial deep mantle material to shallow depths. Plumes of different sizes mostly originate from the thermal boundary layer at the core–mantle boundary, the base of the mantle transition zone (at 660 km depth), or the hydrated portion of the subducting or stagnant slabs. Plume emplacement within the lithosphere alters the rheology of the crust and lithospheric mantle through mechanical and thermal weakening, influencing the dynamic topography and architecture of the lithosphere–asthenosphere boundary. Previous studies on plume emplacement within the lithosphere have described these outcomes, albeit without considering plume-driven weakening. In this study, we quantitatively evaluated the effects of small plume-driven weakening of the lithospheric mantle and crust on the dynamic topography and LAB depth changes using a series of two-dimensional numerical models. Model calculations showed that small plume-driven weakening developed short-wavelength dynamic topography and LAB depth reduction through both mechanical and thermal erosion of the lithospheric mantle by the plume. A higher degree of weakening decreases the lithospheric strength and reduces the LAB depth, thereby transforming the short-wavelength topography from depression to elevation as the extension is changed to compression. Our model findings are verified by comparisons with the lithospheric strength, topography, and LAB depth of natural small plume emplacement zones.

Deformation microstructures of experimentally deformed epidote blueschist and implications for seismic low velocity layer and S-wave anisotropy in warm subduction zones

Yong PARK[1]*, School of Earth and Environmental Sciences, Seoul National University, Seoul 08826, Republic of Korea (dark2444@snu.ac.kr)
Haemyeong JUNG[2], School of Earth and Environmental Sciences, Seoul National University, Seoul 08826, Republic of Korea

Abstract

To understand seismic low velocity layers and S-wave anisotropy at the top of a subducting slab in warm subduction zones, seismic velocity and anisotropy for experimentally deformed epidote blueschist were calculated based on their deformation microstructures. Deformation experiments of epidote blueschist were conducted by using a modified Griggs apparatus in simple shear under pressure of 0.9–1.5 GPa, temperature of 400–500 ℃, shear strain (γ) in the range of 0.4–4.5, and shear strain rate of 1.5×10-5–1.8×10-4 s-1. After deformation experiments, lattice preferred orientations (LPOs) of minerals were determined by electron backscattered diffraction (EBSD) analysis. Seismic velocity and anisotropy of constituent minerals and whole rock were calculated using the LPOs and elastic constants of each mineral. The average P- and S-wave velocity (Vpaver and Vsaver) of glaucophane were in the range of 7.65–7.80 km/s and 4.54–4.56 km/s, respectively, and the anisotropy of P-wave (AVp) and maximum anisotropy of S-wave (Max.AVs) were in the range of 6.9–15.2% and 3.73–8.06%, respectively. The Vpaver and Vsaver of epidote were in the range of 7.31–7.37 km/s and 4.21–4.22 km/s, respectively, and the AVp and Max.AVs were in the range of 3.0–5.6% and 5.31–7.23%, respectively. The Vpaver and Vsaver of albite were in the range of 6.35–6.52 km/s and 3.68–3.72 km/s, respectively, and the AVp and Max.AVs were in the range of 8.4–14.5% and 12.54–15.56%, respectively. The Vpaver and Vsaver of whole rock (epidote blueschist) were in the range of 7.19–7.63 km/s and 4.22–4.47 km/s, respectively, and the AVp and Max.AVs were in the range of 4.5–11.0% and 3.91–6.40%, respectively. The Vpaver and Vsaver of experimentally deformed epidote blueschist were reduced about 8–13% and 6–11%, respectively, compared to the seismic velocities of lithospheric mantle surrounding the slab. The delay time of S-wave calculated from subducting oceanic crust composed of epidote blueschist was generally increased with increasing the subducting angle of the slab and volume proportion of glaucophane. Our results suggest that volume proportion of constituent minerals, LPO types of glaucophane and epidote, and the subducting angle of the slab are important factors in controlling the seismic velocity and anisotropy observed in warm subduction zones.

Formation of the Continent and Surrounding Region from the Perspective of Changes in Subduction Configuration

SANG-MOOK LEE[1]*, SEOUL NATIONAL UNIVERSITY (smlee@snu.ac.kr)

Abstract

The formation of continental crust is a big and contentious issue that requires a deep understanding of the tectonic setting and the region's geologic evolution. The Korean continent consists of several granitoid blocks attached over its geological history and sedimentary basins severely deformed. Several cases do not match the standard development of continental growth. In this presentation, I explore how the changes in subduction configuration (angle and overall shape) could have played a role in forming the landmass and surrounding basins. For instance, if the subduction angle is low, a collision will happen between the island arc material on the subducting plate and the existing continental material on the overriding plate. Low-angle subduction can result from the subduction of a young oceanic slab or lithosphere affected by a plume. Subduction of extinct spreading centers can also lead to shallow subduction. An extreme case would be a flat subduction, which could have been possible when the mantle was hotter, and the subducting slab was more buoyant than the present day. Head-to-head collisions will generate a large resistive force near the surface and eventually cause the subducting plate to dip at a higher angle. A rapid transition of the subducting slab from low angle to high angle may trigger instability, such as trench rollback, which would then cause the creation of back-arc spreading (sedimentary basins). I present preliminary results of our numerical modeling and insights from the simple experiments. Several hypotheses on how the subduction angle could change and how the change in subduction angle would contribute to different tectonic regimes will be discussed in relation to the regional tectonic features of crust and mantle, including the stagnant slab that extends below Northeast Asia.

Unraveling the diversity in arc volcanism and seismicity in Southwest Japan subduction zone: insights from numerical models

Goeun HA[1]*, Seoul National University (goeunh@snu.ac.kr)
Changyeol Lee[2], Yonsei University
YoungHee Kim[3], Seoul National University

Abstract

The Southwest Japan arc, formed by the subduction of the Philippine Sea Plate, exhibits an uneven distribution of both arc volcanoes and seismic tremors. The western part of the arc, encompassing the Kyushu region, features a higher density of Quaternary volcanoes compared to the eastern part, but adakite is not observed. On the contrary, the eastern part covering the Shikoku and Kansai regions has fewer volcanoes but exhibits the occurrence of adakitic magma. Moreover, seismic tremors are mostly concentrated in the Shikoku and Kansai regions, excluding the Kyushu region. Many numerical studies have aimed to explain this phenomenon, considering the age and subduction rate of the Philippine Sea Plate sinking south of Kyushu and Shikoku. Nevertheless, these studies neglected to consider the dehydration and hydration processes occurring in the slab and mantle, and therefore, were unable to explain the presence of a low-temperature sub-forearc mantle, commonly referred to as a “cold nose.” In this study, we performed two-dimensional numerical simulations that consider both dehydration/hydration and fluid transport to explain unevenly distributed volcanoes and tremors in the Southwest Japan subduction zone. In the Kyushu region, where an older plate subducts with a higher angle, most dehydration occurs at 80 - 120 km depth. As a result, the majority of free water is expelled towards the sub-arc region, and a reduced volume of water reaches the wedge tip along the weak hydrous layer. This aligns with more frequent volcanic activities and a lack of tremors in the forearc. Conversely, in the Shikoku region, where a younger plate subducts with a lower angle, slab dehydration occurs at depths shallower than 75 km. The majority of the released water then travels through the weak hydrous layer, reaching the wedge tip. This explains the sparse distribution of arc volcanoes and frequent tremors in the forearc. Partial melting of the wet oceanic crust occurs at depths deeper than the depth limit for adakitic magma generation (<~100 km) in the Kyushu region while it is shallower in the Shikoku region. In the Kyushu region, the active dehydration occurring in the sub-arc and the subsequent substantial flux melting in the mantle wedge could lead to the dilution of adakitic magma through magma mixing. This is consistent with the exclusive presence of Quaternary arc adakite in the Shikoku region.

New Parameterization of Lithosphere-Asthenosphere System Beneath the Oldest Pacific Based on In-situ Seafloor Geophysical Observations

Hogyum KIM[1]*, Seoul National University (kamhokam@gmail.com)
Kiyoshi BABA[2], Earthquake Research Institute, The University of Tokyo
Sang-Mook LEE[3], Seoul National University
Hisashi UTADA[4], Earthquake Research Institute, The University of Tokyo

Abstract

Even though the oceanic lithosphere-asthenosphere is widely accepted as a vital component of the Plate Tectonics paradigm, the exact mechanism and its nature as a system remain a topic of active discussion, varying from the classic half-space cooling to the plate cooling model due probably to sub-lithosphere small-scale convection. However, those widely accepted oceanic lithosphere thermal models mainly focused on global surface observations, such as seafloor subsidence, heat flow, and gravity anomalies. Additional knowledge on the deep mantle structure is a key to understand the thermal evolution of the oceanic lithosphere-asthenosphere system in the framework of mantle dynamics. Recent increases in seafloor geophysical instruments and international collaborative efforts, namely the Pacific Array, have shown that the in situ observations occasionally do not support the conventional global models and even contradict them in some cases. In 2018-2019, a year long seafloor seismic and electromagnetic survey was conducted on the oldest Pacific seafloor as a part of the Pacific Array project by the joint Korean-Japanese science team. The result of this experiment provided a typical example of the aforementioned mismatch between the observation and the global models. This presentation will demonstrate a preliminary result of lithosphere-asthenosphre structure modeling beneath the oldest Pacific basins based on the seafloor geophysical observations. Using the new structure, we aim to reconcile the observation and global models or to create a new global model otherwise, which needs to newly consider other possible parameters which are related to Mesozoic volcanic activities in the west Pacific basin, such as the melt-depleted lithospheric structure and possible hydration contrast across the lithosphere-asthenosphere boundary.

GEOELECTRIC STUDY OF BARAK BASIN USING MAGNETOTELLURIC TECHNIQUE, NORTH-EASTERN INDIAN REGION

Devesh WALIA[1]*, North-Eastern Hill University (deveshwalia.17@gmail.com)
Ilia LOZOVSKII [2], North-Eastern Hill University Shillong
Mrinal Kanti PATHAK[3], North-Eastern Hill university Shillong

Abstract

The study area is situated within the Barak Basin of Lower Assam, specifically in the Cachar region of Northeastern India. The Cachar region is situated in the far northeastern part of the Bengal basin and is bordered by the Shillong plateau to the north and the Indo-Burmese wedge to the east. The Cachar-Tripura thrust-fold belt is a part of the central compressive frontal region of the Assam-Arakan fold belt (AAFB), which constitutes the frontal fold belt of both the Assam and Assam-Arakan Basin. The AAFB comprises an array of elongated, sub-parallel, en-echelon, linear, and closely aligned north-south trending plunging anticlines, set apart by expansive synclinal troughs.

A field MT survey was carried out in the Cachar region of Assam, India. The MT data were acquired from 27 sites using the KMS 820 and LEMI 120 magnetic coils. 2D inversion models were constructed along the profiles to illustrate the variations in subsurface resistivity across the survey area down to a depth of 25 km, along with the boundaries of geological structures and fault zones. The relatively resistive layers in the 2D sections are interpreted as arenaceous sediments predominantly composed of sandstones whereas the relatively conductive layers are interpreted as argillaceous sediments, predominating with shales, claystones, and siltstones based upon the field exposures. The depth of the resistive crystalline basement is estimated to be between 16 and 17 km.

Deformation fabrics of talc and chloritoid and implications for seismic anisotropy in subduction zones

Jungjin LEE[1]*, Seoul National University, Seoul, Republic of Korea (ljj2718@snu.ac.kr)
Haemyeong Jung[2], Seoul National University, Seoul, Republic of Korea

Abstract

Talc and chloritoid are common metamorphic minerals observed in mafic-ultramafic rocks and/or high-pressure metapelitic rocks comprising subducting slabs. Crystallographic preferred orientations (CPOs) of elastically anisotropic minerals have been known to be important for interpreting seismic anisotropy observed in subduction zones. However, studies on the CPOs of talc and chloritoid have been very limited. In this study, CPOs of talc and chloritoid in garnet-chloritoid-talc schist samples from ultrahigh-pressure Makbal Complex (Tianshan, Kazakhstan-Kyrgyzstan) which has been regarded as a part of subducting slab were measured using SEM/EBSD technique. CPO-induced seismic properties of both talc and chloritoid were analyzed and compared. The results showed that both talc and chloritoid displayed strong CPOs characterized by the [001] axes aligned subnormal to the foliation (see also Lee et al., 2021). CPO-induced seismic properties of polycrystalline talc and chloritoid were calculated and they showed that both P-wave anisotropy (AVp = 5 – 72 %) and high S-wave anisotropy (AVs = 10 – 24 %) of talc and chloritoid were much higher than those of garnet (AVp = 0.4 %, AVs = 0.9 – 1.0 %). In addition, the AVp of polycrystalline talc was much higher than that of polycrystalline chloritoid. Analysis of S-wave delay time and fast-polarization direction based on the modelling study of subduction zone geometry showed that the CPOs of talc and chloritoid induced a long delay time of 0.3 – 0.5 s and trench-parallel polarization direction for high dip-angle subduction, which is consistent with the observation of strong trench-parallel seismic anisotropy in subduction zones. Our results suggest that the strong CPOs of talc and chloritoid would influence trench-parallel seismic anisotropy induced by subducting slab in subduction zones.

Abstract

In this study, we report shear-wave splitting measurements in terms of its strength and orientation to resolve upper-mantle seismic anisotropy, which allow for inferences on the style of deformation and flow of mantle below the oldest part of the Pacific Plate (160–180 Ma) known as the Pacific Triangle. Total 195 teleseismic S phases (XKS, ScS, and direct S) recorded by 11 broadband ocean-bottom seismometers are used to estimate fast polarization directions (FPDs) and delay times (DTs).

Although splitting measurements displayed complicated features with some deviations even at the same station, several main characteristics were found throughout the study region. Our findings reveal a distinct frequency dependence in the splitting parameters at two frequency bands (0.05–0.125 Hz and 0.125–0.5 Hz), suggesting the presence of vertical heterogeneity in seismic anisotropic structures. With regard to the FPDs, the dominant orientation in the low-frequency band is a WNW-ESE or NW-SE orientation, aligning with the N73°W absolute plate motion (APM). Conversely, in the high-frequency band, FPDs show a NE-SW orientation, perpendicular to the N40°W paleo-spreading direction.

In addition to FPD results, a higher number of null (non-split) measurements in the low-frequency band were found particularly from four stations on the Magellan Seamount Trail (MST) and northeast of MST, where pronounced slow-velocity anomaly exist at approximately 100–300 km depths (Kang et al., 2023), implying potential mantle upwelling. Alternatively, the high ratio of null measurements may indicate destructive interference as waves traverse multiple anisotropic layers. In summary, the weak correlation between FPDs and APM suggests that a drag-induced asthenospheric flow alone cannot explain most of our observation; the variation in the FPDs might likely result from the complexity of the upper mantle.

Geodynamic Investigation of Subduction Angle and Possible Flat Subduction Beneath East Asia During Mesozoic

Kien Ngoc PHAM[1]*, Seoul National University (phamngockien@snu.ac.kr)
Sang-Mook Lee[2], Seoul National University

Abstract

Mesozoic volcanism in the Korean Peninsula appears to have an interesting characteristic, with the younger volcanic arc located further inland compared to the older ones. This landward migration of the volcanic arcs is explained by the flat subduction of the ancient Izanagi Plate beneath East Asia, which affects the surface tectonics and facilitates the movement of the partial melting above the slab. However, the mechanism of flat subduction is still highly debatable. On one hand, numerical simulation in the case of early Earth hypothesizes that a higher mantle potential temperature, thicker crust, depleted mantle layers, and the effect of dolomitization can keep the subducting plate afloat. On the other hand, the present-day shallow flat subduction model focuses on the effect of the young age of the plate, existence of an oceanic plateau, trenchward movement of the overriding plate, and slab suction force in the mantle wedge. The former scenario may explain the movement of the ancient oceanic plate during the Mesozoic era when the mantle might be hotter than the present day. Many factors that affect the angle and the buoyancy of the subducted slab remain to be carefully examined. In this paper, several numerical models and their assumptions will be investigated to figure out at which temperature elevation and oceanic crust thickness the buoyancy of the subduction plate can keep it afloat right beneath the continental plate. We also compare our results with important geological features in Korea and China.

Anomalous Inclination of Rock Samples from the South Atlantic Transect (SAT) and Their Implications for Variability in Magmatism of Slow-Spreading Ridges

Gilbert HONG[1]*, School of Earth and Environmental Sciences, Seoul National University (hongfellow@snu.ac.kr)
Sang-Mook Lee[2], School of Earth and Environmental Sciences, Seoul National University

Abstract

Analyzing the remanent magnetic signatures inside igneous rocks is crucial for understanding the evolution of oceanic plates. An important part of this process is to examine the fine-scale structure of polarity reversal, which can be used to constrain the nature of crustal formation at the spreading axis. The magnetic direction can change as a result of hydrothermal alteration of magnetic minerals and subsequent magmatism. However, no systematic analysis has been conducted in recent years using updated techniques. In this study, rock magnetic and chemical properties of basalts along the slow-spreading southern Atlantic ridge flank were investigated to identify the anomalous signatures and key factors that have caused them. Cores drilled from a total of 6 sites of different crustal ages (U1556, U1557, U1558, U1559, U1560, U1583) during IODP expeditions 390 and 393 – which are also referred to as the South Atlantic Transect (SAT) were investigated. Our results show that the distribution of inclination values at a given hole is wider at older sites, which reflects that the rocks have experienced more secondary remagnetization as they aged. We suggest that this is a result of persistent hydrothermal alteration during seafloor spreading and an empirical formula is derived. In addition, one of the sites (U1560) display an unexpected distribution where both normal and reverse polarities coexist in one hole. This pattern implies that magmatism and subsequent crustal accretion occurred in different time periods. It is important to check whether other properties besides inclination have changed.

*The South Atlantic Transect IODP Expedition 390 & 393 Scientists have also contributed to this work.

Bole beds and earthquake swarms in Deccan Volcanic Province, India

Rajender Kumar CHADHA[1]*, CSIR-NGRI (rajen0555@gmail.com)
Kusumita Arora[2], CSIR-NGRI

Abstract

Several isolated earthquake swarms of M<3.5 clustering in space and time are observed in the Deccan Volcanic Province (DVP) of India. These swarms are very localized activity confined to shallow depths of <3.0 km. No systematic pattern in terms of foreshocks, mainshock and aftershocks is observed and do not have a dominant mainshock. The number of events in each of these swarms vary from hundreds to thousands and are often associated with loud explosive sounds indicating shallow source. Swarm durations range from a few weeks to months and sometimes reoccur in the same place after a time interval. The Indian Peninsular Shield seismicity shows a diffused pattern typical of Stable Continental Regions. The seismicity is dominated by infrequent moderate tectonic earthquakes of M ≤ 6.5 mostly along known rift valleys with large recurrence periods. The most prominent cases of Reservoir Triggered Seismicity (RTS), including the largest known M6.3 Koyna earthquake on 10 December 1967 also occur in the DVP region of the Indian Shield.

The role of pore fluid pressure in triggering RTS cases is well known but the occurrence of several seismic swarms in the Deccan Traps terrain points to the geological and hydrological controls in triggering such events. The DVP is a continental flood basalt province in India with a maximum thickness of about 1 km extending over hundreds of kilometres in western and central India. Several red clay-rich horizons of few meters between two basalt flows are commonly seen in the outcrops. These are highly weathered erosional surfaces known as the bole beds facilitating lateral groundwater flow in Deccan basalts. Core samples from several deep boreholes of ≥1 km in the Koyna region have confirmed presence of several such horizons. Most of the reported seismic swarms have followed heavy rainfall episodes during monsoon time leading to the suggestion that these are rainfall triggered. The role of bole beds in triggering seismic swarms in the Deccan basalts is explained in terms of consolidation that is linked to changes in effective stress due to changes in pore water pressure. During heavy rainfall episodes, water percolates to bole beds horizons through fractures, and vertical and horizontal vesicular cylinders observed in Deccan basalts, increasing pore water pressure. Since, the bole beds are rich in clay, it has very low permeability and the dissipation of excess pore water pressure lead to volumetric strain deformation that can get transmitted to the deeper faults or fractured medium leading to failure. The number and thickness of bole beds encountered in different boreholes vary indicating their variable lateral extent. It is inferred that seismic swarms occur in the regions that are underlain by bole bed horizons in the DVP and absence of similar swarms elsewhere in the Indian Shield in different geological terrains support this hypothesis.

Remnant mantle pathways of the Deccan volcanic eruption in the Indian subcontinent revealed by 3D magnetotelluric imaging

ABDUL AZEEZ KIZHAKKEKARA KUNJAVARAN[1]*, CSIR-National Geophysical Research Institute, Hyderabad, India (azeez@ngri.res.in)
Prasanta K Patro[2], CSIR-National Geophysical Research Institute
Arvind K. Gupta[3], CSIR-National Geophysical Research Institute

Abstract

The massive Deccan volcanism induced by the Reunion mantle plume upwelling under the Indian subcontinent (Greater India), which produced one of the largest igneous provinces on the earth during the Cretaceous-Paleogene boundary, has been a crucial phase in the geodynamics and evolution of the modern Indian lithosphere. Significant alterations produced in the geological and geophysical characteristics of the pristine Precambrian Indian lithosphere by this youngest (~65 Ma) thermal event operated inside the Indian subcontinent are relatively well reported, however, there is no explicit revelation on the mantle pathways of the Deccan magma ascent through the Indian lithosphere. A 3D magnetotelluric (MT) imaging study was carried out in central-western India that mostly exposes the iconic Deccan flood basalt cover and Proterozoic to Quaternary sedimentary formations to produce a holistic lithosphere resistivity structure of the region. The 3D resistivity model showed high to moderately conductive crustal zones and weak to moderate lithospheric mantle resistivity in most parts of the study region, indicating an intensely modified Precambrian lithosphere due to multiphase tectono-magmatic episodes that affected the region from the Neoproterozoic to Cretaceous-Paleogene boundary. Interestingly, the MT study mapped two prominent high conductive (<30 Ωm) pipes commencing from a common deep mantle conductive zone imaged below the northernmost lobe of the Deccan volcanic province (Malwa plateau) and its proximity. These are inferred to be the remnant of hitherto unknown primary magma ascent channels that originated from a melt-rich deeper mantle zone related to the Reunion mantle plume upwelling. This study gives first compelling geophysical evidence of key eruptive centers of the massive Deccan volcanism in central-western India at a locale not anticipated earlier. The results support the plume origin and negate the inkling impact hypothesis for the Deccan volcanism.

Sanjay KUMAR[3], 1. CSIR-National Geophysical Research Institute, Hyderabad, India

Abstract

Deccan volcanic province (DVP) in west-central India is a large igneous province formed due to the massive outpouring of a magmatic igneous volume at ~65 Ma and is surrounded by Dharwar craton, Bastar craton and Aravalli-Bundelkhand craton in south, east and north respectively. Since the region is totally covered by Deccan basalt, sub-basalt information is difficult due to the poor transmission of seismic energy through basalt. In the present study, we investigate the variation in basaltic thickness and delineate the sub-basaltic structure in the western and central regions of DVP by improving the resolution of the subsurface structure, to be used for further study of seismotectonic and geodynamics of DVP. We conduct high frequency ambient noise tomography using the vertical component of waveform obtained from the dense network of 100 and 23 seismic stations that were deployed in both western and central regions respectively. The deployed network of seismic station provides a good ray path coverage for the study area with the interstation distances varying between 3 - 120 km in the western region and 3 - 23 km in the central part of the region. The 3-D shear velocity model (0-10 km) beneath these regions reveals distinct variation in the basaltic thickness and sub-basalt crustal shear velocity structure.

[Keynote] The Deccan Volcanic Province (DVP) of India hosts three different types of earthquake sequences

Harsh K K GUPTA[1]*, CSIR-National Geophysical Research Institute (harshg123@gmail.com)

Abstract

Mogi (1963a, b) classified the earthquake sequences into three categories. Type 1 earthquake sequence occurs when the material is homogeneous, and the stress is uniformly applied. In this type, a mainshock occurs, with no foreshocks, and the aftershocks follow. Type 2 earthquake sequence is observed when the material has a rather heterogeneous structure and/or the applied stress is not uniform. In this case, the main shock is preceded by foreshocks and the number of aftershocks as well as the duration of the occurrence of aftershocks increases. Type 3 of the earthquake sequence is observed when the material is extremely heterogeneous and/or the applied stress has different concentrations, then there is no main shock, and a swarm kind of activity occurs where the number and magnitude of shocks increase with time and then decrease after some time. In the Deccan Volcanic Province (DVP) of India, all three types of earthquake sequences have been witnessed. Type 1 (Latur earthquake of M 6.2 on 29 September 1993), Type 2 (Koyna earthquake of M 6.3 on 10 December 1967), and Type 3 (Palghar earthquake swarm 2018-2020). It has been proposed that the change in the mechanical properties in the shallow crust due to the loading of the water reservoir has caused the change from Type 1 to Type 2 earthquake sequence for Koyna. Similarly, intense rain is considered to cause the change to Type 3. However, how these changes occur is not well understood.

There is a need to understand the cause leading to three different characteristics of earthquake foreshock-mainshock-aftershock sequence for a single geological domain, which is the DVP. It is hoped that the detailed near-field studies of earthquakes being undertaken at Koyna through a 3 km deep pilot borehole near the Donachiwada Fault hosting the reservoir-triggered seismicity (RTS) will provide an explanation.

Tomographic imaging of sub-trappean Mesozoic sediments and basement configuration using long-offset seismic data in the Deccan Volcanic Province (DVP) of India

LAXMIDHAR BEHERA[1]*, CSIR-NATIONAL GEOPHYSICAL RESEARCH INSTITUTE (CSIR-NGRI) (laxmidhar@ngri.res.in)

Abstract

Abstract

The shallow sub-surface 2-D tomographic P-wave velocity (Vp) image of the Deccan Volcanic Province (DVP) of India is derived using long-offset seismic data along the 90-km long N-S trending Sinor-Valod seismic profile in the Deccan Syneclise region. The tomographic image depicts smooth velocity variations of Quaternary and Tertiary (2.0-3.0 km/s) sediments, basalts/traps (5.0-5.5 km/s), sub-trappean Mesozoic sediments (4.3-4.5 km/s) as well as the basement (5.9-6.1 km/s) geometry down to a maximum depth of 5.0 km. Due to Late Cretaceous volcanism and outpouring of basaltic lava flows, this region is affected by numerous dyke intrusions and thick basaltic trap (2-3 km) exposed on the surface and surrounded by graben structures due to deep-basinal faults forming a large-igneous-province (LIP). Although sub-basalt imaging is a major challenge for the oil industry, with the help of tomographic imaging technique of long-offset seismic refraction data, it is possible to image sub-trappean Mesozoic sediments (< 0.75 km) deposited below the two sequences of thick basaltic flows above the basement. The imaged Mesozoic sediments are expected to contain hydrocarbon because of their wide extension in this sedimentary basin with suitable trapping mechanism due to basalts. The robustness of velocity image is assessed through numerous tests like velocity perturbations, chi-square estimates, RMS residuals of traveltime fit, uncertainty estimates through computation of ray-density (or Hits) and series of checkerboard resolution tests with velocity anomalies having different cell size. The thickness of basalt and sub-trappean Mesozoic sediments along with basement configuration obtained from tomography are constrained through ray-trace modelling and pre-stack depth migration (PSDM) of long-offset seismic reflection data for different shot gathers along the profile.

Crustal geoelectrical structure of Koyna region, India: Role of fluids as inferred from magnetotelluric study

Bantu Prasanta Kumar PATRO[1]*, CSIR-NGRI (patrobpk@ngri.res.in)
Ujjal Kumar Borah[2], Gauhati University

Abstract

The Koyna region in India is known for reservoir triggered seismicity since 1962. This region is covered with Deccan Basalt of 67.4 Ma of age. Under a deep drilling project, broad band MT survey was carried in and around Koyna-Warna seismic zone. Modelling (2D and 3D) studies carried out in Koyna Seismogenic Zone, India brought out moderately conductive (~700-1,000 Ωm) near vertical features within a high resistive (>20,000 Ωm) granite/granite-gneiss basement. The orientation of earthquake hypocenters along the resistive-conductive boundary indicates them as basement faults. Occurrences of these anomalous moderate conductors are corroborated with sensitivity analysis. The conversion of resistivity values to the ratio of seismic P- to S-wave velocity (vp/vs) proposes that the resistivity of the fault zone seems due to the presence of fluid in the fault zone. Geophysical evidences reveal ~2.5-3.6 vol% fluid in the fault zone with ~1.8-2.6% interconnected porosity, which migrates along the structural boundary. It occupies the mechanically strong basement to nucleate the brittle failure within it. The present study proposes two mechanisms for the seismicity in the Koyna region such as: the meteoric water circulation due to the loading-unloading of nearby Koyna reservoir and due to the dehydration of amphibole bearing rocks (as observed conductive feature at 20 km depth). The fluid generated from dehydration might act as a probable source to the triggered seismicity, since the conductive feature has a linkage to the upper crust.

Constraining focal mechanisms of reservoir triggered seismicity in the Deccan Volcanic Province

D SHASHIDHAR[1]*, CSIR-National Geophysical Research Institute (shashi.geo@gmail.com)
K Mallika[2], CSIR-National Geophysical Research Institute

Abstract

Estimation of focal mechanisms of reservoir triggered earthquakes provides understanding on the fault/fracture pattern and features of triggered seismicity. However, focal mechanisms of micro earthquakes (around Mw 2.0) are often not well determined with first motion data alone due to station coverage and feeble signals. In the present study fault planes have been precisely determined using independent methods from the readings of polarities, inversion of amplitudes, amplitude ratios and waveform inversion techniques of the local earthquakes. The Koyna region located near the west coast of India in the Deccan Volcanic Province is a global significant site of reservoir triggered seismicity. CSIR-NGRI is monitoring a network comprising of borehole and surface seismic stations at Koyna-Warna. High-quality borehole data have provided better constraints on the estimation of fault planes. For most of the grid search solutions, more than 50 possible solutions resulted with a 2 degree increment search window. Interestingly, all the solutions aligned in almost similar trend. Further, only a few possible solutions using a 5 degree increment search and ended up with a single best fit solution while used a 10 degree increment search. In this way, the polarities and the station distributions allowed in achieving a best fit for the estimation of focal mechanism solutions of the selected earthquakes, where the solution is well constrained by polarities only, and then amplitude ratios have been used in the inversion which provided confirmation of a solution and helped to select one of several equally good solutions. The seismicity and fault plane data have enabled precise delineation of trends of major causative faults and lineaments in the region. We also discuss the variation of P-axis plunge and tectonic stress with time.

Priyanka Tripathi[2], Geological Survey of India, Western Region, Jaipur

Abstract

Mid-crustal basement below Deccan Volcanic Province: Evidence from multiparametric borehole study
O. P. Pandey1 and Priyanka Tripathi2
1CSIR-National Geophysical Research Institute, Hyderabad-500007 (India)
2Geological Survey of India, Western Region, Jaipur-302004 (India)

Indian peninsular shield has been experiencing moderate intraplate seismic activity since historical times, which includes many recent disastrous earthquakes, like 1967 Koyna (Mw 6.3), 1993 Killari (Mw 6.3) and 2001 Bhuj (Mw 7.7). Interestingly, epicenter of many such earthquakes are located over 65 Ma old Deccan Volcanic Province, which constitutes one of the largest flood basaltic eruptions on the surface of the Earth. In spite of several geological, geophysical and seismotectonic studies, carried out by national and international agencies since last four decades, seismotectonics of the earthquake prone areas of this region still remains poorly understood. We even do not know what kind of geologic terrain is concealed below the thick volcanic pile. In view of this, a deep scientific drilling programme was carried out in two such regions, Killari and Koyna. Out of the two, the first core drilling attempt was made in the epicentral region of 1993 Killari earthquake, which killed almost 10,000 people. 617m deep KLR-1 borehole, was the deepest and drilled by CSIR-NGRI and AMD (Hyderabad). It penetrated 338 m thick column of Deccan basalts, 8 m of infratrappean sediments and a further 270 m of the late Archean crystalline basement. We made a unique attempt and carried out detailed multiparametric geological, geochemical, mineralogical, isotopic, elastic and petrophysical studies on 43 basement cores. These iron-rich rocks (avg. FeOT: 9.0 wt%) are found to be made-up of high velocity-high density (2.82 g/cm3) amphibolite to granulite facies mid-crustal rocks, with intercalations of TTG. Basement samples are highly deformed, retrogressed and metasomatized by mantle fluids and contain 2 wt % of CO2. They have been subjected to temperatures between 540 and 860 °C and pressure 5–7 kb, equating to 15–21 km emplacement depth. The granitic-gneissic layer, which is typical of the upper crust, appears absent. It further appears that the earthquake nucleation in the intraplate stable regions, may have a close link with mantle metasomatism.

Abstract

The rapid and voluminous eruptions of the flood basalts in the Deccan Volcanic Province (DVP) straddling the Cretaceous – Paleogene Boundary (K-PgB) are recognised as a primary causative factor for the environmental stress leading to a dramatic global faunal turnover across this boundary. This makes the computations of the volume of basaltic eruptions important.

The thickness and volume of the Deccan Trap flood basalts have been previously computed using (a) geophysical (gravity, seismic reflection profile, deep resistivity sounding and magnetotelluric) methods and (b) stratigraphic compilations and correlative extrapolations. Whereas the latter use the former only for partial justifications of the estimates. A review of literature shows wide discrepancies between the final tally in both cases. Both these methods assume a smooth basement profile, notwithstanding mapped undulations in the Trap – basement contact, which could seriously modify the real versus estimated thickness values.

In an effort to arrive at a more realistic estimate, we have used mapping data published by the Geological Survey of India, integrated with the emerging revisions in the stratigraphic classifications, projected basement profiles in different sectors elucidated by geophysical methods and drilling with our own observations. The input material used by us has a far superior granularity in terms of data points, and consistency in computations across the entire province. Based on this data we demonstrate that

(a) All previous estimates of the total volume of basaltic lavas were overestimated by a factor of 3 on the conservative side. The total volume of preserved lavas is not more than 0.2 million km3. Assuming more than half is eroded away, still leaves a total eruptive volume of only half a million km3.

(b) Several basement structures have controlled the geometry & spread of lava during the eruptive episodes of Deccan volcanism in different subprovinces. The possibility of their synvolcanic reactivation and movements along them need to be taken into considerations when correlating lava flows and computing their volumes. This also reaffirms that the lava stratigraphy of each subprovince was different.

(c) The Late Maastrichtian volumes of extrusion (and by implication the net magmatism) were far greater in proportion than the Danian volumes, unlike all previous estimates. The case for Deccan magmatism as a causative mechanism is further reinforced. This does not dilute the relevance of

the post-K-PgB volumes of lava in delaying the post-Cretaceous recovery of biotic systems.

The revised thickness computations and volume estimates of the Deccan Traps based on mapping and integration of the pre-Trappean topography opens new vistas for exploring the sub-Trappean data for resources. This study also recognises ancient zones of weakness that have evidence of Cenozoic & Quaternary reactivation.

Hema Sundar Tandule[4], CSIR-National Geophysical Research Institute
Abhey Ram Bansal[5], CSIR-National Geophysical Research Institute

Abstract

The Deccan Volcanic Province exhibits an intricate geodynamic architecture due to the massive magmatic eruption around 65 Ma. The massive eruption ensued in the Late Cretaceous period and started flowing from west to east along the pre-existing zones of weakness in the Indian shield. High-resolution terrestrial gravity data along with magnetic, heat flow, and seismic data have been analysed in the southern part of the Deccan Volcanic Province (south of Central Indian Tectonic Zone) to determine the density discontinuities beneath the region. The primary structural framework in the region has been scrutinized at various depth levels, which delineated prominent W-E to WNW-ESE gravity anomaly trends parallel to the Narmada-Tapti rift zone. An important observation is that the extensions of the Godavari rift basin are observed underneath the Deccan Volcanic Province. The 2.5D gravity modelling along a NW-SE profile suggested that the Moho depth varies between 38 and 42 km. The density model further delineated the presence of low-density zones, which corroborate with the low-velocity layers as inferred in the previous studies. In addition, this study unveils distinct characteristics influenced by the evolution of the Narmada-Tapti rift during the Cenozoic era, effectively distinguishing the northern and southern segments of the Deccan Volcanic Province.

Seismic imaging of southern part of Kachchh region (western India)

CHANDRAKALA KOTESWARA[1]*, CSIR-NATIONAL GEOPHYSICAL RESERCH INSTITUTE (chndrbhat@gmail.com)

Abstract

Seismic imaging of southern part of Kachchh region (western India)
K. Chandrakala
CSIR-National Geophysical Research Institute, Hyderabad- 500 007, India

Kachchh region, situated in the northern part of the western continental margin of India, is a contiguous part of South Indus Basin that extends from onland to the adjoining offshore areas of Arabian Sea. It is the westernmost extension of the Deccan volcanic province, which is considered one of the largest basaltic eruption on the surface of the earth. This region is underlain by thick Mesozoic sequences and on its eastern side, it is surrounded by hydrocarbon-rich thick Tertiary sediments. This region remains one of the most prominent earthquake sites in India since historical times, where deep crustal earthquakes keep on occurring. It has witnessed several large events like, 1819 Kachchh (Mw 7.7), 1956 Anjar (Mw 6.0), and 2001 Bhuj (Mw 7.7) earthquakes. In view of the active seismicity associated with this region, CSIR-National Geophysical Research Institute (Hyderabad) acquired seismic refraction data. In the present study, we have reprocessed the seismic data acquired along Jakhau-Mandvi profile, which traversed through the southern part of the Kachchh region. Our initial study revealed a five layered structure above the basement in which Vp (km/s) varies from 2.10-2.20 (upper Tertiary sediments), 4.40-4.60 (Deccan volcanics), 3.20-3.50 (upper Mesozoic sedimentary layer), 5.30-5.40 (Mesozoic volcanics) and 3.30-3.70 (lower Mesozoic sedimentary layer). Basement characterized by velocity of 5.90 to 6.0 km/s is underlain by mid crustal (Vp:6.30-6.40) and lower crustal (Vp: 6.8-06.90 km/s) layers, which is further underplated by thick magmatic layer (Vp: 7.10 -7.20 km/s) above the Moho. Moho detected at an extremely shallow depth of 29 to 32 km is characterized by velocity 8.10- 8.20 km/s.

Development of rift systems in the Kutch-Saurashtra region-A tale of multiple breakup events: Constraints from geophysical and geochronological data

Munukutla RADHAKRISHNA[1]*, Department of Earth Sciences, Indian Institute of Technology Bombay, Mumbai, India (mradhakrishna@iitb.ac.in)
Pattabhiram Kondepudi[2], Department of Earth Sciences, Indian Institute of Technology Bombay, Mumbai, India
Bhavya K. B.[3], Department of Earth Sciences, Indian Institute of Technology Bombay, Mumbai, India
Kanchan Pande[4], Department of Earth Sciences, Indian Institute of Technology Bombay, Mumbai, India

Abstract

The rift systems in the Kutch-Saurashtra region developed in three major stages related to the continental breakup of India from East Africa (~160Ma), Madagascar (~88Ma), and Seychelles (~63Ma). The north-western Indian shield and adjoining offshore region is blanketed by the Late Cretaceous Deccan Volcanism, up to ~3km thick, inhibiting the understanding of pre-Deccan rift configuration. An integrated approach combines drilled well information, Ar-Ar geochronology, and geophysical data to decipher the complex tectonic history and volcanism (episodic?). The present study reports the Ar-Ar ages of 5 igneous rock samples from the Kutch offshore wells comprising two basalts(b), two dolerites(d), and a rhyolite(r). The Ar-Ar plateau ages of the samples are 80.5 ± 0.5(b), 81.4 ± 0.5 (r), 100.3 ± 0.6 (b), 72.6± 0.4 (d), and 67.1 ± 0.6 (d) (errors quoted at 2σ level). These results were correlated with previous geochronological data from this region. Different rifting events and their directions were identified using multi-channel seismic data. Magmatic bodies, which are strong reflectors, were mapped in the seismic sections at various stratigraphic levels from the Jurassic to Late Cretaceous age and are substantiated by the drilled core data. The seismic data shows that the major fracture systems in this region acted as conduits for the magma to reach the surface. The constrained gravity interpretation of the region provided new insights into the basin architecture and onshore-offshore tectonic linkage. The Present study demonstrates the development of the Kutch-Saurashtra rift systems during different continental breakups and associated magmatism from a geodynamic perspective. The striking similarity of the tectono-magmatic history of the Kutch-Saurashtra region with the Seychelles and Madagascar is fascinating.

Possible sub-surface extension of Deccan Magma in the north Arabian Sea

Vasanthi ANTHWAR[1]*, CSIR-National Geophysical Research Institute
(vasanthi99ngri@gmail.com)

Abstract

Gondwanaland break-up during the late Cretaceous and subsequent geodynamic activities in the Arabian Sea, resulted into the formation of several prominent geotectonic features like, Laxmi, Chagos-Laccadive, Panikkar and Palitana ridges and Laxmi and Gop basins. Out of these features the Laxmi Ridge, associated with conspicuous negative gravity field, is considered extremely unusual. The crustal structure beneath this ridge has been a subject of intense debate since many decades. We have analysed high-resolution satellite gravity field over the Laxmi Ridge and its adjoining areas to address this incongruity. We provide detailed sub-surface crustal and lithospheric density model across this region using residual gravity anomalies, computed by the Finite Element Method. This ridge associated with a residual gravity low of the order of -30 to -80 mGal contrasts with the adjacently located Laxmi Basin, Panikkar and Palitana ridges that are characterised by distinctly positive gravity field. Such a negative character of the gravity anomaly over a ridge structure, is highly unusual in a typical oceanic crustal environment. In the absence of active rifting, it can only possibly be explained with the occurrence of a low-density underplated material below the Moho. The 2½D residual gravity model indicates that the underplated magmatic layer (2.9 g/cm3) below the Moho is about 10 km thick, which can be ascribed to a fractionated and highly differentiated magma related to Deccan Volcanic episode and Seychelles break-up, that occurred at the K-T mass extinction boundary (~ 66 Ma) and covered a large part of west-central India and adjacent offshore region in the Arabian Sea.

Chakravarthi Narasimha Nalluru[2], CSIR-NATIONAL GEOPHYSICAL RESEARCH INSTITUE
Ajay Manglik[3], CSIR-NATIONAL GEOPHYSICAL RESEARCH INSTITUE

Abstract

The western continental margin of India is constituted of significant geomorphological features namely the Konkan coastal plains, coast parallel Western Ghat escarpment and the elevated Deccan plateau; one of the largest igneous provinces of the world. The margin witnessed at least two rifting episodes that affected not only the surface morphology but the concealed pre-eruptive tectonic features in the region. Neotectonic activity has been reported from the region. Here, we present the results from a magnetotelluric study carried out along a 200 km long E-W profile traversing major tectonics features between the Konkan plains and the Deccan plateau. Deep geoelectric structure constructed from two-dimensional modelling of the impedance tensors at 39 sites reveals the presence of highly resistive fragmented cratonic blocks of the Greater Dharwar Craton with variable thickness dissected by the faults/fracture zones of pre-eruptive time. We attribute the recent past and ongoing seismic activity in the western Deccan Volcanic Province to reactivation of these tectonic features. The cratonic blocks are overlain on moderate-to-high conductivity zones representing the relics of the interaction process of the Indian lithosphere with the Réunion plume and indicate the zone of partial melts due to the effect of the residual thermal anomaly. We infer that the magmatic underplating and subsequent uplift might be a plausible cause for persistent and dynamic topography of the western Ghats and gradual eastward thickening of the cratonic blocks.

Delineation of lithospheric structure across the Deccan Volcanic Province and Eastern Dharwar Craton, south Indian shield using joint inversion of receiver function and surface wave dispersion data

Sudesh KUMAR[1]*, CSIR-National Geophysical Research Institute (kumarsudesh77@gmail.com)
Sandeep Gupta[2], CSIR-Nastional Geophysical Research Institute
K. Sivaram[3], CSIR-National Geophysical Research Institute

Abstract

The Deccan Volcanic Province (DVP) is one of the largest flood basalt region in the world, together with Dharwar craton constitutes a large portion of the south Indian shield (SIS). The SIS is influenced by several tectono-thermal events during its evolutionary history. The Deccan volcanism is the last tectono-thermal event (~ 65 ma) which influenced the significant part of SIS. To understand the evolution of the DVP, we determine the lithospheric structure across the Deccan Volcanic Province–Eastern Dharwar Craton (EDC), using seismological waveforms recorded at 18 seismological stations. We infer the nature of lithospheric structure using joint inversion of teleseismic receiver functions and surface wave dispersion data, teleseismic relative residuals, and upper mantle seismic anisotropy measurements.

The results of inversion show the distinct nature of lithosphere beneath the DVP-EDC transacts. The crustal thickness is systematically varying from EDC (32-34 km) to DVP (34-39 km). We found sharp and felsic crust (Vp/Vs ~1.74) beneath the EDC while DVP has gradational and mafic crust (Vp/Vs ~1.78). The calculated lithospheric thickness shows a significant difference in the DVP (~125 km) and EDC (~175 km); it is 50-60 km thinner in the DVP in comparison of the EDC.

From the analysis of teleseismic travel time residuals, the DVP depicts delay of 0.2 -0.4 s with respect to the EDC. The measurement of splitting parameters (i.e. fast polarization orientation, Φ, and delay time, δt) also show distinct splitting patterns highlighting deeper geological structures. In the DVP, Φ is nearly NE-SW for most stations, along with an average (at each station) δt varying between 0.5 s and 1.2 s. In the EDC, our results show Φ predominantly in the NW-SE orientations with δt varying between 1.0 and 1.4 s.

Based on the results obtained, we infer that different evaluation processes are responsible for the DVP and EDC. The DVP is significantly affected by Deccan plume while EDC has remained unaffected since long geological time.

Configuration of Deccan Traps and its effect on triggered seismicity in Koyna-Warna Seismic Zone, India

Ujjal Kumar BORAH[1]*, Gauhati University, Guwahati 781014, India (ujjal.borah6@gmail.com)
Prasanta Kumar Patro[2], CSIR-NGRI, Hyderabad 500007, India

Abstract

Koyna-Warna Seismic Zone (KWSZ), western India is well known for reservoir triggered seismicity (RTS). The entire area is covered by Deccan basalt which is seated on the granitic basement. Configuration of the Deccan Traps in and around KWSZ plays a critical role on RTS in the region; since the increase in trap thickness will lead to the increase of pressure on the basement. This increment in pressure, due to the increased trap thickness, affects the accumulated stress regime inside the basement faults. When fluid percolate into these stressed basement faults under pressure, strain will be released. Therefore, to understand the trap configuration, a magnetotelluric (MT) investigation is carried out in and around KWSZ. The dimensionality analysis of the acquired MT data signifies a one-dimensional (1D) structure for the upper part of KWSZ (0.001 s – 1 s). Therefore, 1D inversion is carried out to configure the trap. The efficacy and the reliability of the 1D inversion output is also tested. The 1D inversion brings out that significant variation in the trap thickness follows mainly E-W trend (average ~800 m thickness) with thicker central part. This central part of the trap in KWSZ exerts an average pressure of 25.6 MPa upon the basement, which is bounded by lower average pressure of 17.6 MPa on both sides. This comparatively high pressurized central part of KWSZ coincides with the observed RTS in the area. This association points towards a probable role of pressure, as catalyst, on stress release for the triggered seismicity in KWSZ.

Abstract

The Kachchh Rift basin, located in the western region of India, is considered to be one of the most seismically active zones after the Himalayas. In order to understand the tectonics and architecture of the rift basin, a deep seismic reflection profiling study was conducted. The data was processed using the common reflection surface stack approach, which provided high-resolution seismic images of the crust. These images revealed a sub-horizontal lower crustal reflection fabric that was approximately 15 km thick, as well as a dome-type structure that extended from the surface to the Moho. The earlier structure was interpreted as magmatic underplating, while the latter was interpreted as the Kachchh Mainland uplift. There were significant variations in the thickness of sediments, ranging from 150 m to 6.5 km, and crustal thickness, ranging from 45 km to 35 km from north to south. The Moho was found to be upwarped by 4 km beneath the Kachchh Mainland fault. Interestingly, the Kachchh rift basin exhibited an unusually thick crust of 45 km, which is contrary to many other rift basins. The study suggested that the syn-rifting and Reunion mantle plume activity, as manifested by the Deccan volcanics, were responsible for magmatic underplating and crustal thickening. The uplift in the region was found to be multi-genetic in origin. The study also revealed new faults and provided insight into the nature of various other faults. Moderate to large earthquakes in the region were attributed to the regional and local stresses resulting from the plate boundary and heterogeneous crustal structure. Based on the mafic lower crust and distribution of aftershocks through the entire crust, the study interpreted that the lower crust is brittle, which is contrary to most models of continental rheology.

Paleomagnetism of KBH-7 core from Koyna, Western Ghats, India

Venkateshwarlu Mamilla[1], CSIR-National Geophysical Research Institute
Venkateshwarlu MAMILLA[2]*, CSIR-National Geophysical Research Institute
(mamillavenkateshwarlu@gmail.com)

Abstract

Deccan Trap surface samples are subjected to Paleomagnetism studies since last three decades but to study the erupted lava at depths is very rare. Basalt flows are considered to be accurate recorders of geomagnetic field direction. Paleomagnetic studies were carried out on 1250 m thick continuous drill core (KBH-7) from Koyna, Western Ghats, India. Basalt sequence along the core is demarcated into 37 flows. Individual flows demarcated by red boles are massive at the bottom and vesicular and/or amygdaloidal at the top. Palaeomagnetic results from 113 slices of the drill core is retrieved. Rock magnetism study indicate that the core samples carry Titanomagnetite and Magnetite as the remanence carrier. Present study core sample inclinations (~30-60°) are determined systematically in a vertical orientation along the axis of the core. The results clearly display a single geomagnetic polarity transition in palaeomagnetic data for KBH-7. The flow samples from surface down to ~640-650 m MSL show normal polarity with upward inclination (I = −50 ± 10°) and the flow samples down to the basement show a reverse polarity with downward inclinations (I = +44 ± 14°). These results establish unequivocally a single geomagnetic polarity transition during the eruption of the entire section of the basalt.

Secondary mineralization and fluid channelization through fractures within the basement rocks of seismically active Koyna-Warna area, Maharashtra, India

Manas GOSWAMI[1]*, Gauhati University (manasgoswami160@gmail.com)
Surajit Misra[2], Gauhati University

Abstract

The Koyna-Warna area is located in the Deccan Volcanic Province (DVP), Maharashtra, western peninsular India, and is well known for persistent seismic activity since 1967. The seismic activities were followed by the impoundment of the Shivajisagar lake, an artificial reservoir of the Koyna dam in 1962. The largest earthquake occurred in 1967, with M~6.3, which was followed by approximately 22 earthquakes of M≥5, 200 earthquakes of M≥4, and thousands of smaller magnitude earthquakes have occurred in the area. Most of these earthquakes are restricted within an area of ~ 20×30 square km. The DVP is underlain by cratonic granitoid basement rocks. Most of the earthquake hypocenters are located within a depth range of 7-10 km, whereas maximum DVP thickness in the study area is 1251 m. Therefore, basement rocks are important to study on deformation signatures related to the ongoing brittle failures below the study area.

Recent scientific deep drilling activities by Govt. of India in the study area facilitate us to direct investigation on the basement rocks. This study helps us to explore multiple brittle deformation events, which are evident from the basement rocks in the Koyna-Warna region. Evidence of these deformations are mainly present in the form of slickensides, slickenlines, and several fault rocks, which include cataclasites, fault breccia, and fault gouge. Further brittle deformation events are recorded in the form of fractures which range from mm to cm scale in width, creating an anastomosing fracture network from surface towards depth. Secondary mineralization has occurred within these fractures which can be broadly classified as siliceous, ferruginous, carbonate, and clay materials. Siliceous and ferruginous materials are the most abundant and present within a wide range of fracture width. Association of both crystallized as well as amorphous ferruginous materials following the same fracture indicate variable conditions of mineralization. Presence of calcite crystals as veins without any deformation attributed their recent formation. Further, occurrences of amorphous carbonates are very few compared to the siliceous and ferruginous materials. Besides, presence of clay materials within the basement fault zone rocks indicates a periodic distribution. Summarily, these fractures are facilitating pathways for fluid channelization at depths. The channelized fluid is carrying materials through fractures for secondary mineralization. The association of different secondary materials within the same fracture indicates multiple episodes of fluid influx with different chemical compositions at seismogenic depth.

Abstract

Electrical imaging logging has been an indispensable means of obtaining subsurface information images in geophysics and an effective technical means for reservoir logging evaluation, but with the rapid expansion of deep-water exploration and development activities, oil-based mud electrical imaging logging has been widely used. However, because the spacing and size of the polar plate cannot be matched exactly with the well diameter, the coverage can be as low as 32%, and the data imaging will show regular blank strips, which seriously affects the image visualization and logging interpretation process. In order to ensure the accuracy of image interpretation and quantitative parameter pickup, it is necessary to carry out blank strips recovery to obtain resistivity information of the whole well wall. In this paper, on the basis of exploring the existing methods for blank strip filling in electrical imaging images, a method based on the combination of CNN and Transformer is proposed, which, combined with the strategy of multiple iterations of the results, achieves the best complementary effect among all the current methods. Compared with the commonly used interpolation method, the image complemented by this method has richer and more reasonable texture and semantic information as a whole, while no artifacts are introduced. The method also outperforms other complementation methods in terms of evaluation metrics such as MAE, SSIM, and PSNR. The method proposed in this paper can meet the practical application requirements of blank strip filling in scale for electro-imaging, and can also provide a reference means for the information processing of measurement missing strips between the measurement polar plates.

chao DENG[6], Northwest University
ze TAN[7], Northwest University

Abstract

Identification of shale lithofacies is a key in understanding the spatial distribution of shale oil and predicting exploration targets. However, it may result in redundant logging information in characterizing complex lithofacies, due to the strong heterogeneity of the shale reservoir, rapid changes in lithofacies, and the highly similar characteristics of logging curves. Furthermore, the highly nonlinear characteristics of logging curves may lead to ambiguity and uncertainty in the mapping relationship between logging curves and lithofacies, which further affects the recognition and prediction results of shale logging lithofacies. A new intelligent lithofacies recognition model is proposed in this study. It can effectively address the above problems by integrating linear discriminant analysis (LDA) and a self-organizing mapping neural network (SOM) model. The four key well logging curves of gamma ray (GR), density (DEN), spontaneous potential (SP), and resistivity (RD), which can adequately provide the physical properties of shale through the application of linear discriminant analysis (LDA), are selected as the discriminant input curves. The geological lithofacies of the shale within the first member of the Qingshankou Formation in the Gulong Sag are systematically categorized, utilizing a shale classification scheme that takes into account organic matter, sedimentary structure, and mineral composition. Furthermore, three neural network algorithms, namely quantitative classification, minimal distance, and majority voting method, are introduced as data label indices for supervised learning modeling. The nine lithofacies recognition models are established for the shale, based on the three neural network algorithms. A shale lithofacies recognition model with the highest universality for the study area is selected from the nine lithofacies recognition models, by verifying the geological lithofacies division. This model can quickly and accurately identify shale lithofacies in a single well and predict their spatial distribution. Consequently, it serves as a solid foundation for providing data support to the subsequent prediction of favorable areas for shale oil exploration.

A review of the utilization of novel artificial intelligence tools for advanced reservoir characterization

SHIB SANKAR GANGULI[1]*, CSIR – National Geophysical Research Institute (NGRI)
(ganguli.ism@gmail.com)
PRAKASH KUMAR[2], CSIR-National Geophysical Research Institute

Abstract

Accurate estimation of reservoir properties is crucial for characterizing hydrocarbon-bearing reservoirs, and conventional methods often face challenges in delivering such precise estimates from geophysical data. Recent technological advancements have significantly improved the accuracy of predictive models, pushing the boundaries of what machines can achieve. This study aims to offer an in-depth examination of both conventional methods and novel artificial intelligence (AI) algorithms for the qualitative and quantitative evaluation of reservoir source rock quality and mapping heterogeneities/facies. For this, a novel approach based on the particle-swarm-optimization (PSO) method and neural network is proposed to develop an accurate predictive model for total organic carbon content estimation in unconventional shales. Moreover, a deep learning-based seismic attribute is utilized to locate the lateral changes in heterogeneities/ facies. The proposed approaches have been tested with a selection of synthetic and field data examples, which will be discussed in this work. The effectiveness of the predictive models was evaluated using established statistical metrics, including the coefficient of determination, correlation coefficient, root mean square error, mean absolute error, and mean percentage error. Once trained, these tools have been found to be robust in predicting reservoir parameters of interest and delineating heterogeneities and facies distribution within the reservoir zones. This study demonstrates the potential of AI algorithms and their role in selecting data features, thereby enhancing prediction accuracy in models for effective reservoir characterization.

Appraisal of gas hydrate saturation in KG basin using synergistic implementation of geophysical log analysis and machine learning approaches

SUMAN KONAR[1]*, Controlled Source Seismics and Gas Hydrates, CSIR - National Geophysical Research Institute, Hyderabad-500007, India (konarsuman2@gmail.com)
BAPPA MUKHERJEE[2], Seismic Interpretation Laboratory, Wadia Institute of Himalayan Geology, Dehradun-248001, India
KALACHAND SAIN[3], Seismic Interpretation Laboratory, Wadia Institute of Himalayan Geology, Dehradun-248001, India

Abstract

Gas hydrate saturation estimation is vital for assessing gas hydrate reservoirs. Resistivity and acoustic logs are traditionally used to estimate gas hydrate saturation, but they often overlook limitations like calibration of exponent terms, unknown hydrate morphology, mineralogy, and bulk modulus terms. Hence, we address these challenges by employing machine learning (ML) algorithms. This study conducts gas hydrate saturation (Sh) prediction using three supervised machine learning techniques namely Decision Tree (DT), Extreme Gradient Boosting (XGBoost) and Gaussian Process Regression (GPR). The practicability of the proposed method has been demonstrated with well log data from the Krishna-Godavari (KG) offshore basin, India. Initial saturation estimates were made using modified Archie's equation and Indonesian equation from log data of two clay-dominated wells. This data was then used to train the ML models, which further predicted Sh in two neighbouring wells. The accuracy of the ML models was validated through root mean square error (RMSE) and correlation coefficient calculation between original and predicted saturation, showing ML algorithms outperform traditional methods. DT showed the lowest RMSE and highest correlation, while XGBoost and GPR also exhibited reliable prediction performance. Predicted saturation levels at the analysed locations vary from 0% to around 43%, providing precise saturation estimates essential for accurate resource evaluation and strategic production planning.

Fine Structure Description and Hydrocarbon Prediction of Fault-karst Reservoir

Hong ZHANG[1]*, Research Institute of Petroleum Exploration and Development (2384224423@qq.com)
Zhipeng GUI[2], China University of Petroleum (East China)
Junhua ZHANG[3], China University of Petroleum (East China)
Dong CHEN[4], Research Institute of Petroleum Exploration and Development
Pengbo YIN[5], China University of Petroleum (East China)

Abstract

Fault-karst Reservoir is an important carbonate hydrocarbon reservoir. Due to the coupling of strike-slip fault and karst cave seismic response, the fine description and prediction are very difficult. For a case study of YJ Oilfield, some practical methods are ultilized including fine structure description and hydrocarbon prediction.

In order to predict the strike-slip fault, we introduce residual blocks to replace all convolutional layers of the 3D UNet to build a new 3D Res-UNet network and select appropriate parameters through experiments to train a large amount of synthesized seismic data. After the training is completed; we introduce the mechanism of knowledge distillation and train the 3D Res-UNet as teacher network, so as to learn more fault information, improve the performance of the network, and optimize the fault recognition effectFor karst cave, the U-Net++ network is selected as the deep learning model. It adopts a hierarchical and gradually refined feature extraction method, which can effectively process multi-scale and multi-resolution images, and can better capture the details in the image. Two data volumes can be fused together according to a certain probability. It can further integrate with the original data volume to carry out targeted interpretation. Using two primary colors display technique, it can also obtain wonderful horizontal slice.

The hydrocarbon direct description effect is poor, for the reservoir in the study area are interspersed in the reflection events with strong energy. Considering that matching pursuit and compressed sensing are only suitable for the removal of a single seismic event, but there are multiple strong reflection layers, a Karhunen-Loeve transform removing the stratigraphic background is developed through treating the stratigraphic structure as noise. In order to improve the accuracy of denoising, the stratal slicing and interpolation technique are used to obtain an equal-length interpolation cube before the transform is used. After processing, it is embedded into the original data volume. For processed volume, finally, the improved S transform is used to perform high-precision spectral analysis. The study found1The frequency spectrum of high-yield oil wells has absorption attenuation phenomenon;2 The frequency of dry well increases without attenuation;3) The frequency of the water well is not attenuated, and the buried depth is relatively deep.

The studies obtain good results. The methods and techniques have certain guiding significance for the exploration and development of fault-karst reservoir at home and abroad.

Quantification of uncertainty in the reconstruction of resistivity tomography image with machine learning

Xixi LAN[1]*, China University of Geosciences (Beijing) (lxx_cugb@163.com)
Changchun ZOU[2], China University of Geosciences (Beijing)

Abstract

The Electrical Resistivity Tomography (ERT) method plays an essential role in researching electrical properties at the core scale, and the resistivity image inversion reconstruction technique is the key to constraining measurement accuracy. In recent years, with the improvement of computer operation capabilities and the acquisition of a large amount of geophysical data, the inversion algorithms represented by machine learning (ML) have made it possible to reconstruct ERT images automatically. However, the solution of ERT image inversion has large uncertainty due to high nonlinearity. Meanwhile, traditional ML methods are not initially developed for evaluating the uncertainty of such reconstruction results. In this paper, we propose a novel MC-Net ML scheme to quantitatively estimate the uncertainty of the ERT image reconstruction by introducing the Monte-Carlo Dropout strategy with one multiple stochastic method to approximate Bayesian inference. As one important evaluation index, the correlation coefficient (CC) between target image and reconstructed image is used to compare the effects of six types of simulated data carried by different ML schemes. The inversion results show that MC-Net increases lower limit of CC on the premise of ensuring average CC. Moreover, the accuracy of regression and classification results defined in this paper also obtained the highest value by MC-Net. With the proposed scheme, we can further provide a quantification of the uncertainty to determine whether reconstructed images are reliable after reconstructing the ERT images, which is of great significance for actual intelligent inversion tasks.

Xudong QIN[2], Northeast Petroleum University
Yangdong CAO[3], Northeast Petroleum University
Tao LIU[4], Northeast Petroleum University
Ling ZHAO[5], Northeast Petroleum University

Abstract

This study focuses on porous media, combining the distribution frequency of pore throat size measured by mercury intrusion porosimetry and the coordination number obtained from CT scans. Taking into account the shape and wettability of the throat, an adaptive porosity method is employed to construct a digital pore network model based on the fitted measured permeability. Utilizing this model, the paper applies theoretical methods from fluid mechanics, seepage theory, calculus, and numerical calculations to simulate the fluid flow process. Mathematical models for processes of oil saturation, waterflooding, and polymer flooding are established and solved. Furthermore, the state of the model after the oil displacement process is visualized using 3DMAX software. The study identifies that the residual oil shapes after polymer flooding can be classified into various forms such as cluster, throat, blind-end, columnar, and droplet shapes. Moreover, the paper employs MobileNet V1, MobileNet V2, and an improved SENet convolutional neural network model to classify residual oil images, demonstrating that the model can accurately identify residual oil forms. The improved SENet surpasses the original MobileNet models in both precision and recall, with an accuracy improvement of 0.6 percentage points. This achievement not only proves the superiority of the improved SENet in the task of residual oil image recognition but also provides a robust reference for subsequent research work.

Particle Swarm Optimization - Gravitational Search Algorithm Tuned Deep Neural Network to estimate the subsurface interlayer boundary

Sunam Kumar SHARMA[1]*, Geotech Solutions International (sunamsharma@gmail.com)
Anil Kumar Khambampati[2], Jeju National University
Manita Timilsina[3], Geotech Solutions International
Kyung Youn Kim[4], Jeju National University

Abstract

Electrical impedance tomography (EIT) is a non-invasive image reconstruction method. It reconstructs the cross-sectional conductivity distribution of the domain. However, it suffers from poor spatial resolution due to the ill-posed and non-linear nature of the problem. Boundary or shape estimation is the alternative approach to solve this poor resolution problem. In this approach, the number of unknowns to be estimated is reduced which improves the spatial resolution. The conductivity of the closed disjoint region of the domain is assumed to be known as prior for the boundary estimation. The subsurface region can be approximated as piece-wise separate regions with constant conductivity in each region; therefore, the conductivity estimation problem is transformed to estimate the shape and location of the layer boundary interface. Each layer interface boundary is treated as an open boundary that is described using front points. A Deep Neural Network (DNN) model is used to estimate the front points describing the multi-layer interface boundaries. This DNN model is tuned for hidden layer nodes using Particle Swarm Optimization - Gravitational Search Algorithm (PSOGSA). The PSOGSA tuned DNN model is trained for interlayer boundary reconstruction using training data that consists of pairs of voltage measurements of the subsurface domain. The tuned DNN model estimation result is compared with the 7-layer DNN model. The study on all three cases shows the proposed method has a better estimation result than the manually tuned DNN model.

A novel method of seismic data reconstruction in reverse time migration

Yue ZHENG[1]*, CNPC (zhengy2022@petrochina.com.cn)
Wencheng Yang[2], SINOPEC
Tao Xu[3], IGGCAS
Youshan Liu[4], IGGCAS
Ren Jiang[5], CNPC

Abstract

With the development of computer cluster, the application of reverse time migration is widely used in the oil and gas production because of its high imaging resolution and precision. However, the seismic data will be sparsely sampled or irregular sampled due to the constraints of production cost, terrain (such as cities, rivers, etc.) in field exploration and acquisition hardware failure which will have a severe impact on the image quality of reverse time migration. The traditional seismic reconstruction method including the Fourier transform, the wavefield reconstruction based on checkpoint technique, the directional 2D interpolation based on partial differential equation, the point spread function interpolation based on density perturbation, the structural-oriented method and etc. These methods above involve massive amount of computation, domain transform, solving the wave equation and the iteration of inverse problem.

In this paper, we proposed a fast method to reconstruct the missing traces which as a result of irregular sampling by applying the opening- and closing- operation. This process only involves addition and subtraction operation which has higher computational efficiency and faster computation speed. An important character of seismic data is that the event is continuous and the amplitude is similar along the event. In terms of that, several seismic traces are regarded as point sets, and the seismic data reconstruction method can be treated as: under the traverse of the structural element through out several adjacent seismic traces, the value to be interpolated can be predicted using different structural element. The value of the predicted results are used as the amplitude of the points to be interpolated which is a true amplitude processing. This method takes advantage of the "sifter" property of the mathematical morphology to detect the size of structure. Only when the structural element format is larger than the missing points can it be successfully interpolated.

In this paper, we adopted the mathematical morphology method, effectively combined with elastic wave inverse time migration imaging to verify the reconstruction quality through the application of simple and complex model. The results show that the seismic data reconstruction method based on mathematical morphology can effectively recover the frequency, amplitude and waveform characteristics of seismic data in complex subsurface. The noise caused by the inverse transformation of space and frequency domain to time domain is avoided, the diffraction wave converges to the original location, and the migration imaging resolution is much higher, and the missing traces with Gaussian noises in seismic data can be reconstructed.

Characterizing electrical properties of hydrate-bearing sediments during dissociation via 3D multifield-coupled numerical simulation

Xixi LAN[1]*, China University of Geosciences (Beijing) (lxx_cugb@163.com)
Changchun ZOU[2], China University of Geosciences (Beijing)

Abstract

Since natural gas hydrate is stable only under low-temperature and high-pressure conditions, it will dissociate and transform from solid to gas state once conditions vary in the course of exploitation. It is fundamental but challenging to characterize the electrical properties of hydrate during dissociation. However, few studies have been conducted on its dynamic electrical mechanism. Based on the finite element approach, this paper studies the electrical properties of marine hydrate-bearing sediments by constructing the 3D model in the pore scale. Two physical fields of electric and thermal are coupled innovatively to achieve the purpose of dynamic characterization. Moreover, the effects of various hydrate distribution morphologies and saturations have been considered at different times during the dissociation process. The results show that resistivity decreases gradually with temperature change and hydrate phase transition. According to temperature change caused by heat conduction, the hydrate dissociation process can be divided into three stages. Moreover, the variation in saturation during the hydrate phase transition affects the speed of resistivity variation but does not change the trend of that. It is also found that the trend of hydrate dissociation with time is similar for different distribution morphologies. Additionally, the relationship between exponent n and temperature during hydrate dissociation is discussed. This study provides insight into the electrical properties of hydrate-bearing sediments with phase transition and shows potential application value in the exploitation of natural gas hydrate.

Structure of the Denizli Graben-Horst System & Acıgo¨l Graben in the Western Anatolian Extensional Province from magnetotelluric resistivity models.

Ümit AVŞAR[1]*, Istanbul Technical University-Department of Geophysical Engineering, İstanbul Türkiye (avsaru@itu.edu.tr)
Erşan Türkoğlu[2], Saudi Aramco, EXPEC Advanced Research Center, 31311, Dhahran, Saudi Arabia

Abstract

The ongoing convergence between Arabia and Eurasia, which performed by active Aegean and Cyprus arcs in the south, makes Anatolia one of the most tectonically active regions on Earth. Related to this tectonic setting, three regions with different tectonic features have formed in Anatolia. The westernmost of these regions is called Western Anatolian Extentional Province where crust extension takes place related to high angle slab subduction and a slab tearing associated with asthenospheric rising. The reflection of this subsurface structure on the surface is seen as E-W Horst-Graben systems. Survey area is controlled by the WNW-ESE trending, approximately 7-28 km wide and 62 km long Denizli graben-horst system and western part of Acıgöl graben developed upon metamorphic rocks of both Menderes Massif and Lycian nappes. Actively growing grabens are bounded by seismically active oblique-slip normal faults from North and South. The sedimentary basin overlies the Palaeozoic-Mesozoic metamorphic bedrock and comprises Early Miocene–Pliocene sediments consist of conglomerate, sandstone, claystone, limestone, marl and siltstone alternations, Quaternary sediments and travertine occurrences.

The magnetotelluric method (MT) is very sensitive to the variations of conductivity changes in the subsurface and MT method is widely used to reveal tectonic structures in active tectonic zones. The main reason for high conductivity in these regions is the presence aqueous fluids, partial melting or both. Magnetotelluric data were acquired at 300 stations over a frequency range of 10,000 Hz to 0.001 Hz. 2D and 3D inversion were performed to reveal subsurface conductivity structures. In the recovered models, low resistivity values are associated to Çürüksu, Honaz and Acıgöl grabens. Strike directions and Phase Tensor (PT) ellipses reflects the dominant effect of the major faults and conductive basin fills and high frequency PT ellipses have 1D characteristic in compliance with the undeformed, nearly horizontal bedding of the neotectonic graben fills. The depth of the basin fills and conductive features of faults are identifiable in sections.

2-D Integrated Geophysical Modelling Over an Anomalous Magnetic Body in North-Western Bangladesh

Mohammad Tawhidur Rahman Tushar[1]*, Department of Geology, University of Dhaka (mtrt@du.ac.bd)
Asif Ashraf[2], University of Oregon
Anwar Hossain Bhuiyan[3], Department of Geology, University of Dhaka
Md. Shahjahan[4], Geological Survey of Bangladesh

Abstract

As of the present, Bangladesh faces a void in operational iron or metal mines. However, our investigation in the Pirganj region of Rangpur district uncovers a distinctive feature—an intriguing magnetic anomaly coinciding with heightened gravity values. This anomaly reignites the possibility of establishing a metal mine in this region, offering new avenues for exploration. Our study specifically focuses on constructing a 2D model targeting the causative magnetic body in Pirganj, Rangpur. To ensure the model's reliability, we conducted meticulous cross-verification, integrating diverse datasets encompassing gravity measurements, magnetic readings, and drilling data. Notably, the basement in our study area exhibits a tilt, aligning with the Mohorovičić discontinuity (Moho) in the southwest-northeast direction. The inclusion of drilling data becomes crucial, particularly to account for the presence of gabbro—a mafic igneous rock—within the continental crust. Emphasizing the essential incorporation of a conically shaped highly magnetic body, ranging from 220m to 280m, potentially housing magnetite, our model establishes a foundational framework for further exploration and development in Pirganj. This research underscores Pirganj's potential significance for the establishment of a metal mine in Bangladesh, with its unique magnetic anomaly and associated features presenting a compelling opportunity for future mining endeavors and contributing valuable insights to regional geological processes.

Oscillatory constituents of the secular variation of the geomagnetic field

Crișan - DEMETRESCU[1]*, Institute of Geodynamics, Romanian Academy (crisan@geodin.ro)
Venera Dobrica[2], Institute of Geodynamics, Romanian Academy
Cristiana Stefan[3], Institute of Geodynamics, Romanian Academy

Abstract

The study is based on values of the geomagnetic field returned by the model gufm1 (Jackson et al. 2000) of the main geomagnetic field in a grid of 2.5x2.5 degrees of latitude/longitude, covering the European continent, for the time interval of the model validity – 1850-1990). Each time series returned by this model was first subjected to a Hodrick and Prescott analysis (1997), to separate a decadal variation from a so-called trend, and then the trend to a Butterworth (1930) filtering, to retrieve inter-decadal and sub-centennial variations (timescales of 20-30 years, respectively 60-90 years). We show first that external origin residual variations in the annual means provided by geomagnetic observatories or in historical values appear in the decadal, inter-decadal, and sub-centennial time scales values returned by gufm1. Characteristics of the sub-centennial variation in case of the horizontal component is compared to the magnetosphere ring current effects at the Earth's surface, with the important conclusion that variations seen in the geomagnetic field are at least long-term effects of the induction in the Earth of the magnetosphere ring current variations. We are aiming to a new concept of the secular variation of the geomagnetic field, with externally-driven long-term variations superimposed on an internal component secular variation.

Nitin Kumar[5], Geological Survey of India,RSAS Bengaluru

Abstract

The amplitude versus offset (AVO) phenomena on multichannel reflection seismic data can provide substantial exploration and development information to detect the possibility of fluid gas migration with the estimation of amplitude information for seabed along with fault layer. The phenomenon also known as Amplitude versus angle (AVA) and is based on the relationship between the reflection coefficient (RC) and the angle of incidence (θ). Seismic AVO can be classified into four different classes (I, II, III, IV) based on the zero offset reflection coefficient (Intercept, Gradient) which are function of offset or incidence angle. Geological survey of India (GSI) has acquired multichannel seismic data onboard R.V. Samudra Ratnakar within the EEZ of Andaman and Nicobar, Bay of Bengal to study the tectonic setup of Andaman-Nicobar Suture zone and also to identify the stratigraphy and structural pattern in the vicinity of Trench and Accretionary Prism. The present analysis involves the AVO analysis on offshore seismic reflection data (interpreted) showing the presence of fault plane reflection to detect fluid gas zone in the vicinity of trench through the presence of nearly vertical fault bearing negative polarity with reference to Seafloor. Based on the intercept and gradient values using AVO Cross plot, two distinct classes of seismic AVO responses are observed; One is class III AVO with increasing negative amplitudes with increasing offsets and the other is class IV AVO with decreasing negative amplitudes with increasing offsets. The presence of class III AVO anomaly can provide evidence of existence of free gas which may be migrating along the fault system exposed up to the surface. Fluid/gas migration in the shallow subsurface from class III anomaly may indicate the zones of hydrothermal mineralization. Further detailed analysis may provide major insight on offshore reflection data regarding gas migration through fault system.

Kwang-Hee Kim[3], Pusan National University
Su Young Kang[4], Pusan National University
Yu Jin Sohn[5], Pusan National University

Abstract

The Gyeongsang Basin is located in the southeastern part of the Korean Peninsula and is a sedimentary basin formed during the Cretaceous and Cenozoic periods, corresponding to the eastern margin of the Eurasian continent. The Gyeongsang Basin is underlain by the Proterozoic metamorphic rocks of the Yeongnam Massif, thickly deposited by non-carboniferous sedimentary layers(K3, K2) and various volcaniclastic deposits of the Late Cretaceous, and intruded by Bulgugsa granite composed with neutral to acidic plutonic granites of the Tertiary Cenozoic after the deposition of sedimentary rocks and volcaniclastic rocks was completed.

It can be observed that the Bouguer anomaly in the Gyeongsang Basin increases toward the southeast (south of Pohang and east of Gyeongju), and the areas with relatively low Bouguer anomalies within the Gyeongsang Basin coincide with the areas where igneous rocks are distributed. This can be attributed to the lower density of igneous rocks on the Korean Peninsula compared to sedimentary and metamorphic rocks, and the relatively deep distribution of igneous rocks in the Korean Peninsula, which results in lower Bouguer anomalies. This study analyzed the density structure of the Gyeongsang Basin through gravity modeling.

A temporary seismic array was in operation between October 2010 and March 2013 in the Gyeongju area of Korea. Teleseismic records of the seismic array appropriate for receiver function analysis were collected, and selected seismograms were split into five groups based on epicenters the Banda-Molucca, Sumatra, Iran, Aleutian, and Vanuatu groups. 1D velocity structures beneath each seismic station were estimated by inverting the stacked receiver functions for possible groups. The 3D velocity structure was modeled through interpolation of 1D composite velocity structures.

The 3D velocity structure was converted to a density structure. The relationship between seismic wave velocity and density was converted to a density distribution using the equation $\rho=0.714VS+0.287$, which was formulated by Christensen and Stanley (2003) as an empirical relationship between S-wave velocity and density for sedimentary, igneous, and metamorphic rocks from about 2000 core data sets. The average densities of the mantle, lower and upper crust are 3.25 g/cc , 2.90 g/cc and 2.65 g/cc, respectively. The average density of the low-velocity layer in the Gyeongju region is 2.60 g/cc, which is about 20% lower than the average density of the upper crust. Gravity modeling was performed using the converted density structure as the initial density structure.

Gravity modeling indicates that the Mesozoic sediments are overlain by K3 to a depth of about 2,

with K2 below to a depth of about 9 km. South of Gyeongju, the Bulgugsa granite (2.60 g/cc) is expected to be at a depth of about 4 km, and north of Gyeongju, the Bulgugsa granite is found to be at a depth of about 8 km. Southwest of Gyeongju, Bulgugsa granite is encountered at a depth of about 8 km and is associated with a low Bouguer anomalies.

Neotectonic deformation in the southwestern part of the Anatolian Block in consideration of palaeomagnetic results in Bodrum peninsula.

Ümit AVŞAR[1]*, Istanbul Technical University-Department of Geophysical Engineering, İstanbul Türkiye (avsaru@itu.edu.tr)
Turgay İşseven[2], Istanbul Technical University, Department of Geophysical Engineering,İstanbul Türkiye

Abstract

Anatolia can currently be described as the amalgamating of various continental platforms with the closure of Neotethyan ocean.. During this period which is from the Late Cretaceous to the Late Miocene, N-S compression and associated calcalkaline type magmatic activity developed in Aegean and Western Anatolia. After the Miocene, N-S compressional regime was replaced by about N-S extension regime and caused the nature of the magmatism to change from calcalkaline to alkaline type in the region. Bodrum Peninsula takes place in the southwest part of Aegean Region and is the southeast section of the Western Anatolian magmatism that gives outcrop.

On the Bodrum Peninsula, magmatism has started from taking place of the Middle Miocene aged calcalkaline monzonitic pluton, and on the surface it has been followed by the Middle-Late Miocene aged felsic intermediate volcanism. Between these two magma rock groups, similar aged hypabisal rocks take place. They are all together, form a common “magmatic complex” in time, in location and in source. Taking into account the relationships between each other of the rocks forming this association that is called as Bodrum magmatic complex.

Palaeomagnetic samples were collected from 53 Miocene volcanic lavas, autochthonus and relatively undeformed, from different area of the Bodrum Peninsula. Natural remanent magnetisations (NRMs) were measured using a spinner magnetometer, after implementing thermal and alternating field demagnetisation methods on samples. 36 normal and 13 reverse polarities have been determined in the statistically reliable sites. Anti-clockwise rotations are predominant in the study area, clockwise rotation has been determined only 4 sites of the Bodrum Peninsula. The site mean direction is obtained as D=341°, I=50° (k=29.6 and alpha95=3.8°) with perfect consistency which indicates that the Bodrum Peninsula has rotated as a single block with a 23.7° anti-clockwise direction since ~10 Ma.

Seismic Fine Description of Facies Change Reservoir in Subei Basin

Zhipeng Gui[1]*, China University of Petroleum (East China) (gzp_upc@163.com)
Junhua ZHANG[2], China University of Petroleum (East China)

Xiangyu ZHU[4], Jiangsu Oilfield Company, SINOPEC
Lianjun XIA[5], Geophysical Research Institute of Jiangsu Oilfield Company, SINOPEC
Zhen LUO[6], Geophysical Research Institute of Jiangsu Oilfield Company, SINOPEC
Chunli ZOU[7], China University of Petroleum (East China)

Abstract

Subei Basin is the main oil area of Jiangsu Oilfield. There are many types of reservoirs such as beach-bar sand, underwater distributary channel and so on. Due to different strata, buried depth, lithology and gray content, the sedimentary facies and seismic facies are complex, which brings great difficulty to the seismic fine description.

Starting from logging facies analysis, combined with drilling data, seismic calibration and facies analysis are carried out to clarify the geological and geophysical mechanism. In the shoreside, the bioclasts are developed, and their velocities are high, they result in the superposition or even composite of the seismic reflection to a single event. In the transition zone, a set of thin calcareous mudstone develops above the target layer, and its existence makes a strong reflection layer appearing above the reservoir, shielding the reflection of the underlying reservoir, and it is necessary to carry out strong shielding suppression. Multiple sets of strong reflection will appear in the seismic data when multiple sets of gray layers are developed in the reservoir. At this time, the suppression of one seismic event can no longer meet the requirements, and the strong energy of the whole reflection background should be removed. In the deep water zone, although there is no gray development, its sand body generally has the characteristics of high velocity, resulting in the phenomenon of reservoir overarching. Underwater distributary channel, the thickness of sand body is thicker, when the reservoir contains oil, there will be strong amplitude of bright spots, and its spectrum also has attenuation characteristics.

In view of the characteristics of thin reservoir, multiple layers and facies change in the study area, some object processing methods are studied, including: 1) matching pursuit to remove strong reflection; 2) compression sensing to raise frequency; 3) (Karhunen–Loeve) KL transform to remove similar background; 4) 90° phase shift technology to improve sand body characteristics. Three fine reservoir descriptions are put to use. First is using the seismic attribute of zero crossing number to characterize nearshore bioclastic belt. Second is developing a high precision spectrum analysis method of (Mask Filter Wigner-Ville Distribution) MFWVD to predict oil. Third is using a cascade technology of compressed sensing and 90° phase shift to identify thin sand body.

Accounting three facies zones exist in the study area, and conventional thickness prediction method without facies separation cannot meet the actual production requirements, a kind of improved thickness prediction methods are developed. These methods include single-attribute direct fitting, multi-attribute multi-linear regression and (Support Vector Machine) SVM. They all

reached good results.
The research method and technique in this paper make up the theoretical gap of reservoir description and prediction for facies change reservoir to a certain extent, and can also be used as a reference for the fine description of complex reservoirs in other oil fields.

Improved C3 coherence algorithm considering structure dip without interpolation

ZiCheng Wang[1]*, China University of Petroleum (East China) (B23010001@s.upc.edu.cn)
JianGuo Song[2], China University of Petroleum (East China)
Zhe Li[3], China University of Petroleum (East China)

Abstract

Reservoir fractures play an important role in oil and gas transport, and reservoir accumulation. it remains a challenging and hot research topic worldwide in recent decades. The coherence attribute, was first proposed by Bahorich and Farmer (1995), which is the one of most important fracture prediction methonds. Then Gersztenkorn and Marfurt (1999) proposed C3 coherence algorithm based on the eigenstructure of covariance matrices of windowed seismic traces. This algorithm has high robustness and resolution, but does not consider the dip information.

Take dip information into account the coherence calculation is necessary, especially in a region with a large structural dip, the steep dips, such as anticline and syncline, usually cause faintness and low-valued artifacts. Then, interpolation is often necessary in the calculation of time window due to the discrete nature of seismic data. However, interpolation is usually time-consuming when calculating the covariance matrix while considering the structure dip. On this basis we propose a C3 coherence algorithm that considers dip information but avoids computationally expensive interpolation operations by using one-time FFT, iFFT, and matrix product operations. And we used the method proposed by Yang et al. (2017) by using original seismic traces and Hilbert-transformed seismic traces to construct the covariance matrix, which improves stability at the zero-phase point and has higher resolution and better noise immunity ability.

In order to add the dip information to the covariance matrix, we first estimate the dip by the GST(Gradient Structure Tensor) method proposed by Bakker et al. 2002. and obtain the apparent dip p,q in the X and Y directions.

Consideration for dip is achieved by tilting the window. The tilt of the window is determined by multiplying the calculated dip value with the 3D seismic signal in the frequency domain. For the time-domain 3D seismic signal u(t,x,y), according to the time shift property of Fourier transform, if there is F[f(t)]=F(ω), then F[f(t-t_0)]=e^(-jωt_0) F(ω), So for the covariance matrix D and its Hilbert-transform H, we can get the feature matrixes: C_F (p,q)=F^(-1) {e^(-jωt_0)·F[(D^T D)×(H^T H)]}, the dip information is included in t_0, t_0=px_j+qy_j, where x_j,y_j denote the distance of the jth data relative to the center point in the x,y direction of the local analysis window. The final C_F (p,q) is a symmetric semi-positive definite matrix with J eigenvalues, and the C3 coherence value is: C_3=λ_max/Tr(C_new) , where λ_max is the largest eigenvalue of matrix C_F (p,q), Tr(C_F)is trace of matrix C_F (p,q), C_3 has a value between 0 and 1, and small values indicate discontinuity.

This process involves once Fourier forward and inverse transform, as well as a matrix product operation. Its computational cost is significantly lower than that of interpolation calculations. And

the method we proposed will not affect the acceleration of the eigenvalue calculation process,therefore, it can be further optimised on the basis of the method proposed in this paper, thus continuing to improve the computational efficiency.

Valentine TYO[5], State Establishment "Institute of hydrogeology and engineering geology"
Khasan Khasanbaev[6], State Establishment "Institute of hydrogeology and engineering geology"

Abstract

Providing access to clean drinking water for populations residing in mountainous and remote areas poses significant challenges. One of the main difficulties lies in reliably identifying sources of freshwater, as the formation of groundwater deposits is not always clearly understood, and their distribution areas are often uncertain. To address this issue, the utilization of mobile electromagnetic methods offers a promising solution, particularly in regions where limited prior information is available.

Circular vertical electrical sensing is employed to study groundwater filtration flows, allowing for the determination of flow presence and directions based on maximum apparent resistance values. This method investigates the mechanism behind the formation of maximum apparent resistance in the direction of flow. Electroosmosis and groundwater movement in filtration streams lead to surface conductivity on capillary surfaces, resulting in anisotropic properties and the manifestation of electrical anisotropy paradoxes. Electrical resistivity decreases in the direction of flow due to the development of surface conductivity in capillary-porous media.

Filtration flow is not only reflected in electrical properties but also in generated electric field structures, necessitating a comprehensive investigation of development mechanisms. The medium is considered electrically anisotropic, characterizing groundwater movement, with lower resistance in the flow direction. Surface conductivity plays a crucial role, oriented strictly along groundwater flow. Anisotropic property occurrence depends heavily on applied electric field structures.

A model has been developed to study groundwater's anisotropic properties, utilizing symmetrical installations. Dipole sensing installations rotate pie charts by 90°, aligning the major semi-axis perpendicular to flow and the minor semi-axis with flow direction, corresponding to current line and groundwater movement structures. Circular soundings are influenced by filtration flow intensity and geological heterogeneities within the sounding point spacing.

The specific electrical conductivity of the medium, characterizing surface conductivity, correlates closely with aquifer water conductivity. A method for detecting groundwater filtration flow presence in the field has been developed based on these features, focusing on electrical resistivity and anisotropy coefficient parameters, which strongly correlate with water conductivity indicators.

Through the application of this technique, deposits of fresh groundwater have been identified in mountainous and foothill zones, enabling the identification of well sites with higher productivity.

Generalized linear inversion of prestack data based on exact Zoeppritz equation

Guobin HU[1]*, China University of Petroleum (East China) (z22010037@s.upc.edu.cn)
Jianguo Song[2], China University of Petroleum (East China)

Abstract

Geophysical inversion is the study of geophysical inverse problems. The methods of obtaining the elastic parameters of the subsurface medium from seismic data can be categorized into post-stack inversion and pre-stack inversion. Unlike post-stack inversion, which can only obtain impedance, pre-stack inversion can obtain independent elastic parameters more precisely. Pre-stack seismic data inversion is to use the pre-stack seismic data to invert the elastic parameters of the subsurface medium, using these parameters can identify the subsurface fluids, they are also an important basis for evaluating the characteristics of hydrocarbons in the subsurface reservoir. The generalized linear inversion method is a very important part of seismic data inversion. The inversion of pre-stack seismic data is composed of two kinds: full waveform inversion based on fluctuation equation and AVA/AVO inversion based on Zoeppritz equation and its approximation. However, due to the limitation of its approximation, this will make the pre-stack seismic data cannot be effectively utilized. To address this problem, in this paper, the reflection coefficient and transmission coefficient equations for the longitudinal and transverse velocities and densities are derived directly from the Zoeppritz equation based on the elasticity theory, and the longitudinal and transverse velocities and densities are directly inverted based on the generalized linear inversion. The use of the exact Zoeppritz equation effectively avoids the approximation assumptions and angular limitations brought by the use of various approximations, and provides a reliable theoretical basis for the theoretical study of AVO in front of the superposition with higher accuracy. The direct inversion can effectively avoid the cumulative errors brought by repeated calculations, thus improving the inversion accuracy. Through the model test and the actual seismic data data test, it is proved that the above methods can reliably obtain the information of underground medium, which lays the foundation for the subsequent lithology identification and hydrocarbon evaluation.

Optimized spectral decomposition method based on Restart and Adaptive Rapid Iterative Shrinkage Threshold

Jifei Qi[1]*, China University of Petroleum (East China) (qjf1093094085@gmail.com)
Jianguo Song[2], China University of Petroleum (East China)

Abstract

With the development of thin-layer analysis detection methods based on the frequency variation of seismic data, there is an increasingly urgent need for high-precision time-frequency analysis algorithms. Conventional Constrained Least Squares Spectral Analysis (CLSSA) offers high time-frequency resolution, but its matrix inversion process primarily uses Gaussian elimination for solving, which is inefficient and struggles to meet the demands of practical production when facing large matrices. In order to better apply this method in practical seismic data, this paper improves its efficiency in spectral decomposition in practical applications by introducing the efficient optimization inversion algorithm of restarting and adaptive fast iterative shrinkage thresholding (Rada-FISTA).Firstly, by using trigonometric functions as kernel functions, the forward equation between seismic signals and trigonometric functions is established. Diagonal matrix-form model weights and data weights are introduced to constrain and reduce the uncertainty of the inversion solution. At this point, the forward spectral analysis is transformed into the process of solving the inverse problem. To improve the efficiency of the subsequent matrix calculations, a sliding time window is applied to the data to transform it from one-dimensional data to a two-dimensional matrix. Based on the principle of L1 regularization-constrained least squares, the seismic signal's spectrum can be obtained through the introduced Rada-FISTA iterative solution.Comparative analysis with Short-Time Fourier Transform (STFT), Continuous Wavelet Transform (CWT), and CLSSA in theoretical models, as well as practical application results, shows that this method can not only obtain high-precision time-frequency spectra but also has high computational efficiency, with broad application prospects.

Analytical study of geomagnetic observations using automated absolute measurements collected in 2023 at the Cheongyang Geomagnetic Observatory in South Korea.

Sohyeon Park[1]*, Kangwon National University (077psh@kangwon.ac.kr)
Seokhoon Oh[2], Kangwon National University

Abstract

Geomagnetic observations with longer time series and greater absolute accuracy are used in geophysical applications such as producing International Geomagnetic Reference Field(IGRF) and monitoring of secular variations. In particular, the IGRF is used as an important reference model in studies of the dynamics of the Earth`s core field space weather, and localized magnetic anomalies in the Earth's crust(Thébault 2015). The IGRF model is generated based on various data obtained from satellites, ground observatories, and magnetic survey, which are measured in real time, standardized, and shared through the International Real-Time Magnetic Observatory Network(INTERMAGNET) organized by the International Association of Geomagnetic and Aeronomy(IAGA). In South Korea, the Korea Meteorological Administration(KMA) provides geomagnetic field data observed at the Cheongyang Geomagnetic Observatory(CYG Observatory) to INTERMAGNET.

The CYG Observatory utilizes proton magnetometers and fluxgate magnetometers to continuously monitor the total magnetic field and its component variations. And, absolute measurements are performed through weekly visits by observers who measure the declination and inclination. The resulting definitive data are shared internationally via INTERMAGNET and consist of component and total field values for HDZ coordinates. These definitive data require precise values measured in a stable environment and require the skill of the observer to minimize machine errors, especially during manual absolute measurements. At the 2008 IAGA-workshop, an automatic absolute instrument was introduced that automatically performs this manual absolute measurement process without the need for an observer. In 2022, the Korea Meteorological Administration introduced AutoDIF mk2.2, an automatic absolute measuring instrument developed by the Royal Meteorological Institute(RMI) of Belgium, to improve the data quality and maintenance efficiency of the CYG Observatory.

In this study, we analyze the observed declination and inclination measured by the AutoDIF mk2.2 automatic absolute measuring instrument, collected from 2022 to 2023. The automatic absolute measuring instruments at the CYG Observatory measured declination and inclination at hourly intervals and showed a diurnal variation. These variations were confirmed by manual absolute measurements taken at 1-hour intervals during the daytime hours of the summer solstice in 2023. In addition, when the K-index was higher than 4 for declination and inclination, the value fluctuated abruptly. Due to these characteristics of the automatic absolute measurement data, we found that the quality of the data decreases if the definitive data is produced using both the declination and inclination data measured during the day. Therefore, in order to produce stable

definitive data using automatic absolute measurement data, it is necessary to extract time periods that are less affected by diurnal variations and time periods where magnetic storms do not occur. To this end, we proposed a method to analyze the automatic absolute measurement data to consider the variation and compare it with the K-index data. The definitive data produced using the automated absolute measurements data extracted by this method was of stable quality.

Deterministic Approaches and Machine Learning Approaches for fluid detection: a comparison and integration

Mohammed FARFOUR[1]*, Sultan Qaboos University (mfarfour@squ.edu.om)

Abstract

Detecting fluid expression manifested in seismic data is of great importance in reservoir characterization studies. Over time, numerous deterministic techniques have became available for interpreters and explorationists. Attributes extracted from Reflectivity-based AVO (e.g., Gradient, Fluid Factors, Scaled Poisson, etc.) and from Impedance-based AVO (Poisson Ratio, Bulk Modulus, Lambda-Rho, etc.) are good examples of the fluid deterministic approaches. Recently, Machine Learning (both shallow and deep) approaches have increasingly emerged in reservoir characterization and fluid detection workflows and tasks, including Multilayer Perceptron (MLP) Neural Networks, and Convolutional Neural Networks (CNN).

In this study, all the above approaches are examined on synthetic and real seismic data from a gas-saturated field. The approaches are compared in terms of their complexity, accuracy, and resolution. Different modern data analysis tools are implemented to help accomplish the comparison task.

The deterministic approaches are capable of achieving fluid detection with good accuracy but suffer from their lengthy workflows that are prone to error accumulation. Moreover, the latter approaches require special attention and expertise all the way along to mitigate uncertainty. Machine Learning approaches, on the other hand, offer faster implementation with less effort; however, they require special care in the data preparation and during training. In terms of accuracy, both approaches reach a similar level of precision and uncertainty. In conclusion, the choice of approach ultimately rests with the interpreter, taking into into consideration factors such as workflow preferences, expertise, and project requirements.

Abstract

The type of geophysical method used in mineral exploration depends on the characteristics of the type of ore body to be targeted. It has become common nowadays for using different geophysical methods in advanced stages of geophysical mapping after surface geological mapping and geochemistry. This case study highlights the potential of the ground magnetic survey coupled with geochemistry in copper-cobalt exploration in the central African copper belt where there outcrops are less and therefore clear delineation of different lithologies remains challenging. The objective of this study is to highlight how-to low-cost methods can be used i.e. soil geochemical survey and ground magnetics for defining future targets for copper and cobalt exploration. Perhaps, the same method could also be used in other types of copper deposits. In this study, ground magnetic data was used in the preparation of reduced to pole magnetic maps. Further regional-residual anomalies were separated to filter the regional anomalies from depth to keep only the residual anomalies for which causes are geological and located in shallow depth. These residual anomaly maps along with geochemical anomaly and geological maps by superimposition were used in interpreting ore mineralisation. It is inferred that both positive and negative anomalies marks different types of mineralisation mainly disseminated sulphides and oxides. This method of using ground magnetic data in conjunction with geochemical data offers tremendous potential in the exploration of copper-cobalt mineralisation in blind areas with fewer outcrops.

A seismic geomorphology study of the fluvial and shallow-delta facies of the Oligocene Huagang Formations in the East China Sea Shelf Basin, China

Huafeng LIU[1]*, China University of Petroleum (East China) (liuhuafeng1989@163.com)
Chengyan LIN[2], China University of Petroleum (East China)
Xianguo ZHANG[3], China University of Petroleum (East China)

Abstract

The Xihu Depression in the East China Sea Shelf Basin is a significant natural gas-producing region in China, with the primary gas-bearing layers situated in the upper section of the Oligocene Huagang Formation. During this period, the depression was in the post-rift stage, characterized by the development of a fluvial and shallow-delta sedimentary system. The presence of widespread thin sand bodies within the fluvial and shallow-delta sedimentary system poses challenges for the exploration and development of lithologic oil and gas reservoirs in sparse well areas due to rapid lateral and vertical changes in sedimentary facies.

In this study, we primarily utilized high-resolution 3D seismic data and employed a comprehensive set of techniques, including seismic attributes, stratigraphic slicing, wavelet transforms, RGB fusion, and multi-attributes fusion driven by AI. These techniques were applied for seismic geomorphological analysis of the fluvial-shallow water deltaic sedimentary system. Concurrently, modern sedimentology (including braided rivers, meandering rivers, and shallow-delta) were incorporated to better guide the quantitative seismic geomorphological interpretation of different channel types within the fluvial and shallow-delta sedimentary system. Based on quantitative interpretations of typical seismic geomorphology within high-frequency sequence stratigraphy (fifth-order) in the study area, multiple types of in-channel deposites with obvious characteristics are developed in the target layer, including braided channel, lager high-curvature meandering channel, micro meandering channel and underwater distributary channel. The evolution of channel patterns is mainly driven by paleoclimate change, paleogeography and base-level change (medium-term cycles). Within the fourth-order sequence, the base level rose, the paleoclimate became drier, and the paleo-slope gradient decreased, leading to a transformation of channel types from braided channels to meandering channels and underwater distributary channels.

This study integrates model-driven and data-driven seismic geomorphology interpretation methods, establishing a new quantitative seismic geomorphology interpretation workflow. It accurately characterizes various channel systems within the upper section of the Huagang Formation in the southern part of the Xihu depression, yielding reliable sandbody distribution results and providing guidance for the exploration of lithologic traps in the area.

Research On The Frontier Technology Of Continuous Coring For Directional Drilling

Jie Ren[1], Jilin University
Yinlong MA[2]*, Jilin University (ylma@jlu.edu.cn)
Xiaoyang Li[3], The Institute of Exploration Techniques, CAGS
Qingquan Zhou[4], Jilin University

Abstract

How to obtain rock or ore core samples quickly and continuously to provide accurate parameters for the evaluation of mineral resources reserves is a key technical challenge in the stage of domestic mineral exploration. Aiming at the exploration technical problems of "low ore content and low core monitor rate" of strategic rare-earth metal minerals and scarce strategic iron ore resources in the coal system, the company intends to independently research and develop high-precision, low-cost, high-efficiency precision directional drilling and continuous core-taking technology, overcome the incompatible bottleneck between directional drilling and core-taking, and realize the precise regulation and improvement of drilling trajectory, and help build a transparent mine system. Meanwhile, in the process of strategic mineral resources exploration and sampling, the traditional vertical holes are faced with the problems of high investment in a single hole and limited access to geological information, which can't meet the needs of efficient reserve exploration. In this respect, based on wireline coring and directional drilling technology, a continuous coring technology for directional drilling is proposed, which is intended to realize efficient and accurate acquisition of geological cores in underground three-dimensional space. This study formulated the continuous coring drilling process for directional drilling, determined the specification size of drilling tools and borehole caliber, and carried out the structural design of directional coring drilling tools and the trial production of drilling tools. Innovative design of small-diameter, high-flexibility directional drilling continuous coring new technology, the formation of a push against and hollow single-bend short section synergistic drilling tool attitude precision control technology, the development of salvageable small-diameter high-torque screw motors and storage-type drilling probe tube and other core key components, and strive to provide rapid and efficient drilling tools and process methods for the exploration of mineral resources to increase reserves.

Research on Anti-Adhesion and Drag Reduction Performance of Bionic Sampling Tube for Shallow Submarine Sediments

Pengyu ZHANG[1]*, Jilin University (pengyu1213@jlu.edu.cn)
Yuan Wang[2], Jilin University
Rui Jia[3], Jilin University
Xiaochu Wang[4], Jilin University
Wei Guo[5], Jilin University

Abstract

The ocean floor harbors abundant mineral resources, and the coring and acquisition of high-quality core samples from deep-sea sediments are prerequisites and foundations for exploring the occurrence of deep-sea mineral resources. Due to the high water content, high clay content, and high plasticity of submarine sediments, they are easily disturbed and damaged during sampling, resulting in low sample recovery rates and sample plastic deformation, which affect the determination of engineering geological properties of submarine sediments and the evaluation of marine resources, posing technical challenges in marine exploration engineering.

Evolved over billions of years, active soil organisms in soil have self-cleaning properties on their body surfaces, attributed to their non-smooth surface and material composition. Based on the self-cleaning and low adhesion characteristics of dung beetles in soil, a material-non-smooth structure-coupled bionic sampling tube for marine sediment sampling was developed. Submarine sediment samples were prepared according to the material composition and particle size distribution characteristics of submarine sediments. The coring effect of the sampling tube was analyzed using a drilling and sampling test platform. The results show that the non-smooth corrugated structure can effectively reduce the penetration resistance of the sampling tube, and the low interfacial energy of the polytetrafluoroethylene coating can effectively weaken the clay adhesion. Under the combined action of low interfacial energy materials and non-smooth structures, the sample recovery rate can be effectively improved, and the sample quality can be enhanced.

Complete high-fidelity samples are an important basis for evaluating marine resources. This study introduces the theory of biomimetic engineering and develops material-structure-coupled sampling tubes for submarine sediments, providing technical support for the accurate evaluation of submarine mineral resources.

Abstract

Due to the advantages of high specific strength, low density, low bending stress, stable mechanical properties, and corrosion resistance, aluminum alloy drill pipes can better meet the needs of deep drilling compared to traditional drill pipes. As a high-strength forging alloy,7075aluminum alloy is the most commonly used material for aluminum alloy drill pipes. It is easy to process and can be heat treated to enhance mechanical properties such as strength and hardness. In this study, the new 7075Al composites reinforced by 3.0 wt.% micro-TiC particles and nano-SiC particles (n-SiCp) with different mass fractions (0, 0.2, 0.5 and 1.0 wt.%) were successfully prepared by powder metallurgy method. The precipitated phases became more homogeneous with increasing amounts of added n-SiCp. Furthermore, there were no apparent reaction products at the interface between the n-SiCp and the 7075Al matrix. As the content of n-SiCp increased, the compactness of the new 7075Al composites first improved and then declined. The maximum compactness of 7075Al composite material was 97.88% when the n-SiCp content exceeded 0.2 wt.%. The wear resistance of the composite materials had been improved after adding n-SiCp. The wear resistance of the 0 wt.% n-SiCp/7075Al composite material was the worst, and the composite that filled in 0.2 wt.% n-SiCp got the most excellent wear resistance. Furthermore, with the increase of n-SiCp addition, the friction coefficient and wear quality of the composite material gradually increased. Under the load of 15N, the friction coefficient and wear mass of the 0 wt.% n-SiCp/7075Al composite material reached maximum, with the friction coefficient of 0.3290 and the friction mass loss of 8.6 mg. The friction coefficient of the 0.2 wt.% n-SiCp/7075Al composite material reached minimum, with a decrease of 16.6%, at 0.2745. The friction mass loss of 0.2 wt.% n-SiCp/7075Al composite material was 3.9mg, which as 54.7% better than the 7075Al matrix. It was the relatively uniform distribution of n-SiCp and the well-bonded interfaces between the n-SiCp and the 7075Al matrix that led to improvements in the wear properties. The results are preliminary but can be used to significantly promote the development of n-SiCp reinforced aluminum metal matrix composite materials.

[Keynote] Identification of prospective regions for selected critical minerals through integrated geophysical, geochemical and geologic data

Carol A FINN[1]*, US Geological Survey (cfinn@usgs.gov)
Cliff D Taylor[2], US Geological Survey

Abstract

Exploration for critical elements requires integration of a variety of geophysical, geochemical and geological data as most deposits are not exposed. Mineral resource assessments and prospectivity mapping exercises identify the potential for undiscovered minerals deposits and help project future resource development. Here we present a few examples of approaches to prospectivity mapping of several critical minerals. Platinum-group element (PGE) exploration in layered mafic intrusions such as the Stillwater, Duluth and Bushveld Complexes relies heavily on understanding the geophysical signature of the entire magmatic system. Mapping the 3D geometries of layered intrusions and their staging chambers are important for exploration because large igneous systems are more likely to have PGE-enriched deposits than small ones. The presence of cyclical layering indicates possible PGE targets and knowing the stratigraphic order of the layering may help trace economic horizonsbelow cover. Gravity models constrained by geologic mapping, rock properties, upper and lower crustal thickness and/or densities typically derived from seismic velocities, and magnetotelluric (MT) data constrain the areal distribution of the Stillwater, Bushveld and Duluth Complexes. Although the thickness of the intrusions are poorly constrained due to uncertainties in crustal and mantle densities, reasonable ranges of 1-10 km can be obtained. The Stillwater and Bushveld Complexes extend significantly beyond their extents mapped at the surface.

Mauritania is the 15th largest iron producer in the world but recent depletion of high-grade hematitic ores requires prospecting for lower grade iron in highly magnetic banded iron formations. High amplitude aeromagnetic highs identify target areas where magnetite BIF that contains low magnetization hematitic ore is likely to be thickened by faulting or foldingDepth to basement calculations from the aeromagnetic data indicate prospective regions for iron deposits buried beneath sand and less than 1000 m depth.

Assessment of tungsten mineralization in central Uzbekistan is based on regional geological, remote sensing, geochemical and geophysical data that allows identification of potential tungsten-bearing skarn in carbonates adjacent to plutons. Geologic mapping and remote sensing, extended beneath cover based on borehole data, identifies the carbonates. Aeromagnetic data image magnetite-poor plutons, and the soil geochemistry identified anomalous tungsten values. Estimates of undiscovered tungsten skarn deposits in permissive tracts are combined with grade and tonnage distributions of known deposits to generate probabilistic estimates of undiscovered resources.

Rare Earth element prospectivity in southeastern Botswana is related primarily to alkaline

complexes and carbonatites. Aeromagnetic highs identify carbonatites and geologic mapping and gravity data identify structural corridors in which the deposits may have formed. Radiometric data identify granitic plutons enriched in potassium, uranium and thorium, which could be sources of REE's. Because many of the carbonatites are buried beneath sand, the REE prospectivity map relies on mapping magnetic anomalies with similar shapes and amplitudes as those associated with known carbonatites that are on or near major structural corridors.

Identification of River Sand Body Based on Deep Residual Shrinkage Network

yufei SU[1]*, China University of Petroleum (East China) (b22010044@s.upc.edu.cn)
Jianguo Song[2], China University of Petroleum (East China)
Zhe Li[3], China University of Petroleum (East China)

Abstract

The study of channel sand bodies has always been a key and difficult point in the exploration of oil and gas resources in terrestrial sedimentary basins. At present, the methods of using seismic data for oil and gas detection can be summarized into three categories: pre-stack AVO technology, multi-wave and multi-component oil and gas detection methods, and post-stack seismic attribute analysis technology. The prediction methods based on amplitude, impedance, and other factors have not fully explored the inherent information contained in seismic data, resulting in a strong multiplicity of solutions.

Based on known cases of river sand research, utilizing various information such as seismic data, logging curves, and drilling cores, and introducing artificial intelligence theory, a deep residual shrinkage network is constructed. The deep residual shrinkage network is mainly based on three parts: deep residual network, soft threshold function, and attention mechanism. The deep residual network adopts a cross-layer, identity path approach to alleviate the training difficulty of deep networks. Utilize attention mechanism to achieve soft thresholding of features and learn features for highly redundant data. Before training, preprocess multiple seismic attributes. By integrating multiple seismic attributes and using logging curves as label constraints, an intelligent network can be trained to achieve intelligent prediction of river sand bodies. This network can integrate multiple seismic attributes, eliminate redundancy between attribute data, and obtain a new attribute. The fused output attributes can effectively indicate the distribution of river sand bodies. Combined with logging data verification, it has very high accuracy.

New progress in research of lightweight wear-resistant drilling pipe materials

Shaoming MA[1]*, CCTEG Xi'an Research InstituteGroupCo., Ltd. (mbright@163.com)
Chuanliu WANG[2], CCTEG Xi'an Research InstituteGroupCo., Ltd.
Geng LI[3], CCTEG Xi'an Research InstituteGroupCo., Ltd.

Abstract

With the integrated development of drilling and geophysical exploration technology, the proportion of drilling projects with precised controlled trajectories such as horizontal wells and directional wells is increasing. The traditional steel drill pipe is hard to satisfy the safety and efficiency due to its large weight, poor corrosion resistance, and serious drag pressure. Aluminum alloy is the most mature and widely used non-steel lightweight structural material, but the engineering practice has proved that the surface wear resistance of aluminum alloy drilling tools is insufficient, which is easy cause wear failure. Therefore, lightweight wear-resistant composite pipe has become a potential replacement material for drill pipe used in current drilling construction. The steel and aluminum alloy are combined by advanced preparation and connection technology, making full use of the advantages of light and high strength of aluminum alloy and good wear resistance of steel. The thin layer of alloy steel is coated in the outer wall of the thick wall aluminum alloy tube to prepare light wear-resistant bimetal composite pipe. The inner layer of the drill tool is light aluminum alloy, which plays the role of bearing pressure. The outer layer is thin wall steel pipe, which plays the role of wear resistance and protection. The bimetal composite pipe can effectively reduce the weight of drilling tools per unit length without reducing the wear resistance of drilling tools, providing solutions for the lightweight and life extension of drilling tools required for coal field geological exploration, underground gas extraction, water damage prevention and comprehensive utilization of coal seam gas mining. At the same time, it provides new materials and new technical support for lightweight wear-resistant drilling tools for ultra-deep drilling such as oil, gas and scientific drilling.

Enhancing Reservoir Performance Prediction Through Advanced Data Analytics and Machine Learning: A Study on Reservoir Evaluation Management for Improved Oil and Gas Recovery in the Orange Basin, Namibia.

Freddie Nampa KAFULA[1]*, YES Network Namibia, Geological Survey of Namibia (kafulafredricka@gmail.com)

Abstract

The oil and gas industry's pursuit of innovative strategies for optimizing reservoir performance and augmenting recovery methodologies has led to the integration of advanced data analytics and machine learning techniques. With the current oil discoveries in Namibia, this research focuses on leveraging these technologies to enhance reservoir performance prediction, specifically emphasizing reservoir evaluation management in the unique geological context of the offshore Orange Basin, Namibia. The primary objective is to advance the understanding of reservoir dynamics and improve the accuracy of recovery forecasts, thereby facilitating more informed decision-making in the field of oil and gas production. The research methodology involves the comprehensive integration of historical reservoir data, encompassing geological, petrophysical, and production parameters, into a unified dataset. Advanced application of geological modelling software such as Petrel and seismic interpretation software, and machine learning algorithms will all be utilised to unveil intricate relationships and patterns within the dataset. The study also explores the incorporation of real-time data streams from sensors and monitoring devices to enhance the temporal aspect of reservoir performance prediction. This real-time data integration allows for dynamic model adjustments, enabling adaptive management strategies to respond promptly to changing reservoir conditions. Therefore, this culminates in the development of predictive models capable of deciphering intricate patterns, optimizing exploration and development, and mitigating unique risks associated with the basin's complex geological setting. Additionally, accurate predictions will contribute to maximizing recovery rates and minimize uncertainty in geological interpretations and the overall environmental footprint. In conclusion, this study contributes to the broader reservoir management knowledge by showcasing the efficacy of advanced data analytics and machine learning in comprehending reservoir dynamics within the unique context of the Orange Basin, Namibia. The results offer valuable insights for industry professionals and decision-makers seeking to maximize oil and gas recovery while navigating the challenges of this specific geographic and operational environment.

ShengPing GONG[5], Institute of Geophysical and Geochemical ExplorationCAGS
HongYu GUO[6], Guilin University of Technology

Abstract

Due to the rapid development of China's economy and significant improvement in national living standards, the demand for copper, nickel, and other mineral resources in key industries such as energy, automobiles, and construction is continuing to grow. However, meeting the rapidly expanding demand for nickel resource reserves and production in China is a challenge. Therefore, exploring copper-nickel and other polymetallic resources is particularly crucial. Long-term resource development gradually depletes surface and shallow, easy-to-mineralize deposits. Therefore, there is a urgent need to explore new areas to alleviate the shortage of resources. Currently, global exploration efforts are focused on exploring deeper continents and overburden directions. The conventional approach of relying on geological outcrops for the discovery of ore bodies and mineralization information is also shifting towards geological theoretical predictions and integrated physico-chemical exploration techniques.In recent years, comprehensive geophysical exploration methods have played an important role in the field of metal ore detection. Breakthroughs have been made in the detection of hidden ore bodies in the covered area. The Jing'erquan area in the East Tianshan Mountains of Xinjiang presents challenges to surface geological exploration for ore bodies due to its shallow coverage. This study overcame these challenges through a combination of geophysical methods. The exploration process began with magnetic anomaly mapping to identify areas of interest. Next, the TDIP method was used to estimate mineralization extents and structural distributions within the mining area. Finally, the Controlled Source Electromagnetic (CSEM) method was employed to generate resistivity section maps, revealing underground structural characteristics and ore body occurrences.

Comprehensive data processing and interpretation identified two magnetic anomalies and two IP anomalies. The results of these applications provide

foundational support for future drilling projects in the mining area and offer valuable insights for similar regions seeking copper-nickel polymetallic deposits. In summary, integrated electromagnetic methods can achieve economical and effective metal ore detection in the study area. The obtained physical parameters are consistent with each other and minimize the influence of polydisintegration, resulting in better outcomes. These results not only provide a scientific basis for subsequent drilling work in the Jing'erquan area but also offer a valuable methodological and empirical reference for exploring Cu-Ni polymetallic deposits in other areas with similar geological features.

An efficient 3D inversion algorithm for the inversion of large-scale magnetic dataset when remanence exists

Xiaohong Meng[1], China University of Geosciences, Beijing
Jun WANG[2]*, China University of Geosciences, Beijing (wangj@cugb.edu.cn)
Yuan Fang[3], China University of Geosciences, Beijing

Abstract

In mineral exploration, the ores with magnetic susceptibility contrasts with the surrounding rocks can be well studied by using the physical property inversion of the magnetic data. However, in real applications, the inversion of magnetic data is often affected by the existence of remanence. In addition, computational efficiency is another challenge faced by the inversion of large-scale dataset. In order to address the above two issues, this study introduces an efficient magnetic inversion method in the presence of strong remanence. In this algorithm, the objective function for the converted magnetic component is established based on the weighted data misfit term and regularization terms. Then, the complex nonlinear relationship between the transformed magnetic data and magnetic susceptibility is linearized using the Taylor series approximation. To achieve efficient computation, the objective function is further derived to a general Tikhonov form using matrix equivalence transformation. Afterwards, a fast randomized algorithm is adopted to solve the standard Tikhonov problem efficiently. Notably, the regularization parameter can be determined simultaneously utilizing the intermediate parameters of the randomized algorithm based on the generalized cross-validation (GCV) criterion. The effectiveness and efficiency of presented method is tested on synthetic examples, and is successfully applied to two real magnetic datasets in China.

Accurate first arrivals picking method combining dynamic threshold control and bisection in complex geological environment.

Hongyan Yan[1]*, China University of Petroleum (East China) (1362568562@qq.com)
Zhenchun Li[2], China University of Petroleum (East China)
Haotian YANG[3], China University of Petroleum (East China)

Abstract

In today's world, the pursuit of oil and gas exploration is reaching deeper and more complex territories. However, the significant variations in the near-surface low-velocity zone present greater challenges in accurately positioning and characterizing exploration targets, thus increasing the difficulty and complexity of tasks in this domain. The precise identification of first arrivals is essential in seismic exploration, as it lays the groundwork for further calculations related to surface velocity, layer thickness, and plays a pivotal role in static corrections. Given the challenge of achieving precise first arrivals picking under complex surface conditions, greatly affected by the signal-to-noise ratio, we propose a novel and comprehensive methodology. This technique integrates dynamic thresholding with the dichotomy method for the efficient picking of first arrivals. Unlike the traditional fixed thresholding method in the time domain, our approach employs a sliding window technique to concentrate on local features, thereby capturing signal variations over time. By adjusting weights based on various parameters such as signal-to-noise ratio, local energy, and local gradient, we establish local thresholds. These thresholds are then used to plot threshold curves, which in turn delineate the estimated range of the first arrivals. This method is more adept at accommodating the temporal variations of seismic signals and is versatile enough to handle different types and changing amplitudes of seismic signals, optimizing the initial picking outcomes. To pinpoint the exact onset of the first arrivals wave more accurately, a bisection method is employed for focused searching within the preliminary picking range. Through iterative refinement of the time window, the precision of first arrivals picking is significantly improved. Upon evaluation, this comprehensive strategy demonstrated superior performance, especially in complex geological settings and noisy environments. Overall, this method meticulously accounts for the time-domain characteristics of seismic signals and achieves accurate picking of first arrivals by harmonizing dynamic thresholding with the bisection method.

Abstract

It is a trend in the development of geophysics to seek wave theory closer to the physical reality and derive corresponding wave equations to achieve the highly accurate forward modeling, imaging, and inversion of complex structures. There always exist complicated internal microstructures, common for both the natural rock and soil medium and man-made materials. Recently, researchers have introduced the framework of generalized continuum mechanics (GCM) theory to seismic wave propagation, taking into account the influence of heterogeneity caused by complex microstructure characteristics of the medium, and derived the corresponding asymmetric wave equations (Wang et al., 2021; Wu and Ma, 2022). The GCM theory enriches the context of the classical continuum mechanics theory by introducing the additional higher than the first-order displacement gradients and the first-order rotation gradients, and the additional characteristic length scale parameters characterizing the microstructure characteristics of the medium (Yang et al., 2002; Kong et al., 2009; Karparvarfard et al., 2015; De Domenico et al., 2019). The couple stress theory, as a branch of the GCM theory, is relatively successful and widely used (Wang et al., 2020; Bai et al., 2023). In the frequency band of seismic waves, Wang et al. (2020) derived elastic wave equations based on the modified couple stress theory and simulated the seismic waves excited by high-speed trains under the viaduct system.

In this abstract, based on the asymmetric wave equations in the framework of the modified couple stress theory, we derive the decoupled asymmetric wave equations according to the Helmholtz decomposition theorem. The expression of the phase velocity of P- and S-wave in the modified couple stress theory is given. Then, according to the theoretical analysis and numerical modeling, we focus on the influence of heterogeneity caused by the microstructure characteristics of the medium on S-wave propagation. The results of theoretical analysis and numerical modeling indicate that the heterogeneity caused by the microstructure characteristics of the medium leads to the dispersion of the S-wave. The perturbation of the S-wavefield caused by microstructure interactions of the medium increases with the increase of the characteristic length scale parameter.

Improving Seismic Profile Resolution through Inversion of Reflection Coefficients based on Short-Time Fourier Transform and Restarted Fast ADMM

Wei SONG[1]*, China University of Petroleum (East China) (2969623819@qq.com)
ZhenChun Li[2], China University of Petroleum (East China)
Min Zhang[3], China University of Petroleum (East China)
Min Hu[4], China University of Petroleum (East China)
XiangDa Feng[5], China University of Petroleum (East China)

Abstract

As exploration efforts intensify, thin beds and interbeds underground have emerged as primary targets. However, their thickness being below the conventional tuning threshold results in waveform interference between layers, compromising layer resolution. Enhancing seismic profile resolution is crucial in seismic exploration. Traditional methods for resolution improvement, such as compression-aware sparse inversion, face two significant challenges. First, the Fourier transform's limitation in correlating specific frequencies with time can lead to an overemphasis on local high-frequency components during frequency expansion. Second, the vast volume of seismic data, combined with conventional iterative algorithms like the alternating direction method of multipliers (ADMM), greedy algorithm, and iterative shrinkage thresholding algorithm, results in high computational costs and diminished accuracy. To address these challenges, we propose two innovative solutions. Firstly, we employ the short-time Fourier transform (STFT) over the traditional Fourier transform (FT) for frequency band expansion across various time intervals. This approach ensures that the frequency magnitudes throughout the time domain are consistent with the seismic wave propagation law. Secondly, we introduce the restart fast ADMM (READMM) algorithm to the sparse inversion challenge. Unlike ADMM, READMM incorporates the acceleration principle found in Nesterov's gradient descent method, allowing for variable updates based on the outcomes of the two preceding iterations. This method also integrates a "restart" mechanism that mitigates oscillations during iterations, enhancing both computational efficiency and accuracy. Empirical evidence from both synthetic and real-data experiments validates that our method not only reduces computational expenses but also significantly enhances the resolution of seismic profiles.

Wave propagation and analysis under the single-parameter second-order strain gradient theory

Chaopu CHEN[1]*, Institute of Geology and Geophysics, Chinese Academy of Sciences (bh_ccp@163.com)
Hong LIU[2], Institute of Geology and Geophysics, Chinese Academy of Sciences
Lifeng WANG[3], Hainan Branch of CNOOC (China) Ltd
Wenlei BAI[4], Institute of Geology and Geophysics, Chinese Academy of Sciences
Zhiyang WANG[5], Beijing University of Chemical Technology
Youming LI[6], Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

To reflect the finer subsurface structures and construct the relation between the microstructures of the medium and seismic response, it is needed to seek the wave theory and corresponding wave equations closer to the physical reality. There always exist complicated internal microstructures in both man-made materials and natural rock and soil media. Recently, researchers have introduced the framework of generalized continuum mechanics (GCM) theory to seismic wave propagation, taking into account the heterogeneous response caused by complex microstructure characteristics of the medium, and derived the corresponding generalized wave equations (Wang et al., 2021; Bai et al., 2023).

In the second-order strain gradient theory, a relatively successful and widely used branch of the GCM theory (Mindlin, 1964; Aifantis, 2011; Wang et al., 2021), the smaller-scale microstructural interactions can be described by introducing the higher derivative and the additional characteristic scale parameters of the medium. According to the Cosserat theory (Cosserat, 1909), Mindlin (1965) introduced the second-order strain gradient into the strain energy density function and proposed the second order strain gradient theory. Askes and Metrikine (2005) applied the continuum method to convert the discrete heterogeneous medium at a small scale into a continuous homogeneous medium at a large scale, and derived the equivalent constitutive equation including the second-order strain gradient and the characteristic scale of the medium. Aifantis (2011) proposed the nonlocal-gradient linear elasticity theory by combining the nonlocal theory, that is, the stress at one point is related not only to the strain at the point, but also to the strain at all points in a certain neighborhood of the point. According to the nonlocal theory, Wang et al. (2021) investigated the constitutive equations of the single-parameter second-order strain gradient theory, and derive the mathematical expression of the generalized elastic wave equations by incorporating the geometric equations and the differential equations of motion, and also analyzed the influence of scale effects caused by microstructure interactions of the medium on seismograms.

In this abstract, based on the generalized elastic wave equations in the framework of the second-order strain gradient theory, we derive the decoupled generalized wave equations according to the

Helmholtz decomposition theorem. And the expression of the phase velocity of P-wave and S-wave considering the microstructure characteristics of the medium is given. Then, according to the theoretical analysis and numerical modeling, we focus on the influence of heterogeneity caused by the microstructure characteristics of the medium on wave propagation.

A holistic approach towards geophysical characterization of the Quick Clays in Norway; A case study from Gjerdrum

Saman Tavakoli[1]*, NGI (saman.tavakoli@ngi.no)
Christos Boufidis[2], TEM Company
Thue Bording[3], TEM Company
Søren Bjørn[4], TEM Company
Le Hue Thi Minh [5], Norwegian Geotechnical Institute (NGI)

Abstract

About 5,000 km2 of Norway is covered by marine deposits, with 20% of this area consisting of highly sensitive clay, or quick clay. In the early hours of 30.12.2020 at Ask village in Gjerdrum, Norway, a quick-clay landslide costs the lives of several 10 residents and led to destruction of several houses. To better understand the ground conditions, a combined geophysical-geotechnical investigation took place at and around the landslide area in Gjerdrum.

Geophysical investigations were conducted to, together with geotechnical results, improve the existing ground model. These geophysical investigations include Electrical Resistivity Tomography (ERT), Towed Transient Electromagnetic (tTEM), ground magnetic and refraction seismic data which were conducted in three zones in and around the landslide area. In this paper, we present results from tTEM and ERT data. Data processing, filtering and inversion was applied on all geophysical data prior to the interpretations. Resistivity contrast was observed between the values for leached clay (potentially quick), unleached clay, and bedrock, which made it possible to identify potential high-risk areas. Results from interpretations of the multidisciplinary data indicate three major stratigraphic units. A thin layer of dry crust with generally higher resistivity (ca. 200 – 400 Ωm) compared to the underlying (predominantly) clay layer.

Our holistic approach proved efficient for indirect characterization of the quick clay areas based on e.g., estimating depth to the top of bedrock and identifying slope steepness. This information, when combined with direct characterizations based on geotechnical investigations, can provide significant information about ground conditions, and thereby reduce the risks associated with quick clay landslides.

Quick clay landslides, geophysical mapping, electromagnetic, geotechnical investigations

Interpretation of aero-magnetic ring features in Sausar fold belt, Bastar Craton, Central India

SHEIKH MOHAMMAD SHAKIL HASHMI[1]*, GEOLOGICAL SURVEY OF INDIA
(sheikhmohammad.hashmi@gsi.gov.in)

Abstract

The central India exposes rock formations ranging from the Archaen to Quaternary period which are represented by cratonic segments of Bundelkhand and Bastar along with Proterozoic fold belts like Sakoli, Sausar, Mahakoshal and Betul. Owing to its unique geological set up, the central India is known to host plenty of mineral deposits of gold, base metals and industrial minerals.

The study area is located in Seoni and Balaghat districts of Madhya Pradesh and Bhandara and Gondiya districts of Maharashtra, Central India. The area is known for manganese deposits and geologically comprises Tirodi gneiss overlain by rocks of Sausar fold belt which include quartz muscovite schist, biotite schist, quartzite, marble and calc gneiss.

Multi-Sensor Aero-Geophysical Survey was carried out under the ambit of the National Aero-geophysical mapping program (NAGMP) over block IV in parts of Chhattisgarh, Madhya Pradesh and Maharashtra covering an area of 48000 sq. Km. The survey was carried out at an altitude of 80m with a line spacing of 300m which helped in generation of high resolution geophysical maps and delineation of concealed mineral potential areas.

Three aero-magnetic ring like features were identified in the area using the aero-magnetic reduced to pole map and other derivative maps like ANS and 1st vertical derivative which were correlated with the occurrence of manganese deposits found in the area to identify new/concealed locales of manganese mineralization.

On ground its was observed that the known occurrences of Tirodi, Jam, Arjuni, Jarahmohgaon, Hatoda and Garra Chowki manganese mines lie along the margins of the identified magnetic ring features. It was also observed that these manganese mines are associated with magnetite and hematite within muscovite schist having sheared contact with granite. In the areo magnetic tilt derivative map, two major shear zones trending NNE-SSW have been identified in the area along the peripheries of ring structures which are related to mineralization as evident from the sheared contact between granite and muscovite schist. The presence of magnetite is responsible for high magnetic intensity at the mineralized locations thereby creating a ring like pattern in the aero-magnetic map and its derivatives. At a few places along the ring, lateritic zones were also observed. A linear magnetic feature trending NE-SW intersects one of the ring features at two locations near Tirodi and Jaramohgaon villages and both these locations host huge manganese deposits suggesting a possible control of this feature in deposition of manganese.

Based on these observations, it may be concluded that manganese mineralization in the area is structurally controlled and majority of known mines/old workings lie along the margins of the ring features thereby opening possibilities of exploration of new/concealed deposits of manganese along the margins of the ring features in gap areas like west of Jam, south of Jarahmohgaon and

Garragusai. The present study therefore throws light on utility of aero-magnetic data for direct mineral targeting at mineralized zones associated with magnetite and other ferrimagnetic minerals.

Slope Failure Back Analysis from Ground-Based Radar Data to Estimate the Safe Re-entry Time After Failure

Dio Yudha PRATAMA[1]*, GroundProbe (dio.pratama@groundprobe.com)
Muhammad Ikhsan Nasrullah[2], GroundProbe
Ignatius Ega Putra[3], GroundProbe

Abstract

The main objective of modern mining operations is to extract resources safely and efficiently, economically maximizing production. On the other hand, slope failure hazard is one of the factors that could affect the conformity between the mine production plan and the actual mining activity. As a result, slope failure hazard management is essential to ensure that the site personnel is always working in a safe environment and that mine production is in accordance with the actual plan. In that case, real-time slope monitoring to evaluate and control risks associated with unstable natural and engineered slopes is crucial.

Slope monitoring tools that are widely utilized to control slope failure risk is interferometric ground-based (GB) radar which offers capabilities for real-time measurement, sub-millimetre precision, and broad area slope coverage. Following a slope failure, intensive and close monitoring can be conducted using the GB radar to facilitate effective risk management.

GB radar data used for this paper such as deformation and coherence graphs is provided from GroundProbe's Slope Stability Radar (SSR). Deformation and coherence data of the failure event could be determining factors in deciding when mine personnel can safely resume mining activities around failure area. At the time of failure, the maximum rate of slope movement will certainly exceed the limitation of any GB radar using the interferometry method. Any deformation exceeding the maximum measurement threshold may result in ambiguity or the loss of accurate tracking of deformation magnitude. In addition, the coherence data could also depict the slope surface condition during and after the failure event.

Furthermore, by integrating the analysis of SSR deformation and coherence data, a total of 14 slope failures from undisclosed gold and coal mines will be analyzed to understand the behaviour of the slope during and after each failure, particularly concerning the time required to ensure the area is safe for resuming mining activities. 7 failures originated from a gold mine which has a brittle rock material while the other 7 failures occurred in a coal mine with a ductile rock behaviour.

All in all, comparing both sets of results reveals that the approach of analyzing deformation and coherence data in the course of a failure event could be utilized to comprehensively estimate the required waiting time. This allows for the optimization of mining processes while efficiently

managing the risk associated with re-entering affected areas.

Multi-thematic geoscience study in Hamirgarh Bhiyana segment, eastern Aravalli Craton Rajasthan, Western India: Evidences of existence of dual mineral systems

Rana BANDYOPADHYAY[1]*, GEOLOGICAL SURVEY OF INDIA
(rana.bandyopadhyay@gsi.gov.in)
Reenika Ms[2], Geological Survey of India

Abstract

South central Rajasthan is a metal-endowed zone in NW Indian shield where Zn-Pb-Cu are accumulated over time in different metallogenic environments. The current study utilised newly acquired high resolution multisensor airborne geophysical data and evaluated the mineralisation potential of the eastern Aravalli Craton through magnetic data interpretation and integration in Hamirgarh-Bhiyana sector. The domain host a combination of rocks displaying a spectrum of ages and genetic makeup, including rocks of Mangalwar Complex, Berach granite, Hindoli group and Rajpura-Dariba group, hosting major Pb-Zn deposits. The southern part is characterised by migmatite and gneisses of Mangalwar Complex with enclaves of felsic and mafic volcanics. The domain is characterised with sheared lithological contacts between Hindoli Group and Berach Granite in the north, Rajpura Dariba Group and Hindoli Group in the south west and a tectonised contact between Hindoli Group and platformal sediments of Vindhyan in the east. In addition to the sheared contacts between various litho domains, the area is also affected by a series of deformational events mainly D2 and D3 which affected entire NW Indian Shield.

Integrated geophysical study has been executed in this domain through interpretation of high resolution airborne magnetic data, airborne gamma ray spectrometric data, airborne electromagnetic data (AEM) and ground gravity data for delineation of zones of metal concentration. Study of the geophysical derivative maps viz. Reduced to Pole (RTP) and Tilt Derivative (TDR) of RTP, Horizontal Gradient Bouguer Gravity map identified areas with sharp susceptibility and density contrast and facilitated in understanding lateral and vertical continuity of existing faults, shear zones and litho contacts in areas of thick soil cover and limited outcrops. Structural fabric identified through magnetic and gravity lineaments analysis decipher areas with high lineaments density and rock permeability with possible hydrothermal fluid migration pathways. Anomalous radioelement enrichment of potash (K%), K composite maps (K, eTh/k and eU/K), eTh/K lows are some of the characteristics of the hydrothermal zones over the basement granitoids.

Ground appraisal of such zones of high lineament density and their intersection, identified a segment where quartz reefs impregnate the fracture system created by later deformational events in the northern part of Hamirgarh-Bhiyana sector. Such fracture systems are manifested as linear magnetic highs owing to creation of secondary magnetite during the hydrothermal activities Sulphide/ Copper mineralisation is also manifested in the sheared and altered portions of Berach granite and hydrothermally affected quartzites in the northern part. The southern sector of the area

exhibits as layer parallel occurrence of copper mineralisation within amphibolite, meta-rhyolite and quartz-sericite schist in close spatial proximity of a major NW-SE trending magnetic anomaly which is in turn the sheared contact between Mwangar al Complex and Rajpura Dariba Group of rocks .A linkage between copper mineralisation and strong physical property contrasts viz. magnetic susceptibility, density and conductivity is a striking character of the VMS type deposit owing to its peculiar mineral assemblage in the form of pyrite, pyrrhotite, magnetite, sphalerite, galena, barite etc. As an outcome of this multi-thematic geoscience data analysis, a dual mode of base metal

Nuclear magnetic resonance constrained triple-water resistivity model to estimate the fluid saturation in Zao 34 block, Bohai bay basin

XueJuan ZHU[1]*, China University of Petroleum (East China) (04012126@163.com)
ShaoGui Deng[2], China University of Petroleum (East China)
YiRen Fan[3], China University of Petroleum (East China)
XinMin Ge[4], China University of Petroleum (East China)
Jin Li[5], Tianjin Branch, China National Logging Corporation

Abstract

The reservoir of Zao 34 block in Cangdong Sag is characterized by a typical low resistivity and low permeability, with high shale content, fine particle size, complex pore structure. The resistivity of the oil layer is close to that of the water layer, making it challenging to calculate oil saturation through well logging.

The triple-water resistivity model comprehensively characterizes several different conductivity mechanisms of rocks, taking into account the unique conductivity characteristics of clay water and the significant impact of micropore water on rock resistivity. It is an important bridge to establish the relationship between resistivity and saturation in low-resistivity reservoirs. However, there are limitations in the application of the calculation process, which requires knowledge of the contents of free water, microporous water and clay water, as well as their corresponding petroelectric parameters. To address this issue, a method is proposed to calculate the parameters of the triple-water resistivity model using nuclear magnetic logging constraints on conventional logging, ultimately calculating the oil saturation of the reservoir. Firstly, the quantitative relationship between resistivity and fluids of different components is derived based on the parallel conduction mechanism, namely the triple-water resistivity model for pure water layers. Secondly, the volumes of free water, micropore water, and clay water are determined based on the NMR logging response characteristics of pure water layers and substituted into the triple-water resistivity model. The optimization method is applied for iteration to obtain the cementation index of different component waters. Meanwhile, the conventional logging curves are constrained by nuclear magnetic logging to establish a method for calculating the volumes of clay water, micropore water, and free water using conventional logging data. Finally, a triple-water resistivity model for oil-bearing reservoirs is established, and the free water saturation index is calculated using optimization methods with core saturation data. This method effectively avoids the limitations of having to rely on experimental data such as mercury injection, petroelectrical experiments, clay analysis, and cation exchange capacity measurements to determine the parameters of the triple-water resistivity model. It can still obtain relatively accurate model parameters in the absence of experimental data. The saturation calculation of the low- resistivity oil and gas reservoirs in the study area was carried out using the triple-water resistivity model, and the final calculation results show good agreement with core saturation measurement data and oil testing results, proving the feasibility of this method.

Proximity Excavation in Down Town area Using High Tension Net

BYUNG DON RO[1]*, Architecture Safety Center, Gangseo-Gu, Seoul, Korea (engeo@naver.com)

Abstract

Recently, along with the construction of group housing facilities, redevelopment or reconstruction of existing sites is being carried out more actively than ever before. Most of these are often carried out in existing dense urban centers, and as a result, not only group complaints, but also various environmental issues and technical reviews are emerging. We will face numerous practical problems such as noise, dust, and hazardous materials such as asbestos generated during the demolition of existing buildings, various problems related to excavation and blasting, technical restrictions due to tight construction conditions. In particular, blasting stones, noise, and dust will be unavoidable challenges during proximity excavation along public roads or in adjacent buildings. Therefore, in this study, it is an example of applying an excavation method using a high-strength tension net after reinforced an existing slope based on various field survey results in conditions where it is impossible installation of protection barrier during excavation near a roadside or adjacent structure during public use. In order to apply this method, an overall geological survey of the site was carried out, a slope stability assessment on the exposed outcropping surface was carried out, and necessary stabilization measures were carried out. After that, careful investigation and evaluation of the architectural characteristics, usage characteristics, and maintenance conditions of nearby structures were carried out, and the high-tention net was adopted in consideration of the construction limitations, costs, and complaints. In particular, in situations where various methods for rock excavation, such as blasting methods, installation of blasting barriers, and rockfall prevention measures, etc., are restricted, considerations were taken to minimize inconvenience to users of adjacent building due to secondary damage such as rockfall, noise, and dust.

Correlation between consolidation of soft ground and time-lapse gravity

YeongJae LEE[1]*, Geo-information Research Group Co. Ltd (dudwovjscl@naver.com)
SungWook Kim[2], Geo-information Research Group Co. Ltd
Sungchan Choi[3], Geo-information Research Group Co. Ltd
DaeHong Go[4], Geo-information Research Group Co. Ltd
EunKyeong Choi[5], Geo-information Research Group Co. Ltd
TaeHyung Kim[6], National Korea Maritime & Ocean Univ.

Abstract

The study area is a soft ground that is being improved by applying a free-loading method, and changes in the gravity field were observed at intervals to confirm changes in the ground during the construction process. The gravity field was measured by crossing the soft ground in the north-south direction. The spacing between measuring points was 10 m, and field data for a length of 360 m were obtained. Additionally, to observe the gravity effect over time, measurements were repeated 5 times at the same location with a time difference of about 2 months. The soft clay, which is consolidated by load, lies on top of the bedrock, and because the bedrock does not deform due to ground improvement, the change in gravity observed in repeated measurements can be interpreted as consolidation of the soft clay. An increase or decrease in time-lapse gravity indicates changes in the density of the clay layer. As a result of the gravity field interpretation, the degree of consolidation of the clay layer varies depending on the location, and the consolidated portion and the unconsolidated portion in the profile of the continuous Bouguer anomaly could be distinguished. This is considered to be suitable as a method of diagnosing the condition of the layer in the soft ground improvement stage because it can determine the discontinuity of consolidation.

Keyword

time-lapse, gravity, Bouguer anomaly, soft ground, consolidation

Gravity and Gravity Gradient Joint Fast Inversion Method

Zhengyuan JIA[1]*, China University of Geosciences Beijing (jzy@cugb.edu.cn)
Luofan Xiong[2], China University of Geosciences Beijing

Abstract

High-precision airborne and marine gravity gradient measurements are quick, efficient, and cost-effective, playing a crucial role in studying crustal structure, as well as the distribution of minerals, oil, and gas resources. As exploration depths increase, the joint inversion of gravity and gravity gradient data becomes essential for a more comprehensive and unique revelation of underground density structures. However, this brings challenges of large computations, slow convergence, and high memory requirements. To enhance both the computational speed and precision of joint inversion for three-dimensional gravity and gravity gradient multi-components, addressing key challenges related to the large computational memory and slow processing speed requirements of inverting extensive airborne and marine gravity gradient measurements datasets, this study introduces a novel fast forward modeling algorithm for gravity and gravity gradient fields. The algorithm is based on exploiting the inherent Block Toeplitz-Toeplitz Block (BTTB) matrix structure of the forward problem, allowing for highly efficient matrix-vector multiplication during the inversion process. It is integrated into a hybrid optimization workflow employing an outer loop based on the Gauss-Newton method to linearize the inverse problem. Within this, an inner loop utilizes the conjugate gradient method to solve the normal equations rapidly. By taking advantage of the BTTB structure, computation of gravity and gradient responses for the dense model meshes required for 3D inversion is accelerated by over an order of magnitude compared to conventional approaches. At the same time, solution precision is also improved. The accuracy and effectiveness of the proposed joint inversion algorithm, combining the new fast forward solver within its optimization framework, was systematically validated through a series of synthetic modeling experiments. Results demonstrated convergence to high-quality models could be achieved in significantly reduced processing times compared to previous techniques while still satisfying misfit targets. This makes joint 3D inversion of extensive multi-component datasets now feasible where it was not previously possible. Finally, the method proposed in this paper is applied to jointly invert airborne full-tensor gravity gradient data and ground gravity data in the Winton Salient region. The inverted density structure aligns with geological data for the region, demonstrating the method's promising application prospects in handling real-world data with short inversion times.

Distribution of plume-shaped low-gravity zone in the southeastern part of the Korean Peninsula estimated through 3D gravity modeling

sung-wook KIM[1]*, Geo-information Research Group Co. Ltd. (suwokim@chol.com)
Sungchan Choi[2], Geo-information Research Group Co. Ltd.
Eun-Kyeong Choi[3], Geo-information Research Group Co. Ltd.
Jeoung-Seok Yoon[4], DynaFrax UG

Abstract

To provide 3D density distribution around the Yangsan fault (YSF) situated in the Gyeongsang sedimentary basin (GB), the southeastern part of the Korean Peninsula, 3D gravity forward modelling was performed using the IGMAS+ software package. A total of 3,000 gravity stations were compiled and used to calculate the Bouguer gravity field. From the Bouguer anomaly field, the residual gravity field was calculated by subtracting the gravity effect of the Crust-Mantle boundary (Choi et al., 2023). The residual gravity field along the YSF shows that the mean value of the southern segment (approx. 34 mGal) is very similar to that of the northern segment (approx. 35.5 mGal), meanwhile, the mean gravity value of the central segmentation (C-YSF) is about 27 mGal, significantly lower than those of the other segmentations. This implies that the crustal structure and petrophysical properties (e.g., density) of the C-YSF are significantly different than those of the other segmentations. Several polyhedral and density constraints (e.g., gravity field interpretation, Vs-tomography, measured rock density, faults and rock type) obtained from geologic and geophysical interpretation, were considered for the 3D gravity forward modelling. The results of the modelling indicate that the prominent low gravity zone shown in the C-YSF is explained by combined density effects from the modelled Bulguksa-Granite (2.60 g/.) and Low-Velocity Zone (LVZ) with a mean density of about 2.65 g/. Comparing the low gravity zone with the geological map, receiver function analysis and spatial distribution of the Heat Flow Unit (HFU), we conclude that the low gravity zone is caused by the Plume-Like-Structure (PLS) which should be uplifted from the Mantle. The maximum depth of the PLS exists in the central part of the C-YSF and is assumed to be about 20 km from the lower crust to the basement of the GB. The bottom depth of the PLS in the southern part of the C-YSF is about 15 km, where the Gyeongju earthquake (2016M5.8_GY) occurred. Meanwhile, the bottom depth of the PLS is about 7 km in the area where the Pohang earthquake (2017M5.4_PO) registered. All points of our gravity field interpretation and modelling results indicate that the Gyeongju- and Pohang earthquakes that occurred in the vicinity of the PLS are closely related to the tectonic movement of the PLS. In other words, it is assumed that the Pohang earthquake was caused as the largest aftershock of the Gyeongju earthquake by transmitting of seismic wave through the PLS.

Investigation on the magnetotelluric (MT) survey from the Yeonil Tectonic Line and Ulsan fault zones in the Gyeongsang Basin of Korea

Kyeongho Ryu[1]*, Kangwon National University (rudgh2942@kangwon.ac.kr)
Hyoung-Seok Kwon[2], Kangwon National University
Seokhoon Oh[3], Kangwon National University

Abstract

In 2016 and 2017, earthquakes with magnitudes of ML 5.8 and ML 5.4 occurred in the Gyeongju and Pohang regions of southeastern South Korea, and lots of micro-earthquakes were observed not only near the epicenter but also below the Yeonil Tectonic Line and Ulsan faults.

A magnetotelluric (MT) survey has been proposed as a geophysical method to identify the deep geology of micro seismic zones. Prior to the MT survey, numerical modeling was performed to account for the influence of the topography and ocean on the MT data.
The study area is mostly mountainous and is bordered by the sea to the east. The ocean is a very strong conductor that has a strong influence on the MT data and can be misinterpreted as a distribution of false low resistivity anomalies if ocean effects are not considered.

In the model considering the ocean, the MT response curves are similar to those in homogeneous model at high frequencies. However, at low frequencies, the difference between the XY and YX mode resistivity curves becomes larger due to the electrical conductivity of the ocean. At the closest point to the ocean (0.2 km), the XY and YX mode curves differ in the 100 Hz frequency band, and the frequency at which the two modes differ decreases with distance from the ocean.

The MT survey was carried out in the study area in July and August 2023, and a total of 28 data points were acquired along a 70 km long survey line with a spacing of 2-3 km between survey points. To obtain reliable MT data, a minimum of 88 hours, a maximum of 208 hours, and an average of 144 hours of data were collected per survey point. Two-dimensional inversion was applied to the MT data to generate a 35 km deep electrical resistivity cross-section, which was used to understand the deep geologic structure and distribution of geologic soft zones beneath the Yeonil Tectonic Line.

In the electrical resistivity cross-section, steep dip low-resistivity anomalies are clearly distributed in the lower part of the Yeonil Tectonic Line and Ulsan faults, and east of the Yeonil Tectonic Line, the low-resistivity layer of the Yeonil Basin, composed of sediments of seafloor origin, is imaged to a depth of 8 km.

In the future, audio magnetotelluric (AMT) surveys, which acquire high-frequency data with higher resolution than MT surveys, are expected to provide more reliable information on the

geological characteristics of the Yeonil Tectonic Line and the Ulsan fault at depths of several kilometers.

PROFESSIONAL INITIATION RESIDENCE PROGRAM LATO-SENSU IN EARTH SCIENCES AT THE GEOLOGICAL SURVEY OF BRAZIL – CPRM

Patricia DURINGER Jacques[1]*, cprm (patricia.jacques@sgb.gov.br)
Alexis Rosa Nummer[2], UFRRJ
Geraldo Advíncula[3], CPRM
Andrea Sander[4], CPRM

Abstract

The Professional Initiation Residency Program in Earth Sciences (Residência SGB) aims to qualify recent graduates (up to two years after graduation) through immersion in a professional environment (in the Geologycal Survey of Brazil – CPRM), enabling them to efficiently practice their profession. Consequently, it facilitates their entry into the job market, contributing to the development of geosciences in Brazil in line with the socio-economic demands of the country. The inspiration for this program is drawn from the medical field, where a doctor, after completing their degree, undergoes medical residency in a hospital, engaging in daily practical activities and specializing in a specific area of medicine after two or three years. The program was developed through several stages, starting with the mapping of hole process, establishing technical cooperation agreements with a higher education institution (in this case, the Federal Rural University of Rio de Janeiro - UFRRJ), and formulating a risk matrix, culminating in the publication of the residency policy by the Geological Survey of Brazil - CPRM (https://www.sgb.gov.br/publique/media/sobre/governanca/politica_residencia.pdf). The inaugural class started in August 2023 and will run for two years until July 2025. The class comprises eighteen professionals with backgrounds in geology across various fields of knowledge, including geological mapping in the Amazon region, hydrogeology and hydrology, environmental geology, geoscience mediation, paleontology, data science, tectonics and fluids, geomorphology, prospective geochemistry, economic geology, and mineral production systems. Each student has a mentor from the geological service and a professor from the UFRRJ. The lato sensu program offered by UFRRJ operates within the geological service's facilities and is funded by CPRM, covering project expenses and residents' scholarship amounts, which are comparable to a master's degree scholarship (stricto sensu). Residents are encouraged to participate in internal and external scientific and technical events, presenting their work and engaging with the scientific community, alongside full immersion in geological service projects. Upon completion of the residency, residents are required to disseminate the final product through CPRM's institutional systems, such as publishing geological or geomorphological maps available on RIGEO (https://rigeo.sgb.gov.br/) and GeoSGB (https://geosgb.sgb.gov.br/), developing products mediated by geoscientists available on SGBeduca (https://sgbeduca.sgb.gov.br/), or alert products for floods available on SACE (https://www.sgb.gov.br/sace/). The residency program aims to enhance knowledge, skills, and essential professional conduct while fostering ethical

responsibility. It provides an opportunity for practical experience in a corporate environment, involvement in company projects and actions, and participation in supervised and guided theoretical and practical training. Additionally, the program contributes to the development of public policies for the professional development of young and adult individuals in Brazil, solidifying the Geological Survey of Brazil - CPRM as an institution for extension and training in Earth Sciences and related areas.

ERASMUS+: a strategic tool to build partnerships among continents to enhance Geoscience through Higher Education.

Lola PEREIRA[1]*, University of Salamanca (mdp@usal.es)
Helio Vasco Nganhane[2], Universidade Pùngué
Giovanna Dino[3], University of Torino
Daud Jamal[4], Universidade Eduardo Mondlane
Pedro Dinis[5], Universidade de Coimbra
Nelson Rodrigues[6], Universidade de Coimbra

Abstract

Sustainable and responsible management of geo-resources requires a rethinking and redesign of our production and consumption patterns. Awareness of the natural environment as a common good to be preserved, and knowledge of the close link between the natural environment and the socio-economic system are prerequisites for a profound change in human attitudes at both individual and societal levels. In this context, training and education of all actors involved in the management of geo-resources is an indispensable starting point for the acquisition of critical, ethical, and conscious thinking and the technical skills necessary to solve local problems and initiate sustainable development.

The present research focuses on two consequential ERASMUS+ projects: SUGERE and GEODES. Both had the common goal of the international standardization of Higher Education training and teaching in Earth Sciences and Mining Engineering.

SUGERE (Sustainable Sustainability and Wise Use of Geological Resources) was successfully completed in September 2023, involved 3 European universities (from Portugal, Spain, and Italy) and 6 non-European universities (from Mozambique, Cape Verde, and Angola). The objective was to enhance capacity building for the responsible and sustainable use of geological resources by supporting the didactic organization and standardization of 5 degree courses at Bachelor, Master and Doctorate levels in Earth Sciences and Mining Engineering. Both online and face-to-face training sessions were organized in European and African universities.

Deepening technical skills in geomining from a sustainable perspective is crucial for developing critical thinking and acquiring ethical values necessary for solving local problems. SUGERE and GEODES contribute to this outcome with a solid network of research, training, sharing and exchange of expertise and research activities between European and non-European universities interested in mining issues. A careful analysis of the local economic development of the countries involved in the projects is required to achieve the most effective methods for the exploration and sustainable exploitation of underground georesources.

GEODES, started in June 2023, represents the continuation of the SUGERE project and involves a total of 9 partners. The same 3 European universities and 6 African institutions, formally attributing teaching and training roles to 2 universities that participated in SUGERE, already achieved a good standard in terms of infrastructures and have long teaching experience in the field of geosciences, and receiving 4 young institutions from less favored regions of Angola and

Mozambique.

SUGERE and GEODES aim to strengthen the role of geosciences in the development of up-to-date strategies for the sustainable management of natural resources and to implement new collaborations thanks to an international network focused on local economic and social development and respect for the natural environment in the geological-mining context. The culture of sustainability and the deepening of skills in the field of geological mining form the basis for the development of the critical thinking necessary for local problem solving, the acquisition of ethical values and the technical skills that underpin sustainable development.

Deepening technical skills in geomining from a sustainable perspective is the basis for developing critical thinking and acquiring ethical values necessary for solving local problems.

Towards a common understanding of raw materials education worldwide – An international Qualification Framework for Raw Materials

Vitor Correia[1]*, INTRAW (vcorreia@intraw.eu)
Philipp Hartlieb[2], Montanuniversitaet Leoben
Manuel Regueiro [3], Geological Survey of Spain
Christopher Keane[4], American Geosciences Institute

Abstract

Different training and education requirements prevent the free flow of workers from one region or industry to another, hampering local and regional development. This is driving countries to develop National Qualification Frameworks (NQFs) and attempt to relate those NQFs to international systems.

This presentation advances an international sectoral qualifications framework for the raw materials sector (SQF-RM), hence improving relevance, transparency and coherence between qualifications along the minerals value chain and the corresponding international recognition. The proposed SQF-RM is based on extensive literature study, linking regulatory constraints and currently taught engineering discipline and their skills and learning outcomes.

The SQF-RM is focused on the areas, subareas, professional roles and sets of key competences of the raw materials sector. Because the spectrum of approaches across the world of professional qualifications in the minerals sector is vast, the SQF-RM is based on the existing European Qualification Framework (EQF). The EQF is a common reference framework that allows qualifications from different countries to be easily compared, using learning outcomes associated with each qualification. This establishes a basis for improving the quality, accessibility, linkages and employers' recognition of qualifications in the raw materials sector, within a country and internationally.

An internationally acknowledged qualification framework for raw materials is strongly needed to enhance interchange of geoscience expertise and people. Two important factors, namely governance and quality assurance are key assets for successful implementation and need to be well-designed.

Vision and Change – Transforming Geoscience Education in the United States

Christopher KEANE[1]*, American Geosciences Institute (keane@americangeosciences.org)

Abstract

The geosciences in the United States boast a rich history of educating students who have pursued careers in the resource, environmental, and engineering consulting industries. Traditionally, these students embarked on a geology curriculum comprising approximately 60 hours of geology coursework, which included traditional field camp and classroom-based courses. However, over the last 15 years, both the nature of the geosciences as a discipline and its related employment landscapes have undergone significant changes. This evolution prompted the National Science Foundation to sponsor the Vision and Change project, which convened over 1,000 geoscientists from academia, government, and industry. Their mission was to reevaluate both undergraduate and graduate-level geoscience education to ensure it meets the needs of the country as well as those of the students. This collaborative effort has produced several critical recommendations, many of which are being implemented by geoscience programs to varying extents. Key among these recommendations is the shift towards structuring curricula around learning outcomes rather than specific courses. This approach empowers students by allowing them to map their educational pathways, highlighting achieved outcomes, and developing work portfolios for employment purposes. Additionally, the importance of enhancing quantitative skills and recognizing the value of business and communication skills were emphasized. Various strategies have been adopted in response to these insights, notably the redevelopment of curricula focused on learning outcomes. This has led to the creation of geology degree programs designed to enable graduates to meet professional licensing requirements. A recurring observation concerning graduate education in the United States is that while geoscience graduates excel as researchers capable of conducting sophisticated studies, employers often note a gap in practical skills for non-academic settings. Graduates frequently struggle to identify and effectively tackle real-world problems. Addressing these challenges is crucial for preparing geoscientists who are not only adept at research but also equipped with the necessary skills to excel in professional environments.

Geoscientists for Ireland's future – What are we doing to encourage their creation?

Siobhán Eilís Power[1]*, Geological Survey Ireland (Siobhan.Power@gsi.ie)

Abstract

Ireland has a relatively good education system and a population that shows an interest in the natural world, but geoscience-related subjects are not a strong component of the national curriculum nor the mainstream media, nor national conversations. Ireland is good at publicly supporting science education at secondary school level (13 – 18-year-olds), funds teaching and research at third level education, and benefits from local and international industry investment in science-related companies, but there are still gaps in the work towards a national understanding of climate and environment issues, and deficiencies in how we encourage geoscientists for Ireland's future.

Governmental, professional, cultural, and educational organisations have worked independently and together over the last few years to address some of these issues, but progress is slow, and it is difficult to quantify success. Some of the activities include a temporary exhibition at the national museum, a primetime television series, professional scientists input to national curriculum development, sponsoring of national young scientist prize, and co-creation of teaching resources. A review of some of the activities lead by Geological Survey Ireland, a division of a national government department, is presented here, as well as an overview of other related activities carried out by professional and educational organisations to bring geoscience to national attention, connect it to climate and environmental questions, and show it as a possible and worthy profession.

By reviewing current work in Ireland, looking to best practice in other countries, and giving careful and focused consideration to future plans for education, outreach, and the geoscience aspects of the busy field of science communications and messaging, it is hoped that we can improve our methods of creating new and essential geoscientists for Ireland, and by extension, for the stable human habitation on our planet in the future.

The role of the NATIONAL FORUM OF GEOLOGY COURSES IN BRAZIL in the training of geologists and geological engineers

Alexis Rosa NUMMER[1]*, UFRRJ (rosanummer@gmail.com)
Celso DalRé Carneiro[2], casado

Abstract

In Brazil, the training of geologists and geological engineers in undergraduate courses is offered by 27 federal public universities, 04 state public universities, and 04 private higher education institutions. The Ministry of Education and Culture (MEC) establishes standards, controls the organization and supervises the performance of the courses. The minimum duration of the courses must be equal to or greater than 3,600 hours, including field activities, whose minimum duration is 720 hours. Control of professional activity is exercised by the Federal Council of Engineering and Agronomy, which manages the so-called CONFEA-CREA System. Each state is under the jurisdiction of a Regional Engineering and Agronomy Council (CREA), which supervises the performance of professionals in the different activities carried out in accordance with social demands on the environment and natural resources. In 2001, the National Forum of Geology and Geological Engineering Courses was created, composed of researchers, university professors and representatives of the National Entity of Geology and Geological Engineering, to organize and evaluate the direction of teaching in Geology in Brazil more effectively. In this aspect, the most relevant issues that are discussed in these meetings include evaluations and construction of regulations regarding the Curricular Guidelines for Undergraduate courses in Geology, dropout rates, workload of undergraduate courses, degrees in geosciences, field activities and the market for work. Curricular Guidelines allow defining the different profiles of graduates in Federal and private Higher Education Institutions and adapting them to the rapid changes of the modern world.

Enhancing Geoscience Education Through Critical Thinking: Insights on Teacher Development and Student Engagement

Lixian Tian[1], Hebei Normal University
Liang Qiu[2]*, China University of Geosciences, Beijing (qiul@cugb.edu.cn)
Man Zhu[3], China University of Geosciences, Beijing

Abstract

Engaging in argumentation serves as a vital component of geoscience education, facilitating both the professional growth of teachers and the cultivation of critical thinking skills in students. By fostering critical thinking, educators promote in-depth processing of information and enhance students' conceptual understanding of scientific concepts. This research focuses on the role of argumentation in geoscience education, examining how teachers structure lessons to incorporate argumentation and how students actively participate in critical discourse. The study involved teachers and undergraduate students enrolled in a foundational geoscience course at a northern university in China, specializing in geoscience education. Various argumentation tools such as argument schemes, critical questions using argumentation vee diagrams, model-evidence links, and both oral and written discourse were employed. Employing a mixed-method approach, the study collected quantitative data through self-efficacy and critical thinking surveys administered to both teachers and students, along with qualitative data including interviews, student work samples, and collaborative discussions. The findings revealed that teachers in the experimental group demonstrated increased confidence in utilizing argumentative pedagogy, particularly in employing critical questions, over the course of a semester. Similarly, students in the experimental group exhibited greater engagement in critiquing arguments and delving deeper into geoscience scenarios, notably by presenting more counterarguments. This research underscores the significance of integrating argumentation, particularly critical questioning, into the design of geoscience curricula, offering a pathway to enhance teachers' professional development and nurture students' critical thinking abilities.

Promoting Geoscience Education in a South African Science Centre

Tanja REINHARDT[1]*, University of KwaZulu-Natal (reinhardtt2@ukzn.ac.za)

Abstract

Informal educational settings such as science centres play an important role in science education around the world. Science centres are known to have a positive influence on promoting visitors' curiosity, interests, and knowledge of science because visitors can interact with real objects and engage with exhibits in a relaxed informal environment. They can also watch science shows, or consult websites. In addition to the informal education that takes place in science centres, learning can also be non-formal through organized, systematic, educational activities such as workshops.

The Science and Technology Education Centre at the University of KwaZulu-Natal (STEC@UKZN) in Durban, South Africa which includes the Geology Education Museum, is one of these science centres. It is a place of hands-on science learning with an emphasis on Geoscience education. Our aim is to develop programs, workshops and undertake outreach programs, which focusses on creating awareness, promoting and teaching science and technology particularly in disadvantaged communities, e.g. rural areas and townships.

Geoscience forms an integral part of South Africa, with its rich geological heritage. They feature in the curriculum at primary and secondary school level (Earth and Beyond and geography) and are an important factor of the South African economy and society (e.g. mining of diamonds, gold, platinum or evolutionary aspects). Over the years, STEC@UKZN was involved in the development of numerous low-cost geoscience-related activities, exhibits and educational material using an informal and non-formal education approach. While we usually operate face to face, the Covid-19 crisis had us also explore online avenues.

In the presentation we want to highlight how we introduced geoscience education as a basic science in a science centre, be it non-formal or informal, face to face or online and the situation on promoting geoscience education in other science centres.

geoscience education, science centre, informal education, non-formal education

Teaching with toilet roll and learning with LegoTM to address the geosciences knowledge and skills gaps in the UK and beyond. -Teaching in the shadow of a king

Phillip MURPHY[1]*, University of Leeds, UK (p.j.murphy@leeds.ac.uk)

Abstract

The place of geoscience education in the English state schools system historically was mostly under the banner of geography as a subject. This has been a contributing factor to the problematic nature of recruitment to university level geoscience courses as few schools offered a geoscience qualification. Geoscience does form part of the national curriculum science in England but has often been ignored or poorly taught. The Earth Science Education Unit (ESESU) was formed in 1999 under the leadership of Professor King in order to address these issues through in service training for teachers. Since the demise of the ESEU in 2015 recruitment to university geoscience courses has become even more challenging partly due to its association with the hydrocarbons industry in the eyes of young people and a further decline in the number of schools offering the subject.

The reality is the need for geoscience graduates has never been higher as the move towards a zero carbon economy and the requirements for geological input into modern infrastructure developments has driven a jobs boom in the sector. Geologist, engineering geologist, hydrogeologist, geochemist, geoscientist and geophysicist are listed in the government skilled workers visa list showing vacancies are having to be filled from outside the UK.

Examples of how ideas and practices developed by the ESEU have been further developed to engage a new generation of young people in the UK with geoscience as well as ensuring much of the work of the ESEU and associated educational communities has been disseminated beyond national borders. Central to the ethos of the ESEU was ensuring there was no or at least very little cost incurred during teaching delivery which has proved a vital part of ensuring the ESEU legacy has grown beyond any of our expectations.

Geoscience outreach for visually impaired learners: A journey to “see” Earth and space differently

Tanja REINHARDT[1]*, University of KwaZulu-Natal (reinhardtt2@ukzn.ac.za)

Abstract

The Science and Technology Education Centre at the University of KwaZulu-Natal (STEC@UKZN) which includes the Geology Education Museum is a place of hands-on informal science learning with the emphasis on Geoscience Education. Numerous geoscience related workshops and educational material have been developed by us.

Over the last few years the South African Department of Science and Innovation aim is to provide inclusive science education, and to provide equitable learning opportunities for learners with diverse abilities. This provides to be difficult for learners with visual impairment, as the majority of science experiments are heavily relying on visual instruction techniques.

In collaboration with astronomy researchers, we as a Science Centre wanted to provide the same informal teaching and hands-on geoscience activities to learners with visual impairment. In this inclusive education approach, we decided to adapt some of our geoscience material for learners with seeing difficulties. We used different innovative strategies to improve their learning experience by employing a multisensory approach. Usually traditional teaching methods rely heavily on visual cues, creating barriers for learners who can’t see. To address this challenge, our method incorporated tactile, and experiential elements, such as two- and three-dimensional models, as well as audio and sensory stimulations.

Especially models are beneficial to learners when learning about science. This is particularly true for learners with visual impairments, as they have to rely on senses like touch to be able to “see”. With our astronomy and volcano models learners are provided with a tactile experience in which they can explore and examine different planets and a volcano. They are for example able to distinguish between rocky and gaseous planets, identify planets by their size and to recognize the different features of a volcano.

In our presentation we will showcase our astronomy and geology models, and share our experience with hands-on astronomy and geology workshops for learners with visual impairments.

The Transformative Power of International Geoscience Experiences for Students

Tara Schielein[1]*, Department of Environmental Sciences Southern Illinois University Edwardsville (tschiel@siue.edu)
Sharon LOCKE[2], Southern Illinois University Edwardsville
Mariam Sani[3], Southern Illinois University Edwardsville
Adriana Martinez[4], Southern Illinois University Edwardsville

Abstract

The decline in university geoscience enrollments in the U.S., U.K., Australia, and other countries creates an urgent need to develop strategies and activities that will increase student interest in earth and environmental sciences. In the United States, inconsistent earth science education in primary and secondary education means that many students enter university unaware of the career opportunities in critical fields such as natural hazards, climate change, and energy. To raise geoscience career awareness, our team provided an active learning program for first- and second-year university students that included an international field excursion to a geological setting that is very different from the geology in the region where they live. The field excursion included visits to a volcano, river, coast, plantation, and archaeological sites, along with cultural activities and an opportunity to teach science to secondary students. We administered surveys and conducted interviews to examine student learning outcomes resulting from the international experience and the other program activities. Interviews showed that the students found the international experience to be the most significant and beneficial part of the program. Students described the field excursion as “life-changing,” and they noted that the experience affected them in “unexpected” ways. Students also thought that observing and being part of an international collaboration helped them to better understand the work of a scientist. The findings indicate that geoscience educators and funding agencies should prioritize learning experiences with an international component, with the goal of broadening students’ understanding of the modern geoscientific enterprise, where teams of scientists work together to solve problems of global scope.

Sharing outreach and educational materials through YouTube: a case study from the Shear Zone Channel.

Rob BUTLER[1]*, University of Aberdeen (rob.butler@abdn.ac.uk)

Abstract

This presentation shares experiences of delivering educational and outreach content via YouTube. It examines the reach of videos, their longevity and the utility of the platform for sharing materials – based on a personal case-study of a relatively popular and content-rich YouTube channel.

In common with many university teachers, during the Covid pandemic I developed online educational resources, including a suite of videos. These not only covered content previously delivered through in-person lectures but also enacted worked demonstrations of practical exercises. The content supported teaching in the interpretation of geological maps, field techniques, structural geology/tectonics and the geological interpretation of seismic reflection profiles. Initially these videos were hosted through the university's Panopto account but in April 2021 I decided to collate these and publish through YouTube. Even though teaching has returned to pre-pandemic norms, I still use the videos, largely to permit flipped learning activities and for providing debriefs on practical classes. I continue to populate the channel (a new video every c 2 weeks) – chiefly making short documentaries "on location" to share geo-sites, geological techniques and concepts (including the history and primary publications behind them), and practical exercise demonstrations. While students and professional geoscientists seeking educational materials remain key audiences, the videos also target "engaged amateurs" – especially those interested in discovering field locations. Moderated discussion and clarifications are delivered through the "comments" facility on YouTube. There is a parallel website (hosted on WordPress) that holds many of the practical exercises, creating an open-access resource for geological training.

But how effective is the channel at sharing geology with diverse audiences?

YouTube provides statistics on viewer demographics and view-times. As of February 2024, the Shear Zone Channel hosts 231 videos, with c 415 k views and has attracted 6.36 k subscribers. Unsurprisingly most users are based in the UK, with few based elsewhere in Europe. Significant user-communities live in North America, India, Indonesia and the Philippines. Through weeks there is a drop-off of views on Fridays. Annual viewing peaks occur in early-mid December, with a rapid drop-off through the festive season that follows, as might be expected for a student-dominated viewing population. Life-time views of individual videos are remarkably variable: some show steady accumulation, others plateau after a few days of publication, a few grow exponentially. These differences reflect video content, and presumably therefore, the type of viewer. The algorithms used by YouTube to expose content to site users, and the ways users search for content, preferentially display recent video along with popular content (watched, liked, commented upon) along with that from channels to which the user has subscribed. Interrogation of activity statistics shows few users explore hosting channels or their playlists. Many find channel

content through YouTube (algorithm-based) recommendations.
Content exposure on YouTube, in common with many digital resources, is prone not only to recency bias but also herding, whereby viewing populations repeatedly access the same content. Content creators can modulate this by pairing with other social media platforms or soliciting peer-recommendations.
The channel is available at: https://www.youtube.com/channel/UCIUYjr1yPCZQWYl9cJCO1mA

Participatory Photography Methods in Geoscience Education

Sharon LOCKE[1]*, Southern Illinois University Edwardsville (slocke@siue.edu)
Jennifer Zuercher[2], Southern Illinois University Edwardsville
Charlie Blake[3], Southern Illinois University Edwardsville
Andreia Dexheimer Figueiredo[4], Southern Illinois University Edwardsville
Candice Johnson[5], Southern Illinois University Edwardsville
Carol Colannino-Meeks[6], Emory University
Ben Greenfield[7], University of Southern Maine
Georgia Bracey[8], Southern Illinois University Edwardsville

Abstract

Participatory photography is a research method for engaging the community in understanding environmental and social problems and developing systems solutions. In an education program for students in grades 6-8, our team applied photography as a tool to support student learning about their environment using the Environmental Photovoice method. Photovoice is a structured process in which participants observe their surroundings over one or more sessions, taking photographs of places and features that interest them or surprise them. After this, the participants respond to a series of questions that prompt them to examine what is represented in the photographs and the potential impacts on the community. As a final product, students develop a written narrative about the photographs that includes ideas for taking action to solve a problem. Using Photovoice as a foundation, we have developed an out-of-school curriculum that facilitates student exploration of sources of pollution and environmental hazards, such as lead in soils and particulate matter in air. Through active learning about environmental exposure, students are empowered to understand how the environment can affect their health, while they also learn how to use scientific tools such as environmental sensors to practice science. This participatory photography process could be adapted to other natural hazards topics, such as volcanic hazards, flooding, landslides, and water scarcity. Survey and interview data collected from the students in our program indicated that students began to gain awareness of the personal and/or community relevance of geosciences topics. This is a first step towards increasing awareness of geosciences among students, their parents, and community members, which is needed to increase interest in geoscience careers.

UK Perspectives on Educating for "No Natural Disasters"

ILAN KELMAN[1]*, University College London / University of Agder (ilan_kelman@hotmail.com)

Abstract

This presentation offers UK perspectives for "natural disaster" education. Around the UK, education for secondary schools and universities covers many disaster subjects. One approach of particular prominence is challenging the idea of a "natural disaster". Disasters do not happen because of nature, but because people and society cannot or choose not to deal with typical phenomena from nature, such as earthquakes, meteorites, microbes, and storms. These phenomena are more correctly called "hazards".

We put ourselves and others in the way of hazards without using existing knowledge and techniques to avert casualties, damage, and disruption. Consequently, we fail to take measures which we know would stop hazards from becoming disasters. Evidence comes from numerous examples of "disasters avoided", in which pre-hazard action was taken and so a disaster did not occur, even though a hazard did.

Fundamentally, disasters are rarely "natural". UK educational material on this point includes a website nonaturaldisasters.com, hashtags #NoNaturalDisasters and #DisastersAreNotNatural, and my book "Disaster by Choice" used across secondary schools in England detailing the choices we make to permit disasters and the choices we could make to avoid disasters. Rather than being "natural", disasters arise from the political processes dictating where and what we build as well as from social circumstances which create and perpetuate poverty and discrimination.

The real cause of disasters is humanity's decisions, as societies and as individuals. The real solution to disasters needs to be emphasised in all education: making better decisions that will stop disasters, irrespective of hazards.

Incorporating Natural Blessings and Disasters to Develop an Integrated School Curriculum

Hisashi OTSUJI[1]*, Toyo University (otsuji@toyo.jp)

Abstract

The Japanese junior high school National Curriculum (Course of Study) includes the term “Natural benefits and disasters”; thus, school science textbooks present both the positive and negative aspects of nature. When students in grade 7 learn about volcanoes and earthquakes and those in grade 8 learn meteorology, they study the mechanisms of not only natural phenomena but also natural disasters. Moreover, there are many cases in which natural disasters, not just blessings, are historically and culturally related to human activities. Examples include the development of the bicycle, various famous paintings or stories, the rise of historical figures, gardening soil, and eating habits. To organize and develop an effective integrated school curriculum, it is important to include the perspective of the relationship between nature and humans in all subjects. Based on this idea, I examined the present Japanese school curriculum and found that it could be enriched by adding and emphasizing the perspective of natural blessings and disasters. Thinkers have pointed out that human life is disconnected from nature. In order to develop global citizens in the 21st century, we need to look beyond individual subjects and consider the school curriculum as a whole; students should be taught about human relationship with nature from an early age. Among various subjects, geology (geo-sciences) not only deals with the foundations of our lives but also serves as the key to our educational curriculum for future generations.

Natural Disaster and Education in South Korea

Young Shin Park[1]*, Chosun University (parkys@chosun.ac.kr)

Abstract

We face more and more natural hazards due to climate change now. This is worse in Asia regions which locate on the boundary of Plate Technics, ring of fire. When we talk about natural hazards, most cases of earthquakes, Tsunami, landslide, and more are from Asia regions. When we assume that those natural hazards can be severer than before, we need to stop ruining the Earth where we live and we need to hand over the better environment for future generations. Therefore, it is our responsibilities to make students and citizens informed of what those natural hazards are, why those happen, how we can restore them, and how we prevent them in advance to reduce the loss of people and economics. We are not free zone any more from earthquakes (we had over 5 magnitude in Gyeongju and Pohang in 2016) and we are starting to be very concerned about Tsunami since Korean peninsula is surrounded by the ocean. Students learn about natural hazards from K to 12 and the content of natural hazards cover the followings; climatological disaster like typhoon, flood, heavy rain, drought, and heavy snow, and geophysical disaster like earthquake and volcanic activity. Students learn why, when, where those disasters happen, and what kinds of advantages we can get from those natural hazards. However, those contents are covered in social studies or science subjects and those contents deal with common knowledge which doesn't make students feel belongings to the community nor responsibilities to solve those disasters to reduce the loss of people and economics.

At the level of secondary schools, for equipping students with competencies of facing the natural disaster issues, recognizing the problem, and solving the problem, I need to develop the integrated science programs through which students learn scientific concepts related to natural disasters. More than anything else, students learn how to prevent those natural disasters with the use of engineering and technology (which has been called STEAM program). More than beyond learning natural disasters by concepts, we need to provide chances for students to apply those concepts in finding out the solution through engineering-based experiments on the basis of scientific concepts. During this process students feel belongings to the community and responsibilities to preserve the earth from natural and human-made disasters. I could say that we need to provide students with chances where students build concepts through science experiments to understand natural hazards and build device through engineering-based experiments to solve the problem.

From the examples of natural disaster education in secondary education carried out by my research team, I can conclude the following for natural hazard education. Engineering-based experiment is pivotal for students to be equipped with competencies of applying the concepts to find the solution. Students experience scientific thinking during scientific experiment to understand its principles and they also experience computational thinking during engineering-based experiment to find out the solution.

[Keynote] Systematization of Education for Disaster Risk Reduction from the Viewpoint of SDGs

Tatsuya FUJIOKA[1]*, Shiga University (fujioka@edu.shiga-u.ac.jp)

Abstract

In the Japanese archipelago, where natural disasters occur frequently, disaster prevention, mitigation, and reconstruction have been addressed from the individual level to the national level since recorded history. However, today, due to the effects of climate change, responding to natural disasters has become an international issue. Although it cannot be said that Japan has many opportunities to take leadership in the international community, it can be said that Japan has made a certain contribution to the world regarding disaster prevention, as the United Nations World Conference on Disaster Risk Reduction has been held three times in Japan.

The Cabinet Office's Central Disaster Prevention Council is the highest organization responsible for dealing with natural disasters in Japan. Under this system, Japan's disaster prevention system will be established to respond to major natural disasters and to deal with anticipated natural disasters. For meteorological disasters and associated landslides, which are among the most predictable natural disasters, alert levels and other information are first announced through scientific forecasts by the Japan Meteorological Agency. Based on this, the government will issue instructions to residents, such as issuing evacuation orders in each area. However, no matter how advanced science, technology, and social systems are, the extent of damage will ultimately depend on the actions residents take to prepare for natural disasters. Herein lies the importance of disaster prevention education in schools and awareness of local residents.

On the other hand, Japan's educational system has a national curriculum called the Curriculum Guidelines. However, because the content is uniform across the country, it cannot be said to be sufficient as disaster prevention education for natural disasters that is tailored to local characteristics. For this reason, various disaster prevention education initiatives are being carried out in each region, and the national government supports them.

Under these circumstances, there is a need to develop human resources who can think on a global scale and act in accordance with their local area, using the same stance as environmental education. Today, people's awareness of building a sustainable society is increasing. Education also requires an attitude of not leaving anyone behind even in the face of natural disasters. The SDGs consist of 17 goals and 169 targets. There is a lot of content about reducing natural disasters related to climate change. The importance of education is related not only to the achievement of Goal 4, but also to the realization of all goals.

Today, in Japanese education, there is a need to develop a "zest for living" in preparation for the uncertain future of the VUCA era. In addition, cross-curricular curriculum management and STEAM education that integrates the arts and sciences are expected. Education on natural disasters based on the SDGs can be expected to serve as a concrete example of this. In this report, I would like to discuss the current state of disaster prevention/mitigation and reconstruction

education in Japan, as well as the challenges of Japan's geoscience education, which is the foundation of this.

Current Status and Issues of Earthquake Disaster Prevention Education in a Major City that Experienced The 1995 Southern Hyogo Prefecture Earthquake: A Case Study of Kobe City

Toshio ARIMICHI[1]*, Graduate School of Regional Resource Management, University of Hyogo (ta54angel@yahoo.co.jp)
Norihito Kawamura[2], Graduate School of Regional Resource Management, University of Hyogo

Abstract

According to USGS data, 17.9% of all earthquakes of magnitude 6.0 or greater that occurred between 2011 and 2020 in the world occurred around Japan. Japan is located at the boundary of four plates. Therefore, not only earthquakes near plate boundaries, but also inland earthquakes occur when active faults shift within the continental plates.

The 1995 Southern Hyogo Prefecture Earthquake that occurred in Kobe, a major city in southwestern Japan, was an inland earthquake with a magnitude of 7.3 and depth of epicenter 16 km. Three faults are estimated to have moved during the earthquake. The city of Kobe suffered unprecedented damage from this earthquake. On January 17, 2025, it will have been 30 years since the earthquake occurred. In order to ensure that citizens do not forget the earthquake and pass it on to future generations, the Kobe City government has designated January 17 as "Citizens' Disaster Prevention Day" and is holding events to help each citizen prepare for increasingly severe natural disasters. All elementary and junior high schools in Kobe City hold "Earthquake Disaster Memorial" events on this day, which include memorial services and earthquake disaster prevention education. However, 30 years have passed since the 1995 Southern Hyogo Prefecture Earthquake, and most of the teachers who taught at the schools at that time have retired. As a result, there are few teachers who can talk about those days. In addition, more than 50% of citizens have not experienced the earthquake. Furthermore, a trench-type earthquake along the Pacific coast has been proposed as a new earthquake risk. The speakers believe that earthquake disaster prevention education needs to be reviewed.

In this study, the speakers will present the results of the 30 years of earthquake disaster prevention education in Kobe City, including the use of the supplementary reader for disaster prevention education, " Shiawase- hakobo " prepared by Kobe City for elementary and junior high school students, and the efforts of earthquake disaster prevention education in the classroom. In addition, the speakers will discuss issues in disaster education in preparation for the coming massive earthquakes, and aim to promote earthquake disaster prevention education.

Educating Local Communities in the Southeastern USA through a Natural Hazards Course

Athena Owen NAGEL[1]*, Mississippi State University (amo58@msstate.edu)

Abstract

At Mississippi State University, a research institution in the southeastern United States, a Natural Hazards course is primarily offered as part of the Broadcast Meteorology Program. The course is specifically housed in this program because Broadcast meteorologists are community scientists and the public looks to them for information about all types of natural hazards, especially weather-related ones, and how to prepare for them. By providing a thorough and detailed education for Broadcast meteorologists, a greater number of people in the community can be reached over time.
Our Natural Hazards course is offered as a split-level for both undergraduate upper classmen and graduate students, and it is taught as both a face-to-face class and as an asynchronous online course. The curriculum focuses upon hazards in the USA as well as globally, with the first half of the course addressing meteorological hazards, and the second half of the course considering common geologic hazards . Each of the 12 units focuses upon a different hazard, with each unit addressing how or what causes the hazard to occur, how people should prepare for the hazard, historic occurrences of these events, and more current events. The curriculum incorporates active learning strategies where students address their own preparedness for the different hazards they might face in their location. Class discussion topics also include the effects of climate change on hazard severity and frequency, as well as notable events that occur during the time the class is offered . By engaging future Broadcast meteorologists in natural hazards and having them apply this content to their own geographic areas, the natural hazards curriculum has impact beyond the students for a well-informed community.

Development of Volcano Disaster Prevention Education Program from the Perspective of STEAM Education

Shintaro SATO[1]*, KYOTO NOTRE DAME UNIVERSITY (ssato@notredame.ac.jp)

Abstract

To develop the ability of residents and climbers to take action to reduce damage from volcanic eruptions, it is necessary to link scientific knowledge related to volcanoes with disaster prevention, such as understanding the meaning of eruption warning levels.

One effective way to develop this is through STEAM education related to volcanic eruptions, where volcanic observation methods are covered in Technology and Engineering, and the knowledge learned in Mathematics is used to understand the observed data.

In addition, when dealing with volcanic activities broadly from the perspective of ARTs, it is possible to relate efforts to ESD perspectives and SDG Goal 14 and SDG Goal 15. Geoparks and volcano museums are places where education from such a comprehensive perspective can be conducted.

Against this background, this study will reconstruct the educational content related to volcanoes from the viewpoint of STEAM education, ESD, and SDGs. The objective of the study was then to develop a volcano disaster prevention education program for school education in collaboration with Geoparks, volcano museums, and the Japan Meteorological Agency. The research subjects were sixth-grade elementary school students in Izu Oshima, a volcano that is feared to erupt in Japan.

The following is a description of the content of the volcano disaster prevention education program developed. First, students acquire knowledge of the phenomenological aspects of volcanic eruptions by visiting a volcano museum.

Next, the students will visit the volcano observation equipment on Izu Oshima. We will observe seismographs, tiltmeters, airborne seismographs, GNSS, and a long-range camera on Izu Oshima. In addition, JMA staff will explain how to read data on volcanic earthquakes and what can be learned from the data measured by optical wave rangefinding observation. Afterward, iPads with MESH (manufactured by Sony Marketing Inc) blocks and the MESH application downloaded will be distributed, along with volcanic eruption models, and the class will create a program to reduce damage from volcanic eruptions. Specifically, students will place MESH blocks that look like volcanic observation equipment on a volcanic eruption model, which will resemble volcanic bombs and cinder cones.

Next, the participants will visit one of the Geo-sites on Izu Oshima Island, where they can understand the symbiosis with volcanoes and the benefits of volcanoes, and listen to a talk by a Geopark expert committee member from Izu Oshima. In addition, a model experiment of a "Training dike" will be conducted, in which the bottom of a conduit channel that serves as a pathway for lava flows is dug out and the soil is filled in on the village side to build a dike. Then, we will consider how to protect the community from the lava flow. Afterward, the participants

will visit the Izu Oshima Geopark site "Omiyasawa Training Dike".
In this study, we reported on the development of a volcano disaster prevention education program from the viewpoint of STEAM education. In the future, we will conduct a detailed analysis of the effectiveness of the volcanic disaster prevention education program through classroom practice and add further studies.

Examples of SDGs that raise awareness of disaster prevention and mitigation in schools and local communities.

Ichiro MATSUMOTO[1]*, Shimane University (chromim@edu.shimane-u.ac.jp)

Abstract

Japan is a region where natural disasters occur frequently, and in order to maintain a sustainable region, there is an urgent need to raise awareness of disaster prevention and mitigation. For this reason, voluntary disaster prevention organizations and schools such as elementary and junior high schools, which are members of local communities, are important as places for disaster prevention and mitigation education. In order to promote education in the San'in region, where awareness of disaster prevention and mitigation is said to be relatively low, this study conducted a questionnaire survey on the disaster prevention awareness of students mainly at elementary schools in the area. We will also report on examples of study sessions held in collaboration with voluntary disaster prevention organizations.

In light of this situation, we will also consider educational methods to prepare for various natural disasters. Additionally, as activities related to SDGs (Sustainable Development Goals) become more active in schools and local communities, it has been reported that various education and disaster prevention/mitigation initiatives that are integrated with SDGs are extremely effective. and discuss.

It should be noted that the SDGs have passed the halfway point in their implementation period, and the overall results are beginning to be seen. In the past few years, as wars and conflicts have occurred frequently in various places, the goals of the SDGs have been affected, but there are concerns that measures to protect the natural environment, including climate change, will be delayed. Everything in human life comes from the Earth's land, and now is the time to demonstrate the power of earth science education and promote environmental protection, especially among the younger generation. Matsumoto (in press) proposes a global pyramid, which is a fusion of the ecological pyramid and the human pyramid, as a theoretical study of this consciousness reform and earth science education. SDGs initiatives connect and support these two pyramids, and it is important to thoroughly learn about the blessings and disasters of nature, with a focus on disaster prevention and mitigation.

Exploring Learning in Virtual Geological Field Trip: A Theoretical Approach Based on the Revised Novelty Space Concept

YOONSUNG CHOI[1]*, Seoul National University (Center for Educational Research)
(clever123123@gmail.com)

Abstract

Following the pandemic, there has been an explosive surge in demand for and research on Virtual Learning Environments (VLE). Various terms such as remote learning environments, VR, AR, AI-based learning, and online learning are used interchangeably with VLE in educational settings. This study interprets the concept of VLE as a paradigm beyond traditional classroom, laboratory, and outdoor learning environments. Focusing on the Geoscience education, particular attention is given to learning in geological field trip as an area where both traditional and virtual learning environments can be applied. Building upon empirical cases of virtual field trip (VFT), this research conducts a theoretical analysis of in-person field trip and its virtual counterpart. The study introduces the concept of the "Revised Novelty Space," which extends the previously proposed notion of Novelty Space associated with traditional learning environments. The Revised Novelty Space incorporates technical and social aspects in addition to the cognitive, geographical, and psychological dimensions defined in the context of learning in geological field trip. In essence, it redefines and expands these dimensions within the context of VFT while introducing technical and social elements. The Revised Novelty Space is composed of five elements, offering a theoretical framework and methods to facilitate smooth implementation of VFT. This contribution adds scholarly significance by proposing theoretical approaches and methods for the successful advancement of learning in virtual geological field trip.

Anthropomorphic characters: “Lucky charms - Geo-Mascots – Geo-Cartoons – Geo-Emoji Mascots” in Geoscience communication and popularisation

Maria-Luise Luise FREY[1]*, Global Geoparks Network (frey@terra-outreach.de)
Cristian CIOBANU[2], University of Bucharest, Hațeg Country UNESCO Global Geopark (Romania)
Joana Rodrigues[3], Institute of Earth Sciences, Pole of the University of Minho; Naturtejo UNESCO Global Geopark (Portugal)
Cristina Toma[4], Doctoral School of Geography "Simion Mehedinți"- Nature and Sustainable Development, University of Bucharest, Hațeg Country UNESCO Global Geopark (Romania)

Abstract

People from different cultures have been familiar with lucky charms since the beginning of human civilization and express their hope for happiness in life. In modern society, they have been an integral part of moving picture stories on archaeological and historical themes since the middle of the 20th century. They are increasingly being used in product advertising as an incentive to increase the attractiveness of their sale. Their use nowadays seems to vary from culture to culture, but with globalization they seem to be attracting increased attention in other parts of the world, starting in Asia. They have been used to advertise tourist destinations and education in geosciences, as well as to improve the situation in disaster-stricken destinations. Scientists from various disciplines are working on the successful use of anthropomorphic characters in the broadest sense. Such characters, which are often simply referred to as "mascots", have been appearing in natural science topics, particularly geosciences, since the mid-1990s with the development of geopaths and geoparks. With the aim of communicating scientific information, processes, findings and working methods to a broad public, the number of "geo-mascots, geo-cartoons - geo-emojies" has increased significantly in recent years. However, this development is often countered by acceptance from the scientific side with the question of the "seriousness of scientific content" in discussions. With the successful creation of the Global Geoparks Network, there is a demand from the general public to convey complicated facts in a valuable and appealing form. Despite existing infrastructures for geo-paths and geo-routes, museums and interpretations centres, numerous offers of lectures, activities and guided tours for conveying geoscientific information, it is recognisable that in the context of IT development, its application and use: “gamification” - by people of all ages, training and education, as well as in the course of generational change and the existing UNESCO Global Geoparks, the question is being asked whether the communication of geoscientific topics via anthropomorphic characters is a new perspective for communicating to a broad public. Numerous characters have been developed in the UNESCO Global Geoparks to address this question in a serious manner. This presentation addresses and explains the development and its perspective in the mediation and communication of a geopark as a marketing tool for educational and geotourism activities in the broadest sense.

Understanding time scales: which teaching materials do students find easier to understand? - Cosmic (Geologic) Ticker Tape, Cosmic (Geologic) Calendar, and Cosmic (Geologic) historical film in case of undergraduate students –

Hiroo NEMOTO[1]*, Ritsumeikan University (nemo@fc.ritsumei.ac.jp)

Abstract

In subjects dealing with earth science content, such as Chigaku-kiso (Basic Earth Science) in upper secondary schools in Japan, Cosmic (Geologic) Ticker Tape (e.g. 100 million years in 10 cm), Cosmic (Geologic) Calendar (e.g. 13.8 billion years in 1 year, or 4.6 billion years in 1 year) and Cosmic Historical Film (e.g. 1 million years in 1 second) are well known as teaching materials to give students a real sense of geological time scales (e.g. Morikawa, 2016; Geoscience Research Committee of Saitama Pref., 2017). It is usually difficult to find time to use all or several of these in the classroom. Thereby, teachers are likely to select one of these materials for use. In such cases, which teaching materials are most likely to give students a real sense of the geological time scales (13.8 billion years, 4.6 billion years)?

In this study, I aimed to provide a guideline on how to choose from these materials. In order to do that, a questionnaire survey was conducted among university students who would like to become science teachers at secondary schools to find out which teaching materials would give them the best sense of the geological time scales. The results showed that the proportion of students (n = 21) who found the time scale easy to understand was around 4.8 % for the Cosmic (Geologic) Ticker Tape, around 76.2 % for the Cosmic (Geologic) Calendar, and around 19.0 % for the Cosmic (Geologic) Historical Film when the completed teaching materials were used in class. Although it was expected that the percentage would be low, as the Cosmic (Geologic) Historical Film was almost exclusively thought experiments, it was surprising that a large difference opened up between the Cosmic (Geologic) Ticker Tape and the Cosmic (Geologic) Calendar. However, when the students were asked to make their own Cosmic (Geologic) Ticker Tape and to consider them on a single tape (13.8 m), more than 80% of them said that the geological time scales were easy to understand. This may be due in part to the fact that the calculations required for the creation of the Cosmic (Geologic) Ticker Tape are easier than those for the Cosmic (Geologic) Calendar.

The results suggest that the use of the Cosmic (Geologic) Calendar is appropriate when teaching with pre-made teaching materials, and the use of the creation of the Cosmic (Geologic) Ticker Tapes is appropriate when making them as a practical exercise. Therefore, teachers are expected to be competent in handling both the Cosmic (Geologic) Ticker Tape and the Cosmic (Geologic) Calendar as teaching materials. However, given the small number of survey subjects and they were undergraduate students, future work is needed to increase the number of survey subjects so that the results are statistically significant and to clarify whether the same results would be obtained if upper secondary school students were the subjects.

Geodyssey: Forging a new path for app-based geoscientific teaching and learning

Cameron Roy PENN-CLARKE[1]*, Evolutionary Studies Institute, University of the Witwatersrand, Johannesburg (Cameron.Penn-Clarke@wits.ac.za)
Robyn Symons[2], School of Geosciences, University of the Witwatersrand, Johannesburg

Abstract

Geoscience is a complex scientific discipline that has been key to the development of societies and their welfare for millennia. An understanding of geosciences and the world around us has allowed us to access and exploit geological resources that have been used for technological advances that have been utilised to access food, water, and shelter among others. Geosciences has given humanity the opportunity to learn from the past to prepare for the future and explore our present environment in a way no other species has yet been able to achieve. Such insight is, regrettably, wasted on geoscientists alone. If made accessible this, wealth of contextual geological knowledge drawing from both physical and natural sciences in both observational and experimental settings can greatly enrich both our philosophical and practical appreciation of our planet. What wonders this discipline could permit our species had they the same grasp of geosciences as we do…

Geoscience is only comprehendible by few owing to a number of factors, including (but not limited to) comprehension of linked processes and systems, poor understanding of physical sciences, overly complex jargon, access to information and, quite simply, poor marketing. In a society as unequal as South Africa this is complicated further by socioeconomic, basic educational and language barriers (among others). Geoscience education needs to transcend these issues and embrace new technologies to become more accessible if it is to help uplift others. One of these ways is using mobile applications. Geodyssey is an integrated ESRI-driven mobile app for iOS and Android that has been developed by the GSSA WC in partnership with Forge New Frontiers and with the generous financial support of the 35th IGC Legacy Fund, DSI-NRF GENUS, CIMERA and the University of the Witwatersrand.

Since simplicity is key to the communication of geoscientific information in the Geodyssey app, the data displayed in app, has been modified to suit the needs of the user. From interactions with users and focus groups, Geodyssey uses only two layers to display geoscientific information. These are constrained in two feature classes, namely a) an interactive geological basemap and b) geosite point layer. The interactive geological map of South Africa is resolvable at various scales. The interactive geological map uses shapefiles from 1:1 million and 1:250,000 scale maps of the Council for Geoscience, South Africa, with detailed larger scale maps at specific sites. Individual geological units appearing on these maps have been linked to an in-house developed geodatabase which captures most known information pertaining to these units, from various sources. The data which appears in the app is simplified to display only a few fields of interest for the public. The geosite point layer includes known geoheritage sites identified from various sources, as well as sites of geological interest (i.e. stratotypes, historically important sites, sites that appear in

publications of the GSSA and Witwatersrand University, etc.). This allows the user to explore and learn from their environment, unhindered by guides books and maps, while having the wealth of expert knowledge at their fingertips.

Elementary Students' Understanding of Fossil Formation and Geological Change

Younkyeong Nam[1]*, Pusan National University (ynam@pusan.ac.kr)
DongYoung Lee[2], Pusan National University

Abstract

Fossils captivate elementary students with their mystery and tangibility, making them an excellent tool for teaching about geological changes and paleontology. Teachers often use indirect methods to represent fossil formation processes, as direct experiences with these processes and excavation are nearly impossible. Yet, these methods have their shortcomings and can lead to misconceptions. A prevalent misunderstanding among students is the concept of time regarding fossil and sedimentary rock formation, often perceived as rapid processes. This study surveyed 100 elementary students, already familiar with strata and fossils, about their perceptions of the time it takes for fossils to form. Through qualitative analysis, we aimed to identify students harboring misconceptions about the temporal aspects of fossil formation and categorize their understanding of geological time. Analyzing their responses, we found commonalities and differences in time concepts, shedding light on why misconceptions arise. The study outlines the origins and mechanisms behind common misconceptions about fossils -from everyday experiential conflicts, media influences, scientific understanding, to educational shortcomings-and categorizes these causes. By elucidating these aspects, the study provides significant insights and practical implications for educators in elementary earth science. The ultimate goal is to enhance the pedagogical approaches employed in teaching complex geological concepts, thereby fostering a more accurate and comprehensive understanding among young learners.

Promoting Use of the UN Sustainable Development Goals in Pre-college Geoscience Education

Lindsay Mossa[1], American Geosciences Institute
Lauren Brase[2], American Geosciences Institute
Sequoyah McGee[3], American Geosciences Institute
Ed C. Robeck[4]*, American Geosciences Institute (ecrobeck@americangeosciences.org)

Abstract

The American Geosciences Institute (AGI), like many organizations worldwide, recognizes that successfully addressing the most pressing issues of the day—such as access to clean water, climate change, and enhancing community resilience—calls for meaningful action across societies, including (and especially) by young people. AGI has been exploring ways to make young people more aware of the United Nations Sustainable Development Goals (SDGs), especially in terms of their intersection with geoscience knowledge. As a result, we have developed and applied several approaches to our work in pre-college education, including labeling educational materials with associated SDGs and providing SDG information in educator professional development workshops, as well as designing interactive lessons to help students learn about and contribute to the global sustainability goals. The enthusiastic reception of such approaches by educators, as well as the outcomes from actual classrooms, such as student applications of content they're learning to potential solutions, have been encouraging. While most of AGI's activities have taken place in the United States, we has begun to extend this work through its broadening international network.

This presentation will provide examples of these techniques and related materials (including those being made freely available online) to support the ongoing dialogue about effective ways to bring the SDGs into education, thereby empowering students to take transformative action in their communities, and beyond.

The activities that AGI has undertaken in education are now part of a much broader enterprise titled Geoscience for Sustainability (GfS), which AGI began in 2023 to marshal geoscience expertise and understanding to drive the transformative action needed to achieve the SDGs. GfS is a multi-year initiative designed to increase understanding of the vital link between the geosciences and global sustainability. Additional facets of GfS will be outlined in the presentation, as well as ways for interested individuals and organizations to connect with AGI in this initiative to support, create, share, and/or implement techniques and resources will be provided.

Earth of all, Geology for all

Michele LUSTRINO[1]*, Sapienza University of Rome (michele.lustrino@uniroma1.it)
Fabrizio Berra[2], Università Statale di Milano
Gaia Crippa[3], Università Statale di Milano
Patrizia Fumagalli[4], Università Statale di Milano
Andrea Garavaglia[5], Università Statale di Milano
Sara Ronca[6], Sapienza University of Rome
Giuseppe Saracino[7], Sapienza University of Rome
Gianluca Sottili[8], Sapienza University of Rome

Abstract

Different lines of evidence document the effects of anthropogenic actions on present-day climate change. The concept of change is
intrinsic in the nature of the Earth, but the awareness to live on a restless planet is strong in geologists only, who continuously face
major and often dramatic changes recorded in the recent and remote past. Being used to deal with time at every scale, geologists
can have an important role to share the concept of Earth dynamics with citizenry, explaining the differences between anthropogenic
and natural changes. The absence of the awareness that humans live on a changing planet limits the understanding of the
implications of possible activities that we are planning to act on climate changes, i.e., transition to a different way of producing
energy to reduce emission of greenhouse gases. A common approach is to think that we can neutralise our impact on the planet simply by switching energy tapping from fossil fuels to something apparently less impacting, associated with renewable energies.
Unfortunately, things are much more complex and there is no button to press to easily improve our future life quality. Indeed, the
shift to a carbon-free economy is strongly based on the availability of a bunch of “rare minerals” (or, better, elements contained in
them). These rare minerals are defined as critical materials, because their shortage can lead to a collapse of the so-called "green
deal" or "green transition". The need of several minerals essential to support green technologies (i.e., those based essentially on
direct or indirect solar energy) can have an impact in terms of sustainability stronger than fossil fuels, due to the necessity to
increase exploitation in mines with a decreasingly grade of ore minerals.
The geological community in Italy poorly promotes the dissemination of Earth Sciences. Geology instead needs to play a major role
in understanding and explaining the effects of the lifestyles of the rich countries on the entire

planet. Geologists should promote a
correct and sustainable use of natural resources, emphasizing that the transition from fossil fuels to renewable energy sources
necessarily will lead to a strong dependence on elements contained in critical minerals, such as REE, Co, Li, and many others. To
achieve these results, it is necessary to merge the geological sensibility with the competence in social and educational sciences, by
a correct and efficient scientific dissemination, in order to promote a "public understanding of science". The main goal of the project
is therefore to promote sensibility toward a more sustainable management of the Earth resources and increase the awareness to the
complexity of the natural processes that rule our planet. The public we refer to are: 1) school groups (both students of various orders
and their teachers); 2) adults (mostly as member of groups, such as associations, teams and administrative staff) and 3) people with
vision and audio impairment.

Communicating like Hutton and Muir: Connecting geology and ecology (Geocology) to improve public support for critical raw material extraction

Maureen Gallagher[1]*, European Federation of Geologists (maureen.gallagher@eurogeologists.eu)

Abstract

First came the geology then came the ecology. Life grew from the Earth. The two are inextricably linked and must be considered together in developing solutions for the Green Transition. Significant critical raw material extraction is necessary to build the clean technology of the future. Extraction is often controversial and unwanted by local citizens concerned with environmental destruction. Understanding the linkage between local geology and the ecosystems it supports will allow better global, regional, and site scale planning. Connecting geology with ecology (geocology) in communicating with non-scientists builds greater understanding and trust when scoping local projects.

Siccar Point, the birthplace of modern geology and Dunbar, Scotland, the birthplace of notable naturalist and conservationist John Muir, provide a backdrop of storytelling that illustrates the connection between geology, ecology, and human connection to the land. By investigating the relationship between bedrock geology, biodiversity, and human impacts along the 10 miles of coastal Scotland that separate the two, the author will identify and demonstrate communication techniques for geologists to build trust with the public.

Listening to understand, storytelling, and reframing are critical techniques in communicating with local citizens. Understanding their connection to the land and demonstrating your knowledge of their needs and the ecological impacts of an extraction project, will build trust.

Geology and Disaster Risk Reduction Training for Non-Specialist Science Teachers: Implications for Professional Development of Teachers

Magnolia Vida Ante CANO[1]*, Bicol University (mvacano@bicol-u.edu.ph)
Miguel Cerna Cano[2], St. Stephen's High School

Abstract

The Philippines is located in the Pacific Ring of Fire. This fact has created natural wonders but, at the same time, brought disasters. Bicol region, in particular, is home to volcanoes, crater lakes, faults, and other geologic features that make people vulnerable to disasters. The basic education curriculum has included Earth Science and Disaster Risk Reduction in its program, yet many science teachers are not ready to teach it. Teaching Earth Science is particularly difficult for non-specialist teachers. To address this concern, two training programs were conducted in 2018 by RCSMED, a teacher training center based at Bicol University, through a partnership with government agencies and experts to provide lecture sessions, hands-on activities, and field visits.

Eighty (80) secondary science teachers from senior high public schools in two provinces of Bicol participated. The training immersed teachers in lectures and varied ways of teaching geology and DRR concepts. It allowed them to visit geologic sites in their localities to contextualize the concepts learned in the lecture sessions. During the training, data were gathered through written tests and daily logs. Five years after the training, interviews were conducted to determine if the training was helpful and applied in teaching high school students.

The training evaluation results revealed increased teachers' conceptual understanding of geology, endogenous and exogenous hazards, and disaster risk reduction principles. It clarified misconceptions, made the concepts more real through their interaction with practitioners and experts and exposure to sites in their locality, and introduced them to the systems approach in teaching. Furthermore, the training increased their confidence and motivation to teach earth science. Five years after the training, the follow-ups revealed that the concepts, information, and strategies learned during the training were helpful in teaching. Their knowledge of the geologic features of their area was also integrated into their teaching. Narratives of students' responses in their lessons revealed increased engagement in learning science.

Enhancing the professional development of non-specialist teachers in geology and disaster risk reduction needs significant attention. This paper explores a multifaceted approach, suggesting that teachers be equipped with relevant content through hands-on experiences and interactive lectures of experts and practitioners. By engaging them in diverse teaching methodologies and showcasing real examples of geologic features in their local environment, educators can foster a deeper understanding and enthusiasm for earth sciences. This heightened awareness and interest will likely positively influence their students' learning experiences.

The Geological History of Colombia Told by Its Rocks

Vanessa Rey León[1]*, Servicio Geológico Colombiano (vannerey0722@hotmail.com)
Jorge Gómez Tapias[2], Servicio Geológico Colombiano
Ana María Saldarriaga Nieto[3], Servicio Geológico Colombiano
Daniela Mateus Zabala[4], Servicio Geológico Colombiano
Marie Joelle Giraud López[5], Servicio Geológico Colombiano

Abstract

The Geological History of Colombia Told by Its Rocks is a science outreach book performed by an interdisciplinary team from the Colombian Geological Survey. This text is primarily intended for students in their final years of high school, students at introductory levels of geology in fields such as biology, topography, and engineering, and people who have no knowledge of geosciences, but are interested in learning how Colombia was made. The base of this book is The Geology of Colombia multivolume book published in 2020.

As a basis for creating the outreach texts, a group of geologists reviewed over 500 scientific articles and developed technical texts. But how do they explain terms like subduction, orogeny, volcanism, and sedimentation to those who are not familiar with geology?

In order to know how the book should be written, nine workshops were conducted with teachers and students from many schools and universities in the country. The aim was to understand the concerns of the intended audience and thus design the format, language, and structure of the book. Also, many fieldworks were carried out in the most impressive places in Colombia to obtain pictures and audiovisual material.

The book's content is presented in nine chapters organized chronologically from the Proterozoic to the Quaternary with an introductory geological chapter. Throughout them, you will find information about the oldest rocks, evidence of the meteorite impact that ended the lives of the dinosaurs, the major volcanoes and their history of formation, when and how the mountain ranges uplifted, and the largest ocean that existed in Colombia, among other topics.

Each chapter includes a scientific illustration that recreates the organisms and paleoenvironments that existed millions of years ago. Additionally, the chapters contain photographs of the most iconic locations, rocks, and minerals in the country.

During 2024 and 2025, the book will be promoted and disseminated in schools and universities, particularly in rural areas of Colombia. The idea is for these events to include educational materials and activities to explain, for example, the formation of a volcano inside the Earth, rock samples to help students become familiar with the textures and structures characteristic of each type, and a map so that, based on what they learned in the book, students can build their own

geological history of Colombia.

Advancing geography education through 3D geospatial information

yuichi S. hayakawa[1]*, Hokkaido Univ. (hayakawa@eis.hokudai.ac.jp)
Yasuhiko Tamura[2], Univ. Tokyo
Sahoko Aki[3], Univ. Tokyo
Ryusuke Ito[4], Hokkaido University of Education

Abstract

Recent advances in capturing three-dimensional (3D) information of geography through technical developments have opened new avenues for enhancing geography education. The potential inherent in these 3D data allows for immersive and interactive learning experiences, providing students with a deeper understanding of geographical features and landscapes. These technological breakthroughs enable educators to incorporate dynamic and visually rich content into their teaching, fostering a more engaging and effective educational environment. In the study site of Taya Cave located in Yokohama, Japan, we present an approach to understanding local geographical and historical backgrounds, including Satoyama (hilly forest and surroundings) and underground built heritage (caves and historical carvings therein) through advanced geospatial technologies. The study employs terrestrial Lidar (laser scanning) for point cloud data acquisition in caves and SfM-MVS photogrammetry, along with Lidar, for aerial measurements in Satoyama. The resulting 3D data facilitate comprehensive environmental assessments, which are then harnessed for educational purposes. The applications of the 3D data are performed as elementary school classes aimed at enhancing students' understanding of regional environments and cultural heritage. Workshops are also conducted for local residents, utilizing 3D print models and paper-clay crafts to actively engage the community. Additionally, the study explores the potential of exhibitions featuring 3D print models to enhance geographic imagination with an artistic touch, fostering a deeper connection to the cultural and environmental significance of the studied sites.

Sandsnap: Engaging the Public in Coastal Geoscience Through Social Media and Education Outreach

Brooke Marlo WALKER[1]*, US Army Corps of Engineers, Coastal and Hydraulics Laboratory (brooke.m.walker@usace.army.mil)
Brian C McFall[2], US Army Corps of Engineers, Coastal and Hydraulics Laboratory
David L Young[3], US Army Corps of Engineers, Coastal and Hydraulics Laboratory
Daniel Buscombe[4], MARDA Science
Shelley Whitmeyer[5], James Madison University
Jacob Stasiewicz[6], ORISE Fellow, US Army Corps of Engineers, Coastal and Hydraulics Laboratory

Abstract

Sediment size is often the largest uncertainty for coastal sediment transport modeling input parameters. Collecting this data using conventional methods is unfeasible for large spatial or temporal extents. The SandSnap project builds a comprehensive beach grain size database with the help of smartphone-equipped citizen scientists. Taking a SandSnap requires taking a photo of sand at the beach with a coin in the frame for scaling, uploading the picture to the user-friendly SandSnap web application (www.sandsnaperdcchl.hub.arcgis.com) and filling out a brief questionnaire about the type of coin in the image and beach where the image was taken. The web application passes the photo to a cloud environment, where it is run through two open-source neural networks – one to detect the coin in the frame and one to estimate the grain size. The results are returned to the web application and logged in the freely-accessible beach grain-size database.

The scale of the grain-size database produced by SandSnap hinges upon public outreach and engagement. The SandSnap team employs a multi-faceted approach to build public awareness and interest in this effort, including science kits hosted by public libraries, Science, Technology, Engineering, and Mathematics (STEM) outreach events with youth organizations and universities, the development of lesson plans for use within classrooms of all age ranges, and a continually-growing social media campaign. Through this multi-faceted approach, Sandsnap presents a unique model for maximizing citizen science initiatives in coastal studies and bridging the gap between professional geoscientists and the public.

While initially developed for the North American shoreline, international interest has been growing, and Sandsnap has now reached six continents. Harnessing the power of citizen scientists worldwide with SandSnap is the next step to building a global beach grain-size database, while also encouraging the public to be informed on and engaged with our ever-evolving coastlines.

MING Shu Jun[4], Guanghua Institute of Gemology and Mineral ResourcesGIGM
ZHU Chen[5], Guanghua Institute of Gemology and Mineral ResourcesGIGM
HUANG YAN[6], Guanghua Institute of Gemology and Mineral ResourcesGIGM

Abstract

Role-playing activities, as an emerging new method for science popularization, have introduced unprecedented levels of interactivity, engagement, and experiential learning to natural history museum exhibitions. The Liu Guanghua Museum of Natural Heritage, located in Nanchang, China, fully utilizes its extensive collection of minerals, meteorites, and fossils for interactive explanations and displays. The museum has designed and implemented role-playing activities and narratives centered around themes such as the formation of the universe, the development of the Earth, and the origin and evolution of life. For example, in our museum's activities, visitors or guides often take on roles such as miners or fossil excavators, geologists or paleontologists, engaging in the collection or excavation of minerals and fossils. This is followed by sorting and identification processes, through which participants gain scientific knowledge and methodologies in geology, mineralogy, and paleontology, while also experiencing enjoyment and engagement. Moreover, through various role-playing activities, our museum has enhanced the interest of youths and the broader community in the natural heritage museum and earth sciences, thereby increasing the museum's popularity and visitor traffic.

These activities, leveraging earth science knowledge through innovative interactive gaming experiences, not only convey scientific knowledge and encourage scientific thinking among participants but also transform museum visitors into active experiencers. This approach offers new methods and insights.

Geolchat Fossil Edition: Using Paleontology as an science outreach strategy in social media

María Daniela MUÑOZ-GRANADOS[1]*, Universidade de Coimbra (mdaniela.munozg@gmail.com)
Lina Perez-Angel[2], Institute at Brown for Environment and Society (IBES) and Department of Earth, Environmental and Planetary Sciences, Brown University, Providence, RI, USA.
Carolina Ortiz-Guerrero[3], Geolchat

Abstract

GeoLchat is a bilingual (English and Spanish) science communication project based on social media, aimed at connecting and promoting the work of Earth, Atmospheric, and Planetary scientists worldwide, with a strong commitment to diversity and inclusion. Founded by three Colombian female geoscientists with a passion for geoscience education and communication, the project addresses the challenge of limited Earth Sciences literacy. This issue is critical, given the urgent need to understand and communicate about climate change, the use of fossil fuels, increasing fires, hurricanes, El Niño and La Niña climate phenomena, earthquakes, and other natural hazards. The challenge is especially acute in the Global South, where educational resources in Earth Sciences are scarce.

Social media has emerged as a transformative tool to share science content with a variety of audiences around the globe. These digital platforms offer an open and accessible resource for education beyond the traditional formal educational institutions. To increase Earth Science awareness and engagement, we designed a social media-based science communication strategy: “Geolchat Fossil Edition: A bilingual science communication project in paleontology using social media”. The implementation of this six-month project was the result of being awarded the PaleoSociety Outreach and Education Grant in July 2023, enabling us to reach a broader non-scientific audience.

Leveraging the popular appeal of Paleontology andGeolchat's established follower base, we formulated a communication strategy based on freely available audiovisual content on paleontology topics, shared through GeoLchat’s social-media platforms (Instagram, Twitter, YouTube,TikTok, and Facebook) in both English and Spanish. Additionally, we collaborated with Latin American Paleontology communicators and researchers. A key part of GeoLchat’s mission is to increase the representation of historically underrepresented scientists in Earth Sciences, and we consistently aim to highlight the research of such groups in our social media content. This approach not only bridges society with Earth Sciences through paleontology but also fosters connections between the Global North and Latin America.

The "Geolchat Fossil Edition" significantly expanded our reach and follower base from March 2023 to March 2024, evidencing the effectiveness of our communication strategy. Our Instagram

followers increased by 47.4% (from approximately 3,340 to 4,922), YouTube by 39.4% (from 216 to 301), and X (Twitter) by 19.3% (from 800 to 991). This initiative has demonstrated the power of leveraging paleontology's allure to engage and educate a wide audience. Moving forward, we plan to continue producing audio-visual resources not only on paleontology but also on topics crucial to society, including climate change and the broader impact of geosciences on our daily lives.

School Rock Maps: Geological information translated for society by the Geological Survey of Brazil

Andrea SANDER[1]*, Geological Survey of Brazil (andrea.sander@sgb.gov.br)
Patricia Duringuer JACQUES[2], Geological Survey of Brazil
Gabriel Guimarães FACURI[3], Geological Survey of Brazil
Francisco Ferreira de CAMPOS[4], Geological Survey of Brazil
Marina das Graças PERIN[5], Geological Survey of Brazil
Cimara Francisca MONTEIRO[6], Geological Survey of Brazil

Abstract

The geological map represents the synthesis of geological knowledge of a location, often being recognized as one of the main products produced by a geologist. It is a complete and dense product of information that can be interpreted and used by geoscientists in their daily work, but it is practically incomprehensible to those who are not in the field, especially society in general. In Brazil, the national common curricular base that guides the pedagogical subjects that must be applied in schools, includes cartography as a form of develop representation and space thinking. It starts from the grade six onwards, and children must develop skills to interpret and prepare thematic maps identifying spatial patterns, regionalization and spatial analogies. It is an axis that permeates geography with the aim of mediating knowledge for a better understanding of the world and the places in which they live. In this way, seeking an inclusive and citizen science, SGBeduca, the Geosciences Popularization Program of the Geological Survey of Brazil, developed the Rock School Map, which is a reinterpretation of the geological map, but simplified to be used in teaching geosciences in schools and accessible to the public. Using the Geological Map of Brazil (1:1,000,000) as a data source, state sections were made and the lithotypes were reclassified into the main types of rocks: volcanic igneous, plutonic igneous, metamorphic, sedimentary, and unconsolidated sediments. The caption presents a brief description in mediated language of what each type of rock is and how to recognize it. All cities in the state represented on the rock school map are identified, as well as the main roads and rivers, under a shaded relief background. Additionally, points of geotouristic interest are marked, with four highlighted photos, takenmainly from state geodiversity books prepared by the Geological Survey of Brazil and the register of geological sites (Geossit). The objective is to create a relationship between already known points with the type of rock that appears in the location, as well as encouraging visits to new places. This type of information awakens a connection and a sense of belonging to the place in children and young people, valuing local knowledge. The last insert presents photos of examples of rocks and outcrops that occur in the state itself, taken mainly from geological mapping reports from the Geological Survey of Brazil. It is noteworthy that, despite being simplified, the information contained in school maps of state rocks maintains the scientific rigor of the original databases and its use in the school environment allows us to understand the relationship between rocks and the environment in which we live, as well as their reflections on the relief, soils and occupation of space. School rock maps are an efficient tool for studying geosciences in schools.

Popularizing Brazilian paleontology through fossil replica workshops at the Geological Survey of Brazil

Andrea SANDER[1]*, Geological Survey of Brazil (andrea.sander@sgb.gov.br)
Patricia Duringuer JACQUES[2], Geological Survey of Brazil
Flasleandro Vieira OLIVEIRA[3], Geological Survey of Brazil
Samanta Bittencourt SUPRANI[4], Geological Survey of Brazil
Irinea Barbosa da SILVA[5], Geological Survey of Brazil
Juliana Stewart FERRAZ[6], Geological Survey of Brazil
Eliane Godoy MOREIRA[7], Geological Survey of Brazil
Cimara Francisca MONTEIRO[8], Geological Survey of Brazil

Abstract

Paleontology makes it possible to tackle a wide range of topics, from the evolution of life to discussions about climate change and its impact on the planet and its inhabitants. Fossils are the gateway to the world of science for children. Despite this, in Brazil the pedagogical potential of paleontology is not fully exploited, and this science is not present in classrooms. This is partly due to the difficulty in finding teaching material in accessible language, suitable for the age of the students. This material, when available, is expensive. Another difficulty is access to fossils, as Brazilian legislation is extremely restrictive on the possession of fossil material. Brazil's laws state that fossils are the country's property, prohibiting the possession of fossils outside research institutions and their sale. However, fossils, particularly dinosaurs, permeate the imagination of children and young people and are an attractive subject for them. As an alternative to this reality and to enable students to come into contact with fossils, the Geological Survey of Brazil, through the SGBeduca Program, has developed plaster replicas of various fossils. Plaster is a cheap, nontoxic material that can be painted in different ways. Pieces that appeal to children's imaginations were chosen from iconic invertebrates such as Trilobite and Ammonite shells; the media dinosaurs and other prehistoric animals, with Tyrannosaurus and Megalodon teeth, Velociraptor and Deynonychus claws, and megafauna mammals from the "Ice Age" franchise, such as Lestodon claws; Glyptodon scute; Smilodon and Notiomastodon teeth. These replicas are used in workshops in schools. In 2023, 38 workshops were held, serving around 1,800 children. Schools located on the outskirts of cities and in rural areas, which are generally the poorest in terms of financial and teaching resources, are given priority. The children listen to a short talk about paleontology, the fossilization process and each of the animals, covering the period in which they lived, their habitat and eating habits, and see artistic reconstructions of these animals and their fossils. Afterwards, they make an artistic painting of the pieces. At the end of the activity, they receive a label identifying each piece with basic information and take home a small collection of fossil replicas. The aim of the workshops is to bring elementary school students closer to paleontology through practical activities related to scientific knowledge, stimulating artistic skills and creativity through the painting of fossil replicas in plaster. The activities presented and aimed at children and young people are of fundamental importance in the relationship between the tripod

of science, education and sustainability, because the greater the knowledge of children and young people about our Planet Earth, the greater the awareness that we have only one planet and that we need to broaden conversations about sustainability and environmental preservation.

Dissemination of Geosciences: SGBeduca's teaching collection of minerals and rocks donated to teachers

Andrea SANDER[1]*, Geological Survey of Brazil (andrea.sander@sgb.gov.br)
Patricia Duringuer JACQUES[2], Geological Survey of Brazil
Maiza Moreira RIBEIRO[3], Geological Survey of Brazil
Juliana Maceira MORAES[4], Geological Survey of Brazil
Cimara Francisca MONTEIRO[5], Geological Survey of Brazil

Abstract

The Brazilian Geological Service, aiming to fulfill its institutional mission of "generating and disseminating geoscientific knowledge with excellence, contributing to the improvement of the quality of life and sustainable development in Brazil", encouraging inclusive and citizen science, created SGBeduca, a program to popularize geosciences. SGBeduca serves primary, secondary, and higher education teachers by donating educational collections of mineral and rock samples. This material, when available on the market, is usually restricted to those with gemological value, generally expensive. Even if teachers and students obtain the samples, there are difficulties in classifying them, as stores often use trade names or even incorrect denominations for minerals and rocks. The teaching collections donated by SGBeduca are packaged in a resistant cardboard box that can be sent by mail. Each box contains 26 samples of approximately 5 cm, distributed as follows: 4 samples of igneous rocks (identified by red labels with the rocks granite, rhyolite, basalt and gabbro), 4 samples of sedimentary rocks (identified by yellow labels, with the rocks sandstone, siltstone, varvite and coal), 4 metamorphic rocks (identified by blue labels, containing schist, gneiss, slate and marble) and 14 minerals (identified by green labels: quartz, agate, hematite, pyrite, chrysocolla, gypsum, fluorite , apatite, lepidolite, calcite, kyanite, alkali feldspar, tourmaline and emerald). The identification labels contain the name of the sample, its origin, the chemical formula (if it is a mineral), and on all samples its usefulness in everyday life is described. It is noteworthy that the lack of awareness of the role that geosciences and, in particular, mineral assets, have in everyday life, leads society to consider that activities related to geology are harmful to society. When the subject arises among the lay public, the debate focuses on the socio-environmental impacts resulting from mining, ignoring the role of mineral goods, omnipresent in everyday life. For this reason, handling the collection of minerals and rocks is essential, as in addition to its didactic value, the collection materializes the theory of disciplines such as science, biology, and geography, and awakens understanding of humanity's dependence on mineral goods. Between the years 2021 and 2023, 642 collections were distributed, mainly serving geography teachers (98.2%), distributed across all 26 Brazilian states and the Federal District, mainly from the public education network (82.5%), of primary education (38.6%). The teachers attended, to refer to the impact of the collection on their students, used words such as: stimulus, practice, dynamism, curiosity, and materiality. And when referring to the impact of collections in their classes, they used the following words: interdisciplinarity, practice, understanding, depth and scope.

GEOLOGISTS.COM—the global digital platform fostering communication and collaboration among geologists and other professionals across Earth science disciplines

Pavlo ZAGORODNYUK[1], Ukrainian Association of Geologists
Olena IVANOVA[2]*, Ukrainian Association of Geologists (olena.ivanova@geologists.org.ua)

Abstract

In the 21st century, the global geological community remains fragmented, despite active offline efforts by professional associations and the rise of online data exchange tools. Aiming to bridge this gap, connect specialists across the geological field, and foster their continuous communication and collaboration, in 2024, a group of geological companies and professional societies, including the Ukrainian Association of Geologists, launched a Global digital platform GEOLOGISTS.COM. The platform unveils the crucial role of geology in serving global society and the potential of Earth science disciplines to meet the dynamic needs of humanity in the 21st century, considering Environmental, Social, and Governance (ESG) aspects of development. It informs society about the opportunities brought forth by New Geology, which is presently tasked to shape new global trends in natural resource management and provide comprehensive high-tech support for green transition and transformation processes. This includes reconstructing historical climate changes, adapting to climate change, forecasting changes in natural systems to ensure their stability, preventing and minimizing natural hazard risks, exploring the potential of natural resources, ensuring their sustainable management, developing efficient environmental protection strategies, and preserving the planet's natural wealth.

GEOLOGISTS.COM focuses on such areas as Earth’s material composition; endogenous and exogenous geological processes; historical geology; regional geology; exploration and extraction of energy, mineral, and water resources; E&P and P&A technologies; financial landscape of the geological industry and economic geology. A separate essential platform’s section is dedicated to the development of New Geology in the context of dual digital and green transitions, the synergy of scientific disciplines, and the development of integrated solutions to support sustainable global progress.

By bringing together stakeholders—experts, scientists, companies, professional societies—in a unified digital space, the Platform mobilizes geologists and professionals across Earth science disciplines to promote and elevate the status of geological sciences, enhance the professional level of stakeholders’ employees, address global issues, and accelerate the achievement of Sustainable Development Goals (SDGs) through the application of geological knowledge, participation in green transformation and green transition processes, conducting collaborative scientific research, offering scientific guidance in governmental decision-making processes, disseminating scientific knowledge to facilitate transformative processes, fostering comprehensive collaboration among geologists, and promoting innovative interdisciplinary and intersectoral partnerships.

The GEOLOGISTS.COM platform facilitates the establishment of constructive dialogue among

all stakeholders, enhancing professional connections and disseminating information about activities of international public geological organizations, industry alliances, findings from global scientific research, and sectoral professional events. The mission of the Global digital platform GEOLOGISTS.COM is to facilitate the integration of geological knowledge with other understandings of Earth's natural conditions and resources, aiming to develop the planet's resource potential, ensure effective, balanced, and sustainable use of natural resources, while also protect the surrounding natural environment, preserve ecosystems and shape the green future we want.

REGIONAL DRILL CORE REPOSITORY, GSI, NAGPUR: A CENTRE FOR GEOSCIENCE INFORMATION DISSEMINATION

praveer PANKAJ[1]*, Geological Survey of India (prpankaj@gmail.com)
GAURI VAIBHAO MOTGHARE[2], Geological Survey of India
VANDANA JAYANT UMREDKAR[3], Geological Survey of India

Abstract

Geological Survey of India, Central Region, Nagpur has one of the largest drill core repository of India. Drill core samples provide the glimpse of subsurface geology, caters to the need of students, academicians, mining and multinational companies, mineral related government offices and helps in studying lithology, mineralogy, ore minerals, alterations, structures and many allied details of rocks. The drill core samples attract earth science fraternity to develop new ideas about host rock and their mineral resources and to assist exploration activity. Drill core samples limits the need for additional drilling and the cost of acquiring new samples is also very expensive. These are used in planning of different new projects based on their characteristics, also saves money in terms of lessening the transport cost and time by providing different cores at same place. Drill core is an important tool for industry stakeholders to develop geological models and exploration programs. The repository houses drill cores of 158 projects belonging to cratons, mobile belt,CITZ, Proterozoic sedimentary basins and different tectonic settings such as Bundelkhand, Bastar Bhandara, Betul, Mahakaushal, Sausar, Sakoli, Chhattisgarh basin, Singhora basin, Indravati basin, Deccan trap, Kotri rift belt, Gondwana coal field Malanjkhand area, Western Ghat Maharashtra from Central India. The drill cores have a range of mineral commodities, style of mineralization and tectonic setting, excellent examples of stratigraphy with significant structural features. Cores of precious mineral bearing rocks such as kimberlite, gold, basemetal, copper, tungsten, REE, RM, PGE, chromite, manganese, bauxite, iron, limestone, coal, geothermal, kyanite, sillimanite, phosphorite, molybdenum, nickel, graphite, glauconite, barite, fertilizer, Regional Mineral Targeting, stratigraphy from different parts of Central India. Kimberlite cores belonging to Mainpur kimberlite field, Tokapal kimberlite field, panna lamproite field are significant alongwith Tungston deposits of Kuhi-Khobna –Agargaon. The core repository has cores of 158 projects 13582 core boxes, 264 stratigraphic boreholes, 877 skeletonised boreholes and the total length of core is around 49,600m. The database of all the cores preserved have been prepared in digital mode and available online in Geological Survey of India under CLIS module of OCBIS portal. Regular visit is done by students of many colleges, trainee officers from GSI and Engineering colleges and universities across and acts as a good centre for dissemination of Geoscientific information to the earth science community. Students from RTM Nagpur University, Fergusson college Pune University of Madras Chennai, Shri Shivaji science college, Nagpur, from Akola, Centre Point School, katol road, BVM school Ashti, National college, Trichy, J.D. College of Engg. & NGT Nagpur, MECL, Nagpur, Somalwar Nikals school, Nagpur, Civil Engg. KDK college Nagpur, Civil Branch, Trainees from MECL., S. S Jain Institute of

Tech., Yashwantrao Chawhan college lakhandur, Bhandara, Kamptee polytechnic college, govt. polytechnic College, Nagpur, geologist from Vedanta group, Data code with expert from Australia, G.H. Raisoni College department of Mining Engineering, MP. Section officers from Ministry of Mines, New Delhi and G.H.Raisoni College Department of Mining Engineering , Saikheda , MP have visited in recent past.

The importance of informal educators in improving geoscience education in Namibia

Josephine UUSHONA[1]*, Geological Survey of Namibia (Josephine.Uushona@mme.gov.na)
Martin Hipangwa[2], Geological Survey of Namibia

Abstract

Geoscientific research and its practical applications are critical in a variety of fields, including resource management, environmental conservation, natural hazards assessment and mitigation, climate change research, and improving our understanding of the Earth and its evolution. As a result, geoscience significantly influences numerous aspects of our lives and society. As a result, it is critical to launch activities aimed at educating and creating awareness about the value of geoscience in society. These initiatives could take the form of geoscience education programs that not only provide individuals with the knowledge they need to understand geological processes, but also empower them to engage with and address current societal issues such as environmental protection and climate change. Furthermore, such education fosters the development of environmental awareness, promotes sustainable development practices, and enhances overall scientific literacy among the public.

Notwithstanding the obvious necessity of geoscience and geoscience education in Namibia, the discipline is not widely understood in society, let alone in the school system. Namibia, like many other countries worldwide, does not feature a standalone geoscience subject within its school curriculum or as part of teachers' training. On the contrary, geoscience aspects are rather incorporated in traditional disciplines such as chemistry, geography, physical science, and life science. However, avenues exist to bring geoscience closer to students, teachers, and communities, through informal education, including science outreach programs and public engagement initiatives. Geoscientists can play a crucial role in this endeavor, by serving as informal educators who inform, educate, and raise awareness about the relevance of geoscience and its practical applications in schools and communities.

The Geological Survey of Namibia has been actively involved in science communication initiatives aimed at increasing awareness of the significance of geoscience among schools and communities. These efforts include hands-on activities, posters, videos, and presentations designed to engage participants interactively. By utilizing such participatory methods, the survey hopes to improve the accessibility and sustainability of geoscience education. Furthermore, the Geological Survey of Namibia has initiated a geoscience teacher training program, inviting teachers from across the country to learn about earth science and how to incorporate it into existing curricula. This program equips teachers with innovative approaches to enhance students' understanding of earth science, such as implementing hands-on activities in the classroom. These efforts aim to enable the integration of geoscience ideas into classroom education by encouraging collaboration between educators and geoscientists, ultimately leading to a more aware and environmentally responsible society.

The Importance of Science Communication About Hydrogeology in Culturally Sensitive Arid Areas

Barbara REYES[1]*, Scientists in Parks (breyes0021@gmail.com)

Abstract

The importance of science communication in regards to water protection in the southwest region of the United States is crucial to the survival of water resources in the area. Managing water resources in the Arizona Strip, an arid region in northwest Arizona, United States, has been a struggle for decades. The National Park Service (NPS) is looking for ways to effectively communicate water conservation practices to various communities with different priorities and opinions about the uses of water. Part of this includes highlighting agricultural practices that require low culinary water and prioritizing low water consumption technology at the park.

This poster focuses on water conservation efforts explored at Pipe Spring National Monument. The decline of the spring flow at the monument that holds historical and cultural significance has been a concern since the initial hydrogeological study conducted in the 1970s. Countless reports since then, have drawn a connection between our local water use and the decline in spring flow. One step Pipe Spring has taken to educate the public about water conservation, is to first effectively educate them about the geological processes that occurred during the Sevier Orogeny and Laramide Orogeny that allowed the area to become a welcome oasis in an arid region. The topic of water conservation becomes a delicate subject matter as tribal sovereignty, public lands, and religious freedom debate about the best uses of the springs that are fed from the confined aquifer of the region. The importance of science communication and cultural understanding allows for various communities in the area to understand how the geology of the area has allowed this unique source of water to come about and and why we must protect it.

GAO Pan Pan[7], Guanghua Institute of Gemology and Mineral ResourcesGIGM, Jiangxi University of Applied Science and Technology, Nanchang 330100, China

Abstract

Dinosaurs, which are ancient biological fossils emerging from the geological history, are often translated into "dragon" in Chinese — a motif recurrent in traditional culture. The dragon in China embodies auspiciousness and epitomizes power, a deity that has evolved from millennia-old myths and religious narratives, with the Chinese regarded as the progeny of dragons. In line with the Chinese traditional lunar calendar, 2024 is earmarked as the Year of the Dragon, making the dragon the emblem of the year. The Liu Guanghua Museum of Natural Heritage has adeptly leveraged dinosaurs and akin prehistoric fossils identified with "dragons" to launch an array of educational and science outreach activities. These initiatives have been notably successful in simultaneously elevating Chinese traditional culture and advancing the knowledge of paleontology.

This document employs the educational endeavors of the Liu Guanghua Museum of Natural Heritage as a focal example. It capitalizes on the emblematic significance of dragons within Chinese traditional culture as a seamless conduit for the propagation of paleontological science, elucidating the splendid epochs and pivotal contributions of "dragon-shaped" prehistoric entities in geological history. It augments the visitors' comprehension of ancient life forms, revealing their varied distributions and evolutionary morphologies across marine, terrestrial, and aerial realms. Furthermore, juxtaposing the mythical dragons of Chinese lore with their scientific counterparts unravels fascinating parallels, such as the sovereignty of dragons in the marine domain and their morphological versatility. Through its exhibitions and programming, the museum amplifies its indispensable role in promoting earth science, fostering cultural heritage, rectifying

misconceptions, and enhancing natural science education.

ALTERNATIVE E-ASSESSMENT WITH INTEGRATED ACADEMIC STUDENT SUPPORT: CASE STUDY- ENVIRONMENTAL SCIENCES

Helena (prefer ELNA) Johanna VAN NIEKERK[1]*, UNISA (vniekhj@unisa.ac.za)

Abstract

Although the University of South Africa (UNISA), a Comprehensive Open Distance e-Learning (CODeL) institution, has a history of more than 150 years offering quality Distance Education (DE), student support has always been a challenge. Initially, meticulously developed study material was provided to all registered students via the post. Formative assignments had to be completed for a year mark which provided access to summative venue-based examinations. However, the transactional distance between lecturer and student and amongst registered students often caused individual students to feel isolated and alienated, which lead to a series of complaints raised against DE.

In the digital age where the internet increased the speed and amount of information available and provide numerous different technologies to communicate fast and effectively, online modules can be designed and activities can be developed to enable students to collaborate, engage in dialogue and reflect on their learning according to the constructivist learning theory. Students can also be joined together in a digital, online learning community where they can share, discuss and deliberate, and make connections between fields, ideas and concepts according to the connectivist learning theory.

Several High Impact Practices (HIP) related to student support was researched and reported by Higher Education Institutions across the globe. The question arose whether the HIPs identified for face-to-face institutions could be applied to an online module at Unisa. This paper will focus on the application of the academic student support HIPs and show how it could be integrated into one online, writing intensive honours (4th year) module in Environmental Sciences, offered in the College of Agriculture and Environmental Sciences (CAES) at UNISA. The HIPs were integrated through a series of alternative assessments such as discussions, blogs, games, research reports, peer review reports and a debate. The high impact academic student support practices include the following: orientation; goal setting and planning (time management); first time experiences; supplemental instruction; student success courses; class attendance and engagement; learning communities and collaboration; tutoring (regular feedback); research (real-world applications); alert and intervention; writing, presentation, and reflection.

Conceptions of risk in the face of crises and the memory of events in tropical island territories. Ways of establishing a risk culture in the French West Indies.

Yves MAZABRAUD[1]*, Université des Antilles (yves.mazabraud@univ-antilles.fr)
Alexandra RENOUARD[2], Imperial College London
Adam ABDOU-ALOU[3], Université des Antilles
Michelet CLERVEAU[4], Université d'Etat de Haïti
Béatrice JEANNOT-FOURCAUD[5], Université des Antilles
Thomas Forissier[6], Université des Antilles

Abstract

The Lesser Antilles arc is made up of different island territories that are subject to natural hazards that shape their geography and influence their societies. The various disasters that have marked the archipelago's recent history are memorial markers that leave a more or less deep and lasting mark on people's relationship with their environment. Throughout the world, certain societies have developed historically by forging a link with the natural hazards to which they are subject. This link can be expressed simply by a strong awareness of the issues at stake, visible in the institutional and educational preparation for risks to mitigate their effects and improve resilience. Indonesia and Japan are emblematic examples of this (for example, the god Kashima, associated with earthquakes), and myths linked to volcanoes and earthquakes can be found in many ancient societies.

Our study focuses on two aspects: the first is the persistence of the memory of disasters within society and families. Using questionnaires, we are assessing the duration of memories of crises in Guadeloupe (the Pointe à Pitre earthquake of 1843, the volcanic crisis of 1976, cyclones Hugo, 1989, and Maria, 2017) within generations, depending on the intensity of the impacts. The aim is to provide descriptive information on the establishment and persistence of a culture of risk. The second part of the study consists of establishing individual profiles modelling the interactions of subjects with each other and with their environment. These profiles are intended to be used operationally to help target the awareness-raising or educational initiatives that are best suited to a given social group in its context. Our aim is to define the psycho-social and geographical parameters that enable us to identify groups of individual profiles that are consistent in terms of preparedness for natural hazards, so that we can strengthen the population's preparedness and resilience in the face of crises, in a targeted manner.

This study is resolutely multidisciplinary (geography, geosciences, science education, linguistics) and is supported by the French Red Cross Foundation.

Deciphering the Scientific Conceptions of Students and Teachers: from Interaction-Based Modelling to Machine Learning Perspectives.

Alexandra RENOUARD[1]*, Imperial College London (a.renouard@imperial.ac.uk)
Yves MAZABRAUD[2], Université des Antilles

Abstract

The description of students' and science teachers' conceptions of fundamental scientific topics is a key factor in improving the effectiveness of science teaching, as it enables the detection of alternative conceptions that hinder the acquisition of officially accepted scientific conceptions. For this reason, it has long been the subject of numerous studies and models. Individual conceptions are now well described in many scientific fields, such as earth sciences. However, despite all these studies and the efforts made by the community (e.g. scientists, academics, secondary and primary school teachers, educators) to develop good teaching practices, some pre-existing alternative conceptions still persist among students. Here, to take things a step further, we present a conceptual model aimed at studying the origins of individual conceptions and the ways in which they are acquired and disseminated. Symbolically based on the crystalline structure of silicates, this model describes the educational context of each student in order to design targeted actions to encourage the acquisition of scientific conceptions by intervening upstream of their acquisition (Renouard and Mazabraud, 2018).

We then propose some perspectives offered by the use of unsupervised machine learning (ML) tools applied to this model. Artificial intelligence and ML are still underused in the field of science education, despite their growing presence in many scientific fields. Our aim is to transfer the ML know-how developed in geophysics to geocognition studies in order to open new doors, while avoiding an over-simplified or black-box use of these newly available tools.

Languages and natural risk prevention in diglossic territories: a study in Guadeloupe

Béatrice JEANNOT-FOURCAUD[1]*, Université des Antilles (beatrice.jeannot@univ-antilles.fr)
Yves MAZABRAUD[2], Université des Antilles
Adam ABDOU-ALOU[3], Université des Antilles
Alexandra RENOUARD[4], Imperial College London
Chloé ROUSSEAU[5], Unversité des Antilles

Abstract

Our experience of many natural disasters, regardless of their nature or location in the world, shows the importance of people's awareness and knowledge of the risks they may face. We know that these elements can be crucial in determining the human toll of natural disasters. In this respect, prevention efforts must always be considered, especially in cases where the risk culture appears to be less developed. In this study, we focus on prevention, not in its material aspects (adapted infrastructures, etc.), but in terms of preparing the population, particularly in terms of appropriate gestures and behaviour. This being the case, whether we are talking about institutional communication or risk education, a key question that arises in bilingual contexts is which language is the most effective for conveying preventive messages. It is on this point that we focus our reflections, through the study of data collected in Guadeloupe, a bilingual territory characterised as diglossic due to the unequal status and representation of the two languages that coexist there, Creole and French. Using questionnaires collected from primary school children, we aim to investigate the relevance of using Creole, the regional language, or French, the national language, in risk prevention campaigns in Guadeloupe, with a view to improving them. To this end, we are interested in the students' ideas, practices and linguistic skills, as well as the pragmatic effects of using one or the other language (in particular, the effect of the message on the recipient).

This study is supported by the Foundation of the French Red Cross.

Strategies and challenges for risk education in the city of São Paulo, Brazil

Natalia Leite de MORAIS[1]*, Sao Paulo City Hall Civil Defence Coordination
(nlmorais@prefeitura.sp.gov.br)
Malena D'Elia OTERO[2], Sao Paulo City Hall Civil Defence Coordination
Thaís Feitosa TREVISANI[3], Sao Paulo City Hall Civil Defence Coordination

Abstract

The city of São Paulo (Brazil) has more than 11 million inhabitants and, despite being the richest city in Brazil, the Municipal Defence Coordination (COMDEC) has mapped more than 700 areas of geological and hydrological risk with 200,000 estimated vulnerable homes exposed to those risks.

Regarding risk management and prevention, COMDEC also promotes actions for education and social mobilization focused on risk perception and risk reduction. Despite carrying out several outreach actions, the limited technical staff working in COMDEC are not enough to meet the needs of all risk areas and their inhabitants.

Given this limitation, COMDEC adopted a strategy based on articulating and developing training courses for municipal public servers from other municipal departments. Target groups for these courses are chosen considering servers' capillarity and access to populations who live in risk areas.

In this work, we present two educational and social mobilization actions developed by the COMDEC team: (i) one with teachers from the public educational system and (ii) another one with public health servers. Both courses were organized in classroom and on-site classes, regarding risk types, prevention actions and risk management.

(i) Course for teachers (2019-2020): developed in partnership with the Departments of Education, Health and Environmental Affairs and Forestry, for 592 teachers from early childhood education, elementary school and upper secondary education.
The main objective of the course was to provide teachers with information on risk management and encourage them to develop teaching activities with their students that focus on risk perception and reduction.
During 2019, on-site classes were held in risk areas. In 2020, because of COVID-19 pandemy, the on-site classes were canceled and teachers were asked to develop a practical activity for the students that gathered the theoretical knowledge that they acquired during the course.

(ii) Course for health servers (2024): between February and July of 2024, a training course will be held for Environmental Promotion Agents of the “Green and Healthy Environments Program”, of the Department of Health. The target group is estimated at 330 agents.

The objective is to provide tools for these agents so they can identify the evidence of risk and the conditions that worsen the risk situation.

Recognizing the institutional limitations that pose challenges in the development of public policies is the first step towards creating strategies that adapt to these scenarios. The partnerships formed with teachers from the public educational system and with Environmental Promotion Agents proved to be effective because they work in close contact with risk areas inhabitants. Hence, by training them, they become multipliers of the perception and reduction of risks. As a result, it promotes the creation and improvement of a culture of risk prevention.

CREDO-L: An Innovative Landslide Mitigation Strategy for Highschool Students (Study Case: Depok, Indonesia)

TWIN HOSEA WIDODO KRISTYANTO[1]*, Geology Study Program, Universitas Indonesia (twin.hosea@sci.ui.ac.id)
Marlina Tjendra[2], Universitas Indonesia
Abigail Priskila Anna Pratiwi[3], Universitas Indonesia
Fajar Multi Ksatria[4], Universitas Indonesia
Muhammad Badhar Gibran[5], Universitas Indonesia

Abstract

Landslides are Indonesia's most common natural disasters, including in the Depok City area. Through 2022, about 200 landslides were recorded in the Depok City area. This condition is at odds with the ability of Depok people to face the landslide hazard. Therefore, this study aims to build an innovative landslide disaster curriculum for high school students to increase the awareness of Depok citizens, especially the younger generation, and enhance their ability to accommodate their lives to landslide disasters. It used a qualitative method called action research, initiated by constructing a written concept in a learning plan. The study plan includes key topics on landslide disasters, learning methods, and innovative properties in the classroom. The curriculum was tested in Depok High School for several sessions, and each session was assessed to understand the impact of the teaching on students' awareness of the landslide disaster. The disaster teaching curriculum is called CREDO-L (Creative Hazard Education – Landslide Series). CREDO-L also incorporated local wisdom regarding the landslides that occur in Depok. CREDO-L was taught and tested for 91 Depok Senior High School students majoring in science and humanity. The success rate of the curriculum was evaluated using pre- and post-tests. The results show that CREDO-L improved students' understanding of landslide disasters. The learning process also offers benefits in encouraging the students to share their experiences learning the hazard through CREDO-L with their buddies and family members. It is concluded that CREDO-L has successfully enhanced the understanding and awareness of landslide disasters among senior high school students in Depok City, Indonesia. It has also been proven that CREDO-L can encourage students to share their experiences and knowledge with others.

Stephen Macko[14], Education Committee of EGU
Teresita Gravina[15], Education Committee of EGU

Abstract

The mission of the European Geosciences Union (EGU) is, through advances in Earth, planetary and space sciences, to realise a sustainable and just future for humanity and the planet. To achieve this goal, EGU organises topical meetings, and education and outreach activities in addition to publishing more than twenty diverse scientific journals. The Education Committee (EC) of EGU was founded in 2002 with the aim of bringing state-of-the-art science into tomorrow's classrooms via high-school teachers.

The current strategy of the Committee envisages four main objectives. The longest running and most important objective is the organisation of Geosciences Information for Teachers (GIFT) workshops. These are two-and-a-half-day teacher enhancement workshops held in conjunction with EGU's annual General Assembly in Vienna, Austria. There, selected top-level scientists working in the Earth sciences offer the invited teachers talks centred on a different theme every year. Teachers are, in addition to free access to the Assembly and travel grants, also provided with teaching strategies and hands-on activities related to the theme.

With very many teachers keen to get more access to research experience, the European GIFT concept also became international, with the EC helping to organise workshops at different locations worldwide, like in Merida (Mexico, two times), Penang (Malaysia), Cusco (Peru), Port Elizabeth (South Africa), Istanbul (Turkey), Addis Ababa (Ethiopia) and Cape Town (South Africa, four times) with notable success (amongst the latter a GIFT workshop in cooperation with the 35th IGC in 2016).

Until today more than 2500 teachers from over 50 countries had the opportunity to take part in these workshops. For the past 15 years some of the lectures were filmed during the workshop. Along with all the other workshop material (programmes, brochures, abstracts and files of the

presentations) these recordings were made available as web streams and are accessible free of charge via the EGU website.
In addition, the EC has recently started the enormously popular Geoscience Education Field Officers (GEFO) programme as a second objective, which allows for momentarily eleven GEFO to organise local and international teacher training sessions. With almost 3000 participants of roughly 160 workshops in 11 European countries so far, this concept has proven to be an overwhelming success.
Our third objective centers on Tertiary Education. We provide grants for higher education geoscience teaching material to be made freely available to everyone who teaches university-level geoscience and we support one Early Career Scientist (ECS) with experience in teaching Earth, planetary, and space sciences at the university level every year.
Last but not least we financially support geosciences events worldwide like currently Lab and Field Schools in the Mediterranean, a seismology workshop in Nepal or the participation at the International Earth Science Olympiad.
The EC consists of 15 colleagues, professors at universities (active and retired), researchers and high-school teachers. We hope to be able to serve the public even more in the near future.

Measuring and Communicating the Impact of Earth Science Research on Society and the United Nations Sustainable Development Goals

Phoebe MCMELLON[1]*, GeoScienceWorld (mcmellon@geoscienceworld.org)

Abstract

The earth sciences cover a range of sub-disciplines that aim to deepen our understanding of the natural world and to apply that knowledge to enable global communities to mitigate disasters, discover and manage natural resources, and be better stewards of the earth. Quantifying and communicating the impact of earth science research on sustainability is critical for attracting new scientists to the field, for advancing and improving quality of life, for mitigating risks, and for addressing the challenges that threaten our future. The impact of research on society is reflected in scholarly research. (1, 2) This paper presents the results of a study undertaken by GeoScienceWorld (GSW) to quantify the impact and contribution of the earth sciences on society and on advancing the United Nations' 17 Sustainable Development Goals (UN SDGs) by leveraging a variety of metrics associated with scientific research output.

The UN SDGs are a call for action to eradicate global poverty, end unsustainable consumption patterns, facilitate sustained and inclusive economic growth, social development, and environmental protection. Leveraging data from Digital Science's Dimensions database (https://www.dimensions.ai), GSW aggregated and analyzed global research output between 2015-2023 across four scientific disciplines(3): earth sciences, biological sciences, chemical sciences, and physical sciences to quantify the impact and contribution towards advancing the UN SDGs and influencing policy. The preliminary results show that the earth sciences have the greatest contribution in terms of total research output (19%) followed by the biological sciences (11%), chemical sciences (7%), and physical sciences (5%). In addition, the grant awards for SDG-related research were highest in the earth sciences (20%), followed by chemical sciences (12%), biological sciences (9%), and physical sciences (7%). All science disciplines contributed to all 17 SDGs; however, research output in the geosciences significantly impacted more SDG categories than the other scientific disciplines.

This study highlights the value of quantifying the impact of scientific research and communicating the impact of the earth sciences on sustainability, and can be used to attract new students, to influence future funding priorities, and to accelerate innovation, new discoveries, and understanding our planet and beyond.

Between Fieldwork and Classroom Training: the School of Geology and the Early Geological Survey in China (1913-1916)

Lijuan YANG[1]*, School of History, Zhejiang University (yang-lijuan@zju.edu.cn)

Abstract

In 1913, the School of Geology affiliated with the Geological Survey of China was established. The aim of the school was to train specialists in carrying out geological surveys. During the years 1913-1916, the School of Geology had cultivated talented people with different educational backgrounds. At the beginning of 1916, the old Geological Section of the Bureau of Mines was reorganized into an independent geological survey, and became the National Geology Survey. Dr. Johan Gunnar Andersson (1874-1960), then Director of the Swedish Geological Survey, was appointed Mining Adviser to the Chinese Government, and his two assistants F. R. Tegengren and E. T. Nyström, all became members of the Geological Survey in 1916. In the summer of the same year, the students who graduated from the School of Geology also became members. Several geological surveys were organized during 1913-1916. This paper combines an investigation of some newly discovered materials with an exploration of the past, to trace the routes by which geology developed in modern China. The author will focus on geological surveys conducted by Chinese geologists between 1913 and 1916. Since then Chinese geologists conducted careful investigations in Northern and Eastern China, and could be considered some of the earliest geological surveys organized by Chinese authorities. This was a period when China trained geological specialists at the School of Geology, and established the National Geological Survey of China. China became able to conduct its own independent geological surveys after the students from the School of Geology graduated and became qualified professionals.

Fostering geoheritage education through Virtual Reality technologies

Paola Coratza[1], Department of Chemical and Geological Sciences, University of Modena and Reggio Emilia, Via Campi 103, 41125 Modena, Italy
Mauro Soldati[2], Department of Chemical and Geological Sciences, University of Modena and Reggio Emilia, Via Campi 103, 41125 Modena, Italy
Vittoria VANDELLI[3]*, Department of Chemical and Geological Sciences, University of Modena and Reggio Emilia, Via Campi 103, 41125 Modena, Italy (vittoria.vandelli@unimore.it)

Abstract

Education on geoheritage can play a pivotal role in fostering sustainability and sustainable development. Geoheritage is an essential part of the global natural and cultural heritage including key sites and elements (e.g., rocks, minerals, fossils, and landscapes) for the understanding of Earth's history. Geoheritage has been shown to provide essential ecosystem services benefiting all humans. Given its non-renewable nature, the conservation and promotion of geoheritage are deemed crucial. In the last few years, dedicated courses or contents regarding geoheritage have been introduced in universities. However, there is still the need to improve awareness on these topics especially at higher education level.

This paper presents the outputs of a research carried out in the frame of a project centered on "Training new generations in geomorphology, geohazards, and geoheritage using Virtual Reality Technologies", run under the Erasmus+ Programme's Key Action 2: Partnerships for Cooperation under the European Commission. The project aims to propose uniform and integrated teaching guidelines that promote distance education, by utilizing the most recent trend in technologies. VR-based experiences, in the form of Virtual Field Trips (VFTs), were implemented to create immersive lessons on geoheritage with the broader aim to promote its deeper understanding and appreciation. Definitions and values of geoheritage were exposed through virtual itineraries in specific locations chosen for their high educational potential. The selected locations include a Natural Reserve in the Emilia Apennines (Northern Italy), distinguished by spectacular mud volcanoes and badlands. Additionally, a coastal area in the northwestern sector of the Island of Malta (Central Mediterranean Sea) was selected, due to the variety of its landforms. The VFTs were developed through a sequence of stops corresponding to points of interest that exemplify the scientific, aesthetic, ecological, socioeconomic, and historical values of geoheritage. While the VFTs cannot entirely substitute traditional on-site field trips, their integration into geoheritage education has proven highly beneficial. This utilization has enabled: i) Overcoming the challenges posed by site inaccessibility and unpredictable weather conditions; ii) Prevent students/users from being threatened by potential geological hazards; iii) Safeguarding the integrity of the sites. Additionally, in a single lesson, VFTs allow students to explore and compare a wide range of geoheritage features, whether concentrated in a single site or scattered on a global scale.

The implemented virtual itineraries were successfully used as teaching material in bachelor and master degrees including courses on: Geomorphology, Georesources and Physical Geography.

Evolution and Achievements of the IUGS Commission on Geoscience Education (COGE)

Ian Francis CLARK[1]*, University of South Australia (ian.clark@unisa.edu.au)
Sandra Villacorta-Chambi[2], Charles Darwin University/CSIRO Australia
Susanna Occhipinti[3], Camerino University/Education Department of the Italian Geological Society

Abstract

Originally established as the Commission on Geoscience Education, Training, and Technology Transfer in 1990, COGE's evolution is explored against the backdrop of expanding global needs in geoscience education. The Commission's strategic reorientation from purely facilitating scientific conferences to addressing diverse educational demands across developed and developing countries is examined.

COGE has focussed on improving geoscience education globally, and COGE's significant collaborative ventures, notably with the International Geoscience Education Organisation (IGEO) and the European Geosciences Union (EGU) are used to highlight key achievements such as the formulation of an international geoscience curriculum and impactful educational publications. These collaborative efforts underscore COGE's instrumental role in shaping geoscience education on a global scale.

Key independent achievements include the establishment of the Geoscience Education Field Officers (GEFO) Program, the creation of the Chris King Medal for excellence in international geoscience education, ongoing partnerships with other global geoscience education organisations, and the recent reinvigoration of a social media presence to increase awareness of its initiatives giving more visibility to the commission at the same level as other major IUGS commissions; as well as its reorganisation to improve the commission’s effectiveness, including the creation of sub-commissions and subcommittees. Despite these achievements, COGE faces new and persistent challenges, such as resource constraints and adapting to diverse educational systems. The Commission's innovative responses to these challenges, particularly during the COVID-19 pandemic, showcase its resilience and commitment to advancing geoscience education amidst evolving circumstances.

The presentation addresses these challenges to advance geoscience education globally and emphasises the importance of collaboration and innovation. In addition, COGE's future directions are outlined, emphasising its commitment to global collaboration, teaching innovation, inclusivity, and adherence to geoethical principles. This forward-looking perspective reaffirms COGE's role in enhancing and diversifying global geoscience education.

Philippine Participation in the International Earth Science Olympiad (IESO): A Longitudinal Study

Miguel CANO[1]*, St. Stephen's High School (mcano@ssh.edu.ph)
Marietta De Leon[2], University of the Philippines
Magnolia Vida Ante Cano[3], Bicol University

Abstract

The Philippines has been involved in the International Earth Science Olympiad (IESO) since 2005, participating in the planning stages before its official commencement in 2007. Aside from active participation, the country then hosted the 2nd IESO in Manila and Bicol, Philippines in 2008.

Since 2007 until the country's most recent participation in 2019, the Philippines garnered 1 gold, eight silvers, 18 bronzes, 1 honorable mention during the 3rd IESO in Taiwan, aside from the awards earned in the International Team Field Investigation (ITFI) and Earth Science Project (ESP). A number of former IESO Team members ended up taking Earth Science courses (BS Geology, in particular) even to a PhD level abroad (e.g. most recently at MIT)

The longitudinal study sought not only to account "success stories" of students who later pursued pathways in the Earth Sciences but even those who took different paths and yet elicited narratives of significant appreciation of Earth Science/Systems while in different fields of endeavor. The narratives are categorized into two groups: those arising from their involvement in the written test, camp, and training, and those stemming from their experience during the IESO participation in the host country. The reflections of the former IESO Team members and their experiences in the IESO contribute to the evolution of how gifted students in the Earth Sciences in the Philippines are selected, sifted, and trained for IESO against the backdrop of economic and political milieu in the Philippines. As such, this study has implications on the method of selecting the Team members through the Philippine Earth Science Olympiad (PESO).

Science Olympiads play an important role in the development of scientific talents and giftedness and contribute in building up the science capital of the Philippines. The selection process must therefore be responsive to the experiences of the Olympians and should address the issues of equity, diversity, and winnability.

Practice of Geoscience Education for Guilin Karst World Natural Heritage Site -- Taking "A Drip of Water Travel" as an Example

Lina SHEN[1]*, Institute of Karst Geology, Chinese Academy of Geological Sciences
(24830298@qq.com)
jinfu QIN[2], 13768721786
zhimin HUANG[3], 8618577396464
jinyun TUO[4], 13557032336

Abstract

The Guilin Karst World Natural Heritage Site has the most typical peak cluster and peak forest landforms in the world, with both above ground and underground karst development, making it a natural museum of karst geoscience education. In order to better carry out karst geological education for primary and secondary school students, experts have developed the "One Drop of Water Travel" geological course targeting the Guanyan Underground River Basin in the core area of Guilin Karst World Natural Heritage. The course covers four age groups: primary school, junior high school, high school, and university. Through PBL teaching methods, students are encouraged to explore the origin and development of water in typical karst environments, shape the above and underground landscapes of karst, understand the relationship between humans and karst environments, enhance the public's concept of sustainable development, and protect and inherit Guilin Karst World Natural Heritage.

In combination with China's research travel policy, the construction of the Guanyan Underground River Karst Research and Learning Base has been carried out to systematically carry out karst geological education for primary and secondary school students. This has improved the level of science popularization and education for Guilin's Karst World Natural Heritage, provided practical experience for world natural heritage geological education, and provided new cases for global karst geological education.

[Keynote] Engaged Geosciences: Connecting Students, Teachers, and Community to Solve Local and Global Problems

Sharon LOCKE[1]*, Southern Illinois University Edwardsville (slocke@siue.edu)

Abstract

Global challenges, including climate change, ensuring energy for all, sustaining air and water quality and access, and managing natural resources sustainably, require solutions informed by the geosciences. Engaged science, which is science conducted in mutual partnership with affected communities, is rapidly growing in popularity and in the geoscience scholarly literature. Engaged geoscience ensures that local and community knowledge is integrated with other scientific knowledge to inform solutions. Furthermore, by engaging the community in the scientific process from the beginning, enacted solutions are more likely to account for human dimensions of the problem, leading to better solutions. Our team conducted a geohealth project that engaged grade 6 and 7 students, teachers, scientists, and the broader community to examine sources of pollution in soil and air that contributed to increased exposure to environmental hazards. Using community participation and place-based learning as the theoretical framework, students learned how to design a research study, measure environmental exposures, and communicate scientific fundings to a non-technical audience. The project has the benefit of identifying public areas where soils had elevated lead levels and thus were candidate sites for remediation. The project also revealed opportunities to strengthen communication networks within the affected communities to improve capacity for action. For example, although understanding geohealth is critical to ensuring the health and well-being of residents, this subject area is not taught in area schools. Additional means of creative communication of the results of engaged geoscience projects is recommended, such as public showcases of participatory photography and graphic comics.

Arts and Geoscience: An Interdisciplinary Approach to Enhancing Geoscience Education

Sandra Paula VIILLACORTA CHAMBI[1]*, CSIRO (sandra.villacortachambi@csiro.au)
Heather Handley[2], University of Twente
Susanna Occhipinti [3], Camerino university

Abstract

Integrating arts into geoscience education presents a unique and dynamic interplay, offering an innovative approach to understanding and teaching complex geological concepts. Historically, artistic depictions of geological phenomena have demonstrated the relationship between art and science, blending aesthetic appeal with scientific precision. In modern education, this amalgamation is increasingly acknowledged for making scientific research and ideas more accessible and engaging to a broader audience.

Art, in its various forms, can evoke emotions, connect individuals to the natural world, and inspire action, making scientific ideas more relatable and impactful. This is particularly significant in geoscience education, where artistic representations can demystify intricate concepts, enhancing comprehension and relatability. From hand-drawn illustrations to sculptures and installations, artistic interpretations provide unique perspectives on scientific data, bridging the gap between scientific understanding and public perception. Science museums and research institutions capitalise on this symbiosis by incorporating art galleries to stimulate curiosity and improve scientific literacy, thereby enriching the educational experience.

Notable examples of the successful fusion of art and science include art galleries in scientific venues and interdisciplinary conferences focusing on the union between these fields. Such collaborative efforts allow artists and scientists to transcend traditional disciplinary boundaries, creating transformative knowledge and innovative solutions to complex issues like climate change.

Teaching geoscience through art fosters a holistic learning approach, appealing to a diverse audience and deepening students' understanding of Earth's processes. Educators can discover new avenues for exploring and understanding geoscience when they combine artistic creativity and scientific rigour considering the interactive nature of Art.

This poster presentation highlights the benefits of incorporating arts into geoscience education. This approach expands students' perspectives and makes learning more engaging and inclusive. By using artistic communication, complex geoscience concepts can be conveyed in a rich and inspiring way. Visual examples and case studies show how artistic methods improve student understanding, encourage engagement, and promote a comprehensive and inclusive approach to

learning.

Mobilizing Geoscience Education: The Mobile Laboratory (Laboratorio Móvil - LAM) Experience in Rural Uruguay

Elena Peel[1]*, Faculty of Science - UDELAR (elena@fcien.edu.uy)
Santiago Fort[2], Faculty of Science - UDELAR
Paula Pellegrino[3], Faculty of Science - UDELAR

Abstract

In the face of pressing global challenges such as climate change and sustainable management of earth resources, the imperative role of Geoscience Education (ESE) cannot be overstated. This abstract presents the Mobile Laboratory (Laboratorio Móvil - LAM) initiative, a pioneering project by the Faculties of Sciences and Chemistry at the Universidad de la República (Uruguay), sponsored by a private company, aimed at invigorating interest in science among children and youth. Through a specially designed vehicle equipped with necessary scientific apparatus, the LAM has been instrumental in delivering hands-on science education across rural Uruguay since 2015.

Focusing on engaging students aged 6 to 12 in rural primary schools, the LAM project emphasizes the ludic aspect of learning through experimental activities that include the exploration of minerals, rocks, and groundwater. For example, by observing water movement through porous media, students gain insights into aquifer potential in different lithologies, which is crucial for sustainable resource management and environmental conservation. This hands-on approach also includes 'object hunts' to identify geological materials and tools. Such knowledge is not only fundamental to geoscience but is also vital for planning environmentally sustainable development projects on the Earth's surface, ensuring that industrial activities harmonize with ecosystems. These activities are designed not only to impart fundamental geoscience knowledge but also to foster a deeper understanding of the earth's processes and their significance in our daily lives.

The culmination of each session involves interactive games and questions and answers (Q&A) segments, reinforcing the concepts introduced. By rotating through rural schools every 15 days and inviting nearby schools to participate, the LAM has significantly contributed to democratizing geoscience education, reaching areas traditionally underserved in scientific outreach. This initiative underscores the importance of innovative, mobile, and interactive teaching methods in standardizing and globalizing geoscience education.

Through the lens of the LAM experience, this paper advocates for the integration of such dynamic educational models into global strategies for geoscience education, highlighting the potential for localized projects to make significant contributions to the global educational landscape in Earth Sciences.

CLIMATIC DYNAMICS AND POPULATION TRENDS OF MICROTUS (IBEROMYS) CABRERAE (THOMAS, 1906) IN THE MEDITERRANEAN: A BIOCLIMATIC NICHE MODELING APPROACH

JULIA JIMENO-ALDA[1]*, University of Valencia (jimeno.a.julia@gmail.com)
PATRICIO GUILLERMO VILLAFAÑE[2], University of Valencia
FRANCISCO JAVIER RUIZ-SANCHEZ[3], University of Valencia

Abstract

Past climate changes have had a lasting impact on global biodiversity and ecosystems. Niche models, which rely on climatic data to predict the geographical distribution of species, are a method for the prediction of how environmental changes affect species. Specifically, small mammals have demonstrated a remarkable sensitivity to climatic variation, besides presenting a more or less uninterrupted palaeontological record. The Cabrera´s vole, *Microtus* (*Iberomys*) *carbrerae*, a micro-mammal unique to the Ibero-Mediterranean region with unique ecological and climatic characteristics, currently suffers from a regressive populational trend and has been categorized as endangered by the IUCN Red List of Endangered Species. In this study, the climatic development of *M.* (*Iberomys*) *carbrerae* distribution area from the LIP (MIS 5) to present was predicted and described with bioclimatic niche modeling. The objectives of our study were: i) Detect the populational regression of *M.* (*Iberomys*) *carbrerae* based on the location of palaeontological records, ii) Asses how past climatic changes impacted the historical distribution *M.* (*Iberomys*) *carbrerae*, and iii) Discern the role of the climatic factor in the declining population trend and population decreasing status of *M.* (*Iberomys*) *carbrerae*. Our results showed that palaeontological records from the LIP (MIS 5) to the sub-recent (upper part of MIS 1) indicated wider historical distribution areas for this species than current ones. Furthermore, the climatic suitability of *M.* (*Iberomys*) *carbrerae* potential distributions increased during warmer periods while decreasing during cooler periods. However, from Iron age-Roman Period (in cultural terms) in advance, despite favourable climatic conditions for expansion, population trends declined. As a result, changes in potential distribution were primarily driven by climate from the LIP (MIS 5) to the upper part of MIS 1), while other factors (eg. Interspecific competition or human influence) may have been playing a more prominent role in controlling potential *M.* (*Iberomys*) *carbrerae* distribution from the upper part of Holocene onward. We present a comprehensive cartographical analysis detailing the potential historical distribution of *M.* (*Iberomys*) *carbrerae* across four distinct periods. Our study reveals significant correlations between shifts in *M.* (*Iberomys*) *carbrerae* distribution and climatic changes. Additionally, we believe that factors beyond climate could have impacted the conservation status of this endemic Mediterranean species. By identifying these influences in future studies, we would be able to formulate effective conservation strategies for the protection and preservation of this endangered species.

Evaluation of Interpolation Methods for Mapping Potential Hydrogen for Windhoek Municipal Boreholes

Taleni Silas Taleni David[1]*, Namibia University of Science and Technology
(silasdavid071@gmail.com)

Abstract

Groundwater is one of the most significant spatial phenomena in the world, where its quality and quantity is threatened on. Potential hydrogen is a basic water quality parameter whereby the biological availability of chemical elements and solubility are determined by it. Therefore, mapping the contemporary condition of groundwater quality in boreholes offers a better management in Windhoek municipal boreholes. Furthermore, Interpolation techniques used provide a platform to accurately predict values at un-sampled points and produce a continuous dataset of spatial distributions. In this research, spatial and Geostatistics analytic tools were used to accurately compare the different interpolation methods based on groundwater spatial pattern in Windhoek, using Arc GIS 10.6. Fifty-five municipal boreholes were selected to assess the groundwater potential hydrogen. Moreover, deterministic interpolation method such as Radial Basic Function, Inverse Distance Weighting and geostatistical interpolation method such as kriging were used in both geostatistical and spatial analysis. Additionally, Empirical Bayesian Kriging was used for geostatistical analysis. The method which shows least average standard error, root mean square standardized error, root mean square error and mean square error was selected as the best method to interpolate the spatial variation for potential hydrogen in boreholes. Geostatistical analytic tool such as the Empirical Bayesian Kriging with linear semivariogram model shows the
least error values compared to Universal Kriging in spatial analytic tool. A conclusion can be made that geostatistical interpolation is a superlative method than the deterministic interpolation method for mapping potential hydrogen in Windhoek Municipal Boreholes.

Promoting the equality of research and education in geosciences using 3D digital outcrops: implications of the DDE-Outcrop3D platform

Xia WANG[1]*, Chengdu University of Technology (xiawang@cdut.edu.cn)
Hanting Zhong[2], Chengdu University of Technology
Jianhua Chen[3], Chengdu University of Technology
Zongqi Lin[4], Chengdu University of Technology
Bingqian Wang[5], Chengdu University of Technology
Lingzan Meng[6], Chengdu University of Technology

Abstract

The fundamental activities for research and education in geosciences revolve around fieldwork. However, traditional fieldwork often faces challenges related to outcrop accessibility. On one hand, areas with low investigation levels are typically difficult to access and may pose physical risks to investigators. On the other hand, many geological researchers and educators, particularly those from emerging countries, are confined to regional studies because of the high costs associated with fieldwork in distant areas away from their host institutions. Additionally, regional conflicts or global public health emergencies have notably disrupted day-to-day research and education in geosciences in recent years. These difficulties and challenges have accelerated the development of Virtual Field Trips (VFTs) technology over the past 5-10 years.

Unmanned Aerial Vehicles (UAVs), especially commercial drones equipped with high-resolution cameras, offer cost-effective methods for outcrop investigation. Close-range photogrammetry using UAV-captured images enables the creation of precise three-dimensional models, achieving remarkable centimeter-scale accuracy.

Here, we discuss the possibility of using 3D digital outcrop and open-access online VFTs platforms such as the DDE-Outcrop3D to promote equality in geological research and education. The DDE-Outcrop3D platform (outcrop3d.deep-time.org), a part of the Deep-time Digital Earth (DDE) Big Science Program recognized by the International Union of Geological Sciences (IUGS), provides an open-access web platform for real-scene 3D digital outcrops. Built upon the Cesium open-source 3D earth engine, it facilitates multiple data uploads, sharing, editing, and community outreach. With digital outcrop models from all over the world, it offer a new avenue for scientific research and education.

The why and how of seismic and geomechanical approaches for effective reservoir characterization

SHIB SANKAR GANGULI[1]*, CSIR – National Geophysical Research Institute (NGRI)
(ganguli.ism@gmail.com)

Abstract

Reservoir characterization involves the comprehensive exploration of all aspects of a hydrocarbon-bearing reservoir. This entails utilizing highly precise measurements from various sources to optimize its long-term performance. It refers to the application of different geophysical methods and techniques to understand subsurface reservoirs. The data obtained from these techniques help geoscientists and engineers to delineate reservoir boundaries, map structural features, estimate reservoir properties such as porosity and permeability, and monitor fluid movement within the reservoir. Seismic and geomechanical methods are key tools that significantly enhance the accuracy and effectiveness of hydrocarbon reservoir characterization among various techniques. They offer substantial insights into subsurface geology, rock attributes, fluid dynamics, and stress conditions, thereby contributing to the effective monitoring of reservoir performance and mitigating drilling risks, aiding in casing point selection, optimizing recovery rates, and more. This talk will provide an overview of the rationale and methodologies underpinning the use of seismic and geomechanical approaches in the pursuit of achieving effective reservoir characterization with some case examples. The examples will encompass studies from both Indian hydrocarbon-bearing reservoirs and those from around the globe to validate the approaches and discuss the lessons learned from each case. The fundamental components of these methods will also be discussed, with their role in translating data into valuable insights on physical properties and rock stress emphasized for enhanced understanding of hydrocarbon-bearing reservoirs.

Science Diplomacy in Action: Unveiling Opportunities and Challenges – A Case Study of Namibia's Endeavor to Integrate Science and Politics

Martha Ndapandula Haludilu[1]*, YES Network (marthahaludilu@gmail.com)

Abstract

Science diplomacy, the intersection of science, diplomacy, and international relations, has emerged as a critical tool for addressing global challenges and fostering cooperation across borders. This article investigates the role of science diplomacy in Namibia, a middle-income country striving to integrate scientific expertise into national policy and international relations. Namibia is a country with a rich tapestry of natural resources and a commitment to sustainable development, that faces a variety of challenges that span from environmental, health, social, and economic dimensions. Science diplomacy can play a crucial role in navigating these challenges by fostering international collaboration, leveraging scientific expertise, and contributing to evidence-based policy solutions. Namibia's journey offers a unique case study, considering its recent oil discoveries and its ambitious green hydrogen endeavors, both of which necessitate strategic navigation of the complex interplay between science, politics, and diplomacy. This article further expands on how Namibia can leverage science diplomacy to Inform policy decisions and secure international partnerships. However, the article also acknowledges the challenges Namibia might face such as reconciling competing interests, building scientific capacity, and ensuring equitable benefits.

By examining both the opportunities and challenges presented by Namibia's case, the article aims to contribute to a nuanced understanding of the role of science diplomacy in the contemporary world, particularly for developing nations navigating the intersection of resource wealth, environmental sustainability, and international cooperation.

Erosion, Transport, and Deposition of Microplastics

Ino-Ethandje Thomas[1]*, YES Network Namibia (inothomas9999@gmail.com)

Abstract

Microplastics are increasingly prevalent constituents of beach sediments, yet their fate and transport dynamics in the coastal zone remain uncertain. This experimental study investigated the influence of regular surface waves on the mobilization, transport and deposition of microplastics (190-250*pm*) *mixed with beach sand grains* (80-250*pm*) *on an artificial slope using a recirculating flume. The wave generator created regular waves with stroke lengths of* 100*mm*, 50*mm and* 25*mm, corresponding to wavelengths of* 1.373*m*, 0.990*m and* 0.925*m. Sediment cores extracted before and after each run were analyzed via microscopic particle counting to quantify changes in microplastic distribution. Under high energy waves* (100 *mm stroke*, 0.324*m/s max orbital velocity*), *microplastics exhibited significant vertical transport, with surface enrichment up to* 93.3% *compared to* 18.2% *initially. Moderate energy waves* (50*mm stroke-length*) *displayed variable mixing patterns dependent on sediment size. Low energy waves* (25*mm stroke-length*) *showed negligible alteration of microplastic distribution. High energy waves generated vortex ripples that promote mixing and suspension, mobilizing microplastics buried deeper in sediments. Low energy waves produced rolling grain ripples that limit microplastic entrainment. This study reveals that episodic high-energy storm waves can potentially remobilize microplastics buried in beach sediments and enhance their landward transport, as evident by the up-wave migration of surface MP as well as the upward core MP enrichment. The results have implications for modelling microplastic fate and transport in the dynamic coastal zone.*

JUAN BAUTISTA GUMBAU BELLMUNT[4], EVREN Evaluación de Recursos Naturales SLP
EDUARDO CASSIRAGA[5], UNIVERSITAT POLITÈCNICA DE VALÈNCIA.DEPARTAMENTO DE HIDRÁULICA Y MEDIO AMBIENTE. IIAMA. HIDROGEOLOGÍA

Abstract

The lack of detailed information and studies about the subsurface configuration in the city of Valencia, located in the alluvial fan formed by the mouth of the Turia River into the Mediterranean Sea poses significant challenges in the execution of civil and urban projects, especially in the central area where the works reach greater complexity. To date, most studies have focused on superficial geotechnical or sedimentological aspects, providing a limited understanding of the horizontal and lateral changes in sedimentary facies characteristic of alluvial environments.

In order to address this issue, this work aims to develop a high-resolution model of the first section (50 meters) of the subsurface in a central area of the city, detailing the facies that compose it and the architectural interrelation between them. The implemented methodology included a thorough collection of geological and geotechnical data, followed by drilling in the area of interest that provided direct lithological information from the subsurface. The sedimentological, stratigraphic, and paleoenvironmental interpretation of these drillings allowed for a correlation and a 3D reconstruction of the subsurface.

The result is a high-resolution model that exhibits sedimentary facies such as silt-clay, beach sands, lobes, and conglomeratic channels, clearly expressing their architecture and highlighting their vertical and horizontal heterogeneity. This study set the stays for a deeper understanding of the Valencia subsurface, providing a valuable tool for planning and executing future projects in the region.

PETROGRAPHIC CHARACTERIZATION AND DIAGENESIS OF CARBONATE ROCKS IN THE NAMA BASIN OF SOUTHERN NAMIBIA: IMPLICATION AS VALUABLE RESOURCES.

Sam Shihafeleni SHANGHETA[1]*, University of Namibia - Rosh Pinah Zinc
(semashangheta45@gmail.com)
Collen-Issia Uahengo[2], University of Namibia

Abstract

The Nama Basin in Southern Namibia hosts a significant repository of Ediacaran Nama Group carbonate rocks with substantial potential as valuable resources. This study presents a comprehensive petrographic characterization and diagenetic analysis of carbonate rocks within the basin to understand their composition, structure, and evolution. Petrographic examinations of samples from areas of study revealed diverse lithologies including limestone (light grey, dark grey; calcite and quartz veins-rich limestones), dolomite also referred to as dolostone in some cases (light grey, magnesium-rich dolomites), and various cement phases. Colour alternations observed in the limestone samples indicate changes in microbial activity during the deposition of the limestone. The diagenetic processes such as dolomitization, cementation, and dissolution are identified as one of the key factors shaping the reservoir quality and porosity-permeability characteristics of these rocks. From one of the study's aims, determining the mineralogy and major constituents of the carbonate rocks, classify them according to the Dunham (1962)'s and Folk (1962)'s carbonate classification schemes, five (5) carbonate facies were identified and classified. Namely, crystalline limestone, biomicritic limestone, micritic limestone, planar dolostone and micritic dolostone. Their geochemical analysis indicated (Ca >20%) and (Mg >1%) as the major Understanding the diagenetic history is crucial for assessing the reservoir potential and predicting the distribution of valuable resources such as hydrocarbons and groundwater. Moreover, insights gained from this study contribute to refining exploration and exploitation strategies in the Nama Basin, facilitating sustainable utilization of its geological assets for economic development.

Re-assessing late Holocene Lake level fluctuations in Lago Cardiel, Southern Patagonia (Argentina) – Geomorphological and archeological implications.

Luis Rubén Horta[1]*, CONICET - UNT (hluisth@csnat.unt.edu.ar)
Micaela Della Vedova[2], CONICET
Rafael Goñi[3], INAPL
Patricio Guillermo Villafañe[4], Universitat de Valencia
Juan Dellepiane[5], INAPL
Daniel Ariztegui [6], Université de Genéve

Abstract

Lake level variations in closed basins provide us with an excellent opportunity to reconstruct past climates at various time scales. In this contribution we present new data from the area known as "Patito Destapado (PD)" that allow to refine the existing Late Holocene fluctuations of Lago Cardiel (Santa Cruz province, Argentinean Patagonia). We aim to reconstruct the paleogeographic evolution of the region during this period and its implications for the regional paleoenvironment and, consequently, for the mobility of the hunter-gatherer populations during this time.

Well-dated microbialite levels containing gastropods are used as proxy to reconstruct Upper Holocene paleoenvironmental changes in a peninsula along the northern coast of the lake (PD). Four microbialite levels were identified, alternating with deposits of coarse sand and gravel at 288, 289, 294, and 295 m.a.s.l., respectively. The lowermost level (288 m.a.s.l) has been dated between 2087±21 years BP, while the microbialites located at 294 m.a.s.l. delivered an age of varying between 3327±26 years BP. The uppermost level (289 m.a.s.l) overlays the archaeological PD site which was dated between 3015±31 yr BP (M4) and 3436±35 cal yr BP (M10). The gastropods contained in the microbialite levels belong to the families Lymnaeidae (Lymnaea diaphana) and Chilinidae (Chilina sp.).

A more detailed paleohydrological reconstruction of the region is proposed based on the elevations of the microbialites that are witnessing changes in moisture. They indicate intervals of stability or drought, alternating with other of higher humidity characterized by clastic deposits instead. Changes in the position of lacustrine shorelines over time have created new areas available for both circulation and human occupation. The latter is consistent with the archeological component of the site containing a bone assemblage of guanaco (Lama guanicoe) indicative of hunting and further processing activities. Thus, the combined paleoenvironmental and archeological data of this site is providing new clues about the dynamic of Late Holocene human population for this area of Patagonia.

Abstract

Andean Microbial Systems (AMS) in the Puna region represent an invaluable resource for scientific research. Their ecosystems have promoted significant interest in astrobiological studies and the origin of life, given that the microorganisms thrive in one of the most extreme conditions of the planet. Many of the organisms within these ecosystems give rise to organosedimentary structures that are preserved in the geological record. However, there are a lack of studies on this area regarding the interaction between these structures and metazoans, thus opening an important window to understand biogenic structures associated with the presence of microbialites. The aim of this contribution is to present a study on the relationship between ephydrid flies and MISS found on the margins of Laguna Verde, within the Antofalla Salt Flat, Catamarca province, Argentina. Ephydrid flies (Diptera), also known as shore flies, are adapted to live near water bodies in extreme conditions, including saline and acidic, in benthic and marginal zones, generating a particular interaction with microbial mats. Diverse studies carried out in the Mediterranean Sea and western USA, from Cenozoic to current times, deal with the life strategies of ephydrid larvaes in MISS conditions. In general terms, the first phases of the life cycle of ephydrid flies include a microscopic, non-mobile egg, followed by three larval stages, with the third-stage larva reaching pupal size. The pupa, a stage of quiescence, remains unchanged in size once the larva enters its inactive period. During the larval stages, different types of traces, such as channels, can be left behind, while the pupa only leaves a trace where it was deposited.

The saline soil exhibits different typical surface characteristics of marginal areas, such as desiccation polygons, gas escape structures, and thin layer of stagnant surface water. Four samples of microbial mats were taken, each covered by about 5 cm wide layers consisting of endoevaporitic deposits. The MISS is characterized, from top to bottom in cross-section, by layers of gypsum and sulfates, a green layer of cyanobacteria, an orange layer containing of sulfur photosynthetic bacteria, and a black anoxic layer. Larvae and pupae of ephydrid flies live immersed in the oxic layers of this MISS. Single burrows associated with fly activities, such as escaping or feeding, were identified. They are perpendicular to the stratification, with no

bifurcations or constructed walls, with a variable diameter between 1 mm to 2.5 mm, associated with the diameter of the pupal stage (mean diameter: 1.45 ± 0.03 mm (with a range of 1.18 to 1.64; n=16).
This study explores the dynamics of the community associated to a very extreme environment. However, further studies are necessary to understand the complete life cycle of ephydrid flies in this kind of MISS. This will provide information about the composition of fossil evaporitic lacustrine basin deposits, expand our understanding about the ecology of extreme environments and supply fundamental information for the conservation and management of these unique and fragile environments.

DECIPHERING THE LIMITS OF HABITABILITY: GEOSPATIAL ANALYSIS OF ANDEAN MICROBIALITIC SYSTEMS AS ANALOGUES FOR THE SEARCH FOR LIFE ON MARS.

Micaela DELLA VEDOVA[1]*, Instituto Superior de Correlación Geológica (INSUGEO), CONICET- UNT, Tucumán, Argentina (micaeladvedova@gmail.com)
Patricio Guillermo Villafañe[2], PVC-GIUV, Department of Botany and Geology, Universitat de València, València, España
Francisco Javier Ruiz Sanchez[3], PVC-GIUV, Department of Botany and Geology, Universitat de València, València, España

Abstract

Since the first Mars missions in the 1960s to the most recent projects, the identification of paleoenvironments with high potential to preserve evidence of biological activity has become a priority. However, aspects such as the validation of instruments and detection methods, comparison with obtained data, and the modeling of geological and biological processes make it imperative to complement studies conducted in the Martian record with terrestrial analogs.

Microbialites are often studied when discussing the origin of life on Earth. Thus, microbial systems developing in various lakes and wetlands of the Central Andes are of interest for astrobiological studies due to their development under extreme environmental and climatic conditions. Despite the diversity of organo-sedimentary structures and producer microorganisms they comprise, these systems share geological and chemical characteristics such as formation in water bodies with high evaporation rates, association with areas with meteoric water input, and their relation to volcanic environments. Therefore, studying the components of these systems will help expand our knowledge of the types of environments that could harbor life on other celestial bodies.

This work presents the study and comparison among the elements of three microbial systems in the Central Andes: i) Laguna El Peinado, ii) Laguna Verde, and iii) Laguna Carachi-Pampa. The combination and interrelation of satellite images, analyzed using geoprocessing software, along with data obtained from chemical and petrographic studies, have allowed the identification of patterns and trends explaining the presence of microbialites. Alluvial fans, volcanic cones, basic volcanic lithologies, hydrothermal input points, physicochemical water conditions, and depth of occurrence are some of the parameters quantified and modeled in this work. The comparison and processing of the obtained information provide a new tool to understand the limits of habitability and the conditions under which life can survive and thrive, allowing for the adjustment of current life search strategies.

Leonardo Cury[3], Instituto Laboratório de Análise de Minerais e Rochas (ILAMIR), Programa de Pós-Graduação em Geologia, Universidade Federal do Paraná (UFPR). Avenida Cel. Francisco. H. dos Santos 100, 81530-000 Curitiba, Paraná, Brazil.

Abstract

Travertines are continental carbonate chemical sedimentary rocks; their precipitation occurs from a Ca-rich bicarbonate fluid mainly triggered by degassing or evasion of CO2 gas from the system upon contact with the atmosphere. These rocks create favorable situations for the proliferation of benthic microbial communities, which can influence the genesis of travertine and/or its final form. The study of these systems has acquired relevance in the last decade due to their importance in local hydrology and the development of microbial ecosystems, besides the fact that they are considered important reservoir rocks in the Pre-salt play of Brazil and Angola. In this case study, we made a geochemical and mineralogical analysis of the Vega Verde travertine system located in Botijuela at the western margin of the Salar de Antofalla in the central Andes of Argentina. The methodology involved descriptions of sedimentology, petrography, analyses by X-ray diffraction (XRD), X-ray fluorescence (XRF), and stable isotopes of δ13C and δ18O (V-DPB) and SEM analyses with EDS. The system is developed in a NW-SE 570-meter-long and 50-meter-wide valley at 4000m above sea level, surrounded by Tertiary volcanic materials ending in the Salar de Antofalla basin. The proximal depositional zone is characterized by a 15-meter-high fossil vent conical mound composed of redish-brownish carbonate massive mudstone facies with bubbles, botryoids, shrubs, and goethite identified in some spots. The intermediate area presents laminated mudstones with 2–6 cm pools and oncoidal and intraclast rudstone/grainstone facies. The distal area is characterized by rudstones and grainstones with karst features intercalated with sandstone facies. Mineralogically, the system is mainly calcite (d-spacing ~ 3.038) and impure calcite, with CaO ~ 51.05% and a loss of ignition of ~46.63%. Stable isotope signatures are δ13C (1.97–10.84) and δ18O (-0.67–-8.91). SEM and EDS image analyses showed the presence of pure calcite and Fe-bearing calcite (impure calcite) in those samples, as well as Fe-bearing clays. Data analysis shows a correlation of Fe2O3 with CaO of R2=0.86 in the vent area. Geochemical and stable isotope analyses suggest an hypogene source contribution. The Fe2O3 and As content in all the systems has an R2 of 0.96, suggesting that FeOH acts as a preferential scavenger of As, as well as other metals like Cu and Zn. Acidic to slightly acidic pH in subterranean water would cause the

dissolution of metals such as Fe, As, Cu, and Zn in the surrounding igneous rocks. The Fe2+ in solution, upon contact with the atmosphere, would precipitate ferrihydrite, with further transformation to goethite, and some of it would also be included as impurities in the calcite. The data analyzed suggest that there is a geochemical halo of Fe-bearing calcite, whose highest concentration is located in the fossil vent of the proximal depositional zone and is gradually decreasing towards the intermediate and distal depositional zones. High-resolution facies analysis of travertine systems and the integration of chemistry and mineralogy data constitute a step forward in the understanding of the evolution and geochemical-faciological distribution of these deposits as well as their origin.

Heritage Stones, and their cultural and historical legacy in the Indian subcontinent

VINOD KUMAR SHARMA[1]*, Geological Survey of India (vksharma_gsi@yahoo.co.in)

Abstract

Stones have played a significant role in shaping cultural and social legacy in Indian Subcontinent. Building stones (decorative stone and dimension stone) have been documented as one of the heritage features that describe the cultural, historical, architectural, and artistic legacy of the Subcontinent. Ancient Indian artifacts and stone tools have greatly reflected the innovation and adaptability of early human societies. Different types of stones like flint, quartzite, and chert were used to make these tools. These tools provide a glimpse into prehistoric ancestors' daily activities, survival strategies, and cultural practices. The legacy of stones in India is vast and deeply intertwined with the country's rich history and diverse culture.

Stone played a major role in the Indus Valley civilization or Harappan material culture. During the period intricate handicrafts, especially using products made of the semi-precious gemstone Carnelian have been duly recorded. The best-known artifacts of the Indus civilization are small seals, generally cut from steatite (soapstone), Despite the abundance of stone artifacts, stone sculpture is extremely rare in the Indus Valley Civilization.

The Buddhist architecture comprises many stupas using natural stones with elegantly carved gateways, rock-cut caves, stone pillars, and polished sculptures of sandstones largely using the Vindhyan Supergroup of rocks. Buddhist cave monuments built in Ajanta and Ellora caves are cut into the face of a mountain of Deccan Basalts Province and form unique artistic traditions of rock-cut temples, which are a testament to the artistic and architectural expertise of ancient India.

The grandest achievement of the artistic and architectural genius is the Sun temple at Konark is a vast and wonderful structure, magnificently conceived as a gigantic chariot carved in Khondalite. The Lingaraja temple is perhaps the most marvelous temple erected in the 10th century, the grandest and the loftiest marking the culmination of the architectural activities in Orrisa.

Khajuraho Group of Monuments built between the 9th and 10th Century by the Chandela dynasty in central India, are known for their Nagara-style architecture and intricate carvings in sandstone that depict various aspects of life, including gods, goddesses, animals, musicians, dancers, and monolithic structures, are also famous for their erotic sculptures.

Hoysalas ensembles of temples are veritable treasure houses of ornamental and decorative elements, carved in niches, and intricate vegetal and floral carvings reveal the cultural opulence during the period.

Indo-Islamic architecture of the 12th century started new experiments with stones, ornamental, and semi-precious stones. As the entire work was carried out by native Indian craftsmen, the ornamentation of the screens shows typical Hindu decorative floral elements. The bulk of Indo-Islamic structures, Monuments, and temples used sandstones of the Vindhyan Supergroup, and Marble from the Delhi Supergroup as dimensional and ornamental stones.

The stone usage grew with the development of a social and cultural ethos, opulence, and skills of the societies through the ages. The application of natural stones has developed over time. Preservation of heritage stones is, thus, vital for safeguarding our cultural and social legacy, as these rocks represent historical significance, architectural style, and cultural identity.

Trail of Heritage Stones along the trade routes through the ages

Angela EHLING[1]*, Federal Institute for Geosciences and Natural Resources
(angela.ehling@bgr.de)
Angela Ehling[2], Federal Institute for Geosciences and Natural Resources

Abstract

People were trading very early on in their history. Despite their weight, stones were also transported and traded along trade routes within or between empires. For special uses and representative purposes, even over long distances. In early times, trade routes were based on rivers and geographical features, and in modern times on the development of means of transport.

There are already examples from the Stone Age with the evidence of flint, amber and marble trading in Europe. Trading stones for building purposes is linked to the emergence of great empires and their representative buildings. In ancient times, there was lively trade around the Mediterranean. This is evidenced by the buildings in ancient Greece and in the cities of the Roman Empire.

One example is the Afyon Marble in Turkey. Afyon, in Greek and Roman times Akroinon, was located at the intersection of important caravan routes. The marble was probably already mined by the Phrygians (around 800 BC), later then by the Greeks and above all by the Romans. Especially the purplish-red coloured varieties that were popular at that time were transported to the port of Ephesus and sent to many Roman cities around the Mediterranean Sea. The last heyday of its use was in the Byzantine Empire (Hagia Sophia).

Other famous (Heritage) stones of Antique times are the Red and Green Porphyry (Egypt and Greek), Greek Marble, Verde Antico Serpentinite (Greek), Egypt Alabaster, Giallo Antico Marble (Tunesia), as well as Carrara Marble (Italy).

The stone trade in the Middle Ages in Europe is evidenced in the churches and castles from this period. Main transport routes were along the rivers. One example is the Solnhofen Limestone which was transported along the river Danube for flooring churches and palaces.

Trade organizations like the Hanseatic League in Europe plaid an important role for the distribution of stones in the Middle Ages. Along their trading routes, stones like the Kolmarden Marble (Sweden), Gotland Limestones, German sandstones, English Alabster had been transported and used throughout Europe.

With the rise of trade routes on the world's oceans, stones often have been transported as ballast. The famous Welsh slate found distribution throughout the British Empire as far as New Zealand. Stones from Portugal (Estremoz Marble, Lioz Limestone, Brecha da Arrabida), Spain and Italy were sent to South America since the 17th century.

Heritage Stones in big countries like the Makrana Marble in India or the Tennessee Marble in the USA had and have a wide distribution, even if they were only used within the country.

Today, there is an intensive natural stone trade across the world's oceans, especially from China, India and Brasil.

Portuguese limestones from the Middle Jurassic of the MCE candidate for heritage stone

Luis LOPES[1]*, University of Évora and Earth Sciences Institute, Portugal (lopes@uevora.pt)
Jorge Carvalho[2], LNEG - National Laboratory of Energy and Geology, Portugal

Abstract

The Monastery of Alcobaça (1152 AD), the Convent of Christ in Tomar (1160 AD) and the Monastery of Batalha (1386 AD), are classified as UNESCO World Heritage Sites, having in common the construction materials that built them - Limestones from the Middle Jurassic of the Estremenho Limestone Massif (MCE). The use of these rocks, first as a structural element and later as an ornamental rock, continues today.

In fact, considering the volumes of ornamental rock exploited in Portugal, these rocks have the highest values and are exported annually to more than a hundred countries, playing a decisive role in placing Portugal in the top ten world exporters of ornamental rocks.

Naturally, as they are sedimentary rocks deposited in a basin in distension in the Middle Jurassic – the Lusitanian Basin, they denote lateral and vertical facies variations that translate into variations in texture and colour in the limestones that correspond to the commercial varieties offered by dozens of companies that explore, process and sell them. Note, however, that colour variations are also conditioned by subsequent meteoric changes when, in some way, the rocks encounter the atmosphere and/or fracture zones with water circulation. These variations are evident in the dozens of active quarries, and it is common for the same rock to vary in colour from place to place and, for this reason, to be sold with different names depending on the colour, for example "Ataíja Beije" and "Ataíja Azul ".

It is important to note that because companies are obliged to comply with the most demanding product characterization and certification standards, for each of the varieties offered there is a very complete technical sheet that defends both the supplier and the buyer. Furthermore, the main commercial varieties of limestone from the Middle Jurassic of the MCE are included in the Database of Portuguese Ornamental Rocks published by LNEG (https://geoportal.lneg.pt/en/databases/rop/).

The MCE Middle Jurassic Limestones, in use for over eight hundred years, meet all terms of reference to be classified as a Heritage Stone by the IUGS Commission on Heritage.

A new look at the geology collections of the National museum of natural history - Paris, heritage stones from buildings or sites

Grégoire EGOROFF[1]*, Muséum National d'Histoire Naturelle - Paris (gregoire.egoroff@mnhn.fr)
Pierre Sans-Jofre[2], Muséum National d'Histoire Naturelle - Paris
Caroline Noyes[3], Muséum National d'Histoire Naturelle - Paris
Elisabeth Nicot[4], Muséum National d'Histoire Naturelle - Paris
Isabelle Rouget[5], Muséum National d'Histoire Naturelle - Paris

Abstract

In France, many heritage conservation projects involve the restoration of historic monuments. A recent example is the Notre Dame Cathedral in Paris, which suffered a fire in 2019 whose damage necessitated a major replacement of stones. This iconic project has highlighted the need to find or conserve samples of stones who are coming from historical buildings, quarries or emblematic construction sites, and to make their data available. Comparative collections are essential for finding good substitute equivalents when the sites of origin are depleted. This context has prompted specific work on the collections of the French National museum of natural history – Paris, where it was known that samples of construction rock existed but had been neglected. Indeed, since the 19th century, geologists at the Museum have enriched its geological collections, either by receiving donations from national monuments or by collecting samples from large-scale construction site. Until now, this material had been overlooked and the lack of digitized inventory of such collections hindered their use in research and restoration work.

Since 2022, a work has been carried out to find samples of building stone from among the hundreds of thousands of rocks in the geology collections.

This has led to the discoveries of several hundred building stone samples collected from 19th to 20th century. Some come from construction sites, such as the Paris metro or historic hydrological boreholes while other were collected in quarries. We have also discovered a large number of rocks from monument such as the tomb of Emperor Napoleon 1st. All these samples have collection numbers and associated information in a paper catalog, but no computerization had been done until now.

Today, part of these stones has been cleaned and digitally recorded. This step is the prerequisite for scientific use and dissemination.

We present here an overview of the contents of this "building stone" collection at the French National museum of natural history - Paris, illustrating the variety of rocks used and the historical and cultural evidence they provide. We show that it can be used for research, the history of science and archaeology and support applications for the IUGS "Heritage Stone" designation.

Cultural and Social Legacy of Alpedrete Granite Heritage Stone

David Martín FREIRE-LISTA[1]*, Universidade de Trás-os-Montes e Alto Douro, UTAD, Departmento de Geologia, Quinta de Prados, 5001-801 Vila Real, Portugal. Centro de Geociências da Universidade de Coimbra, CGeo (davidfreire@utad.pt)
Rafael Fort[2], Instituto de Geociencias IGEO (CSIC, UCM) Spanish. Research Council CSIC—Complutense University of Madrid. UCM, 28040 Madrid, Spain
María José Varas-Muriel[3], School of Geology. Complutense University of Madrid UCM. 28040 Madrid, Spain

Abstract

The traditional building stones are part of cities and villages tangible and intangible heritage. Their conservation is essential to maintaining the integrity of their historical centres. For the conservation and valuation of built heritage to attain optimal results, it is necessary to articulate them considering cultural, social and economic factors, in addition to lithological aspects, such as of petrography, durability, and quality. Therefore, a multidisciplinary team with broad inclusion criteria is necessary. Variables such as rarity, accessibility, demand and territorial insertion of each asset must be considered when designing a conservation and appreciation strategy. The diagnosis of the state of conservation and the analysis of the conditions in which the building stone under analysis is located is essential to define how to intervene. A multidisciplinary heritage appreciation methodology must consider the perception of different actors about a certain asset, evaluating the viability, problems inherent to the asset, and the objectives of national and European policies. For the dissemination of the asset to have the appropriate response, the link between heritage and its significance for the public to which it is directed must be studied and defined correctly.

Alpedrete granite was designated Heritage Stone in 2019. It is the main traditional building granite of Madrid (Freire-Lista et al. 2015). It has particular relevance in the "Landscape of Light" UNESCO World Heritage Site declared in July 2021 in the category of Cultural Landscape. "Landscape of Light" is made up of Paseo del Prado (between Plaza de Cibeles and Plaza de Carlos V), El Retiro Park and the Jerónimos neighbourhood of Madrid where the silver Alpedrete granite gives luminosity to the monuments. Alpedrete granite is a monzogranite quarried in the Sierra de Guadarrana (Spanish Central System) foothills in and around Alpedrete, in the province of Madrid, Spain. Used as a building material since prehistory, Alpedrete and the surrounding region are characterised by a quarrying culture that has been maintained for centuries. The area is strewn with historic quarries, along with the one presently in operation. Traditional stone cutters who produce hand-finished granite ashlars are still to be found, while others use more modern techniques to achieve new types of products. Representative monuments including Royal Palace of Madrid, Alcalá Gate and the National Library owe their good conservation state largely to the petrophysical properties and durability of Alpedrete granite. In addition to its use in a substantial number of heritage buildings in Madrid, this stone is also found in most of the city's housing, urban furniture, and nearly all the rural architecture in the Alpedrete area.

This work was financed by A Fundação para a Ciência e a Tecnologia of Portugal (FCT), under the project with the reference CEECIND/03568/2017; [UIDB/00073/2020] projects of the I, D unit Geosciences Centre (CGEO) of Coimbra University (Portugal) and Community of Madrid programme (TOP Heritage-CM, P2018/NMT-4372).

Freire-Lista, D.M., Fort, R., Varas-Muriel, M.J., 2015. Alpedrete granite (Spain). A nomination for the “Global Heritage Stone Resource” designation. Episodes. 38 (2):106-113. https://doi.org/10.18814/epiiugs/2015/v38i2/006.

Geoheritage value of the Fonte Fenix and the Boca de Vaca springs from Panjim: hidden jewels from Goa, India

Vrushali Vilas Dumale[1], Department of Environmental Sciences, Savitribai Phule Pune University, Pune 411007 India
Hemant B Pednekar[2], Department of Geology, Savitribai Phule Pune University, Pune 411007
Raymond Ashirwad DURAISWAMI[3]*, Department of Environmental Sciences, Savitribai Phule Pune University, Pune 411007 (raduraiswami@gmail.com)

Abstract

The Portuguese constructed several churches, chapels, educational institutions, hospitals, roads, bridges, drainage systems, etc. in Goa some such as the Basilica of Bom Jesus, Sé Catedral de Santa Catarina, Church of Saint Augustine, Saint Catherine's Chapel, Church of St. Francis of Assisi, Church of Our Lady of the Rosary, Church of Saint Cajetan that have been designated as UNESCO World heritage sites. Besides these grand sites, the Boca de Vaca spring (1830) and the Fonte Fenix spring (1851-1855) are two very important springs constructed during the Portuguese era as water supply sources for the Panjim city. In this paper, we describe the hydrogeology, architecture and geoheritage of these important springs present on the lateritic Altinho hill in Panjim. The springs are perennial and are in use even today. The Fonte Fenix spring was built as a three-tiered structure with semi-circular arched openings and doorways leads to an underground tunnel. The water in the channel is kept fresh and ventilated by a series of three domed air vents. Steps made from basalt rock lead down to the water source. Earlier, the fountain sported a phoenix which was symbolically destroyed during the Goa liberation. Fontainas neighbourhood, with its brightly coloured alleys, infrastructure development, and lavish houses of bureaucrats is named after the popular Fonte Phoenix spring. Recently, a painting exhibition was held inside the tunnel to promote conservation of spring during the 2022 Ganesh Festival.

The Boca de Vaca (Cow's Mouth) or the Fonte Cabeca de Vaca (Cow's Head) is a spring complex with at least two sprouts and collectively has a higher discharge than the Fonte Fenix and is the most important spring providing drinking water to the public. The spring eventually formed a natural cavern and was fitted with a granitic GOMUKH (face of cow) in an arch-type open structure called Fonte Cabeca de Vaca. Later (in 1851-1855), the horseshoe shaped tunnel complex (95 m long, 2.4 m high and 1.83 m in diameter) was built using laterite and lime-surki (mortar) around the Gomukh and re-named as Boca-de-Vaca. Some efforts to conserve and promote this site as a tourist spot was undertaken by the Goa Tourism Development Corporation limited (GTDCl). The springs described in this paper are important geoheritage sites within the limits of the Panjim city. They need to be promoted as archetypes of several other springs in Goa and need to be protected as cultural citadels of the past and as alternative sustainable water sources for the future generations.

A New Approach to Key Mineral Analysis for Tracking the Provenance of Stone Heritage

Myoungju CHOIE[1]*, National Research Institute of Cultural Heritage, Republic of Korea (mjchoie@gmail.com)
Myeong Seong LEE[2], National Research Institute of Cultural Heritage, Republic of Korea

Abstract

80% of the Korean peninsula consists of mountainous terrain, and as such, the notions of Baesan Imsu (mountain in the back and a river in the front) and Jusan (main mountain) were traditionally appealed to when deciding on the locations of villages and capitals throughout the Bronze and Middle ages. Therefore, Korea's topography and geology are significantly related to the stone heritage of the Korean peninsula insofar as they determine the locations and building materials selected by ancient people. In particular, the 'tumulus', a building that played an important role in the funeral culture and practices of the ruling class, provides an excellent example of ancient material selection, given that these structures are built of durable material.

The stone team of the NRICH, is focused on interpreting ancient quarry sites through geochemical analysis and understanding the stone selection techniques practised by ancient people. However, the area associated with the monuments could have been a simple rock type of single magma origin and was created at a similar time or has been a complex geological setting due to several metamorphic processes over a long time. In this case, the researchers, therefore, had to limit the tracking of quarry sites using only the whole rock geochemical composition method because there are not enough geochemistry indication factors.

This study was conducted to identify the specific quarry site of the two tombs in South Korea using key minerals and explore and apply analytical methods to secure distinction factors. To assess the feasibility of this research method, we located two tombs in South Korea, one situated in a simple geological setting and the other in a complex setting.

The first tomb selected for the study is the 'Twin Tombs' (early 7c), a royal tomb constructed during the Sabi period of Baekja, Iksan. It is constructed on and from Mesozoic granite, which has a simple geochemical composition of a single batholith, which makes it a durable, attractive, and thus desirable material even by modern construction standards. Titanite was chosen as the key mineral of interest in this study and was analyzed using FE-EMPA and LA-ICP-MS analysis methods to yield data on its REE composition.

The second tomb selected for the study is tomb No. 28-1 (5c), the largest among the Jangsu tumulus tombs, Gaya period; it is constructed of Precambrian gneiss in Jangsu, which has a heterogeneous geochemical composition and various lithofacies, despite being situated within a rock body. In this case, the key mineral of interest, zircon, was found within the Precambrian gneiss, and the location of the quarry site was interpreted using the U/Pb dating method with SEM-CL and SHRIMP analysis methods.

In these two study cases, the key mineral analysis method was shown to be able to obtain data

about the age of rocks, chemical changes in the magma chamber, and metamorphic events for interpretation of ancient quarry sites and tumuli, thus demonstrating it to be a practical approach for evaluating the mutual geochemical similarity of the stone from monuments and specific outcrops.

The natural stones of the cemeteries in the PNDO (Ardennes, Wallonia, Belgium): a geoheritage approach linking geodiversity and biodiversity

Xavier DEVLEESCHOUWER[1]*, Institute of Natural Sciences, Geological Survey of Belgium (xdevleeschouwer@naturalsciences.be)
Tiago Basyn[2], Université Libre de Bruxelles
Géraldine Maulet[3], Institute of Natural Sciences
Nadine Mattielli[4], Université Libre de Bruxelles, DGES

Abstract

The "Parc Naturel des Deux Ourthes - PNDO" is a natural park situated in the northeastern region of the Province of Luxembourg within Wallonia, Belgium. Covering a sprawling 76,000 hectares across six districts from Gouvy in the east to Tenneville in the west, it is home to approximately 25,000 inhabitants. The park encompasses the alluvial valleys of the Ourthe rivers, which cut through the highest plateaus of the Ardennes, reaching altitudes of 600 meters, while the lowest points sit around 210 meters.

Throughout the villages within the park, one can find historic churches accompanied by ancient churchyards. These churchyards typically house weathered gravestones and ledger stones, scattered amidst the grass. Dating back to the 19th century, these churchyards contrast with the modern cemeteries established on the outskirts of the villages during the 20th century.

During the 19th century, gravestones and ledgers were predominantly crafted from locally sourced rocks, often extracted from nearby quarries. Within the PNDO, many of these old gravestones and ledgers are fashioned from two types of Ordovician phyllites. The thicker slabs, exhibiting a purplish hue, originate from the Ottré Formation, primarily from the Colanhan and Les Plattes Members. In contrast, thinner slabs, characterized by dark grey to black tones, hail from the Ordovician Jalhay Formation, predating their purplish counterparts. The "Les Plattes" Member is renowned for its coticule layers and the dark black slates of Vielsalm. Coticule, a metamorphic and sedimentary rock, is notable for its fine-grained texture and contains approximately 35-40% small spessartine garnets.

Since the late 19th century, the primary material for graveyards shifted to a Belgian rock known as blue Petit Granit, sourced from numerous quarries across Wallonia. In the 20th century, ornamental stones from various global locations became prevalent in modern cemeteries, marking a transition from local to diverse stone selections for graveyards.

The ongoing project led by the Institute of Natural Sciences focuses on several objectives: first, to characterize the oldest phyllite stones used in gravestones and ledgers, examining their properties and historical applications in both churchyards and domestic architecture, considering their status as a nearly extinct geoheritage rock due to discontinued quarry operations. Second, the project aims to assess lichen diversity on these natural stones, as they harbor a plethora of saxicolous lichens, some of which are indicative of atmospheric pollution sensitivity. Lastly, the project seeks to evaluate geodiversity based on the natural rocks utilized in both old and modern cemeteries within the PNDO area. Additionally, the project will incorporate an air quality assessment,

considering epiphytic lichen species residing on trees surrounding the cemeteries to gauge air pollution levels. Geochemical analyses of major and trace elements have commenced on select saxicolous lichens and phyllites to characterize both the rocks and the geochemical background of the lichen species under examination.

[Keynote] Heritage Stone Subcommission: Showcasing the first 50 IUGS Heritage Stones

Gurmeet Kaur[1]*, Panjab University (gurmeet28374@gmail.com)

Abstract

The International Union of Geological Sciences (IUGS) highlights the essential role natural stones play in architecture and culture. Through the international designation of "IUGS-Heritage Stone," these stones gain global recognition for their historical significance in disseminating cultures and traditions. The establishment of a systematic approach by the International Commission on Geoheritage ensures that only stones with profound architectural and cultural importance receive this honor. This initiative not only preserves and promotes heritage stones but also deepens our understanding and appreciation of the architectural and cultural narratives they embody. To date, 32 stones from around the globe have been ratified as IUGS-Heritage stones and eighteen more stones are expected to be ratified by April 2024.

Releasing the first 50 IUGS Heritage Stone volume at the 37th International Geological Congress (IGC) in Busan, Korea, would be a significant event for the geological community. It would provide a valuable resource for researchers, educators, and anyone interested in the geological heritage of different regions around the world. The IGC will be a perfect platform to showcase such an initiative, given its international reach and the diverse audience it attracts. It would be interesting to see how this event unfolds and the impact it has on promoting awareness and conservation of geological heritage globally.

GOREE ISLAND (Dakar, Senegal, West Africa), UNESCO World Heritage Site without GEODIVERSITY ? Inventory AND Assessment of a GEOMORPHOSITE Sensitive to Coastal Erosion

Cheikh Ibrahima YOUM[1]*, Université Cheikh Anta DIOP Dakar/SENEGAL (cheikhibrahima.youm@ucad.edu.sn)
Rokhaya Samba Diène[2], 5Ministry of Mines and Geology of Senegal (MMG)

Abstract

The Goree Island (28 hectares), located less than 5 km from Dakar was first occupied by black natives and served as a transit point for black slaves who were to be deported to America for about four centuries. The first Europeans to discover it were the Portuguese in 1445 before the Dutch settled there later, followed by an alternation of occupation between the French and the British in the second half of the eighteenth century and the beginning of the nineteenth century. Today, Gorée has become a must-see tourist attraction in Senegal due to its role during the slave trade and remains one of the places where you can still find vestiges of this tragic era. A guided tour of the must-see places of Gorée plunges you directly into the deplorable history of the slave trade: the slave house founded in 1776, the historical museum, attached to the Fundamental Institute of Black Africa (IFAN), the Women's Museum, the Museum of the Sea (IFAN) and restored in 1995, the Former Governor's Palace, the William Ponty School and finally the Castel, It is in a strategic position and offers a panoramic view. Having become a place of passage and contemplation, the island of Gorée welcomes thousands of tourists every year and has received some of the world's greats on an official visit to Senegal. This makes it a place of remembrance of slavery and reconciliation for the respect of human beings, hence its inscription on the UNESCO World Heritage List since 1978.

Geologically, the island of Gorée is part of the Tertiary eruptive system of Dakar represented mainly by basanite and nephelinite flows. It is mainly made up of rocks of sedimentary origin. The southern third of the island is made up of prism-shaped volcanic rocks that form a plateau 40 m above sea level and bounded by sheer cliffs. Their surface features relics of lateritic breastplates. The volcanic rock is an augite-rich basanite, tending towards nephelinite, but with a dolerite structure. It was dated by K-Ar on mesostasis to 13.03 ± 0.28 Ma. From now on, Gorée trembles under the onslaught of the waves: the wall of the mosque and the Mariama Ba educational house as well as the only electric cable have paid the price.

In the long term, this work will make it possible to support the State of Senegal in its geopark implementation programme and to give Gorée the status of an exceptional geological site in Senegal

SOCIAL LICENSE TO OPERATE FOR HERITAGE STONES QUARRIES: IS THIS APPROACH POSSIBLE?

Paola MARINI[1]*, Politecnico di Torino (paola.marini@polito.it)
Rossana BELLOPEDE[2], Politecnico di Torino
Gabriele BALDASSARRE[3], Politecnico di Torino
Alvise MATTOZZI[4], Politecnico di Torino

Abstract

The Social License to Operate, often briefly referred to by the acronym SLO, represents a tool that, although it has been discussed for some time in the extractive sector, continues to be of extreme importance today. The path for SLO can be defined dynamic process, which must be verified and monitored over time and involves, alongside the economic and environmental aspects, also the social one such as the respect and well-being of the community: right to culture, gender equality, human rights.
This approach is used for mining sector and for the infrastructures with relevant impact but is not cited in literature for natural stones quarries. In addition, the SLO approach for ornamental stones quarries is poorly studied, cited and applied. Often the SLO is commonly explained as social acceptability.
At legislation and standardization level, the standard ANSI 373 2022, on Natural Stone sustainability contains a part related to social acceptability, under the aspect of social governance, where several goals are enhanced as demonstration of fair hiring practices; education for applicable employees social accountability issues or practices; corporate ethics and so on. However, this standard doesn't recommend specific methodological tools to evaluate the social acceptability for Natural stones quarries.

We developed a method to ask for SLO and negotiate social acceptability based on the methodology of "controversy mapping", as it has been thought within the field of Social Studies of Science and Technology in the last 20 years, together with a procedure for the application of cases related to heritage stones.
This research will correlate some selected heritage stone quarries in different part of world, the controversy mapping tool and the related standard, in order to evaluate the right instrument to apply this process to the Heritage Stone quarries.

Itria Valley Heritage stones: the new studies on Natural Stone and World Heritage for the Apulian limestones

Paola MARINI[1]*, Politecnico di Torino (paola.marini@polito.it)
Angela Maria QUARTULLI[2], Ministry of culture, Superintendence for the metropolitan city of Bari
Rossana BELLOPEDE[3], Politecnico di Torino

Abstract

The Apulian limestones, wholly constitute the historic building constructions of the Puglia region (south of Italy) named Trulli, representing an outstanding universal value for UNESCO (https://whc.unesco.org/en/list/787), but also other stone buildings of the well-know Itria Valley. The Trulli are drywall (mortarless) constructions made of roughly worked limestone blocks collected from neighbouring fields. These kinds of historical buildings, characterized by a quadrangular shape and a conical roof, are present also in other sides of Apulia region and from the fourteenth century were used mainly as settlements for temporary housing or agricultural storage, but nowadays are widely used as buildings for farm holyday as well as summer residence. The limestones for Trulli are quarried from different Apulian places and, together with other local lithotype, are the stone heritage of Itria Valley. Other stone constructions characterize the landscape of the area of Itria Valley: rural buildings, lamias, boundary walls, cisterns, farmyards, agricultural depots.

The study consists in an introduction on the region of the southern of Italy where Trulli and other typical stone architectures can be found. Itria Valley with its towns e landascape and the Alberobello town will be described from architectural point of view. A second section concerns the different example of building constructions in local stone of the Itria Valley focusing on the ancient and the contemporary quarries. Petrographic and physical mechanical characteristics of the main kind of limestone are reported and discussed. A third part focuses on the main example of stone architecture of Itria Valley, distinguishing the historical rural building from the other historical civil ones. In this section a particular attention will be given to: example of best practice of evaluation action, protection rules and restauration methods for Stone Heritage in Itria Valley and Alberobello.

Crossing Heritages. Geosites, Geoheritage and their History through Images

Maddalena NAPOLITANI[1]*, Museo Galileo (maddalena.napolitani@gmail.com)

Abstract

This contribution explores how historical geosites have been represented by visual arts.
Although the concept of Geological Heritage Site, and the issues related to their preservation and management have been recently defined and studied (see Brilha and Reynard, 2018; Brilha, 2014; and especially the volume dedicated to the first 100 IUGS Geological Heritage Sites, 2021), the history of their visual representation shed further light on their history, their evolution and the dissemination of scientific knowledge related to them.
The analysis will focus on the 19th century, marked by significant progress in Earth sciences – especially geology and paleontology.
As a consequence, during the second half of the century the divulgation press also experienced a major development. Journals and books offer a wide range of images (landscapes, fossils' reconstructions, maps, tools, etc.), that could be implemented by and compared with both the illustrated scientific treatises and the pictorial production of the time. This rich and varied iconographical corpus shows a renewed visual sensibility for the representation of geosites as a whole, and appear as the result of regular and close collaborations between geologists, engineers and visual artists that shared the fieldwork.
Through the analysis of some case studies illustrating such collaborations (for instance, that of the monumental work of Sartorius von Waltershausen on the Etna, "Der Aetna" (1880)), the aim is to analyze how images and their combined scientific and aesthetic features contributed both to spread scientific knowledge on important geological sites and to build the history of these sites, and finally how images' dissemination fostered scientific expeditions and leisure travel on the sites – what is presently defined as geoturism.
Our purpose is also to cross the geological heritage with the artistic and visual one, and to finally reflect on how, nowadays, they can enhance each other. We will thus conclude the analysis and open-up the research perspectives with examples of art works of the 20th century marked by a renewed environmental consciousness towards geological processes: that is the case, for instance, of the Land Art movement and the so-defined – and sometimes controversial – Earthworks.

Maruia Falls (New Zealand) – a Historical Geosite for the Discovery of the Inner Earth Core

Martina KÖLBL-EBERT[1]*, Ludwig-Maximilian Universität Munich (m.koelbl@lmu.de)

Abstract

On 17 June 1929, the MS 7.8 Murchison earthquake triggered numerous landslides in the north-western South Island of New Zealand. One of them diverted the course of the Maruia River westward, where it encountered unconsolidated gravel deposits, which it eroded over the years forming a waterfall. While Maruia Falls is a beautiful geological site in its own right, its significance goes far beyond local geology: Seismic P waves of large earthquakes travel through the whole Earth. By 1929, it was already known that the Earth had a fluid core, as P waves reach the far side of the globe significantly later than would be expected in a homogeneous globe. Also, the core focussed seismic waves acting as a huge lens, creating a shadow zone further out, in which no seismic waves were recorded. In the 1930s, better seismic detectors showed that this shadow zone was not devoid of seismic activity. P-Waves where weak only in terms of surface parallel movements. The vertical movement however, was quite strong. In 1936, explaining seismic activity within the “shadow zone”, using data from the Murchison earthquake, which were recorded at seismic stations in Greenland, the Danish seismologist Inge Lehmann (1888–1993) postulated the existence of an inner Earth’s core, with a faster velocity of seismic waves compared to the outer one.

The Agno Valley and Giovanni Arduino's 1758 cross section: an iconic site and a classic image for the birth of lithostratigraphy

Ezio VACCARI[1]*, INHIGEO - IUGS Commission on the History of Geological Sciences / University of Insubria, Italy (ezio.vaccari@uninsubria.it)

Abstract

Giovanni Arduino (1714-1795) was a leading figure in the Italian scientific community in the second half of the 18th century. Among the contributions made by the European scientists to the origin of stratigraphy, Arduino's system of subdividing rocks into four basic units called "ordini" attained a unique level of precision. His lithostratigraphical theory, presented in 1760 and refined in 1775, has been regarded by several geologists and historians as starting point of the modern chronological subdivisions of the Earth's geological history. Arduino's 'classification' was based on extremely accurate fieldwork. In fact, his essay Due Lettere to Antonio Vallisnieri junior (published in 1760) contained the scientific results of a geological travel through the Agno Valley, in the Venetian Prealps of northern Italy: the data collected during this fieldtrip, undertaken in October 1758, may be found in his handwritten notes and in two sketches, kept in the Public Library of Verona (Italy). These valuable papers show clearly the origin of Arduino's lithostratigraphical theory. In particular, the impressive drawing entitled "Representation of the strata of different kinds of rocks, observed on right riverside and on left riverside of Agno, from Montecchio Maggiore to the highest tops of the Alpi, above Recoaro, during my journey on 19-20-21-22 and 23 October 1758, of these strata are made the hills and the mountains" has become a classic image for the early history of geology. It is a real and graphically modern geological cross-section of the Agno Valley in only one plane, giving sixteen lithostratigraphical units, which are carefully described by Arduino in the handwritten captions below the sketch. The aim of this paper is to reappraise Arduino's cross-section in the light of an 'experimental' approach, which will try to reconstruct the fieldwork carried out by Arduino in the Agno Valley, in order to identify his routes and observations, as well as understand the genesis of his famous visual representation in connection with his lithostratigraphical theory.

Archibald Geikie and Edward Hull Tour 1887: in search of historical georoutes and geosites in County Donegal (Ireland)

Catherine (Kathleen) HISTON[1]*, IUGS INHIGEO (hiscat@interfree.it)

Abstract

Geological field mapping of County Donegal by the Geological Survey of Ireland began in the 1850's and the geological maps and memoirs were published under the authorship of then local director Edward Hull (1829-1917), and survey geologists James Robinson Kilroe (1848-1927) and George Henry Kinahan (1829-1908) for East and South Donegal (1890) and Northwest and Central Donegal (1891). However, interpretation of the geology of Donegal and especially the Donegal granites caused much heated debate among the Geological Survey of Ireland staff. Comparisons with rocks in Scotland and in Canada gave rise to debates about the evidence in Donegal for the age and stratigraphic sequence of the rocks and many studies were done on the origin of the granites.

Archibald Geikie (1835-1924) was appointed local director of the Geological Survey of Scotland in 1867 and held the position of Director General of the Geological Survey of the United Kingdom from 1882 until his retirement in 1901. His interest in the comparison of certain aspects of the geology of Scotland and that of Donegal regarding volcanics, glaciation and denudation of the landscape led him to visit Ireland on many occasions, especially in his role as Director General of the British Geological Survey for inspections related to the progress of the geological mapping campaign of Ireland.

Both Hull and Geikie had published extensively on the physical geography and geology of the British Isles and proposed interpretations related to international debates based on their fieldwork in both Ireland and Scotland.

The aim of this presentation is to trace the route and sites of geohistorical importance visited by both directors during a two-week joint travel around County Donegal in October 1887 and examine how their observations contributed to resolving or not the problems in interpretation encountered during the geological mapping of the county.

MONTE AMIATA (TUSCANY, ITALY) IN THE HISTORY OF VOLCANOLOGY

Luigina Vezzoli[1], Istituto di Geoscienze e Georisorse - CNR, Pisa
Claudia Principe[2]*, Istituto di Geoscienze e Georisorse - CNR, Pisa (c.principe@igg.cnr.it)

Abstract

A review of the main contributions to the scientific literature between the eighteenth and twentieth centuries concerning the geology and volcanology of Monte Amiata volcano (Tuscany, central Italy) is presented. Monte Amiata, and the nearby volcano of Radicofani, are of great interest to the history of volcanology because they have the primacy of being the first to be recognized of volcanic origin in a region (Tuscany) that was not volcanically active, thirty years before Guettard's studies on the Auvergne region in France. Indeed, the Florentine botanist Pier Antonio Micheli identified as extinct volcanoes Radicofani in 1722 and Monte Amiata in 1733. Moreover, the merit of Micheli's work resides in interpreting Monte Amiata as an extinct volcano despite the absence of a conventional cone-shaped volcano morphology, and in his recognizing its rocks as lavas despite their marked differences from those produced by the known active volcanoes of its times, such as the iconic Vesuvius. During the eighteenth century and until the first half of the nineteenth century, Monte Amiata was a destination for scientific journeys by Tuscan and foreign scholars (e.g. Micheli, Baldassarri, Arduino, Fortis, Ferber, Dolomieu, Santi, Repetti, Hoffmann). In addition, its rocks were part of important collections throughout Europe visited by illustrious mineralogists. Furthermore, samples from Monte Amiata were used to illustrate the general discussions on the nature and origin of rocks such as basalt and granite. In the nineteenth century, Monte Amiata was included in the lists of known volcanoes recorded in the early treatises on volcanology made by Scrope, Daubeny, and Hoffmann, and its 'trachyte' was the subject of early essays on microscope petrography and chemical analysis of rocks, performed by vom Rath, Rosenbusch, Williams, Lacroix, and Washington. Between the end of the nineteenth century and the first quarter of the twentieth century, the volcano geologists of the Comitato Geologico Italiano, especially Verri, Lotti, and Sabatini, carried out field surveys on Monte Amiata resulting in geological maps and volcano-stratigraphies. Moreover, modern petrographic (Novarese, Artini, Rodolico) and geographical (Dainelli and Olinto Marinelli) scientific studies were carried out on this volcano. Nevertheless, up to the middle part of the twentieth century, the major interest in Monte Amiata was related not to its volcanological aspects but to its natural resources: drinking waters, diatomaceous earths, earth pigments, and mercury ore minerals.

VESUVIUS GEOROUTES

Claudia Principe[1]*, Istituto di Geoscienze e Georisorse - CNR, Pisa (c.principe@igg.cnr.it)

Abstract

Vesuvius is the most famous volcano in the world and a historical geosite of international importance also thanks to the numerous geohistorical routes that can be traced there, first of all, the excursions carried out by travelers of the past, which culminated between the 18th and 19th centuries with the “Grand Tour” trips. The development and potential of the geological sciences, as well as their role in human society, owe much to this territory, where in the past centuries there was an enormous flourishing of scientific culture. This is particularly true for volcanology, in which case Vesuvius became, starting from the awakening of the volcano in 1631, the paradigm of volcanic activity understood, that is, the place to go to learn "how a volcano is made". Beyond the classic routes (e.g., Naples, Pompeii, the Gran Cono with its Gran Cratere and the cliff of Monte Somma), followed by all visitors, the volcano presents still unexpressed potential for the valorization of many geohistorical sites and routes, which extend to the entire circum-Vesuvian area. Places subject to attention during field studies and mapping during and after the numerous eruptions of a mixed effusive and explosive nature that characterized the volcano activity. It is a vast panorama, populated by several figures of scientists and scholars of the past, each of whom has linked to various aspects and places of Vesuvius volcano a more or less large part of one's life.

[Keynote] IUGS Geological Heritage Sites. A recognition to the history of our science

Asier Hilario[1]*, IUGS International Commission on Geoheritage (flysch@gipuzkoa.eus)

Abstract

The IUGS has activated a joint and global endeavor to give recognition to those sites that have been essential for the development of geological sciences. More than 700 authors from 85 countries participated in the "First and the Second 100". "An IUGS Geological Heritage Site is a key place with extraordinary geological elements or processes of the highest scientific international relevance, used as a global reference, and/or with a substantial contribution to the development of geological sciences through history ".

The IUGs International Commission on Geoheritage is leading a global endeavor with 17 international organizations representing the main geological disciplines. INHIGEO is one of our key partners charge of recognizing the historical value of several sites.

The reconnaissance of geosites of historical relevance is of great importance, as it allows us to recognize the foundation, the development and consequently the scientific potential of the geological sciences, as well as their role in human society. The history of geosciences, from Antiquity to the Contemporary Age, is based not only on archival documents and printed material - such as books, periodicals, papers, letters and manuscripts - but also on places, routes and landscapes which have been described and studied by scholars and scientists since the origins of the geological sciences.

Each geological heritage site has its own history, because it was discovered or identified on a certain date and has also been the subject of a number of scientific investigations throughout time. However, an historical geosite is not just a site with a history, but a site that has made history in the field of the geological sciences: a place where the observation of some specific features determined new ideas, theories and interpretations which have changed human understanding of the geological phenomena and of the history of the Earth. It is evident that an historical geosite is a landmark for the history of science, as well as a milestone for modern geology.

Essential Sites like Phlegrean Fields in Italy, Puy-de-Dôme in France, Caldera de Taburiente in Spain, Giant's Causeway in Northen Ireland , The Moine Thrust or Siccar Point in Scotland, Genbudo Cave in Japan, Maruia fallas in New Zealand or Funafuti Atoll in Tuvalu have been recognized in the first chapter of each book dedicated to "History of Geosciences".

The IUGS Geological Heritage Sites initiative is a good example of a collaborative work among different IUGS commissions and affiliated organizations, with INHIGEO playing a prominent

role.

The Argonauts Campaign to the Ancient Colchis Kingdom: One of the first documented geological exploration in the Human history

Avtandil OKROSTSVARIDZE[1]*, Doctor of Geological Sciences (okrostsvari@gmail.com)
Daniel Tormey[2], Catalyst Environmental Solutions, Santa Monica, USA.
David Bluashvili[3], Faculty of Geology and Mining, Georgian Technical University, 0171 Tbilisi, Georgia.
Mirian Makadze[4], Tbilisi State University, Faculty of Exact and Natural Sciences, Tbilisi, Georgia

Abstract

The exploration for and use of mineral resources has been important since the use of specific occurrences of obsidian and flint for stone tools. These activities were also part of the birth of geology as an important area of exploration. One of the first historical occurrences of exploration for metals was the Argonauts: a group of heroes led by Jason on a quest to find the “Golden Fleece”. Since the Middle Ages Christian Europe has cast the account as mythical, although ancient sources account it as true [1]. The goal of the exploration required the mastery, of alluvial gold mining in the ancient Colchis Kingdom [2]. However, since the Middle Ages, Christian Europe has given this journey a mythical shroud, even though all ancient sources consider it a real story.

We studied considered the account of the Argonauts' expedition according to geological factors. For this purpose, we investigated the provinces of the ancient Colchis Kingdom, in order to determine the presence and mining potential of alluvial gold. We conducted research using both traditional geological and remote sensing methods. The research showed that modern Svaneti (Svania in ancient sources) represents such a province. It is located on the main ridge of the Greater Caucasus and includes the upper part of Enguri river and its tributaries. The results of these studies are also confirmed by the manuscripts of Greek and Roman accounts of the ancient period. In addition, archaeological and ethnographic studies of Svaneti show that this province is rich in narratives and artifacts about Argonauts.

Reconciliation of archaeological, historical, ethnographic and mythological information with geological arguments places the campaign of Argonauts in the kingdom of ancient Colchis was a real event. This expedition would have taken place before the appearance of iron in the region (XIII-XII centuries BC), since in all versions of the legend they were equipped with bronze weapons. According to modern studies, the eruption (1480±10 BC) of the supervolcano Strongea (its remnants are the present-day island of Santorini) effectively destroyed the Aegean civilization. According to Homer, the Argonauts were representatives of the Aegean civilization, and such, after this event, they would not be able to carry out such a large-scale campaign. Because of this, the campaign of the Argonauts must have been carried out, most likely, before the eruption of the supervolcano Strongea, at the turn of the 16th-15th centuries BC.

Our study supports the contention that the campaign of the Argonauts in the ancient Colchis kingdom was a real event, the main goal of which was to explore for gold and master the

technology of alluvial gold mining. If so, this campaign was one of the first documented and consequential geological exploration in the human history, which took place about 3500 years ago.

CHENGSHAN WANG[6], China University of Geoscience, Beijing

Abstract

Since the 18th century, numerous scholars have contributed to the study of geological heritages, outcrops, and landscapes, which play a critical role in the advancement of geology. However, many such sites are being irreversibly damaged due to infrastructure development, reservoir impoundment, and resource exploitation.

To preserve these historically significant geological resources in digital form and make them more accessible to the public, our group (DDE Digital Outcrop Group) has conducted comprehensive digital collection and modeling of over 120 classic geosites from 12 countries including China, the UAE, Italy, France, Germany, Spain, Namibia, and so on. The primary methods employed include high-precision tilt photography by drones, Insta360 panoramic camera photography, DSLR camera photography, and video recordings of geologists' lectures.

In China, 96 geological outcrops were collected, primarily along the georoutes of the 21st International Sedimentological Congress. Europe contributed 24 geosites, while Africa had 3, including UNESCO Global Geoparks, The First 100 IUGS Geological Heritages Sites, and post-conference georoutes of the International Association of Sedimentologists (IAS).

Currently, all collected information of the geosites have been uploaded onto the DDE-Outcrop3D platform (https://outcrop3d.deep-time.org/), which enables the visualization of high-precision 3D models of geological outcrops, combining information such as text, images, videos, panoramas, documents, observation points, geological maps, etc. with 3D models. The platform realizes the co-construction and sharing of geosites and georoutes, allowing scholars and geoscience enthusiasts all over the world to enjoy the world-famous geological heritages, outcrops, and landscapes without leaving their homes, and to share and discuss them with other users.

Abstract

The relationship between biological communities and the deterioration of cultural heritage in temperate and tropical countries remains a subject of debate. In humid tropical climates, plant growth plays a crucial role in both natural and built environments by contributing to increased biodiversity, stormwater and micro-climate regulation, soil protection, food and medicine provision, and global warming mitigation through carbon sequestration. Despite these significant contributions, there is a lack of understanding regarding the role of vegetation on historic cultural heritage sites in tropical countries and how the distribution of greenery impacts the thermal and physical conditions of heritage buildings and monuments. While laboratory and field studies in temperate regions have shown the complex relationship between greenery (algae, moss, ivy) and stone/rock heritage structures, including bio-erosion, protection, and conservation, rather than solely biodeterioration, similar research is lacking in Nigeria. One such example is the Osun-Osogbo sacred grove, a UNESCO World Heritage site surrounded by dense sacred trees and heritage structures colonized by algae and moss. The influence of these greenery and weathering processes on the physical conditions of walls and monuments has not previously been assessed. This research addresses this gap by using a mixed methods approach, including satellite imageries, air and land surface temperature data, rock surface temperature and humidity measurements and millimetre-scale surface change data to examine the effects of greenery on heritage structures within the Osun-Osogbo Sacred Grove UNESCO World Heritage Site (WHS) to improve historical documentation of the Geoheritage site conservation and degradation processes. The heritage features of interest are the forests, walls and sculptures at the heritage site that are in deteriorating conditions aggravated by the devastating floods in 2019 and climate change. The Landsat (30 m) time-series imageries will be used to investigate the spatial and temporal distribution of forest cover and reveal air and surface temperature trends and wet/dry periods within the sacred grove site. To map and develop a weathering/erosion database, crowd-sourced historical photographs, repeat photographs subjected to Structure-from-Motion (SfM) photogrammetry and LiDAR data (2019 - 2023) will be used and integrated into a geographic information system (GIS) to complement micro-climatic records. Surface change (soiling, cracks) and erosion patterns of heritage structures influenced by biology and other weathering processes will be isolated and assessed using three-dimensional (3D) point clouds, digital elevation models (DEMs) and orthophotographs. Findings from this study have the potential to serve as a guiding

framework for identifying the extent and nature of monument degradation to inform sustainable remedial practices and improve heritage site conservation in Nigeria and Africa.

From Cultural Landscape to Aspiring Geopark: 18 Years of Community-Based Landscape Tourism Development in Fengnan Village, Hualien County, Taiwan (2006–2024)

Kuang Chung LEE[1]*, National Dong Hwa University (kclee2000@gmail.com)
Paulina G. Karimova[2], National Dong Hwa University

Abstract

Geoconservation plays a key role in valuing and conserving abiotic nature, while geotourism can be an effective means of achieving this objective. Connectivity between biophysical and socio-economic components and a community-based perspective on appreciation and interpretation of landscape resources are important yet not well understood. This study is a retrospective analysis of 18 years (2006–2024) of integrated landscape management in Fengnan Village, Hualien County, Taiwan, with a focus on the evolution of multi-stakeholder perception of local geodiversity and emergence of geotourism as part of community-based landscape tourism in the area. A qualitative multiple-method approach to data collection and analysis was based on the "know–cherish–show" interpretation model and the theory of collaborative planning.

The results demonstrate the following observations. (a) Geoconservation and geotourism have evolved to become an integral part of the Fengnan living landscape, while connectivity between nature–culture attributes has strengthened over the years. Community-based approach to geotourism and capacity-building activities for bridging Indigenous and local knowledge and expert knowledge have played a central role in empowering Fengnan locals as the hosts and geo-interpreters of their native landscape. (b) Institutional arrangement between primary and secondary stakeholders have evolved over time and benefitted from facilitating efforts of the bridging stakeholder (the authors). (c) Facilitating role of the bridging stakeholder (the authors) was central to the timely introduction of various landscape concepts for long-term geoconservation in the area. Time-, space-, and stakeholder sensitive introduction of relevant landscape concepts ensured trust and reciprocity in the long-term multi-stakeholder partnership. There are several challenges and opportunities ahead: (1) In the future, the Turtle River Aspiring Geopark multi-stakeholder platform will be a central mechanism for ensuring a fair division of responsibilities, benefit-sharing, and diversification of income generating activities (e.g., geo-product development) in Fengnan Village. (2) The support of the government agencies will continue to be important, while the regional government—Hualien County government—will need to start playing a more prominent role as the main geopark authority. Therefore, the sooner it becomes aware of and is involved in the ongoing geopark processes, the smoother the potential designation is likely to be. (3) Eighteen years of continuous on-the-ground engagement in one site and community is a rarely seen phenomenon across action research case studies. The longevity of our partnership with the Fengnan community speaks for their level of approval and trust in us as the bridging stakeholder and in local integrated landscape management processes. However, we need to be observant of strengthening the bottom-up capacity of the local people and their

readiness to manage on their own. As we are now gradually letting go of the facilitating role in the area, we are transitioning into consulting (mentoring) role based on the community's vision and needs.

Evita TSONIDOU[6], Natural History Museum of the Lesvos Petrified Forest
Aggelos LAMPRAKOPOULOS[7], University of the Aegean
Emmanouil ANTONAKIS[8], University of the Aegean
Nikolaos SOULAKELLIS[9], University of the Aegean

Abstract

The Petrified Forest of Lesvos is a unique natural monument formed 20 million years ago due to the intensive volcanic activity in the North Eastern Aegean area and consists of the main geological heritage feature of international significance for the recognition of Lesvos island as a UNESCO Global Geopark (2000, 2012, 2015). The protected area of the Lesvos petrified forest covers an area of 15.000 ha located in the western part of Lesvos island, Greece.

The Natural History Museum of the Lesvos Petrified Forest is a public institution aiming at the protection and rational management of the Lesvos Petrified Forest. Rescue excavations are conducted by the Museum in the protected area of the Lesvos Petrified Forest in case of fossil findings during the construction of public and private works.

During the last decade, a new road is constructed connecting Kalloni with Sigri which is the westernmost village of the Island, crossing the protected area of the Lesvos petrified forest. During the construction of this new road, a large number of astonishing fossil sites with impressive fossilized tree trunks have been unearthed, which lay on the verge of the road. The Museum in collaboration with the Ministry of Public Works took all the necessary measures to change the road construction plan, to secure the preservation of the most significant fossil sites along the road.

The Museum implemented a comprehensive plan to enhance the new fossil sites, to protect them, and to create new visiting parks along the Kalloni-Sigri road. This geoconservation plan includes a series of interventions for the protection of the improvement of the accessibility to the fossiliferous sites, interpretation and information, signage, and infrastructure for visitor services. The various fossiliferous sites along the Kalloni-Sigri road, are now part of a new open-air museum, unique in the world, which will offer to the Lesvos Geopark visitors a new geotouristic attraction. In addition to various awareness-raising activities, a new campaign entitled “Walk the Forest” introduces the new petrified forest parks to the public. The project is funded by the Regional Operational Program “North Aegean 2014-2020”.

Geosensitivity based Geoheritage threat mapping using RS and GIS in the Darjeeling hill region, India

Lakpa TAMANG[1]*, University of Calcutta (ltgeog@caluniv.ac.in)

Abstract

Interest in the perspectives of both studies and management policies has grown substantially about geoheritage research, protection, and conservation, as well as the development and diffusion of geoheritage information. The impact of tourism activities has undermined the global geodiversity which necessitates the formulation of geoconservation strategies by identifying geosensitivity. The Darjeeling hill region faces severe threats with increasing tourism and the knowledge of the regional geodiversity has not yet been addressed properly resulting into depletion of the geoheritage richness. Thus, the objective of this study is to propose an efficient method of quantification and mapping of "geosensitive zones" using a simple Remote Sensing and GIS procedure which would be useful towards the formulation of proper geoconservation strategies for the tourism induced landscape. Thus, an integrated method of Geosensitivity Index (SI) based on geodiversity index (GI) and threat index (TI) using RS and GIS has been undertaken using the sum of four sub-indices: geological diversity, geomorphological diversity, pedological diversity & hydrological diversity, whereas the TI is based upon the summation of three sub-indices: land protection index, degradation index & land use index. The outcome demonstrates its efficacy in determining regional priorities for geoconservation and allows for a quick and easy visualization of areas with varying degrees of geosensitivity with Very high (8%), high (11%), moderate (20%), low (28%) & very low (33%). Besides, this automatic procedure could help in collecting a large quantity of information which ease the process to formulate immediate preservative strategies for the high & very high geosensitive zones and at the same time the geo-environmental concern regarding those regions which are less effected or may get severely affected if mass tourism continues.

Managing natural heritage: geoconservation efforts across Latin America and the Caribbean's landscapes

MARIA DA GLORIA GARCIA[1]*, University of São Paulo, Brazil (mgmgarcia@usp.br)
MARCOS NASCIMENTO[2], Federal University of Rio Grande do Norte, Seridó UGGp, Brazil
JUAN ESTEBAN QUINTERO MARÍN[3], Grupo de investigación en Geología Ambiental (GEA), Universidad Nacional de Colombia, Medellín
MAURÍCIO FARAONE PIMIENTA[4], DINAMIGE - Dirección Nacional de Minería y Geología, Área Geología, Uruguay

Abstract

The geodiversity of Latin America and the Caribbean (LAC), shaped by different tectonic settings including the South American Platform, Andean chain, the Caribbean Plate and the Patagonian block, reflects a rich geological history. This diversity is visible in ancient rocks, sediments, an enormous diversity of contrasting landscapes, and active geological processes, and it has determined the region's unique biodiversity, culture, and economic activities. Understanding and managing this geodiversity is crucial for effective environmental conservation, policy-making, and to tackle some of the major challenges of our era, such as natural resource and energetic management, disaster risk reduction, and adaptation to climate change. Given the region's particularities such as large wealth inequality, the most biodiverse hotspot in the world, high percentages of ethnic groups, and major geological hazards, geodiversity management and policies must be tailored to these characteristics.

Geoconservation efforts in the region vary, influenced by geographical differences, differing geological knowledge, socio-political context, and multiple levels of community engagement. Significant milestones in this field include the establishment of the first geopark in 2006 - Araripe Geopark in Brazil, the first compilatory book about geoconservation and geoheritage in the region in 2016, the creation of the UNESCO Global Geoparks Network for LAC in 2017, and the ProGEO branch initiative in the region in 2023, which highlights the growth of geoconservation initiatives. Presently, the GEOLAC network includes twelve UNESCO Global Geoparks (UGGp) in seven countries, as well as several Geopark projects at different stages of development. Research in LAC has concentrated on aspects such as the evaluation and management of geodiversity and geological heritage, geotourism, and geoparks. Efforts by organisations like the Association of Iberoamerican Geological and Mining Surveys (ASGMI) have focused on the development of a common methodology for the geological heritage assessment, disclosure of geological heritage in Ibero-America, and creation of regional geoheritage maps. Ten geological surveys in LAC are conducting geological site inventories at the national level.

The management of designated protected areas is also challenging. Currently, the region has 150 properties from 28 countries on the World Heritage List, distributed among 33 States Parties, being 104 Cultural, 38 Natural and 8 Mixed. The region is also home to 216 Ramsar Sites covering 61,904,530 ha. In addition, there are currently 134 Biosphere Reserves in 22 countries, which are part of the Ibero-American MAB Network (IberoMAB), created in 1992. Moreover, in

terms of area covered, Latin America and the Caribbean is the most protected region in the world. All these areas involve stakeholders to whom geoconservation strategies should be proposed to be integrated with nature conservation.
Significant contributions to geoconservation research and outreach come from several countries, addressing regional challenges and strategies for managing geological heritage. Establishing a ProGEO regional working group in LAC marks a step towards coordinated geoconservation efforts, aiming to address socio-environmental challenges and promote sustainable development in the region. Overall, these initiatives are a collective endeavour to protect and manage the geological heritage of Latin America and the Caribbean, ensuring its sustainable use and appreciation by future generations.

How can we arrange a geoconservation strategy in our area? some tips based in the Basque Country (Spain).

Manu R. MONGE-GANUZAS[1]*, ProGEO EUROPE (erakatxo@gmail.com)

Abstract

We will present the key milestones to be considered to design a participatory and consensual strategy for geo-conservation in a certain area. We will take as a model the applied case of the territory of the Autonomous Community of the Basque Country in Spain. The Basque Country starts his strategical design for geo-conservation by arranging a participatory process carried out among academia, citizens and public administrations. Its first step is to arrange the diagnosis of the geological heritage of the Area based on a geosite Inventory. After identifying the main actors related to geo-conservation, the second step is to find out how society is in contact with Earth Sciences. The subsequent third step is to analise the normative that applies in the Area and have influence on the management of the geoheritage at different territorial and jurisdictional scales. The fourth step is to establish strategic and operative objectives and a series of proposals for action in order to achieve those main objectives. Finally, it is proposed a method for the evaluation and the monitoring of the strategy. In the case of the Basque Government, it carried out its strategy with the following objectives: (1) To identify and describe the geoheritage of the Basque Country; (2) To obtain a systematised inventory that characterises the geological sites of Basque Country; (3) To delimit and map these places and incorporate the geographical information obtained into the GIS; (4) To establish a geosites assessment of the selected from a scientific, didactic-educational and tourist-recreational point of view that serves to prioritise protection or use measures; (5) To analyse the fragility, vulnerability and risk of degradation of the identified geological heritage; and (6) To define a geoconservation strategy for the conservation and public use of this heritage. To achieve these objectives, The Basque Country proposes 4 strategic objectives, 9 operative objectives, 22 operative sub-objectives and 45 actions. Its evaluation will provide a regular monitoring report assessing its degree of compliance and will propose, if needed, corrective measures. This experience aims to become a management model to be replicated by any Area of the Planet.

Integrating geoconservation and sustainability: a focus on natural resource management in the Brazilian Amazon

MARIA DA GLORIA GARCIA[1]*, University of São Paulo, Brazil (mgmgarcia@usp.br)
André de Oliveira Sawakuchi[2], University of São Paulo, Brazil
Raimundo Humberto Cavalcante Lima[3], Federal University of Amazonas, Brazil
Daniel Souza dos Santos[4], University of São Paulo, Brazil
Thiago Alves Evangelista[5], Federal University of Ceará, Brazil
Raquel Mamblona Marques Romão[6], University of São Paulo, Brazil

Abstract

The Amazon region corresponds to the limits of the world's largest and most biodiverse rainforest, which covers a significant portion of the South American continent across multiple countries. It is home to a vast array of flora and fauna, and plays a crucial role in the global climate system, acting as a significant carbon reservoir and influencing hydroclimate patterns both regionally and globally. The development of Amazonian landscapes underpins the region's exceptional biodiversity, as it influences several ecological processes and habitat diversity. Preserving this rich natural diversity is crucial, yet economic pressures pose significant challenges to conservation efforts. In this scenario, geoconservation arises as an innovative and sustainable socioeconomic alternative. This study explores five projects in which geoconservation strategies are being employed to achieve goals that range from natural heritage management to outreach in the region.
The projects are settled in four Brazilian states. In Roraima, identification and evaluation of geological sites are being used to create a field guide with educational and geotourism purposes in the Takutu Basin, a Mesozoic intracontinental rift between Brazil and Guyana holding important geological information related to the process of the opening of the Atlantic Ocean, with oil and gas exploration potential. In Amazonas, two projects are being carried out. In the region of the lower Rio Negro river, which holds important protected areas such as Anavilhanas and Jaú national parks and is home for riverine people, geoheritage inventories and surveys on abiotic ecosystem services provide data to the implementation of geotourism strategies through the production of virtual materials and interpretative panels. In the town of Presidente Figueiredo, known as "the land of waterfalls" and home for a geopark project by the Geological Survey of Brazil, a Geodiversity Action Plan (GAP) is currently underway. Both of these involve workshops and courses for schools and communities using social learning and participatory methodologies. Geoconservation strategies are also being used to achieve outreach practices in the Trans-Amazon Drilling Project, focused in the states of Acre and Pará, which seeks to answer fundamental questions about the geological, environmental, and climatic development of the Amazon. In these areas, inventory and assessment of geological sites compound the bases for producing educational and dissemination materials using the Design Thinking approach. Also in Pará, geodiversity characterisation combined with multidisciplinary studies in Volta Grande do Xingu, the largest rapids within the Amazon, aims to identify sustainable conservation solutions for a socio-ecological system formed by biodiversity, geodiversity, and traditional and indigenous

communities, threatened by the dewatering effects in the seasonally flooded and aquatic ecosystems due to river diversion to attend the Belo Monte hydropower plant.
Taking into account the whole geoconservation chain, in all the case studies the diagnosis of geodiversity and geoheritage plays a prime role to subside both future statutory conservation and promotion actions. Moreover, these results seek to discover ways to use these elements as means of generating income and sharing knowledge to local communities, through the sustainable use of natural resources.

Addressing geohazards in populated geoheritage sites: the case of Dovžan Gorge Natural Monument in Slovenia

Matevž Novak[1]*, Geological Survey of Slovenia (matevz.novak@geo-zs.si)

Abstract

Dovžanova soteska (Dovžan Gorge) is one of the most interesting geological sites in Slovenia. The Tržiška Bistrica Creek, with the aid of tectonic forces, has carved deep into the Karavanke Mountains, revealing a long cross-section of Late Paleozoic rocks. It is one of the most fossil-rich areas in the Southern Alps and has high scientific and historical significance as the locus typicus of many newly described species. Although several faults transect the section, the original succession is preserved in almost complete stratigraphic order. This enables the recording of the paleoenvironmental evolution of the depositional setting and the paleobiological evolution of several fossil genera.

Since 1988, Dovžanova soteska (Dovžan Gorge) has been protected as a natural monument due to its exceptional geological and geomorphological features. The gorge is inhabited and has a traffic connection between the town of Tržič and its hilly hinterland with extensive, economically important forest areas. Due to the geological structure and topography of the terrain, characterized by steep slopes and the torrential flow of the Tržiška Bistrica, the area is subject to rapid and significant natural changes, which are particularly intense during extreme weather events and can cause material damage. Considerable attention and resources are devoted to reducing the risk of falling rocks. Protective wire meshes, large catching structures and high protective fences enclose virtually all rock walls and gullies along and above the main road and walking paths in the most beautiful and geologically interesting parts of the gorge.

Protected geoheritage areas that are inhabited face the challenge of balancing preservation of the natural environment with human interventions for economic needs and safety purposes. The extreme weather event in October 2018 caused significant changes in the Tržiška Bistrica river basin, which were most noticable in the Dovžan Gorge Natural Monument. This event highlighted several aspects of this issue. The Dovžan Gorge has been proven to be an excellent site for studying natural processes, anthropogenic influences, and human perception of natural disasters and historical memory of them. This is based on the analysis of a weather event and changes in the surface, as documented through photos and historical archives.

The observation that as many as six extreme rainfall events (in 2003, 2007, 2009, 2010 2018, and most recently in 2023), with a return period of 50 or 100 years, have occurred in the last 20 years, and that the resulting material damage and its remediation have been very similar in all cases, suggests that historical and recent data will need to be taken into account in climate change adaptation strategies.

The current status of geoheritage management in Korea: a decade of progress and future directions

Wansang RYU[1]*, National Geoparks Secretariat of Korea (wansryu@knps.or.kr)
Hosahng Rhew[2], Jeonbuk National University
Hyejin Kim[3], Seoul National University
Jeong Young Lee[4], Korea National Park Service

Abstract

The process of documenting geoheritage in Korea began in 2014 with a thorough nationwide survey to create an inventory of geoheritage sites. This was part of the National Geopark Secretariat's initiative funded by the Ministry of Environment (MoE), with the aim of giving support to geoparks. Over the last 10 years, a total of 1,004 sites on mainland and Jeju island have been officially registered, and additional c.a. 400 sites will be included by 2025 when the survey for geoheritage in inhabited islands is finished. The surveyed geoheritage is organized into a GIS database, which offers online services displaying the spatial distribution of each site, along with its current rating. The geoheritage DB serves as a source of e-books for raising awareness about geoconservation and geotourism among the public. The geoheritage evaluation system comprises three modules: fundamental value, associated value, and institutional conditions. It has a total of 20 criteria. The fundamental value module comprises 10 criteria that encompasses scientific, educational, and scenic value. In contrast, the associated value module includes 7 criteria that pertain to ecological , economical, historical and cultural significance. Institutional conditions deals with factors such as the ease of access, the quality of infrastructure, and legal status. While the surveyor assessed all of the criteria on field, just 10 criteria from fundamental value section were utilized to evaluate geoheritage on a five-grade scale, with a specific emphasis on the 'geological' value. Although geoheritage inventory system has developed over the past decade, the corresponding legal framework has not been adequately enforced. From a managerial standpoint, the current inventory system lacks sufficient evaluation criteria to indicate the level of degradation risk caused by natural and anthropogenic factors. To improve these conditions, we have created a diagnositc chart that assesses management priority based on the value of geoheritage and the risk of degradation, together with an legislative effort to support the management and geoconservation of geoheritage. In 2024, we will try to develop a monitoring protocol for the wise use and better conservation of geoheritage within geoparks.

Geoheritage and Geoconservation as a resource and a tool for promoting the United Nations 17 Sustainable Develop Goals (SDGs)

Kevin Neil Page[1]*, ProGEO (kevinnpage@gmail.com)

Abstract

Over the last 15 years or so, there has been a massive international increase in awareness of geodiversity, not least due to the formal adoption of Global Geoparks as a UNESCO programme in 2015. There are now around 195 UNESCO Global Geoparks (UGGs) across 48 countries all promoting geoheritage as the basis for sustainable economic development according to statutes established by UNESCO (https://www.unesco.org/en/iggp/geoparks/about). In addition, the global significance of geological heritage and its conservation, is now recognised by IUGS through the establishment of its International Commission for Geoheritage (ICG; https://iugs-geoheritage.org/) and IUCN through the activities of the Geodiversity Specialist Group (https://www.iucn.org/our-union/commissions/group/iucn-wcpa-geoheritage-specialist-group), part of the World Commission for Protected Areas. However, in a world where the negative environmental effects of human activities are becoming increasingly difficult for governments to ignore, the principles of sustainability are now often being explicitly cited as justifications for nature conservation – including within national and regional geoconservation activity. Crucially, in 2015, the United Nation's Agenda for Sustainable Development, established 17 Sustainable Development Goals (SDGs) (https://en.unesco.org/sustainabledevelopmentgoals) , as both targets and guides against which achievements could be measured or assessed. But can we assess, even measure the global contribution of geological heritage and its conservation to the UN STGs, especially taking into account the vast number of projects and initiatives outwith the very small number of UGGs globally? The answer comes in the form of the published scientific literature, as this change in attitudes towards the role of geological heritage in society, is also represented in a widespread change in academic attitudes towards the subject which is now in many countries considered as a key part of the broader geosciences – hence research and publishing on the subject is widely supported. The journal Geoheritage (www.springer.com/12371), in particular, is a useful guide, as it was set up as a collaboration between the global NGO in the field, ProGEO (www.progeo.ngo), to promote the discipline globally. Now in its 25th year, around 1000 published papers from over 86 countries, reveal that at around 45% describe contributions to one or more SDGs, with Geotourism (12%, i.e. SDGs 1, 4, 5, 8, 10, 11), Urban Geodiversity (10%, i.e. SDGs 4, 11) and Sustainability and Communities (8%, i.e. SDGs 4, 5, 6, 10, 11) being the most frequent themes, along with Education (6%, i.e. SDs 4, 5, 6, 10, 11), Geoparks (5%, i.e. SDGs 1, 4, 5, 8, 10, 11) and Integration with Biodiversity (2%, i.e. SDGs 11, 14. 15) being the other relevant themes. This simple assessment reveals that rather than being considered to be an unimportant 'sideline' for some national academic institutions, or a 'Cinderella' subject within nature conservation (i.e. of little relevance to ecological and species issues), geoconservation activities have a major role to play in addressing the major problems addressing all global societies.

Integrating geo- and biodiversity: Towards a more holistic approach to nature conservation

Kevin Neil Page[1]*, ProGEO (kevinnpage@gmail.com)

Abstract

Although the conservation of geodiversity as part of nature conservation has seen major advances in recent decades, the process has not been straightforward as there often remains a misunderstanding on both the geological and ecological sides, of the objectives and practice of the other discipline. These problems are exacerbated by the frequent development of parallel conservation systems, including at the level of both legislation and administration. In the UK, however, the conservation of geological and ecological heritage nationally has always been carried through the same legal framework. Despite, this promising scenario, however, site management has often been insufficiently integrated, even where prescriptions for geological and biological features could be developed in such a way to benefit both categories of feature. In the 1990s and into the early 2000s, however, initiatives were developed by national and regional governmental authorities with the intention of creating a more holistic framework for nature conservation. These included English Nature's, 'Natural Areas' project, which demonstrated that, nationally, bedrock and superficial geology controls the broad distribution of characteristic habitats, and Countryside Council for Wales 'LANDMAP' programme, which produced a multi-layed GIS mapping and characterisation of Welsh landscapes as a guide for landscape-scale management. As this was the era in which the term biodiversity first became prominent after the 1992 Earth Summit in Rio de Janeiro, it also saw a proliferation of Biodiversity Action Plans, or BAPs, to set target for conservation actions at all level from local to international. Unique, amongst these in the UK was the Devon Biodiversity Action Plan, developed and promoted by the regional government, Devon County Council. The Devon BAP used 'Habitat' Action Plans to set priorities for the management of a range of site types, crucially identifying geological and geomorphological, as well as ecological aims and objectives. The methodology is particularly powerful where geomorphological processes underpin ecosystems, such as 'Active River Systems', but is equally valuable where the primary features may be geological (e.g. in 'Pits, Quarries and Cuttings'), but may be associated with national rare or protected species. Although now replaced by later initiatives, the Devon BAP admirably demonstrated how apparently contradictory geo- and biodiversity aims and objectives can often be reconciliated and even integrated to achieve mutual goals. These common links are now being independent developed at an international scale within a broader concept of Ecosystem Services' which also recognises the importance of nature to human life and wellbeing, including as 'Geosystem Services – although there is still an inherent risk here of developing parallel geodiversity and biodiversity perspectives without adequate integration as has been a problem in the past. Similarly, the development of a programme of Key Geodiversity Areas within IUCN as a parallel to Key Biodiversity Areas, also risks perpetuating an entirely artificial divide within nature conservation practice. Crucially, a

fundamental change in attitudes to nature conservation is needed on both sides, with geoconservationists needing to be more ecologically aware and ecological conservationists needing to consider the physical structures and processes without which there would be no ecosystems..

Geoparks' way of survival in National Parks management system- perspectives from Australia and China

Qian Li[1]*, Shanxi University of Finance and Economics (314126052@qq.com)

Abstract

Geoparks have developed for decades. There are 195 Global Geoparks worldwide which distribute in 48 countries, spanning 4 860 000 km2 in total. It is not just a geological featured area responsible for native economic benefits and scientific education, but also an essential park brand. Australia is home to over 500 national parks, each with its unique features and attractions. National parks in Australia originated from 1879, making it as the second oldest in national parks history. It used to be home to the only one Global Geopark in the Southern Hemisphere. Kanawinka Global Geopark was established as Australia's first geopark by supporters effort in 2008, then unfortunately it was delisted by UNESCO in 2012 due to failing in four-yearly geopark review. The short history of Australia geoparks has been reviewed by Ian D Lewis. This paper mainly reviews Australia's national parks management framework, community participation, infrastructure and social influence, and analyses why and how geoparks couldn't make it in the condition. In contrast, China has hundreds of geoparks and only a few national parks. The number of UNESCO Gobal Geoparks in China had grown to 41 by 2022, while the number of National Geoparks had been 271. Early in 2013, China government proposed national parks establishment plan, then NPs with natural protected areas reform. After NPs pilots process, it was proclaimed in Conference of Parties to the Convention on Biological Diversity that China had established the first 5 national parks successfully in 2021. How could Geoparks survive in the condition of National Parks Management System in China? According to the story of national parks on the earth, It will take a long time to answer. This paper examines China's geopaks as well as national parks short history, management framework, community participation, infrastructure and scientific education, while compares with Australia to gain experience or learn lessons for now.

Dominique Frizon de Lamotte[4], CY Cergy Paris Université, Géosciences & Environnement

Abstract

New outcrops of potential geological interest are regularly uncovered by natural or anthropogenic actions such as land-use planning and public works. These outcrops are most often exposed temporarily as they are deemed to be scars on the landscape and are sooner or later revegetated, filled, or concreted. In France, the number of outcrops uncovered each year that may be of geological interest remains unknown. This can be explained by the fact there is no procedure for examining geological objects during construction projects. In contrast, the context is different for archaeologi-cal remains which are protected by the law on “preventive archaeology”.
Arising from the European Convention signed in Malta in 1992, this law was enacted in 2001 and provides for archaeological interventions on development sites and allows for evaluation and, if necessary, excavation.

To remedy this lack of knowledge, a participatory science program, called “Vigie-Terre”, was set up by the Muséum National d'Histoire Naturelle in June 2000 (https://www.vigie-terre.org/). The program aims to enable volunteers to quickly identify relevant outcrops and bring them to the atten-tion of researchers, enabling data to be saved (i.e. sampling, photos, field surveys).

To participate in “Vigie-Terre”, an online reporting protocol has been set up so that citizen scientists can provide locality and outcrop information for the sites of interest. A network of volunteer experts throughout the territory can then examine the sites and, based on the information provided, assess whether the outcrop is of scientific and/or educational interest, and/or whether it is worth visiting the site to take samples or inform the local authorities.

In the frame of “Vigie-Terre”, researchers from CY Cergy Paris Université came up with the idea of using participatory science to locate old or active landslides in the Vexin Français region (north-west of Paris). The objective is to collect research data and also to raise awareness of regional ge-ology among local populations through dialogue with local authorities. With a few simple adapta-tions, “Vigie-Terre” could be used to meet this new need. This cooperation opens up new pro-spects for extending the scope of the initial “Vigie-Terre” project and using participatory science both to collect data and as a tool for geological outreach.

This presentation will provide feedback on this citizen science project. We will give an overview of the results acquired during the four years since its inception and discuss the benefits and

limitations of such a we have identified.

Abstract

During the last fifty years, numerous international designations have been established with a focus on biodiversity and/or natural heritage conservation, but only a small number are dedicated to geoconservation. This discrepancy underscores the relatively low level of public awareness regarding the importance of geodiversity and geoheritage. Apart from UNESCO's World Heritage and Global Geoparks initiatives, and the recent IUGS Geological Heritage Sites list, there are no other international designations specifically aimed at recognizing geoheritage. As more countries develop their own national inventories of geoheritage, additional geosites are being identified and protected, leading to a growing realization that the number of geosites with international significance far exceeds those recognized by UNESCO and IUGS. Moreover, many key geosites may never be included in these lists due to failure to meet the necessary selection criteria.

In 2020, the International Union for Conservation of Nature (IUCN) adopted Resolution 74, calling for a scoping study on a new initiative termed Key Geoheritage Areas (KGAs). Subsequently, a working group was established to conduct this study and propose guidelines for KGAs. A public consultation was conducted from July to September 2023, and a final version of the KGA Guidelines is currently being prepared, incorporating many of the suggestions raised during the consultation.

A KGA is an area with well-defined boundaries where significant geological features (rocks, minerals, fossils, sediments, soils, landforms and landscapes) represent past or on-going Earth processes contributing substantially to the global understanding of the planet's history and its life-support systems. The primary objective of the initiative is to recognize and conserve geoheritage

values of international significance and to disseminate and promote this information to advance geoconservation efforts worldwide. The KGA initiative does not merely comprise a list of geosites; rather, it is strongly committed to persuading national and local authorities to protect the most relevant geosites and implement IUCN geoconservation guidelines, ideally with active involvement from local communities.
The final establishment of the KGAs initiative is expected to occur in October 2025, following its final adoption by IUCN.

[Keynote] Conservation of geodiversity and geoheritage in protected and conserved areas underpins natural systems and contributes to a sustainable future

John E. Gordon[1]*, School of Geography and Sustainable Development, University of St Andrews (jeg4@st-andrews.ac.uk)

Abstract

Direct and indirect human impacts on the planet present huge challenges for a sustainable future. They include climate change, biodiversity loss and delivering the UN Sustainable Development Goals. Conservation of geodiversity and geoheritage in protected and conserved areas (PCAs) has a key part to play in addressing these challenges. Geodiversity underpins the characteristics, functioning and evolution of terrestrial and marine ecosystems at all scales from the local to the whole planet. Geodiversity also delivers vital ecosystem services through its influence on landscape, habitats and species, economic activities, historical and cultural heritage and people's health and well-being. Furthermore, understanding the physical environment and lessons from the geological record are fundamental to informing climate change adaptation and sustainable management of natural resources, including the land, water, coasts and seas. Therefore, in the face of a variety of pressures and threats, conservation management of geodiversity and geoheritage in PCAs is essential to: 1) preserve the 'memory of the Earth' and its geoheritage values; 2) maintain the physical template for habitats and species and the abiotic ecosystem processes without which biodiversity could not exist and ecosystem services would be compromised; 3) protect the environmental archives that provide the knowledge base for informing ecosystem management, recovery and adaptation to climate change. The presentation examines what this means and requires in practice. It sets out key principles and examines recent progress in geoconservation and the challenges that lie ahead, including climate change and overcoming barriers towards more integrated nature conservation and mainstreaming geoconservation into nature conservation policy and practice.

New geoheritage research initiative of the Saudi Geological Survey aiming to act as national guardian of the abiotic natural values of the Kingdom of Saudi Arabia

Turki Sehli[1], Saudi Geological Survey
Karoly NEMETH[2]*, Saudi Geological Survey (knemeth@geoconservation.org)
Rashad M Moufti[3], Afaaq Geoconsulting, Jeddah
Naser S Jahdali[4], Saudi Geological Survey

Mahmoud S Ashor[7], Saudi Geological Suirvey
Abdulrahman G Sowaigh[8], Saudi Geological Survey

Abstract

The Kingdom of Saudi Arabia is the nation with the largest territory within the Arabian Peninsula. Its geological formations in the west dominated by Neoproterozoic rocks on the surface as part of the old Arabian Shield continental margin that is flanked by some Paleozoic volcanic arc related successions gradually covered by typical carbonate dominated platform rocks formed in the Tethys realm. In the western part of the country is dominated by Neogene volcanic products post-dating the Red Sea Rifting in a form of continental rifting offset of it, forming characteristic black rock or ash deserts as a dramatic arid landscape. The Kingdom's geology is diverse and largely unexplored while tis aesthetic values recently exploited due to the new initiatives to utilize the country natural heritage through geotourism. This new trend resulted major developments around dedicated tourism hot spots such as Al Ula or Khayber in the north, but it can also be seen in other regions such as just around the capital city of Riyadh. These new developments are clearly angling tourism from the biotic (e.g., biodiversity), archaeology (e.g., presence of mystic archaeological sites) or cultural (e.g., living culture, architecture) aspects while geology or even dedicated geomorphology is either expressed in very basic level or not even explored yet in a level they deserved to be. To narrow this knowledge and operational gap, the Saudi Geological Survey established new research initiatives that aim to develop a geological and geomorphological inventory of geosites and pursue research on mapping the geodiversity of the Kingdom. Alongside of this basic research activity, this new initiative within the Survey aim to develop methods to transfer geological and geomorphological knowledge to geotourism operation and design geotrails, geoeducation centers, explanatory boards both in real and virtual environments. The rationale of this new initiative is multi-faced. The Saudi Geological Survey holds a very extensive and valuable geological database in forms of geological maps, reports, sample inventory that are ready to be utilized for specific geosite evaluation. The Saudi Geological Survey is also a national level organization that has the right infrastructure to build geosite inventory. In addition. It has the human resources to be as an advisor or service provider for other end-users such developers or tour operators. The Saudi Geological Survey has also recently recognized the useful aspects of geoheritage to use it to disseminate geological knowledge to the community to enforce geohazard

resilience particularly in volcanic, seismic, and mass flow hazards.

How to save a discovery in an active mine? Cooperation with the mine and its workers to protect the dinosaur heritage

Grzegorz Niedźwiedzki[1], Regional Geology Department, Polish Geological Institute - National Research Institute, 4 Rakowiecka St., 00-975 Warszawa, Poland; Subdepartment of Evolution and Development, Department of Organismal Biology, Uppsala University Norbyvägen 18A SE-752 36 Uppsala, Sweden
Piotr SZREK[2]*, Polish Geological Institute - National Research Institute (piotrszrek@yahoo.com)

Abstract

The Borkowice site has provided several thousand dinosaur footprints, numerous dinosaur bones and coprolites. It is a research material that has just come to light and is already the center of interesting studies. A large part of the footprint specimens shows (especially visible in 3D scans) three-dimensional natural casts of dinosaur feet, on which anatomical features and impressions of the scaly skin are preserved in unusual details. These are the best-preserved traces of dinosaurs so far discovered in Poland and the quality of their preservation is equal to the best-known discoveries worldwide. The collection also includes records of ethology (behaviour) left by dinosaurs running, swimming, resting and sitting on a muddy sediment, as well as many enigmatic biogenic structures, probably related to various life activities of dinosaurs living there. So far, dinosaur tracks representing at least seven different taxonomic groups have been collected and secured in Borkowice, as well as casts of bone remains of ornithischian dinosaurs.
Due to the uniqueness and great significance of the find, the cooperation between the businessman using the clay deposit containing the sandstone with the tracks, local and central government authorities and scientists is noteworthy. Together we are working out unprecedented legal solutions in Poland to protect the site while at the same time developing it for the purposes of natural science education. Numerous challenges are involved in reconciling the property rights of the site. This is because it is leased for mining purposes, but is owned by the Polish State Forests, which have separate regulations for recultivation mation. A major investment is planned, to be financed for the municipality by the central authorities. The currently established form of protection as a documentation site will be developed together with the Polish representatives at UNESCO. The aim is to lead to the establishment of a natural monument, which could be given the title of a natural heritage site in the future.

Toward global modelling of geoheritage and geodiversity loss

Mihai Niculiță[1]*, Alexandru Ioan Cuza University of Iași (mihai.niculita@uaic.ro)

Abstract

Geoheritage and geodiversity are a hot topic these days, especially in the context of their loss. While geoheritage loss is a natural phenomenon, due to the natural evolution of the processes, anthropic changes and climate changes are driving geodiversity loss so a mapping approach at a global scale would be beneficial in terms of the amount of work needed to ramp up the protection approach. For such an endeavor, we have identified first the areas which are not protected yet, and focused the analysis on geodiversity loss, based on a land-cover change analysis. Land cover is used as a substitute, based on the idea that in areas where there is no change in surface conditions, there is a low probability of geodiversity loess, although we also showed that in some areas the loss is happening although there is not much visible change. These areas should be considered for an in-depth analysis were more factors should be considered. Further, we introduced factors such as landforms, geology, habitat type, climate, and climatic variables, to run a statistical analysis that would emphasize the complexity of the geo-environment and finally mapped the areas of change to identify hot spots of environment change and geodiversity. Besides land, we have focused also on coastal and marine areas. The availability of the data, especially in marine areas is a barrier in the analysis of these areas, where even the geodiversity is hard to assess. Anyway, despite these hurdles, actually this environment is the most sensitive to geodiversity loss, given its particularities. The results of this approach are summarized with maps of factors and maps of hot spots that need to be considered in the geoheritage approach. The usability of such a study we believe relates to the need to drive this hot topic toward the areas that need the most geoheritage evaluation and protection.

Interpretation of Underground Structure and Provenance for Rock Properties in Three-story Stone Pagoda and Flagpole Support Stones from Jungchosaji Temple Site of Anyang, Korea

HyeJi Choi[1]*, Department of Cultural Heritage Conservation Sciences, Kongju National University (conan-doil@naver.com)
YOONOH JEONG[2], Department of Cultural Heritage Conservation Sciences, Kongju National University
CHANHEE LEE[3], Department of Cultural Heritage Conservation Sciences, Kongju National University
HEESOO CHOI[4], Top Heritech, Industry-University Research Center, Kongju National University

Abstract

The Jungchosaji temple site in Anyang is the historical site where both Jungchosa and Anyangsa temple built during Unified Silla (676 to 935 AD) and Goryeo Dynasty (918 to 1392 AD) respectively in Korea. The flagpole support stones and three-story stone pagoda are the left heritages of those temple sites. Since 123 characters are engraved on the surface of the flagpole support stone which state its original name, founding date and participants, it is historically and academically valuable. However, it had experienced several conservation and restoration process due to long term weathering and constant deterioration. Furthermore, the three-story stone pagoda has lost some parts of body stones, and has damaged throughout the entire stone components.

In this study, the geological status and petrological weathering characteristics of the stone components were geochemically analyzed to figure out the suitable conservation scheme. Provenance interpretation of the stones were interpreted, and nondestructive diagnosis were conducted to quantitatively assess the extent of stone damages. Especially, the underground of the site was explored in geophysical way to evaluate the structural stability. As a result, all stone components are composed of medium to coarse grained granite, consisting of quartz, plagioclase, alkali feldspar and biotite. These are assigned as large scale Jurassic granite which is distributed in the vicinity. Some quarry marks were discovered at the presumed quarry site, and lithological and geochemical analysis confirmed the homogeneity between the granites of stone components and quarry sites.

In GPR (ground penetrating radar) survey, a variety of reflection intensities were detected through the north to south and east to west profiles right under the heritage sites, which is the evidence of ground stratification. The P-wave velocities were measured as three layers which were divided as follows: weathered soil layer below 700 m/s, weathered rock layer between 700 and 1,200 m/s, and the unweathered rock layer above 1,200 m/s. The electrical resistivity values ranged from 106 to 18,443 Ωm, with relatively higher values beneath the stone pagoda and flagpole support stones. Considering all the result, the underground conditions were estimated to be stable.

According to the stress analysis of the stone pagoda regarding the ground state, the maximum compressive stress was calculated to be 1.31. Structural modeling and numerical analysis results revealed that there are no structural problems. In order to assess the impact of vibration from the

surrounding traffics, the predominant frequency at primary and secondary mode are measured as 6.7Hz and 7.5Hz, respectively. However, these values are interpreted as minimal. Based on the results, this series of study will contribute to the conservation scheme of cultural heritages in Jungchosaji temple site.

U.S. Geological Survey Geoheritage Sites of the Nation Inventory

Christina A DEVERA[1]*, U.S. Geological Survey (cdevera@usgs.gov)
Paco Van Sistine[2], U.S. Geological Survey
Thomas J Casadevall[3], U.S. Geological Survey
Timothy C Henderson[4], Colorado State University, U.S. National Park Service
Leslie F Ruppert[5], U.S. Geological Survey

Abstract

The U.S. Geological Survey (USGS) National Cooperative Geologic Mapping Program (NCGMP) is developing a geoheritage site inventory to showcase the geodiversity and natural heritage throughout the United States (U.S.) and its territories. The site inventory will be produced as a geoheritage geospatial product (GGP) to accompany the seamless 2D and 3D geologic map and model being developed by the NCGMP U.S. GeoFramework Initiative. An interactive WebMap application is being developed to host the GGP with the goals of serving as an education and outreach tool to raise awareness of significant geologic sites across the U.S., communicating the role of geology in our natural heritage, and increasing public accessibility and relevance of geologic mapping and geoscience topics broadly.

Geoheritage sites for this inventory were selected from in situ geologic features that have been previously identified as geologic points of interest on Federally designated public lands managed by the U.S. Federal Government. Due to the non-regulatory nature of the USGS mission, selecting sites on Federal public lands ensures that land management practices are already in place to preserve the integrity of the site. To be included in the inventory, these sites must demonstrate scientific significance of the geologic phenomena and can provide educational opportunities for both formal and informal learning, illuminate cultural connections to the landscape, showcase both historic and present-day examples of economic opportunities, and have an aesthetic allure that generates a geotourism economy within our Federal public lands. USGS and U.S. National Park Service (NPS) collaborators have selected one geoheritage site on Federal public lands within each U.S. state and territory to provide a geographically distributed dataset that highlights the geodiversity of the nation (n=55). There is ongoing effort to expand the initial geoheritage site inventory as the USGS collaborates with other Federal land managing agencies, State geological surveys, academia, non-governmental agencies, and Indigenous groups to identify additional sites that meet our geoheritage selection criteria.

The GGP will provide direct linkages to spatially relevant geologic maps contained in the USGS National Geologic Map Database along with USGS- and partner-produced resources for each geoheritage site hosted on the interactive geoheritage WebMap application, allowing for improved public access to complementary information. The GGP can be queried based on user interests using keywords from controlled vocabularies that describe the scientific, educational, cultural, economic, and aesthetic geoheritage values of the site. These keywords are derived from USGS and NPS geologic glossaries, the American Geosciences Institute Glossary of Geology, Next Generation Science Standards Crosscutting Concepts, and terms employed by U.S. and

international researchers of geodiversity, geoconservation, and geoheritage. Each site features brief, plain language descriptions and includes applicable superlatives presented in a narrative form that enable geologic concepts to be easily understood by the public. Broadening the relevance and accessibility of USGS geologic mapping through a geoheritage inventory can highlight the geodiversity of the U.S., inform geoconservation decisions made by land managing agencies to preserve the unique geoheritage of the country, and foster a deeper understanding of the role geology plays in society.

Lithological Characteristics and Provenance Interpretation of Stone Properties for Jotap-ri Five-story Brick Pagoda in Andong, Korea

Dong Hee JEONG[1]*, Department of Cultural Heritage Conservation Sciences, Kongju National University (ehdgml361@naver.com)
Il Kyu Choi[2], Department of Cultural Heritage Conservation Sciences, Kongju National University
Seok Tae Park[3], Department of Cultural Heritage Conservation Sciences, Kongju National University
Chan Hee Lee[4], Department of Cultural Heritage Conservation Sciences, Kongju National University

Abstract

The Five-story Brick Pagoda in Jotap-ri of Andong is a cultural heritage from the Unified Silla (676 to 935 AD) in ancient Korea. Unlike other brick pagodas, the sandstones were used for the entire body part of the first floor. A rectangular tabernacle was built on the south side of the pagoda body, and statues of the guardians were carved on the left and right sides. The roofs above the first floor were made of bricks, and the bricks with patterns that appear to have been from the time of the first construction remain and in recognition of their value, it was designated as treasures.

The geology around the Jotap-ri pagoda consists of sedimentary rocks with Gyeongsang Supergroup in Cretaceous based on granitic gneisses of Precambrian, and is occupied by the Jinju Formation which is part of the Sindong Group, and the Formations of Iljik, Hupyeongdong and Jeomgok which are part of the Hayang Group. The Jotap-ri area where the pagoda is located a sandstone layers of Iljik Formation, and is composed of various types of sandstone.

The stone properties of the pagoda are made up by four types of sandstone: light gray to green sandstone, conglomeratic sandstone, dark gray sandstone and purple sandstone. The number of stones in the pagoda is 88 properties, and when calculated with elevation by direction, a total of 119 sides are exposed. It is believed that this sandstone was used in the construction process of the pagoda without regard to the location or purpose of the stones, and among these, light gray to green sandstone is confirmed to be the dominant species, accounting for 69.32% of the total stones. However, the two guardian statues on the left and right of the tabernacle were made up purple sandstone of a unique color, giving them special meaning.

In order to secure replacement stones for the original stone properties on the pagoda needed in the repair and restoration processes, geological survey was conducted near Jotap-ri to find stones that were almost identical in lithology, mineralogy, texture, color and magnetic susceptibility to the sandstones of the same type as the pagoda. The estimated production area was explored. Additionally, the identity of the two sandstones were proven through quantitative petrographic and geochemical analysis.

As a result, all four types of sandstones were interpreted to be of the same origin as the sandstones discovered within 2km near Jotap-ri. Some of the sandstones, which are presumed to be of the same type, are used as foundation stones for private houses or are left exposed to the outside.

These stones are evaluated as potential heritage and require special management to prevent damage. It is expected that replacement stones for the Jotap-ri pagoda can conserve the authenticity of cultural heritage by utilizing the provenance interpretation reviewed in this study.

Stability Interpretation for Rock-carved Standing Buddha Triad of Dongmun-ri in Taean, Korea, based on Geophysical Exploration and Slope Analysis

ILKYU CHOI[1]*, Department of Cultural Heritage Conservation Sciences, Kongju National University (illgyu21@naver.com)
HEE SOO CHOI[2], Top Heritech, Industry-University Research Center, Kongju National University
JUN HYOUNG PARK[3], Corporate Research Institute of Creation, Radpion Inc.
CHAN HEE LEE[4], Department of Cultural Heritage Conservation Sciences, Kongju National University

Abstract

The Rock-carved Buddha Triad of Dongmun-ri in Taean is a stone cultural heritage with Baekje Kingdom (18 BC to 660 AD) in ancient Korea which was built in southwest slope of the rock surface. Unlike general rock-carved Buddha statues, this Buddha Triad has the unique formative characteristics of a small Bodhisattva placed between the two Buddha statues. This Buddha Triad is located at a strategic point with China, and is very important in understanding the relationship and influence of the northern Chinese style Buddha statues from middle in the 6th century. As it is the oldest rock-carved Buddha statue from the Baekje period, it is preserved and managed as a national treasure in Korea.

The lower part of the Buddha Triad was buried when it was first discovered in 1962, and the lotus pedestal and cornerstone were confirmed through excavation. In 1989, due to concerns about the collapse of the Buddha Triad, various investigation were conducted, and the buried lower part was covered and preserved. In 1995, the lower part of the Buddha Triad was exposed through repair works and conservation treatment.

This Buddha Triad has undergone several maintenance works since its initial discovery, and it is currently located in a safeguarding facility and protected from the external environment. However, rock slopes and cliffs are distributed around the Buddha Triad, and a collapse of the slope may occur. In this study, geophysical investigations were conducted on the underground around the Buddha Triad to review the overall geological structure and anomaly zone. In addition, the possibility of plane, wedge and toppling failure of the Buddha Triad and surrounding bedrock were examined through slope stability evaluation.

As a result, the boundary between low electrical resistivity and reflection signals were detected in the southern part of ground, and the sloping stratigraphic structure of the north and south elevations confirmed in the excavation in 1994 was the same. This is different from the direction of bedrock in the Buddha Triad, which raised the collapse risk, so possibility of destruction by the ground is interpreted to be low.

Slope stability evaluation of rock mass to the Buddha Triad has a low possibility of slope failure, but the rock mass nearby is exposed to risk. Since the areas that can be destroyed are concentrated around the road above the Buddha Triad, it is necessary to review measures to prepare for the occurrence of safety accidents in the future. This result is significant as it is the first scientific study applied to the bedrock and ground where the Buddha Triad is located, and preservation

schemes and preventive conservation should be prepared based on this data.

Provenance Interpretation and Petrological Characteristics from Hongjueupseong Fortress Wall and Stone Block Foundation of Joyangmun Gate in Hongseong, Korea

JUN HO SONG[1]*, Department of Cultural Heritage Conservation Sciences, Kongju National University (catosaurus@naver.com)
Seok Tae Park[2], Department of Cultural Heritage Conservation Sciences, Kongju National University
Chan Hee Lee[3], Department of Cultural Heritage Conservation Sciences, Kongju National University

Abstract

The Hongjueupseong Walled Town is a stone fortress built during the Joseon Dynasty (1392 to 1910 AD) in Korea. It was the administrative and military center of the Naepo region for hundreds of years, and was the place where the Anti-Japanese Movement, Donghak Peasant Movement, Eulmi and Eulsa Independence Movement took place. It is a cultural heritage with great historical research and conservation value in that it retains the appearance of the Joseon Dynasty fortress and government office. The Joyangmun is the east gate and the most important main gate of Hongjueupseong Walled Town. It served as the starting point for a central road that ran through the fortress and a network of roads leading to other area.

Most stone cultural heritage is damaged by various factors after construction, and its original historical authenticity is gradually lost. This walled town also continued to suffer various damages after construction, and some of its walls even collapsed. Of the total length in the fortress of about 1,772m, the remaining wall is only about 800m. In 2016, a detailed diagnosis was conducted on the fortress walls of Hongjueupseong and Joyangmun Gate. As a result, both structural changes in the wall and ground subsidence were found to be serious.

This walled town has always been a risk to stability, and in 2023, the walls collapsed due to heavy rain. The Joyangmun Gate is also structurally unstable, and the physical properties of the stone block foundation are weak. Thus, it is highly likely that it will be replaced with a new stone when the conservation and restoration project is carried out in the future. The restoration stone must be identical rock from the same source as the original rock. This respects the original form of cultural heritage and enhances the authenticity of the restored stones.

As a result of investigations the rock types and occupancy rates of the Joyangmun Gate, light gray biotite granite (57.05%) was found to be the most used stone. Pinkish biotite granite accounts for 42.62% and is divided into original stone (2.85%) and restored stone (39.77%). Although the three rock types are slightly different, whole rock magnetic susceptibility, petrological, mineralogical and geochemical analyzes indicate that they have the same origin.

The mountainous area surrounding the Hongjueupseong Walled Town is mostly composed of granite. It is believed that stones were also procured from nearby areas in earlier times. Pink feldspar granite collected from the nearby Suamsan and Yongbongsan Mountain area show magnetic susceptibility and geochemical properties similar to the granites that make up the stone

block foundation of the Joyangmun Gate. In the future, when establishing a conservation and restoration scheme for Joyangmun Gate in Hongjueupseong Walled Town, restoration stones will need to be procured from the relevant area.

Cultural ecosystem services as a good presentation of geodiversity in the geopark– A case study in Taitung Geopark, southeast Taiwan

Chuanyao CHI[1]*, Genesis Geological Consultant Ltd. (cychi.geo@gmail.com)

Abstract

Geoparks are promoted through bottom-up approach. Many studies point out it is difficult to promote the geodiversity of a geopark to the public only by the scientific point of view. Thus we need transform the scientific knowledge to what local people are concerned. Recent years many researches used the Ecosystem Services concept to demonstrate the importance and benefits of geodiversity. The cultural services-- one of the Ecosystem Services, which contains value placed by society on some aspect of the physical environment by reason of its social or community significance are highly related to the local people and sense of place. They could be good examples for explaining the geodiversity in the geopark.

Our study focus on the Taitung Geopark located in southeast Taiwan. It is located between Beinan River and East Coast, and is the south-tip of Coastal Range. The geological setting is in the suture zone of Eurasia plate and Philippine sea plate. The bedrock belongs to Lichi mélange which is a tectonic mélange with mudstone matrix and contains exotic rocks of different origins. This study finds out that the long history of man-land relation creates different kinds of cultural services of geodiversity. There are abundant cases which can reveal the characteristics of geological environment such as place names of indigenous people, folklores, spectacular landscapes, historical photos. All of this are good examples for showing the local culture which is based on the geodiversity, and we can furtherly use these cases to explain how geological environment is related to our life. It could increase the local identity and the understanding of concept of geopark.

Integrated geological and geophysical monitoring of the Udo beach sediments (Natural Monument) for geoheritage conservation

WOOSEOK YOON[1]*, Jeju National University (geoyoonws@jejunu.ac.kr)
SEOK-HOON YOON[2], Jeju National University
JAE-HONG MOON[3], Jeju National University
SEONG HUN BYUN[4], Jeju Special Self-Governing Province
KYUNG SIK WOO[5], Kangwon National University

Abstract

This study is to introduce the monitoring results of the beach sediments from 2016 to 2023 in Udo Island, which is located about 2.6 km east of Jeju Island, Republic of Korea. The monitoring site has been designated as a Natural Monument since 2004, because the beach sediments is almost entirely of composed of rhodoliths (red algal nodules), which is unique in Korea. The monitoring has been carried out to understand the distribution and volume change of the sediments upon request by local residents. The integrated monitoring consists of coastal geological and geomorphic changes. The monitoring results are based upon the topographic data of terrestrial LiDAR scanning and drone photogrammetry, referring to weather and oceanographic conditions such as wind direction and intensity of waves, currents, and winds, and are also based on offshore bottom topography and the sediment distribution in shallow marine areas. As the intensity of waves and currents fluctuated and influenced obliquely toward the N-S trending coastline, the beach sediments have been continuously reworked and transported southward or northward mainly by longshore currents, which appear to act as a major control mechanism for any topographic changes of the beach. The volume of the beach sediments varies depending on the characteristics of weather or sea conditions during seasonal basis but remains more or less constant in the long run, while the areal distribution tends to decrease. This indicates that the coastline slowly retreats as a result of sediment erosion in the lower foreshore and the subtidal zone although the subaerial part of the beach sediments maintain the overall volume. This appears to result from a combined effect of enhanced beach erosion by natural and artificial factors. Those are gradual sea-level rise and abnormal high waves due to long-term climate change, and the loss of buffer zone toward land due to the construction of seawall, road and buildings. The integrated monitoring of the Udo beach enable to understand natural environmental change due to natural and man-made influences, and this result may help predict the future environmental changes of the study area and establish effective conservation and management plan for the future.

Can computational geoscientists and digital innovation contribute to geoconservation strategies?

Antoine BOUZIAT[1]*, IFP Energies nouvelles (antoine.bouziat@ifpen.fr)
Julien SCHMITZ[2], IFP Energies nouvelles
Vanessa TELES[3], IFP Energies nouvelles
Youri HAMON[4], IFP Energies nouvelles
Damien BONTE[5], IFP Energies nouvelles
Christophe CORNET[6], IFP Energies nouvelles
Aziz BEN AMMAR[7], IFP Energies nouvelles
Abdelaziz SNOUSSI[8], IFP Energies nouvelles
Angélique MONGUILLON[9], Réserve Naturelle Régionale du site géologique de Limay
Valérie CHALUMEAU[10], Réserve Naturelle Régionale des Coteaux du Pont-Barré

Abstract

One key aspect of an effective protection of natural systems is to increase awareness and knowledge about geodiversity and its importance in the preservation of these systems. This ambitious but critical objective needs contributions from the global geoscience community, involving a diversity of profiles. In this context, a possible role for computational geoscientists and digital innovation specialists consists in developing innovative technologies to support communication and education about geoconservation and the monitoring of geoheritage. For example, such technologies can be used by geosite conservation officers as additional means of scientific outreach and to track the condition of key outcrops through years.

At IFP Energies Nouvelles (IFPEN), a French public center for applied research in the fields of energy and the environment, computational geoscientists and digital innovation specialists closely collaborate with nature reserves in innovation projects. These initiatives aim to develop customized tools to enhance the educational activities of these reserves towards school pupils or the general public. On-going projects include multiple technologies and services: virtual models of geosites, augmented reality for outcrop exploration, 3D printed replicas of geological structures, and a mobile application for rock recognition with Artificial Intelligence.

In the case of areas with access restriction due to security or biodiversity protection, such as the nature reserve of the geosite of Limay (France), virtual 3D models based upon photogrammetry principles are informed with additional geolocated data on geology, biodiversity, geological paleoenvironment and fossils. These Digital outcrop models (DOM) can then be displayed on web platforms or in virtual reality environments. Augmented reality is also being developed to provide basic geological information minimizing on-site facilities and displays. Both technologies enable non-specialists to access educational contents along the detailed 3D representations of the outcrop or the outcrop itself . Besides, DOMs built at different years from new photo acquisitions can register changes in the reserve’s geoheritage, to be considered in geoconservation roadmaps.

In the case of open nature reserves where the outcropping rocks are linked with a complex geological history, such as the one of Coteaux du Pont-Barré (France), printed 3D blocks give an overview of the geological context. Besides, the prototype mobile application called RockNet®, which relies on a deep artificial neural network, can be trained to automatically categorize photos of the local rocks. The idea is to facilitate access from the public to lithology recognition and a first level of geological information.

Finally, a dedicated consortium named SELENA will be launched soon to connect professionals interested in geodiversity and digital technologies. This should foster the sharing of ideas, experience and good practices, and ensure that the contribution from computational geoscientists and digitalization specialists are as relevant as possible to address concrete geoconservation needs.

Geoheritage and Geotourism prospect of Ramu Upazila Cox's Bazar District, Bangladesh

Md. Faruk HASAN[1]*, Geological Survey of Bangladesh (faruk.hasan1981@gmail.com)
Mohammad Omer Faruk Khan[2], Geological Survey of Bangladesh

Abstract

Geoheritage and geotourism studies are gaining increasing popularity among geologists, and Bangladeshi researchers are no exception. Inspired by this trend, a comprehensive assessment of the geoheritage and geotourism potential within Ramu Upazila, Cox's Bazar District, Bangladesh has been conducted. Encompassing an area of approximately 391.71 sq. km, the study zone spans from 21°17' to 21°37' north and 92°00' to 92°15' east. Building upon extensive fieldwork conducted by the Geological Survey of Bangladesh for mineral resource exploration, the investigation meticulously analyzes various geological, climatic, and physiographic aspects alongside the region's rocks and minerals. Notably, the focus lies on identifying geological features with promising geoheritage and geotourism potential. Several geological attributes contribute to the geoheritage potential of Ramu Upazila, including its hilly terrain, diverse and colorful rock formations, and stunning sandy beaches. The hilly landscape itself boasts an abundance of features with significant touristic value, such as numerous streams, valleys, hillocks, gorges, rapids, rock exposures, and cliffs. These potential sites offer immense possibilities for geotourism development; marine drive flanked by a vertical cliff on one side and the boundless sea on the other, hilly stream cascading through a narrow gorge, thrilling rough track winding through the hilltops, rocky hilltop commanding panoramic views of the ocean, tranquil path traversing a forested stream, scenic hilly road carved through rock cuts exposing the contact between the Tipam and Girujan Clay formations, captivating trail traversing the entire geological sequence from Dupi Tila to Bhuban and charming cliff sculpted by a gurgling hilly stream. However, it is crucial to acknowledge that implementing appropriate conservation measures is paramount for ensuring the long-term sustainability of the region's geo-environmental conditions. By striking a harmonious balance between responsible tourism and meticulous preservation, Ramu Upazila can blossom into a thriving geotourism destination while safeguarding its invaluable geological heritage for future generations.

Preserving Belitong Island UNESCO Global Geopark Unique Heritage: Geomorphosites and Anthropogenic Landforms

Santi Dwi Dwi PRATIWI[1]*, Faculty of Geological Engineering, Universitas Padjadjaran, Indonesia.Jl. Raya Bandung Sumedang Km. 21, Jatinangor, Sumedang 45363, West Java, Indonesia (santi.dwi.pratiwi@unpad.ac.id)
Dina Oktavia[2], Graduate School, Universitas Padjadjaran - INDONESIA. Jl. Dipatiukur 35, Bandung, West Java, Bandung 40132, West Java, Indonesia

Abstract

Geomorphosites represent one category among various geosites, carrying both scientific and additional values (such as cultural, historical, religious, ecological, social/economic, and aesthetic) that contribute to the development of geoparks. The research on geomorphosites and geoheritage within the Belitong Island UNESCO Global Geopark has been limited since its establishment in 2017, encompassing 17 designated geosites. Located around 400 km north of Jakarta, the capital of Indonesia, Belitong Island is encircled by the Karimata Strait to the north, the Java region to the east and south, and the Gaspar Strait to the west.The geological composition of Belitong Island encompasses unique tektites created through meteorite impacts and within the Geopark reside more than 300,000 people representing diverse cultures, including the Sawang Tribe. The area is also home to exclusive plant and animal species, such as Cephalopachus bancanus saltator. Notably, the Kerangas Forest, characterized by stunted vegetation, stands out as a unique natural feature in the geopark, offering various benefits, including medicinal plants for the local community. Our investigation focused on evaluating the geotourism potential in East Belitung using a geomorphosite assessment that considers Scientific and Intrinsic Value (ScIV), Educational Value (EdV), Economical Value (EcV), Conservation Value (CV), Added Value (AV), and a geomorphological description at three key geosites (Samak Hill, Burungmandi, and Open Pit Kelapa Kampit). The study aims to ascertain the scientific value of these geosites and present their potential for geomorphotourism and geoconservation in the Belitong Island geopark. Results revealed that East Belitung comprises four geomorphological units: moderately steep hills (12% of the total area), rolling hills (63%), undulating plains (8%), and flat plains (17%). Samak Hill, featuring a Carbonaceous to Permian rock sequence, represents a plateau with sandstone, claystone, and shale lithology. The Bukit Samak Geosite, preserving Dutch Heritage Housing from the Kelapa Kampit Formation, holds historical significance dating back to Dutch colonial trade and reflects cultural integration between the Chinese communities and the local Belitung Malay population. The Granodiorite Burungmandi, characterized by steep hill geomorphology, possesses anthropogenic value, notably the Kwan Im Temple (1774), symbolizing the Chinese diaspora and China's initial expansion in Belitung. The Open Pit Kelapa Kampit geosite, situated in rolling hillside topography with red sandstones, quartzite, and metamorphosed lithology, offers high scientific value, showcasing anthropogenic landscapes and recording geological data dating back 350 million years ago (Paleozoic). Our findings suggest that these areas harbor valuable resources related to geomorphologic heritage, making them suitable for geoconservation and

geoeducation development within the Belitong Island geopark. Furthermore, a comprehensive review of anthropogenic landforms and geomorphosites strongly advocates for the preservation of Belitong Island geopark, emphasizing its unique status worldwide. Therefore, the establishment of a geopark is encouraged as a conservation effort to safeguard natural resources, habitats, and the well-being of both the environment and local inhabitants in Belitong.

Sustainable use of materials from an abandoned quarry in a Unesco Global Geopark in Spain. A proposal.

Lola PEREIRA[1]*, University of Salamanca (mdp@usal.es)
Andrea Bloise[2], University of Calabria

Abstract

Serpentinite is a very valued stone for the information that can be retrieved from it about the petrogenesis and the evolution of the ultramafic rocks, but also for the use as construction material. However, extraction of this rock may be a challenge for the construction industry sector. The many heterogeneities that the serpentinite may show up during its extraction (e.g., carbonation, talc lenses, fractures, shearing, brecciation…) can convert the commercialization of the rock in a defy for the companies. Cabo Ortegal ultramafic complex, in Spain, is very well known scientifically for the splendid outcrops that have been studied from the geochemistry, mineralogy, physical and mechanical behaviour, but also for its relationship with architectonic and cultural heritage of the area. In fact, all this information was the main support for the recognition of Cabo Ortegal as a UNESCO Global Geopark in 2023. Serpentinites were commercialised as building stone during last century. They had been used to build the architectonic heritage of many villages around. The carbonation and conversion into talcose rocks made serpentinite an easily carving stone to build façades and monuments. These same characteristics made the stone very fragile in terms of weathering, and quarries were abandoned in the 21st century, leaving behind large blocks that could not be commercialised for construction. Now that Cabo Ortegal has been designated as UNESCO Global Geopark it will become an attraction for tourists. We propose to take advantage of the abandoned blocks of serpentinite (and carbonated serpentinite and talcose serpentinite) to be used for local artisanal activities. These activities are well known since millennia ago in many places around the world, and many cultures took advantage of the easy carving of the stone to build from small domestic artifacts to figurines representing local activities (e.g., fishing, hunting) and culture (e.g., the serpentine cylinder seal of Shilishu, Mesopotamia; from about 2400 BC) (Calas, 2003), the Inuit serpentinite carvings that are showed in many art museums (Coward Wight, 2003).

It is very important to characterize these rocks to avoid that they can trigger any health issues to artists or sculptors or any other workers dealing with the stone. For this reason, the authors have studied different samples representing the lithologies of interest to assess that the content of hazardous minerals (e.g., asbestos) and/or potential toxic elements, if detected, are within the limits permitted by Spanish law. For this purpose, we have collected seven samples and cross-referenced the data obtained from different analytical techniques (i.e., Petrography, XRPD, SEM–TEM–EDS, DTG–DSC, ICP-MS) to obtain a detailed characterization.

Research funded by: Grant PID2021-123948OB-I00 by the Spanish government.

Paleontological Zoning: a new paradigm for geoconservation in the Uberaba Geopark, Brazil

Thiago da Silva MARINHO[1]*, Universidade Federal do Triângulo Mineiro (thiago.marinho@uftm.edu.br)
Maria Isabel Arcanjo Dias[2], Prefeitura Municipal de Belo Horizonte
Josenilson Bernardo da Silva[3], Universidade Federal do Triângulo Mineiro
Luca dos Santos Lopes[4], Universidade Federal do Triângulo Mineiro
João Vitor Ferreira dos Santos[5], Universidade Federal do Triângulo Mineiro
Januário Chirieleison Fernandes[6], Universidade Federal do Triângulo Mineiro
Ricardo Vicente Ferreira[7], Universidade Federal do Triângulo Mineiro
Luiz Carlos Borges Ribeiro[8], Universidade Federal do Triângulo Mineiro
Fabricio Anibal Corradini[9], Universidade Federal do Triângulo Mineiro
Carlos Alberto Valera[10], Ministério Público de Minas Gerais

Abstract

Fossil occurrences in the municipality of Uberaba, Minas Gerais, Brazil, are internationally recognized. Dozens of taxa of vertebrates, invertebrates, plants, and trace fossils have already been identified in rocks from the Upper Cretaceous Uberaba (Campanian) and Serra da Galga (Maastrichtian) formations, both exclusive to the region. The fossil content of the Serra da Galga Formation stands out in diversity and the number of collected fossils, while understanding of the Uberaba Formation has improved in recent years. Part of this difference can be attributed to the distribution of these two units: the Serra da Galga Formation outcrops in the rural zone of the municipality, while the Uberaba Formation occurs mainly beneath the city of Uberaba, accessed primarily through construction works within the urban perimeter. Even in this scenario, occurrences of Megaraptora and Titanosauria dinosaurs, theropod dinosaur eggs, and at least three different groups of Crocodyliformes, including the only identified species, *Eptalofosuchus viridi*, are currently recognized in the Uberaba Formation. The establishment of 'Geopark Uberaba: Land of Giants' has led to the implementation of geoconservation and heritage education measures in the municipality. Since then, there has been a significant improvement in the relationship between entrepreneurs and paleontologists, reflected in the rescue and description of new fossil occurrences. The Paleontological Zoning of the Municipality of Uberaba aims to map the urban perimeter and expansion areas into three zones based on paleontological potential. These zones will determine the procedures for works involving rock interference in the territory. This initiative, combined with legislation such as 'Portaria Conjunta 003/2015' by the municipal prefecture of Uberaba and the National Mining Agency, reinforces almost eight decades of efforts in the territory's geoconservation. Through Paleontological Zoning, combined with heritage education measures promoted by Uberaba Geopark, a new paradigm for geoconservation in the municipality of Uberaba is expected to emerge, ensuring sustainable urban development.

The Geological Setting of Tanzania with Possibilities of Hosting Potential Geoparks Worldwide

John Desderius Kalimenze[1]*, Member (jokakally@yahoo.com)

Abstract

The geological setting of Tanzania is favorable to host diverse mineral deposits of economic significance and yet still favorable for providing a beautiful scenario for holistic features of geopark possibilities such as landscapes, waterfalls, mountains, lakes, meteorites, minerals, and calderas. In 2012, being the custodian of the national geoscientific data and information, the Geological Survey of Tanzania started initiatives for promoting geo-tourism in Tanzania by identifying a few potential sites of tourist attractions related to geology. The first flyer included sites such as Olduvai Gorge, Kilimanjaro Mt, The East African Rift Valley, Ngorongoro Crater, Oldoinyo Lengai Mt, Calderas (Embakai, Chala, and Ngozi), Mautia Hill, Waterfalls, Meteorites, Hot springs, Eclogites, Rock paintings and some mine sites (Mwadui, Mirerani) just to mention a few. Since the beginning of the new concept of geopark, geo-heritage, and geosites there were serious procedures taken to develop aspiring geoparks and eventually global geopark. In 2018, Tanzania managed to get the first UNESCO global geopark named the Ngorongoro Lengai UNESCO Global Geopark (NLUGG) of which some of the sites mentioned in the first flyer for promoting geo-tourism formed part of the NLUGG territory.

Recently, Tanzania is also running for the second geopark named the aspiring Arusha Meru geopark which covers most parts of Mount Meru, Arusha National Park, Waterfalls, and all historical-cultural heritage within the territory. Geopark phenomena are all about geo-tourism promotion and geo-heritage conservation and protection. While considering geopark should take into account the whole geographical setting of the region and shall not merely include sites of geological implication alone, the potential site should also meet the concept of protection, education, and sustainable development for scientific popularization and socio-economic development. This understanding of the geopark concept together with a favorable geological environment drives the Geological Survey of Tanzania to start an inventory program to identify all potential sites of geo-heritage significance for geo-tourism promotion as well as geo-heritage preservation, conservation, and protection.

Importance of Rock hive/Tafoni structure as geotourism point of view at Harihareshwar beach in Raigad district of Maharashtra, India

SHARAD GAJANANRAO PORATE[1]*, GEOLOGICAL SURVEY OF INDIA
(sharad.porate@gsi.gov.in)
GAURI VAIBHAO MOTGHARE[2], GEOLOGICAL SURVEY OF INDIA
JAYA RASHTRAPAL CHAVHAN[3], GEOLOGICAL SURVEY OF INDIA

Abstract

Rock hive/Tafoni are the weathering feature of many lithologies of the world where they are very common in sandstone, limestone and granites. Tafoni are ellipsoidal, pan- to bowl-shaped, natural rock cavities. These cavernous weathering features include tiny pits, softball-sized cavities, truck-sized caves, and nested and cellular honeycomb forms. Tafoni typically develop on inclined or vertical surfaces and occur in groups. These exquisite and fascinating cavernous weathering landforms are present on the surfaces of many different kinds of rocks located in a multitude of geographic regions around the world.

In the west coast of India, near Harihareshwar, this tafoni is formed in basalt which is very rare to find. The tafoni is generally formed due to salt weathering though many factors are responsible for the development of tafoni such as differential weathering, porosity and permeability of rocks and climatic factors. When waters get absorbed by the rock in the cracks, cleavages, fractures etc. it precipitates and crystals of salt develops. When this crystallized salt creates pressure on surrounding rocks, slowly by slowly the rock gets weathered and tafoni are formed.

At Harihareshwar coast, compound pahoehoe lava exposed with number of small lava lobes. Small lava lobes or units combinedly formed the massive compound pahoehoe flow which can be considered as single lava episode. Also, the small lava lobes or units are having different cooling rates and amygdular nature. As the rock is not homogeneous in nature, the salt weathering of lava lobes also supports the tafoni formation by removing surrounding amygdular top and base where the middle portion of lobe stand behind firmly. The chilled margin remains at its place due to its hardness. A point reaches where this middle portion of the lava lobe lose support from surrounding rock due to continuous weathering processes, thus it gets dislodged and a pit, hole or small tafoni are formed. These are very important and interesting feature for the study of geology and geomorphology of the coastal area.

The tafoni structure in Harihareshwar beach is about 400-500m in length and about 5-7m in width. Though tafoni structure is common along the area of west coast of Raigad district of Maharashtra, what makes this place unique is because of the different sizes of the rock hives. The size of the rock hives varies from 0.1cm to about 0.5m in diameter. The compound pahoehoe flow in the area is also intruded by the basaltic dyke which is about 5-6m in width and continues into the westwards in the sea. The dyke may also trigger this weathering by creating extension in the compound pahoehoe flow.

The place can be visit in view of Geotourism. One has to travel from Mumbai or Pune to

Shrivardhan which are the nearest places for airports. From Shrivardhan, Harihareshwar is about 17Km towards southwest direction. One shiv temple is also famous in the pilgrims. People used to visit this place and circumambulate the tafoni structure.

Alper BABA[7], Department of International Water Resources, İzmir Institute of Technology, Gülbahçe Urla, Izmir, Türkiye

Abstract

Providing significant information about the geological evolution of the earth, geological heritage, when promoted, can have a considerable impact on the various dynamics of rural areas. In this brief framework, this study aims to explore and promote the geological heritage of the Karaburun Peninsula through suggesting geo-routes and geo-parks. A lesser-known by the public, yet significant geological feature of the peninsula is that it is one of the few places in Anatolia where geological units up to the Carboniferous period can be seen as a continuous stack. In addition to these features, mineral deposits, conductive fossils, important faults and water resources formed by regional tectonic movements constitute the geological heritage of Karaburun. Thus, the groundwater and soil properties together with geological formations of the Karaburun peninsula are examined by researchers from various disciplines as part of the study. In relation to these geological richness, now abandoned mine formations, settlements, and buildings are identified, documented and evaluated. Scattered throughout the peninsula these important nodes including marble quarries, manganese galleries, and clay pits are linked by a suggested geo-route. These nodes have different characteristics and were processed in historical periods for use in ancient settlements in Anatolia and abroad, such as Ephesus and Vatican. All these geological formations have also played an important role in trade and port activities between still inhabited Ildır (Erythrai) and Urla (Klazomenai) throughout history, especially in terms of mining. These activities continued during the Ottoman Empire and the early years of the modern Republic of Türkiye. In line with the findings, the proposed geo-route assesses the impact of geological heritage on today's rural life processes and safeguards the sustainable transmission of this heritage to future generations. As a result, the study contributes to the existing literature on the geological, hydrogeological, ecological, and mining features of the Karaburun Peninsula, provides new

resources for cultural, educational, and research-based activities, and assesses the region's potential for inclusion in UNESCO Global Geopark status.

Exploring Hydrogeochemical Characteristics and Impact on Geoheritage Monuments in Odisha: A GIS and Statistical Approach

ROSALIN DAS[1]*, Fakir Mohan University (rosalindas.geology@gmail.com)
MADHUMITA DAS[2], UTKAL UNIVERSITY, BHUBANESWAR
Shreerup Goswami[3], Utkal University, Bhubaneswar

Abstract

Many world heritage sites boast not only cultural but also significant geological importance. These monuments, crafted from distinctive rocks, are vulnerable to environmental factors affecting their stability. This research investigates the hydrogeochemical characteristics of such sites, aiming to assess their impact on monument foundations and longevity. Employing GIS and statistical methodologies, the study delineates groundwater hydrochemical properties, particularly focusing on monuments constructed from Athgarh sandstones prevalent in Odisha's major heritage sites.

Prominent among these monuments is the Konark Sun Temple, a UNESCO World Heritage Site, renowned for its cultural, architectural, and geological significance. Other notable landmarks in Odisha's Upper Gondwana Athgarh formation area include the Lingaraj Temple, Rajarani Temple, Mukteswar Temple, and Udayagiri and Khandagiri caves. These ancient rock-cut caves near Bhubaneswar house numerous inscriptions, sculptures, and reliefs, some fashioned from sandstone, underscoring the region's rich cultural and architectural legacy.

By integrating Geographic Information System (GIS) technology with statistical analyses, this study thoroughly characterizes the hydrogeochemical properties of the Upper Gondwana Athgarh Basin, covering approximately 800 sq. km. Geographically situated between Latitude 20° 45’N to 20°N and Longitude 85°30’E to 86°E, the area features diverse freshwater fluviatile and lacustrine sediments, reflecting climatic variations from arid to humid tropical conditions, with conglomerate, arenite, and extensive fireclay deposits predominating. It represents the northernmost extension of the east-coast Upper Gondwana sediment.

Although portions of the Athgarh sandstone remain concealed beneath laterite and alluvium, subsurface occurrences are evident, especially in offshore regions along the Bay of Bengal. Despite its geological and heritage significance, the Athgarh Basin confronts mounting pressures from human activities and environmental changes. Hence, understanding the hydrogeochemical composition of its water resources is vital for sustainable water management and preserving its geological heritage.

This study conducts a comprehensive evaluation of groundwater quality in the Athgarh basin, employing the Water Quality Index (WQI) and statistical correlations. Analysis of water samples and assessment of major ions and trace elements unveil spatial patterns and potential contamination sources through GIS-generated spatial distribution maps. Statistical techniques such as cluster analysis and correlation analysis identify underlying patterns and relationships among hydrogeochemical variables, complemented by evaluations using Piper's trilinear diagram and Chadha's diagram.

By correlating water quality parameters with the degradation of geological monuments, the study underscores the vulnerability of these sites to changes in water quality. Ultimately, the integration of GIS technology with statistical analyses offers valuable insights into the hydrogeochemical characteristics of the Upper Gondwana Athgarh Basin, informing strategies for preserving Odisha's geological heritage.

Wugongshan Geopark: A natural museum to study the granite dome and associated geological landforms

QINGCHENG HE[1]*, Chinese Academy of Geological Sciences (479400160@qq.com)
FANG REN[2], Chinese Academy of Geological Sciences
CHUNLIN LI[3], Chinese Academy of Geological Sciences
MEIYING HAO[4], Chinese Academy of Geological Sciences

Abstract

The Wugongshan Geopark covers an area of 1470.82 km2 and is 150.0–1918.3 m above sea level. It is characterized by a typical granite dome, and its geological heritages associated with the development of granite dome include the granite weathering crust alpine meadow, granite peak forest, Z-shaped steep waterfall group, and annular "hot spring chain". Meanwhile, the stratigraphic sections, diversified granites, structural deformation, granite tors, tungsten ore depositstungsten ore pit sitekarst caves, etc. present in the Wugongshan Geopark make it as a natural museum to study the granite dome and associated geological landforms.

The formation and distribution of geological heritages and geomorphic landscapes in Wugongshan Geopark are controlled by the tectonic evolution of the granite dome. According to the difference in elevation and tectonic position, the landscapes and heritages can be divided into the Alpine meadow of gneissic granite weathering crust on the top of the dome (> 1600 m), granite peak forest on the core of the dome (1600–1200 m), Z-shaped steep waterfall group at the core of the dome (1200-500 m), and the "hot spring chain" (< 500 m) at the detachment fault zones. The granite dome and the geological heritages constitute an organic whole, which is unique among the UNESCO Global Geoparks.

During the late Mesozoic, the Wugongshan granite dome formed in a large-scale extension setting. This extension event resulted in varying degrees of ductile and brittle deformation and metamorphism of the dome, and caused the formation of penetrating subhorizontal foliation in the Silurian granite. Because of the Protection of the subhorizontal foliation, the weathering rate is relatively slow, merely forming a completely weathering layer with a thickness of 20–40 cm on the surface. In addition, due to the influence of climatic factors such as cold climate and long frost periods on the summit, the top of the Wugongshan granite dome is not suitable for the growth of tall trees, only suitable for the growth of herbs.

The granite peak forest landform on the dome core developed in late Jurassic granite. The granite is characterized by a hard rock texture (high quartz content), which retained an intact primary structure. During the uplift of the Wugongshan granite dome, the domal core formed the near-vertical joints and a certain number of subhorizontal joints due to the depressurization caused by the denudation of overlying strata. The surface water flows from top to bottom along the joints. Visually, a unique Z-shaped waterfall group is formed. With the uplift of the magmatic core and the decrease in temperature and pressure, the deformation of the detachment fault zone gradually changed from ductile to brittle, forming a huge normal fault system. Surface water and

atmospheric precipitation enter the underground along fractures in the domal core, being heated by deep heat sources, return to the surface along the normal fault system at relatively low altitudes to form hot springs. 16 hot springs found and constituted a huge annular "hot spring chain" on the plane, which have not been reported in the world so far.

Study on Features and the Formation Mechanism of the Geomorphic Landscape of Slit-typed Danxia Gorge in the Loess Plateau in China

Hua DING[1]*, Chang'an University (dinghua@chd.edu.cn)

Abstract

The Danxia landform landscape belt in the Loess Plateau region of Northern Shaanxi was discovered in 2015, and is the largest known Danxia landform landscape belt in China with a total area of over 3700km2 and a "S" - shaped strip distribution. Among them, the narrow slit-typed Danxia landform of the Loess Plateau (represented by in Ganquan County of Yan'an City), is the rare geological and geomorphic wonder in China and abroad. The Yucha Canyon Groups with both world scientific research value and tourism value are also known as the "Antelope Valley of China" and the "Loess Rift Wonder". The landscape type is dominated by wave valley of negative topography, and supplemented by the Danxia cliff, thin strip of sky, pothole, and pictographic stones. In landscape category, the canyons of Danxia landscape are the kind of “loess-covered” Danxia landscape with international comparative research value. The landscape aesthetics characteristics of canyons present “narrow, multi curved, vertically high and steep”, as well as “thick, homogeneous, rhythmic and colorful”. However, due to the late discovery of Danxia landform in the area, basic research on landscape characteristics and formation mechanisms is very weak and there are very few systematic achievements.

With the support and sponsor of the National Natural Science Foundation of China, the research team of Chang'an University systematically studied the rock structure, joint characteristics, geologic age and landform evolution stages according to the research theme of "patter-erosion-evolution-mechanism". We proposed the formation mechanism of narrow slit-typed Danxia landform landscape which included the mechanisms of fissure formation, rocks’ differential erosion and their dominant forces, and landscape evolution stages. In the view of the geological structure unit, this area belongs to the Yishan slope of Ordos Basin where the fault structures are not well-developed, but vertical joints are widely developed. The characteristic of "joints controlling valley" is obvious. The dominant joints formed by the Yanshan Tectonic Movement and the Himalayan Tectonic Movement (especially the north-east oriented joints) control the direction of the narrow slit-typed Danxia valley and provide channels for external forces such as flowing water and freeze-thaw cycles. The spacing between joints plays the key role in the uneven distribution and curvature of Danxia landscape. Through rock mechanics experiments of rock infiltration, acid wet-dry cycles and freeze-thaw cycles, landscape formation is mainly influenced by acid erosion and freeze-thaw processes. The landscapes are in the young or middle-aged stage of Danxia landform evolution in general.

Karstological planning and construction control of new motorways and railway line crossing Classical Karst (Slovenia)

Martin Knez[1]*, ZRC SAZU Karst Research Institute (knez@zrc-sazu.si)
Mitja Prelovšek[2], ZRC SAZU Karst Research Institute
Tadej Slabe[3], ZRC SAZU Karst Research Institute

Abstract

Slovenia lies at a crossroad of major traffic routes connecting Central Europe with the Mediterranean Area, Pannonian Basin, and Alps, lies in the direction of two major European traffic corridors, the X. and the V. Pan-European corridor. Almost half of Slovenia consists of karst and more than half of the country's water supply comes from karst aquifer. Slovenia is the country of the Classical Karst, which gave its name to a peculiar landscape on carbonate rocks in numerous languages, and is, in fact, cradle of karstology. The delicate karst landform requires thorough knowledge of its characteristics, and concerted preservation efforts for it is an integral part of Slovenia's natural and cultural heritage.

The karstologists of the Karst Research Institute are actively involved into planning and construction of the Slovene motorways over karst. More than 350 karst caves were discovered during the building of 60 km of new motorways. Two of the most important caves are accessible to researchers from the roadside by concrete tubes. The largest, almost 500 m long cave system, was discovered during the construction of one of the tunnels, and is almost entirely preserved. The protection of this cave may serve as a good example how to preserve natural heritage. Caves, discovered during the building of the motorway assisted at gaining a new knowledge about development and karstification of this part of karst.

When siting the railway route, it was discovered that it crossed one of the larger known water caves at a contact between the carbonates and flysch, and that in its vicinity the groundwater table was occasionally higher than the railway line. That is why it was moved this section of the route away from the area with known cave passages and envisaged the design of a non-draining tunnel with potential bypass water tubes. By studying the karst terrain and taking into account all the karstological data known so far, it was predicted the number of caves and the largest diameters of cave passages for individual sections of the route of the railway line. By conducting several tracer tests of groundwater, it was greatly contributed to the knowledge of the water flow in this part of the Classical Karst and the cross-border aquifer between Slovenia and Italy, and demonstrated the importance of protecting the karst aquifer.

STATE AND DEVELOPMENT OF GEOPARKS IN THE REPUBLIC OF UZBEKISTAN

Jurabek Nafiddinovich AZIMOV[1]*, The Ministry of Mining Industry and Geology
(zarafshan3335@gmail.com)

Abstract

Nowadays, the territory of the Republic of Uzbekistan has an advantage for considerable geotourism potential, in particular rich history and geological heritage sites.

From the standpoint of modern geology, the territory of the Republic of Uzbekistan represents an area that was formed over more than 1,000,000,000 years as a result of the manifestations of all known geological processes and environments, indicating the complex processes of the development of our planet.

In recent years, geologists have been doing large-scale research on the geological heritage. Analysis of geodynamic, geomorphological, petrographic, mineralogical, and structural factors allows us to identify interesting geological objects and landscape regions. Shortly, based on these geological objects, there is a possibility to organize complex geoparks and geotours of national and international significance.

In total, about 2,000 paleontological objects have been studied and inventoried. Based on the study results, more than 150 locations with remains of ancient fauna and flora were selected, which, in terms of their scientific, educational, and other features, were recognized as extraordinary and recommended for assignment to the status of state geological natural monuments. In the interests of future generations A list of objects was also compiled that, for one reason or another (usually anthropogenic), they need urgent protection and conservation.

The Ministry of Ming Industry and Geology of the Republic of Uzbekistan has the necessary information for the scientific substantiation and organization of geoparks on the territory of the Republic of Uzbekistan, as well as the ability to identify new geological formations to expand the geotourism base and, within its competence, is ready to participate in the implementation of sustainable development and responsible tourism in the Republic of Uzbekistan.

Geoheritages of Georgia (The Caucasus) and potential for aspiring UNESCO Geoparks

Avtandil OKROSTSVARIDZE[1]*, Doctor of Geological Sciences (okrostsvari@gmail.com)
Irakli Gamkrelidze[2], Georgian National Academy of Sciences, Georgia
Daniel Tormey[3], Catalyst Environmental Solutions, Santa Monica, USA
Giorgi Boichenko[4], Institute of Earth Sciences, Ilia State University., Georgia.
Salome Gogoladze[5], Institute of Earth Sciences, Ilia State University., Georgia.
Rabi Gabrielashvili[6], Institute of Earth Sciences, Ilia State University., Georgia.

Abstract

The Caucasus orogeny is an active Alpine collisional zone, between Eurasian and Arabian lithospheric plates and extends about 1200 km from the Caspian to the Black Sea. It consists of three main structural units: The Greater and the Lesser Caucasian fold-and-thrust belts and Inner Transcaucasian microplate. In the IUCN Volcanic Thematic Report identified the Caucasus region in a continental collision zone as underrepresented on the World Heritage Site List [1].

The territory of Georgia is located in the central part of the Caucasus and covers the southern part of the Greater Caucasus, the Transcaucasus and northern part of the Lesser Caucasus. Because of this, the small territory of Georgia (69700 km2) hosts a wide variety of geological formations, representing a large time frame, from Precambrian to Quaternary. Due to its geological diversity, tectonic significance and excellent exposures, researchers often call it a "natural geological laboratory" for understanding collisional tectonics.

More than 300 natural monuments have been identified in Georgia and are the subject of active scientific investigation. Many of them represent globally significant geological heritage, preserving the history of Earth's important geological processes. Among these monuments we can highlight: A magnificent Shkhara Late Paleozoic granitoid massif, 5203 m e.s.l.; A Middle Jurassic remarkable granodiorite pluton of the Ushba, 4700 m e.s.l.; Middle Jurassic diabase-pillow lava beautiful Chiukhi massif, 3864 m e.s.l.; "the bride" of the Greater Caucasus and mythical home to Prometheus, the glacier-covered Pliocene volcano of Kazbegi (5054 m e.s.l.); tectonic wedge of Darial Late Paleozoic granitoid massif; hydrothermally altered rocks of Storey Canyon; dinosaur footprints of Sataplia, with two types of footprints (of an herbivore and a predator); Kumistavi Grand Cave in Upper Cretaceous limestone; Quaternary mud volcanoes of Kilakupra and Takhti-Tepa; reliks of Upper Miocene Niala Megacaldera and its an ignimbrite flow (35 km length); Goderdzi fossilized forest in Upper Miocene volcanic tuffs; Quaternary continental basaltic flows of Tsalka and Samshvilde and their canyons; Dmanisi hominids site and others [2].

Most of these sites of geoheritage harmoniously coexist with cultural heritage objects as well. Vardzia rock-cut city in southern Georgia is a good example of that, which is a cliff-dwelling complex carved in the walls of upper Miocene ignimbrites. We believe that there is excellent potential for international recognition of the significant geoheritage of Georgia with an emphasis on aspiring UNESCO Global Geoparks. On these many sites Vardzia and its surrounding area

may be the most promising regions for establishing such a Geopark.

xiaoxu Zhou[5], Guanghua Institute of Gemology and Mineral Resources (GIGM), Jiangxi University of Applied Science, Nanchang,301000, China;

Abstract

This paper embarks on an overview of the historical development of natural history museums, tracing the origins of these museums with an emphasis on mineralogical collections back to the mid-16th century. Initially, these institutions primarily functioned as private collections, offering limited access to the general public. A pivotal moment occurred with the inauguration of the Paris Natural History Museum in 1635, representing one of the earliest instances of museums opening their doors to the broader public. This movement gained momentum with the establishment of further museums in England and Germany between 1680s and 1760s. Over the subsequent centuries, the spread of mineral and paleontological museums across Europe and North America has resulted in their ubiquitous presence worldwide. Currently, most of these institutions are established by scientific bodies, the mining industry, or associated entities, with a focus on facilitating scientific research and presenting professional exhibitions. Nonetheless, the academic and technical emphasis of these exhibits, characterized by extensive scientific terminology and intricate narratives, often fails to resonate with a wider audience, offering limited appeal to non-specialists and students. Consequently, many museums today face challenges in attracting visitors due to their overly scholarly content, cluttered and aesthetically unpleasing displays, outdated exhibition techniques, and a scarcity of interactive and engaging exhibit technologies. These issues significantly impede the museums' potential for sustainable development and commercial viability.

In an innovative response to these challenges, the Dr. Guanghua Liu Museum of Natural Heritage in Nanchang, China, was established, transcending traditional educational and research roles to integrate elements of art and tourism. Situated within the Jiangxi University of Science and Technology, the museum spans 6,000 square meters and is divided into three primary exhibition halls, showcasing over two thousand specimens collected globally by the geologist Dr. Guanghua Liu. The Gem & Mineral Hall, the centerpiece of the museum, covers approximately 4,000 square meters and features around 1,500 specimens.

This paper focuses on the Gem & Mineral Hall, detailing the advanced design and presentation tactics utilized to accomplish its wide-ranging goals. The museum adopts a contemporary and artistic design ethos, striving to create an atmosphere that is both elevated and accessible. Exhibit selection emphasizes both aesthetic beauty and educational value, including rare and commercially valuable specimens, ensuring the exhibition is captivating and informative. The use of cutting-edge display technologies and interactive installations significantly enhances the visual appeal and educational effectiveness of the exhibit. Named "Earth’s Treasure," the Gem & Mineral Hall is organized into eleven thematic zones, each dedicated to different facets of mineralogy and gemology.

Since its opening on May 20th, 2021, the Guanghua Liu Museum of Natural Heritage has attracted significant attention, drawing a large number of visitors and earning acclaim for the quality and educational value of its exhibits. This paper highlights the museum's achievement in integrating education, research, art, and tourism, serving as a benchmark for future developments in museum projects.

Zurab Baratashvili[5], Ilia State University

Abstract

The Greater Caucasus fold-thrust belt occupies the northern segment of the Caucasus collisional orogen and traces along the Scythian platform an NW-SE direction over 1,100 km between the Black and Caspian Seas. The belt began rapid uplift and exhumation during ~5 Ma ago [1] and it is currently one of the most beautiful mountains of our planet. Two major formations are distinguished in its geological structure: pre-Jurassic crystalline basement and Meso-Cenozoic sedimentary formations. The pre-Jurassic basement in the Paleozoic was an active continental margin, along which Paleo-Tethys oceanic crust was subducted to the north (Variscan orogeny) At the end of the Late Triassic, the oceanic basin of the Southern slope of the Greater Caucasus closed. At the beginning of the Jurassic, the Southern slope crust extending began and a thick series predominantly of shales and sandstones was deposited in this basin. In the Middle Jurassic these sedimentary rocks were intruded by gabbro-diabase dykes, of mantle generation [2]. These dykes form a magmatic belt along the entire southern slope of the Greater Caucasus. Their thickness ranges from a few meters to tens of meters, and extends from tens of meters to hundreds of meters. However, there is an exception: a unique and impressive Chaukhi massif. This beautiful massif is exposed on the Eastern Greater Caucasus, between the villages of Roshka and Juta, in Georgia. It runs for about 18 km in the NW-SE direction and forms two parallel rocky ridges, the slopes of which are covered with snow. The distance between these ridges varies from 800 to 1500 meters.They are separated by a graben-like depression which is filled with glaciers. Both these ridges have several peaks whose heights exceed 3900 meters and are a paradise for mountaineers.

Geologically, Chaukhi massif represents a fragment of the Neotethys mid-oceanic ridge, which is predominantly built by gabbro-sheeted dykes, diabases, diabase porphyries and pillow lavas. In the western part of the southern ridge of this massif 10 gabbro-sheeted dykes are exposed, the thicknesses of which vary from 2.5 m to 40 m. Pillow lavas, with diameters from 30 to 120 cm, are mainly exposed in the eastern part of this massif. This ensemble of rocks is crossed by diabase porphyries. The primary minerals of these rocks are: pyroxene, basic plagioclase and olivine, and the secondary minerals are: chlorite, epidote, zoisite and prehnite. According to the chemical composition, they are basic rocks, in which the SiO2 content ranges within the 46.5-50,3%, Al2O3 - 15.5%-20.5%, MgO - 6.7-8.3%, Na2O - 2.1-2.6%, and KO2 - 0.14-0.22%.

Based on the analysis of Chaukhi massif data, we believe that it represents an impressive

geoheritage of international importance, with geotouristic and educational significance.

Geotourism Sites of the Outer Ukrainian Carpathians

Ihor BUBNIAK (BUBNYAK)[1]*, Lviv Polytechnic National University (ihor.m.bubniak@lpnu.ua)
Andrij Bubniak[2], Lviv Polytechnic National University
Lev Horodyskyj[3], Science Voices, USA; Blue Marble Space Institute of Science, USA; Universidade Estadual de Campinas, Brazil

Abstract

The Outer Ukrainian Carpathians, forming a part of Western Ukraine, are not only a testament to the region's varied topography but also a treasure trove of geological and ecological wonders. This region, bordering nations like Poland, Slovakia, Hungary, and Romania, encompasses several oblasts including Lviv, Ivano-Frankivsk, Zakarpattia, and others. The landscape here transitions beautifully from the northern plains to the majestic Carpathian Mountains in the south, comprising the Eastern Beskids and the Ukrainian Carpathians.

The Carpathian Mountains, a part of the grand Alpine mountain system, are geologically divided into the Outer and Inner Eastern Carpathians. This division brings out a rich tapestry of geological formations, including diverse sedimentary rocks, intriguing volcanic structures, and a wealth of mineral resources. The region's mineral wealth spans from salt to oil, gas, ozokerite, and various ores, making it historically significant for mining activities that date back centuries.

This geographical and geological diversity lends the Ukrainian Carpathians not just their natural beauty and ecological significance but also embeds them deeply into the cultural and historical fabric of the region, influenced by the diverse European cultures over the ages.

Geotourism, an essential aspect of sustainable tourism, plays a pivotal role in this region. It underscores the importance of preserving natural and cultural heritage while promoting responsible tourism. In the Carpathians, geotourism fosters environmental conservation and offers unique educational experiences, blending exploration with learning.

Our presentation delineates the most remarkable geotourism sites within the Outer Ukrainian Carpathians. These sites, numbering 32, are organized into four regional transects. Each site – be it a natural landmark, geological formation, park, protected area, or a unique landscape – has its own story. We delve into the geological features of these sites, discussing their ecological significance and historical or cultural importance.

The Carpathian region is renowned for its diverse ecosystems, home to an array of flora and fauna, making it a haven for biodiversity. The geological formations here offer insights into Earth's history, with rock structures and fossils that tell tales of the past. The protected areas and national parks, such as the Carpathian Biosphere Reserve, play a crucial role in conserving this biodiversity.

Visitors to these geotourism sites can engage in various activities, from hiking and rock climbing to more relaxed sightseeing tours. These activities are not just recreational but also educational, allowing visitors to gain a deeper understanding of the geological processes that shaped these landscapes.

Moreover, the presentation also touches upon the socio-economic impact of geotourism. It highlights how geotourism contributes to the local economy, supporting community livelihoods, and fostering a sense of pride and stewardship among the local population. We will detail a project we are working on with the US-based nonprofit organization Science Voices to improve the socio-economic impact of geotourism in Sukel' River communities in the Bolekhiv region, as well as how this collaboration provides students from Lviv Polytechnic experience in co-developing socio-economic and geoeducational projects with local communities.
In conclusion, the geotourism sites of the Outer Ukrainian Carpathians offer a unique blend of natural

The Spatial-temporal evolution and determinants of homestays in the Dabie old-revolutionary-base-region, China.

Qiankun LIU[1]*, West Anhui University (lqk19890627@163.com)
Tongfei Li[2], West Anhui University

Abstract

The 20th National Congress of the CPC emphasized the imperative to comprehensively advance rural revitalization, that faces challenges in old revolutionary base regions (ORBR). Homestay is a major breakthrough in the process of revitalizing ORBR in China. However, existing academic attention on the temporal-spatial evolution and driving mechanism of homestays is lagging behind. In this study, with official statistics and field research data, the spatio-temporal pattern and contributing factors of homestays in Dabie ORBR were systematically analyzed using the spatial process analysis method with the aid of ArcGIS and Geodetector. The results show that: (1) homestays present a “one core and multiple centers” spatial pattern in Dabie ORBR. From 2019 to 2023, the total number and spatial distribution range of homestays in Dabie ORBR had been expanding, while homestay expansion remains comparatively sluggish in the low-density area. The center of spatial development changed steady, gradually moved northward. (2) Homestays in Dabie ORBR are characterized by high agglomeration in space, showing the multi-core cluster distribution. Spatio-temporal patterns of different grades of homestays are significantly different. The spatial agglomeration process is closely related to the natural environment, tourism resources, traffic trunks and market demand. (3) Geodetector revealed that 11 factors are all contributing factors of the spatial heterogeneity of homestays in Dabie ORBR. In terms of influence, tourism resources(0.532) > natural environment(0.419) > social factors(0.280) > geographic conditions(0.280). Significantly, traditional villages distribution is the decisive force. Further analyses suggested that the influence of the interaction between two determinants of dimensions appeared to be larger.

Tourism Intelligence in Cabo Ortegal Geopark. Case of San Andrés de Teixido (Spain)

Sergio MUINO FREIRE[1]*, University of Santiago de Compostela (sergio.muino@rai.usc.es)
Begoña Muíño Sar[2], University of A Coruña

Abstract

Tourism intelligence has become an ally in the management and planning of destinations, as well as in the sustainable development of the Cabo Ortegal Geopark (Spain) with the case study: San Andrés de Teixido, a consolidated tourist spot in the territory. This research highlights the advantages of having information and knowledge available for the governance and sustainability of the destination.

A mixed methodology was used. On the one hand, with a quantitative approach, surveys were carried out in the field to find out the profile of tourist demand and model forms were created for the collection of tourist data in the tourist offices, data that were dumped into the Business Intelligence tool. On the other hand, a qualitative approach was used to carry out in-depth interviews, participant observation in the territory and an analysis of social networks.

The research has been innovative and reflects the potential of smart management to support the development of geoparks. The main results have been, firstly, a socio-demoscopic study of visitors to San Andrés de Teixido, reflecting characteristics of their journey through the Cabo Ortegal Geopark. Secondly, the identification of San Andrés de Teixido residents needs for the sustainable development of the local communities in the geopark. Thirdly, an approach to the most photographed spots in the geopark on the social networks of those visitors who post with the tag San Andrés de Teixido.

In conclusion, after carrying out this study, it has been determined that scientific and tourism research in the territory can be a differentiating element for the planning and management of the Geopark. The replication and implementation of this methodology in other tourist sites would favour the creation of a network of useful, accurate and real-time information on tourist activity in the destination. This would be an advantage when carrying out actions for the conservation, promotion and sustainable use of the resources of scientific, educational and aesthetic value of the Cabo Ortegal Geopark.

Geological Characterization of the Geoparks within the Central Zone of the Limpopo Mobile Belt: Implication to the development of E - virtual geo-tourism, South Africa

Humbulani Rejune MUNDALAMO[1]*, University of Venda (humbulani.mundalamo@univen.ac.za)
Thangeni Mphanama[2], University of Venda
Jason Sammuel Ogola[3], University of Venda

Abstract

In the space of scientific studies, recently, the focus has been more on machine learning for developing scientific knowledge through E-learning. Therefore, this project aims to comprehensively assess the geological heritage sites within the Limpopo Mobile Belt, a region known for its significant geological and tectonic features. Primarily, the study focuses on the identification, characterization, documentation, and evaluation of various geo-heritage sites within the Central Zone of the Limpopo Mobile Belt and the development of the E-learning system for virtual access of the geological hot spots within the Limpopo Mobile Belt.

Geographical, cultural, aesthetic value, geology, structural, mineralogical, and chemical characterization were conducted in each of the identified geological heritage sites. Geographical and cultural aspects were used to unpark the historical beliefs and importance of the sites. Physical and landscape description was used to bring up the aesthetical value of the identified sites. Geological processes that evolved the occurrence of the geo-heritage sites as well as the description of the geological structures, mineral composition, and chemical constituents of materials from the sites were used to characterize the geological sites identified.

Integration of various geospatial analysis, data management systems, visualization, and machine learning techniques are a focus to interpolate the characteristics within the geo-heritage sites. At this stage, ArcGIS and QGIS were used for spatial analysis, mapping, and visualization of geological data. Remote sensing softwares (ENVI, ERDAS), Statistical tools, and visualization tools such as Python Matplotlib, and Seaborn will be used to develop an E - virtual geo-tourism system.

The geoheritage and geodiversity framework of the newly listed Second 100 IUGS Geological Heritage Site, the Pleistocene Al Wahba dry maar of Saudi Arabia within the Kishb monogenetic volcanic field

Karoly NEMETH[1]*, Saudi Geological Survey (knemeth@geoconservation.org)
Rashad Mohammed Moufti[2], Afaaq Consulting, Jeddah
Turki Sehli[3], Saudi Geological Survey

Abstract

Al Wahbah is one of the largest dry maar crater on Earth with spectacular dimensions of around 250-m crater depth and 2.3 km rim-to-rim crater width. The volcano is a classic example of the hole-in-the-ground morphometry with textbook type flat crater floor and steep crater wall exposing the Neoproterozoic crystalline basement as well as pre-maar lava Quaternary basaltic lava flows all typify it as a maar crater. Al Wahbah is not only impressive by its geometry but also its sedimentary successions that showing clearly that the maar crater cut half an older scoria cone that was already suffered advanced erosional stage. The half-sectioned scoria cone forms a significant geosite as it exposes its proximal to distal pyroclastic facies as well as its conduit filling sub-volcanic body. Al Wahbah also unique in a sense to show clearly that the large maar crater was the likely product of complex collapse events due to repeated phreatomagmatic explosive eruptions in short time scale (days to weeks) creating a scalloped crater outline and overlapping complex base surge succession within its tuff ring. While Al Wahba is undoubtfully unique by its geometry, the Kishb Volcanic Filed where it belongs to have numerous explosion craters known mostly in its southern region where large intracontinental lake system operated and still recognizable. Within this region, however Holocene aeolian processes engulfed most of the larger craters hence they are difficult to recognize. In the northern region however, a remote and difficult to access volcano Aslaj stands another alternative, globally unique entity. At Aslaj, phreatomagmatic explosion(s) essentially excavated upper mantle sourced xenoliths and dispersed them over 10 km from its source. It is therefore suggested that at the Kishb Volcanic Field experienced at least two very similar violent explosive events from what Al Wahbah formed a perfect maar crater while Aslaj produced a more complex volcanic complex, both probably in a very short time scale in geological sense. In addition, the Kishb Volcanic field inferred to formed very young, potentially Holocene alkaline basaltic to phonolite lava flows engulfed the volcanic landscape filling morphological gaps between volcanic edifices. The volcanic geodiversity of the region is high and the natural aesthetic value of the location together justify to consider the region as an Aspiring UNESCO Global Geopark within geosite inventory, geoconservation strategy, geotourism goals and geoeducation aspects need to be developed. The Saudi Geological Survey new geoheritage initiative aims to serve this goal.

HEISEI SHINZAN LAVA DOME / THE SECOND 100 IUGS GEOLOGICAL HERITAGE SITES

Setsuya NAKADA[1]*, The University of Tokyo (nkd.sty@gmail.com)
Marekazu Ohno[2], Unzen Volcanic Area UNESCO Global Geopark (presently, Mt. Chokai & Tobishima Island National Geopark)

Abstract

Heisei Shinzan ("a new mountain in the Heisei era") is a dacite lava dome appeared in the "Heisei Eruption" (1990–1995) at Unzen Volcano, Japan. This is one of the best scientifically documented examples of dome growth during an eruption. Its formation was accompanied with thousands of pyroclastic density currents (flows and surges) due to its frequent partial collapses of the dome lava (Nakada and Fujii, 1993). In the June 3, 1991 eruption, 43 people were killed by a pyroclastic surge, including local residents, media, and volcanologists (Maurice Krafft, Katia Krafft and Harry Glicken). The 15 September 1991 pyroclastic flows burnt down the elementary school located on their way. Pyroclastic flows changed their directions, reflecting the moving of the growing dome. The dome growth changed its style from exogenous to endogenous, depending on the magma discharge rate (Nakada et al., 1999; Umakoshi et al., 2011). The foot of the dome was filled thickly with talus and pyroclastic-flow deposits, furthermore, mud flows repeated in rain seasons. This volcanic disaster, along with the June 1991 Mount Pinatubo eruption in the Philippines, triggered a reconsidering of volcanic disaster preparedness at that time. Agricultural lands and residential areas damaged by pyroclastic flows and mudflows were rebuilt through desilting and reclamation operations and the construction of safe infrastructure on top of them, providing a good example of building back better from severe natural disasters.

The dome growing and associated pyroclastic-flow generation were recorded in detail by geophysical, geochemical, and geological and visual data during the Heisei eruption, and timestamped erupted materials were used for petrological research. This eruption was in contrast to the explosive eruption of Mount Pinatubo, although the magma composition was similar. This question led to scientific drilling into the volcano immediately after eruption, carried out as part of the International Continental Scientific Drilling Project (1999-2004) (Sakuma et al., 2007; Yilmaz et al., 2021). The magma conduit of the Heisei eruption and the surrounding volcanic material were targeted for excavation, and research results regarding the eruption mechanism of the lava dome and the development of the volcano were obtained.

Heisei Shinzan was designated as a national natural monument, and access is permitted only for the purpose of scientific research and monitoring, it is currently the symbol of the Unzen Volcanic Area UNESCO Global Geopark.

Las Hoyas fossil site (Cuenca, Spain): an extraordinary Early Cretaceous faunal and floral wetland

Angela D. D. BUSCALIONI[1]*, Universidad Autónoma de Madrid (angela.delgado@uam.es)
Jesús Marugán Lobón[2], Universidad Autónoma de Madrid, Paleontology and Centre for the integration in Paleobiology
Hugo Martín Abad[3], Universidad Autónoma de Madrid, Paleontology and Centre for the integration in Paleobiology
Candela Blanco Moreno[4], Universidad Autónoma de Madrid, Paleontology and Centre for the integration in Paleobiology
José Luis Sanz García[5], Universidad Autónoma de Madrid, Centre for the integration in Paleobiology
Jerónimo López Martínez[6], Universidad Autónoma de Madrid, Centre for the integration in Paleobiology

Abstract

Las Hoyas stands out as an exceptional fossil site, renowned for preserving with remarkable fidelity, a Barremian wetland biota during the Cretaceous Terrestrial Revolution—a pivotal epoch in the evolution of the biosphere. Situated in a microbasin within the Cuenca sub-basin of the Iberian Domain, this locality forms part of a depositional system with lacustrine and palustrine facies within the La Huérguina Formation. The sediments, aged by charophyte and ostracod associations, consist of finely laminated limestones deposited in depressions formed by tectonic activity over pedogenic and karstified Jurassic marine limestones. The site represents a shallow lake within an extensive, perennial, carbonate wetland system devoid of marine influence. The lake's drainage, facilitated by carbonatic-rich water from karstic aquifers, was regulated by a seasonal subtropical climate controlling water-level oscillations. Microfacies with stromatolite appearance correspond to layers of microbial mats that grew during drier periods, while wetter periods exhibit finer carbonate particles, preserving fewer fossils but displaying higher diversity. The microbial mats played a crucial role in the exceptional fossilization of plants and animals, including the phosphatization of soft tissues, resulting in an impressive collection of over 20,000 curated fossils housed at the public Museum of Paleontology of Castilla - La Mancha. Trace fossils also abound, featuring invertebrate galleries, fish tracks, and dinosaur and crocodile trackways. Beyond the uniqueness of iconic organisms like multitoothed dinosaurs and dwarfed sharks, Las Hoyas has provided crucial evidence offering significant evolutionary insights into the early radiations of various organisms, along with remarkable novelties in the plant and animal realms. These include the initial stages of angiosperm flower origin, the development of maneuvering abilities in early birds, and the evolution of hair polymorphism in mammals. The systematic layer-by-layer excavation, spanning over three decades, is proving instrumental in retrieving detailed sedimentary and paleontological information, offering an even more realistic portrayal of the site's past. This systematic approach, indeed, reflects intricate ecological interactions in the wetland, serving as milestone data for the initial steps towards the ambitious quest of understanding the foundations of modern ecosystems during the Early Cretaceous.

Paricutin: The Volcano born in a Mexican cornfield

Lucero MORELOS-RODRIGUEZ[1]*, UNAM (lunalucerom@yahoo.com.mx)
Dante Jaime MORÁN-ZENTENO[2], UNAM

Abstract

Parícutin volcano is the first monogenetic volcano whose eruption was observed in detail by modern scientists since its birth in a cornfield in the state of Michoacán in central Mexico. It is the youngest edifice of the Michoacán-Guanajuato volcanic field, which is one of the most extensive monogenetic fields in the world, formed by more than 1,100 Quaternary volcanic centers. The historical record of the volcano is exceptional because its entire activity was documented in real-time by an international group. It is an emblematic volcanic feature due to its history, beauty and excellent state of preservation. It is in a region with a rich indigenous culture. The lava flows buried the indigenous village of San Juan Parangaricutiro but the church tower still stands in the middle of a lava flow.

Parícutin is an 81 years old volcano that consists of a pristine 424 m-high scoria cone and a 25 km2 lava flow field which formed during a 9 years-long eruption (1943-1952). The evolution of the volcano has been divided into four stages. The first two stages (1943-1945) are related to the main growth episodes when the cone almost reached its present-day height, and the lavas attained their maximum distance from the vent (4 km). These stages consisted of Violent Strombolian activity with high gas and ash columns, and the birth of a subsidiary vent that fed abundant lava. Parícutin emitted at least 23 distinct lava flows and a widespread ash blanket. The calc-alkaline composition of Parícutin´s rocks is related to the active subduction of the oceanic Cocos plate beneath the North American continent along the Middle America Trench. The volcanic products vary from olivine-bearing andesitic basalt to orthopyroxene-bearing andesite. Nonetheless, a recent geochemical study indicates that compositional variability can be explained by mantle source heterogeneity and fractional crystallization.

The population of the region interpreted the appearance of the volcano as a divine punishment in an attempt to understand something never seen before. The darkness caused by the ash rain, the losses of crops, forests, and livestock, the mudflows that destroyed rivers led to hunger and desolation, and the evacuation of two populations that were completely buried by lava and sand. This eruption changed the physical appearance of the region and the economic activity of the residents, who transitioned from farmers to tourist guides from around the world, fascinated by the unique volcanic eruption that represented a spectacle of nature.

Outstanding geoheritage values of the Korean Getbol

Kyung-Sik WOO[1]*, IUCN WCPA Geoheritage Specialist Group (happyman369@naver.com)

Abstract

The Korean Archipelago Getbol (Island-type Tidal Flat) is located on the east side of the Yellow Sea on the western and southern coasts of the Korean Peninsula. Due to the highly dynamic and complex combination of geological, oceanographic, and climatic conditions, the area is characterized by extremely dynamic past and ongoing sedimentary processes, thus representing one of the most intricate and diverse sedimentary systems in the world. Korean Getbol is a natural, stable and sustainable region and encompasses all geological, geomorphic, and ecological characteristics and processes of archipelago tide flats, which are a rarity in the world.

Thousands of islands are scattered around a vast area adjacent to the land. Rapid macrotidal currents flow between these islands through tidal channels that are narrow or wide, short or long, shallow or deep, changing their direction every six hours. This creates one of nature's most spectacular phenomena along the coast with various coastal landforms. Tidal sedimentation is also greatly influenced by the seasonal changes of the Asian Monsoon climate regime, resulting in high geodiversity exposed to constant changes in hydrology and sediment supply. As a result the littoral environment includes tidal channels and gullies, intertidal and subtidal mudflats and all the related ecosystems to sustain highly dynamic yet stable mudflat sedimentation regimes. At the same time, the system has maintained a sustained sedimentation equilibrium, resulting in one of the world's thickest Holocene intertidal mud deposits as a result of sea-level rise since the Last Glacial Maximum. Typhoon deposits such as chenier and sand stringer are the unique sedimentary feature.

Korean Getbol also includes tidal flat habitats and ecosystems based on various tidal flat (muddy, sandy, mixed and rocky) substrates that have developed around rocky archipelago islands. Thus, it may well represent one of the best examples of a coastal ecosystem of high biodiversity with abundant threatened and endangered species as well as migratory birds. It can be noted that high biodiveristy is underpinned by geodiverity, and Korean Getbol display the outstanding relationship among geodiversity, biodiversity, and cultural diversity. The Korean tidal flat system therefore demonstrates unique and outstanding coastal landforms with ongoing dynamic and sustainable coastal processes, which may be the best in the world.

Jurassic Coast: Lyme Regis

David A.T. HARPER[1]*, Durham University (david.harper@durham.ac.uk)
Jonathan Larwood[2], Natural England

Abstract

The Jurassic Coast exposes an outstanding sedimentary succession displaying 185 million years of the Earth's history - a near-continuous Mesozoic stratigraphical record. It is a globally unique near-continuous Mesozoic coastal succession exemplified by the classic Lower Jurassic of Lyme Regis. The succession encompasses the transition from terrestrial to marine Triassic (Gallois 2019; Proceedings of the Geologists' Association, 130) and Jurassic sediments, and culminates in the Upper Cretaceous Chalk (Mortimore 2019; Proceedings of the Geologists' Association, 130) exposed in the iconic Old Harry Rocks. This coastline provides "one of the finest sections of marine Jurassic rocks anywhere in the world" (Callomon and Cope 1995; Field Geology of the British Jurassic, Geological Society, London) - a statement exemplified by global reference sections in the marine Lower Jurassic at Lyme Regis. This area is noted for its prolific invertebrate (including a near complete Jurassic ammonite zonation) and marine reptile fossil fauna, first collected by Mary Anning (1799-1847). Today, housed in museums the world over, Mary Anning's discoveries included the world's first complete pleisosaur, many complete ichthyosaurs and fossil fish, and the first British pterosaur. She collaborated and corresponded with many contemporary scientists inspiring the world's first published palaeoecological reconstruction, De la Beche's Duria Antiquior. Fundamental to our modern biostratigraphy for the Lower Jurassic (Simms et al. 2004; Geological Conservation review Series, No. 30) Lyme Regis remains one of the most readily accessible and studied sources of Lower Jurassic marine fossils in the world (Jurassic Coast Trust 2021).

The combined Esmark Moraine and Otto Tank's Moraine (Norway)

Ezio VACCARI[1]*, INHIGEO - IUGS Commission on the History of Geological Sciences / University of Insubria, Italy (ezio.vaccari@uninsubria.it)
Geir Hestmark[2], CEES, Department of Biosciences, University of Oslo (Norway) and INHIGEO

Abstract

The discovery of ice ages is one of the most revolutionary advances made in Earth sciences. In 1824 Danish-Norwegian geoscientist Jens Esmark (1762-1839) published a paper stating that there were indisputable evidence that Norway and other parts of Europe had previously been covered by enormous glaciers carving out valleys and fjords, in a cold climate caused by changes in the eccentricity of Earth’s orbit. Esmark and his travel companion Otto Tank arrived at this insight by analogous reasoning: enigmatic landscape features they observed close to sea level along the Norwegian coast strongly resembled features they observed in the front of a retreating glacier during a mountain traverse in the summer of 1823. Which glacier they observed up-close has however remained a mystery, and thus an essential piece of information in the story of this discovery has been missing. Based on previously unknown archive sources, supplemented by field study, the key locality has been identified as the glacier Rauddalsbreen. This is the northernmost outlet glacier from Jostedalsbreen, the largest glacier in mainland Europe. Here the foreland exposed by glacier retreat since the 'Little Ice Age' maximum around AD 1750 contains a rich collection of glacial deposits and erosional forms. The point of enlightenment is more precisely identified to be a specific moraine and its distal sandur at 61o43’26’’ N, 7o26’43’’ E. In memory of Esmark’s travel companion who possibly was the first to realize the analogy, it is proposed to name this moraine Otto Tank’s Moraine, a pendant to the already famous Esmark Moraine at Forsand by the sea. The two moraines are situated transversally in two valleys, and mainly differ in size. The Esmark Moraine, deposited at the end of the last ice age close to sea level, is about five times bigger than the Otto Tank Moraine. They both contain a mixture of rock sizes, from boulder to clay, a diamicton deposited by the northern tip of glacier Jostedalsbreen at the culmination of the 'Little Ice Age', at 1040 m. above sea level in Breheimen National Park.

Mesoproterozoic Belt-Purcell Supergroup

Kylie CAESAR[1]*, National Park Service (kylie_caesar@nps.gov)
Stan Finney[2], California State University at Long Beach

Abstract

The Belt-Purcell Supergroup of western Montana, central and northern Idaho, and southwestern Canada recently earned the honor of being accepted into The Second 100 IUGS Geological Heritage Sites. The site is also part of Waterton-Glacier International Peace Park UNESCO World Heritage Site.

The Belt-Purcell Supergroup is one of the largest and best studied Mesoproterozoic sedimentary basins in the world. These ancient rocks are relatively undeformed by tectonic forces and undisturbed by plants and animals, resulting in the preservation of pure sedimentary processes, making them one of the world's finest examples of Precambrian sedimentary rock. Intensive glacial erosion of this strata has led to spectacular exposures that have fascinated geologists for over a century.

This immense package of sedimentary rocks resulting from passive rifting within supercontinent Nuna starting approximately 1.5 billion years ago. This event created a large, intracratonic basin that, during the mesoproterozoic, filled with up to 11 mi (18 km) of sand, silt, clay, and carbonate sediments resulting in the thickest sedimentary succession on earth. Concepts stemming from these rocks not only capture a unique stratigraphic setting, but have implications for other strata of pre-Cambrian age, and the entire Phanerozoic. Extensive quaternary glaciation throughout northwestern Montana, USA and southwestern Alberta, CA has resulted in incredible exposures of Precambrian age Belt-Purcell Supergroup in Waterton-Glacier International Peace Park, which, in tertiary time, were displaced eastward onto Cretaceous age rocks by the Lewis overthrust fault. The site contains seventeen stratotypes all within the Belt-Purcell Supergroup: two type sections, fourteen type localities, and one reference section. These stratotypes serve as world-class references for exceptionally preserved sedimentary features like ripples, mud cracks, and crossbedding as well as "molar-tooth" structures, and a variety of stromatolite fossils comprising one of the richest accumulations of Precambrian life in North America.

For decades, the Belt-Purcell Supergroup's incredible exposure of unique strata has drawn generations of geologists to study Earth's early geological processes. Researchers investigating the complexity within facies are challenging long-held interpretations, leading to continuously evolving conclusions and passionate debates on its origin and depositional environment.

Italian sites for the history of geosciences: Vesuvius and Agno Valley

Catherine (Kathleen) HISTON[1]*, IUGS INHIGEO (hiscat@interfree.it)
Ezio Vaccari[2], IUGS INHIGEO / University of Insubria, Varese (Italy)
Claudia Principe[3], Istituto di Geoscienze e Georisorse, CNR, Pisa (Italy) and INHIGEO

Abstract

During the 18th century, some significant geological research took place within some Italian sites and led to the definition of new interpretations and the establishment of new theories, particularly in the field of volcanology and stratigraphy. Two sites, Mt. Vesuvius and Agno Valley, are particularly relevant for the development of these scientific disciplines within the history of geosciences.

The science of volcanology was born at Vesuvius, with the first description of the phenomena which occurred during an explosive volcanic eruption. This account is included in two letters by Pliny the Younger to Tacitus about the 79AD eruption, that destroyed Herculaneum and Pompei. During the following centuries, the activity of Vesuvius, with its major eruptions (e.g. 472AD, 1631, 1906, and the last in 1944), was taken as a paradigm for the study of all possible volcanic activity by European scientists. From the 18th century to date, Vesuvius and its crater have been visited by several scholars and considered a natural laboratory for understanding the behavior of an active volcano. Positioned on the outskirts of Naples, Vesuvius has been studied by travellers, scholars, naturalists and scientists in particular after the devastating eruption of 1631. For centuries volcanologists described volcanoes by comparison with Vesuvius. Consequently, the available documental record on Vesuvius is one of the best of the world.

Within the new science of stratigraphy, Giovanni Arduino's 1758 study and representation of the lithostratigraphical sequence of the Agno Valley (in the Venetian Prealps, north-eastern Italy), led to the publication, in 1760 and in 1774, of a new theory of sub-division of rocks into four units according to the chronological order of their formation. This classification included mountains - defined as 'Primary' (with a basement of schists and mineral-bearing crystalline rocks; now Paleozoics) 'Secondary' (stratified limestones with fossils; now Mesozoics) and 'Tertiary' (clays, fossiliferous sandstones and some volcanic material; now Cenozoics) - as well as the most recent terrain of the plains, defined as the 'Fourth unit'. Arduino's system established the scientific notions of Primary, Secondary and Tertiary strata, and contributed to the later definition of Quaternary. This lithostratigraphical theory can be considered at the basis of modern stratigraphic chronology.

Wakulla Spring, Florida, USA: A preeminent example of karst hydrogeology

Guy MEANS[1], Florida Geological Survey
Jonathan ARTHUR[2]*, American Geosciences Institute (jarthur@americangeosciences.org)

Abstract

Wakulla Spring, located in northern Florida, is one of the largest artesian springs in the United States and perhaps the world. The spring is connected to a vast network of conduits that extend both to the north and south of the spring and are part of the longest mapped underwater cave system in the United States. As of January 2023, cave divers have explored and mapped approximately 72,153 meters of cave passage in what is called the Wakulla/Leon Sinks cave system. More than 30 entrances, through sinkholes and springs, to the Wakulla/Leon Sinks cave system are known and more than 35,405 meters of cave passage exceed a depth of 58 meters.

Wakulla Spring, the main source of water for the Wakulla River, discharges approximately 1,135,624 cubic meters/day from the upper Floridan aquifer. The watershed that supplies water to Wakulla Spring is estimated to be 2,525 square kilometers and encompasses parts of North Florida and South Georgia. Water that discharges from Wakulla Spring is a mix of older groundwater and younger shallow or surface water that recharges rapidly through multiple large swallets located throughout the watershed. Dye trace studies conducted in the Wakulla Spring watershed (or springshed) have verified that water flowing into four major swallets discharges at Wakulla Spring. Because of the complex interplay between surface water and groundwater within the Wakulla Spring watershed, Wakulla Spring has the largest observed range in discharge of any large magnitude spring in Florida.

Visitors to Wakulla Spring bring millions of dollars to the local economy. Wakulla Spring and the Wakulla River also provide recreational opportunities like fishing, boating, wildlife viewing and others. It is also one of the most studied spring systems in the United States. Early scientific work conducted at Wakulla Spring led to the discovery and excavation of mastodon remains by the Florida Geological Survey in the 1930's. Numerous skeletal remains from extinct Late Pleistocene megafaunal animals have since been discovered along with archaeological evidence of the first people that inhabited Florida. Today, ongoing research using cutting-edge SCUBA technology and autonomous underwater vehicles is revealing more information about this world-class artesian spring.

Like many springs around the world, Wakulla Spring and the Wakulla River have experienced ecological degradation due to anthropogenic impacts. Nitrate concentration in the spring water has increased over the last several decades along with increases in exotic invasive species. The State of Florida recognizes the significance of Wakulla Spring and has made some progress in enacting protection measures. Wakulla Spring is an Outstanding Florida Spring, a designation made by the

Florida Legislature to limit groundwater withdrawals deemed harmful to springs. Wakulla Spring is also a State Geologic Site designated by the State Geologist of Florida in 2018 as an outstanding example of a Florida spring. With its recognition by the IUGS as a Geological Heritage Site, Wakulla Spring will benefit from becoming an internationally recognized site of scientific and cultural importance.

IUGS GEOLOGICAL HERITAGE SITES

Asier Hilario[1]*, IUGS International Commission on Geoheritage (flysch@gipuzkoa.eus)
Stanley Finney[2], IUGS
Juana Vegas[3], CSIC - IGME
Gonzalo Lozano[4], IGME - CSIC
Benjamin Van Wyk de Bries[5], Université Clermont Auvergne
Jianping Zhang[6], Chin University of Geosciences

Abstract

The announcement on October 28, 2022, of the “First 100” Geological Heritage Sites recognized by the International Union of Geological Sciences follows a 60-year tradition of the IUGS establishing globally recognized geostandards through international collaborations. The chronostratigraphic units and GSSPs, the IUGS Classification of Igneous Rocks and the Global Geochemical Reference Network represent good examples of these global standards.

IUGS ratified geostandards have authority. They are of the highest importance to the practice of geology and, thus, receive international recognition. Their legitimacy derives from the well established, transparent, deliberative process by which decisions are made and proposals are approved often by consensus or unanimously by the voting members of a subcommission, who are experts and internationally diverse. The proposals must then be analyzed and approved at the Commission level, and finally the IUGS EC must vote to approve the proposal. It is then ratified as an international geostandard.

For IUGS Geological Heritage Sites, a first group of 20 international experts on geoheritage from 13 different countries developed the high standards for recognition. More than 700 authors from 85 countries have participated in the Firts 100 and the Second 100 endeavor. 350 proposals have been received and were evaluated by a group of 92 experts. The result of this international collaboration between IUGS and 17 commissions and affiliated organization is the selection of the “First 100” and "Second 100".

IUGS recognition of Geological Heritage Sites gives visibility to those sites. It identifies them as being of the highest scientific value. They are sites that served to develop the science of geology, particularly its early history. They are the world’s best demonstrations of geologic features and processes. They are the sites of fabulous discoveries of the Earth and its history.
Their visibility is greatly enhanced by IUGS recognition. Some of the sites are classic and known to almost all geologists, but few geologists know most of the sites because of their diverse types and geographic settings. The announcement of the “First 100” and the attractive book and webpage will lead to many of the sites becoming known for the first time to large numbers of geologists and the public. Interest in individual sites will increase as will geo-visitors. Many of the

“First 100” are well protected in national parks, geoparks, and natural reserves, but many are not. Recognition and visibility of the “First 100” IUGS Geological Heritage Sites can lead to their further appreciation, to their use as educational resources, and, most importantly, to their preservation.

Molassic sediments and pinacles of Meteora, Greece

Nikolaos ZOUROS[1]*, University of the Aegean (nzour@aegean.gr)

Abstract

Meteora landform is a complex of impressive rock pillar formations composed of molassic sediments belonging to the Mesohellenic trough. The spectacular pinnacles are 200 m high and up to 300 m wide. The Meteora rocks belong to the “Pentalophos Formation,” of Upper Oligocene - Lower Miocene age (Brunn 1956). The maximum thickness of the formation sediments is about 4.000 m. The sediments are essentially of marine origin however have been accepted as fluviatile and terrestrial material, and therefore there is a high turnover of sediments in this formation. The sediments of the formation change laterally to Meteora conglomerates. The stratigraphic succession of the Meteora conglomerates includes the Lower Meteora Conglomerates (LMC, composed of fan-deltas) and the Upper Meteora Conglomerates (UMC, composed of dominantly fluvial deposits in this area). The conglomerates were deposited in a Gilbert-type deltaic system, where large channels occurred, entrenched vertically to the progression axis of the delta. The formation of Meteora landforms is due to: (a) tectonic fracturing, (b) erosion due to flowing water and, (c) to a smaller extent, aeolic erosion. However, the tectonic activity had a significant impact on their formation and distribution, to form this unique morphology.

Meteora is one of the most iconic geological landscapes of the World. It is a complex of impressive rock pillar formations made by a huge accumulation of molassic sediments. The complex of Meteora is a perfect conjunction of tectonic, sedimentologic and geomorphologic processes which are very important for understanding the geology of the Hellenic orogen Byzantine monasteries were built on the top of many of these rocks pillars, creating a unique sacred lanscape declared as a mixed UNESCO World Heritage Site in 1988, including criteria viii for its geological value. Meteora is one of the most important touristic destination of Greece with over 2 million visitors every year. The most comprehensive sedimentary description of the formations comprising the Meteora rock spires is that of Brunn (1956). Since then several other national and international researchers studied the area from different geological disciplines. Meteora is a common destination for universities from all over Greece and surrounding countries.

Iconic Colorful Navajo Sandstone of The Wave at Coyote Buttes, Vermilion Cliffs National Monument, Arizona, United States

Winston SEiler[1], KCSI Aerial Patrol, Inc.
Marjorie A CHAN[2]*, University of Utah (marjorie.chan@utah.edu)

Abstract

The Lower Jurassic Navajo Sandstone preserves the largest erg in Earth's history. Of all Navajo Sandstone outcrops in the desert southwest of the United States, the Coyote Buttes is globally renowned for stunning coloration and sculpted outcrop features including The Wave — where vivid colors accent aeolian cross strata to resemble a cresting ocean wave. The Wave is one of the most photographed and iconic sandstone outcrops worldwide.

Rich hues of red, orange, pink, purple, yellow, brown, and white colors document a complex history of chemical interactions between iron enriched fluids and ground water, resulting in concentration or removal of iron oxide grain coatings and cement within the sandstone. Coloration patterns are influenced by sedimentary textures and tectonic structures at laminae to outcrop to regional scales. The Wave's sculpted form initiated with water incision along a prominent joint; winds actively scour and smooth the sandstone walls to accentuate the aeolian bedding.

The larger Coyote Buttes area likewise displays unique and spectacular alcoves, bowls, faces, and bluffs shaped by wind and dramatically colored by past fluid flow. Large dune sets show cyclic cross bedding driven by paleoclimate. Dinosaur tracks document a rich paleontologic history. Extensive soft sediment deformation suggests seismic shaking and liquefaction during the Jurassic. Contemporary weathering crack patterns compose analogs to Mars.

Kikaijima Island – the history of coral reefs over 100,000 years

Atsuko YAMAZAKI[1]*, Nagoya University (yamazaki.atsuko.x5@f.mail.nagoya-u.ac.jp)
Taro KOMAGOE[2], KIKAI Institute for Coral Reef Sciences
Rintaro SUZUKI[3], KIKAI Institute for Coral Reef Sciences
Yoshitaka UECHI[4], Kikai Town
Etsuo KUMASAKI[5], Kikai Town
Tsuyoshi WATANABE[6], Research Institute for Humanity and Nature

Abstract

The coral reef terraces of Kikaijima Island are unique worldwide and were formed by sea-level changes during the Late Pleistocene glacial cycle as the seafloor rose at an extremely high rate. The seafloor of Kikai Island has been uplifting at 2.1-2.3 m/ky over the past 100,000 years. The Ryukyu Formations form the basement of Kikai Island, where coral reefs have continuously developed and been repeatedly uplifted. The flat surface of the coral reef terraces represents prolonged periods of sea-level stasis followed by rapid uplift. The contrast between the flat terraces and cliffs, formed from the coral reefs during this cycle, creates a beautiful stepwise topography and represents one of the best records of late Pleistocene sea-level change, including marine isotope stage 3. The uplift rate on Kikaijima Island has been maintained from the late Pleistocene to the present, and the series of four terraces & cliffs provide a record of past seismic activity, repeated. In addition, well-preserved coral fossils from Holocene reefs surrounding the coast of Kikaijima Island have been used as continuous paleoclimatic indicators for the Northwest Pacific. The coral reef terraces in Kikaijima Island provide us with the history of the coral reef ecosystem with global environmental changes.

Middle Jurassic dinosaur footprints from the Serras de Aire and Candeeiros

Luis LOPES[1]*, University of Évora and Earth Sciences Institute, Portugal (lopes@uevora.pt)
Artur A. SÁ[2], University of Trás-os-Montes e Alto Douro / CGeo - Geosciences Center
Jorge CARVALHO[3], LNEG - National Laboratory of Energy and Geology
Lia MERGULHÃO[4], ICNF - Institute of Nature and Forest Conservation
Mário CACHÃO[5], University of Lisbon / IDL - Dom Luiz Institute
António Marcos GALOPIM DE CARVALHO[6], University of Lisbon

Abstract

The Dinosaur Footprints Natural Monument of Ourém/Torres Novas, known as Galinha quarry, and the Vale de Meios quarry, are located in the Serras de Aire e Candeeiros Nature Park (Central Portugal). They are two geosites, duly geoconserved, of recognized international scientific value, due to its exceptionality regarding to the age, size, and quality of preservation of ichnites. Both quarries are located in limestones of the Serra de Aire Formation (Bathonian, Middle Jurassic) (Azerêdo 2007). The Galinha quarry preserves 20 trails with sauropod footprints, in an excellent state of conservation, and it is possible to observe finger marks and a ridge formed by the sediment that was removed under the weight of the animal. This deposit has some of the oldest and longest sauropod tracks known in the world (up to 147 m long) and allows to obtain a dynamic image of the locomotion of these sauropods (Santos et al 2009). The Vale de Meios quarry preserves more than 700 theropod tracks. They are organized in at least 80 unidirectional trackways, arranged in a bimodal orientation pattern (W/NW and E/SE). Paleoenvironmental studies in this quarry indicates an inter-tidal flat located at the margin of a coastal barrier (Razzolini et al 2016).

These quarries constitute a world-class Serial Site for understanding some of the oldest paleoenvironmental and paleoethological interactions involving sauropods and/or theropods. The ichnites of the Galinha quarry, with oval pes prints and speech-bubble–shaped manus prints (Castanera et al 2016), have provided an important contribution to the knowledge of sauropods at an early stage of their development. It was even possible to describe Polyonyx gomesi as a new sauropod ichnotaxon (Santos et al 2009). Vale de Meios quarry, is one of the most important sites with Middle Jurassic theropod tracks. The occurrence of Megalosauripus tracks represents the oldest occurrence of this ichnotaxon (Razzolini et al 2016).

Discovered and studied since the 1990s, multiple scientific studies have been carried out on these dinosaur track sites (Santos 2016), involving several international researchers. Similarly, since their discovery attracted educational and tourist visits, from nationals and foreigners, and they are currently duly protected and equipped for this purpose.

A Dinosaur Quarry, the World's Wonder: The Dashanpu Middle Jurassic Dinosaur Fossils Site

Yi LI[1]*, Zigong Dinosaur Museum (hellen-lida@163.com)
YE YONG[2], Zigong Dinosaur Museum
JIANG SHAN[3], Zigong Dinosaur Museum
LI BIAO[4], Zigong Dinosaur Museum
WANG WENWEI[5], Administration Center for Zigong UNESCO Global Geopark
WANG LINGLING[6], Administration Center for Zigong UNESCO Global Geopark

Abstract

The presentation will introduce the site and its history, conservation, research and utilization, as well as share its sustainable development ways.

Dashanpu Middle Jurassic Dinosaur Fossils Site was found in 1972. It's valuable both in geology and paleontology. It is situated at the northeastern end of the Ziliujing Anticline of Sichuan Basin, a well-known red basin in the Upper Yangtze Platform of South China. There is a series of terrestrial strata during the Late Triassic to Early Cretaceous exposed on the surface of the basin. The dinosaur fossil-bearing Lower Shaximiao Formation (J2xs) of the Middle Jurassic is about 180 meters thick and comprises lacustrine and fluvial clastic deposits, mainly purplish red mudstones with several intercalations of yellowish grey or greyish green middle to fine-grained feldspathic quartz sandstone or feldspar lithic sandstone. The dinosaur fossils are concentrated in a layer of 3-5 meters thick of greyish green fine-grained feldspar lithic sandstone in the lower part of the formation.

The site is one of the most important dinosaur fossil sites in the world, and covers an area of about 70,000 square meters. Over 200 dinosaurs and other vertebrates uncovered in the Dashanpu Dinosaur Fossils Site and there are still numerous fossils preserved in the site. 29 species of 26 genera have been identified and described, including sauropods, theropods, basal ornithischians, stegosaurs, fishes, amphibians, turtles, crocodiles, plesiosaurs, pterosaurs and therapsids. Most of them are only and one globally, and are basal positions in the evolution of dinosaurs and other vertebrates; so as to fill the gap of dinosaurs research history. Such as Huayangosaurus taibaii(note: the words of Huayangosaurus taibaii should be in Italics) is the most primitive stegosaurs, providing important evidence for the origin of Stegosauria; Shunosaurus lii(note: the words of Shunosaurus lii should be in Italics) is the best example for the inheritance and evolution between the basal sauropods and eusauropods. They form a highly diversified vertebrate assemblage of the Middle Jurassic. 6 monographs, 2 special issues and more than 100 papers have been published so far.

The site has been well-preserved, well-protected and well-utilized. A site museum, Zigong Dinosaur Museum, had been built over it and officially opened in 1987, now is a core part of the

Zigong UGGp. The scientists of the museum coperated with the professors of local university developed successfully a protective nanomaterial for fossils and site, and which is now widely utilized on paleontology sites. Over 40 years, there are more than 50 million people, especially family visitors and children, benefited from Zigong Dashanpu Dinosaur Site, through dinosaur exhibitions, popular science events and activities, movies and books, community cooperation etc.. And the dinosaurs from the site toured over 30 cities abroad and more than 70 cities at home, attracted nearly 30 million visitors. Moreover, a new large dinosaur and tetrapod burrows have been found in the site, and a new exploring building has been built for protection and exhibition. The site created more and more value for the people, and earned more ways to be protected.

Mackenzie Delta - coastal landforms created by giant sediment deposition of the fluvial system under Arctic permafrost conditions

Zbigniew Zwoliński[1]*, Institute of Geoecology and Geoinformation, Adam Mickiewicz University in Poznań (zbzw@amu.edu.pl)

Abstract

The presentation is about one of the proposed sites for the list of "The Second 100 IUGS Geological Heritage Sites" in the category "Geomorphology and active geological processes". This site is the Mackenzie River delta, which represents complex coastal landforms of diverse origin: glacial, permafrost, fluvial, and pseudokarst in the north-west Canadian Arctic.

The maximum extent of the Laurentide Ice Sheet in the Mackenzie Delta area was 30,000 years ago. The vast delta, with its branching channels, ponds and wetlands, covers more than 13,000 square kilometers of alluvial coastal plain. The delta stretches nearly 210 km from north to south and is 50 to 80 km wide. Below Fort McPherson, the Mackenzie River divides into several major channels and hundreds of smaller tributaries, the largest of which flows north-northeast and empties into the Beaufort Sea west of Tuktoyaktuk. The Mackenzie Delta is a labyrinth of shifting channels and pseudokarst lakes. Most of the land in the delta is permafrost, with great depths to bedrock and patches or taliks of unfrozen ground due to the influence of shifting channels. Retrogressive thaw slumps, up to 200m wide, are common where ground ice is exposed by bank erosion. Rivers and lakes are ice-covered for more than half the year. The Mackenzie River carries a large load of sediment, transporting about 128 million tonnes to its delta each year. A characteristic feature of the delta are the numerous pingos (1400, the largest population in the world). They are conical, ice-cored, 50m high, and >100m in diameter at the base.

The Mackenzie Delta (the second largest Arctic delta) is the best example of a complex landscape combining forms of different origins, from post-glacial rocky islands, through permafrost-related landforms such as polygons and pingos, to contemporary pseudokarst lakes, slumps and numerous migrating channels carrying huge bedloads and suspended sediment (Carson et al. 1998, Burn 2010, 2017). Sedimentation rates over much of the outer delta are less than the rate of subsidence associated with sea-level rise. Permafrost is ubiquitous and the surrounding landscape testifies to the enormous forces that can be unleashed by seasonal freezing and thawing of the ground.

The Mackenzie Delta is the best-studied of the polar regions. Especially the research and field experiments of J.R.Mackay (1998) have contributed to the understanding of permafrost phenomena. The Mackenzie Delta is the most spectacular geoecological landscape in the Arctic, which is nourished by the annual flooding of the Mackenzie River.

Vatnajökull - a complex interplay of rift, fire and ice

Zbigniew Zwoliński[1]*, Institute of Geoecology and Geoinformation, Adam Mickiewicz University in Poznań (zbzw@amu.edu.pl)
Małgorzata MAZUREK[2], Institute of Geoecology and Geoinformation, Adam Mickiewicz University in Poznań

Abstract

The presentation is about one of the proposed sites for the list of “The Second 100 IUGS Geological Heritage Sites” in the category “Geomorphology and active geological processes” and “Volcanology”. This site is the Vatnajökull Glacier, which represents a unique landscape forged by the constant conflict between fire and ice in the rift zone at the divergent plate tectonics.

The area of the Vatnajökull covers almost 10% of Iceland's territory and is characterised by the coexistence and ongoing interaction of an active oceanic rift on land, a mantle plume, and an ice cap that have varied in size and extent over the past 2.8 million years. Earth system interactions are constantly modifying this area, creating remarkably diverse landscapes and a wide variety of plate-tectonic, volcanic and glaciovolcanic features. There are eight subglacial volcanoes. Some of them are among the most active in Iceland (e.g. Grímsvötn, Bárðarbunga; Gudmundsson 2004). Particulary interesting and unique in this regard are the basaltic lava shields, volcanic fissures and cone rows, vast flood lavas, and features of ice-dominanted glacio-volcanism, such as tuyas and tindars. Geothermal heat and subglacial eruptions produce meltwater and jökulhlaups that maintain globally unique sandur plains, to the north and south of the Vatnajökull ice cap (~8000 km2), as well as rapidly evolving canyons. In addition, the area contains a dynamic set of glaciological and geomorphological features, created by 40 expanding or retreating outlet glaciers in response to climate change. These features can be easily accessed and explored at the snouts of Vatnajökull’s many glaciers and their forelands, especially in the southern lowlands (e.g., Skeiðarársandur).

Vatnajökull is an outstanding example representing interactions between volcanism and glaciation (Baldursson et al. 2018). The most spectacular are the jökulhlaups – sudden floods caused by glacier margin breaches during an eruption with a huge water discharges. This recurrent phenomenon has led to the formation of unique sandur plains, among the best of their kind in the world (Magilligan et al. 2002, Thórhallsdóttir, Svavarsdóttir 2022), braided channel systems and rapidly evolving canyons. Vatnajökull also illustrates different types of glaciation, from ice cap to outlet glaciers, while glacial landforms around the ice cap provide evidence of ice advance and retreat.

The pioneering descriptions of the Vatnajökull glacier were made by the Finnish geologist Jöns Svanberg in 1794. In the late 19th century, interest began to focus on the relationship between the geology and dynamics of the Vatnajökull glacier in an attempt to understand how the glacier responds to climate change.

The Durbuy Anticline: a top geoheritage site in the UNESCO Global Geopark Famenne-Ardenne, Belgium

Boyeon JEON[1]*, IGC 2024 (bjeon789@gmail.com)

Abstract

The natural cross section of the Durbuy Anticline represents an archetype anticline and as such it is a classical site used for the education of geology and geoscience students from Belgium and neighboring countries. This geosite is situated in the medieval town of Durbuy within the UNESCO Global Geopark Famenne-Ardenne. It boasts a base of 90 meters, a height of 37 meters and is composed of about 25 layers of Mid-Frasnian (Upper Devonian) marine limestone of the Philippeville Formation. The slightly faulted disharmonic anticline is an excellent example of Late Carboniferous Variscan deformation in Europe. The structure was carved out by the Ourthe River, which originally meandered on a Cenozoic sandy cover, and subsequently eroded underlying folded Devonian formations irrespective of their resistance to erosion.

This wonderfully exposed outcrop is commonly referred to as the Anticlinal d'Omalius, in honor of Jean-Baptiste d'Omalius, widely recognized as the Father of Belgian Geology ((16 February 1783, Liège, Belgium - 15 January 1875, Brussels, Belgium) who described the Durbuy Anticline as early as in 1807. This description was part of a much larger endeavor: in 1813, d'Omalius completed the first geological map of France and bordering areas, which was published only in 1822 due to the political turmoil in western Europe. He subdivided the northern geological terrains into three parts, which subsequently through the works of Roderick Murchison and others, became well-established as the Silurian, Devonian and Carboniferous periods. Notably, d'Omalius is also the discoverer of the mineral halloysite formally described in 1826 by the French mine-engineer Pierre Berthier.

The Durbuy Anticline stands as an easily accessible and captivating geological feature, drawing in a diverse audience. Its significance is deeply rooted in the local culture and heritage, actively embraced and promoted by the town of Durbuy. The apex of the anticline is the highest point of the medieval town of Durbuy, serving as a popular destination for both residents and tourists seeking leisurely strolls and panoramic views. In 2023, the Durbuy Anticline was proposed as a candidate geosite to feature in the esteemed "Second 100 IUGS Geological Heritage Sites".

Wuda Plant Fossil Site: Permian Vegetational Lagerstätte unveiling ancient coal forming plants and forest

boyeon JEON[1]*, test (coastal1803@naver.com)

Abstract

Coal, well known as fossil energy resources, about which a commonly queried mystery exists: what plants has formed coal? and what does an ancient coal-forming forest look like? As one of the Second 100 IUGS Geological Heritage Sites, the Wuda Plant Fossil Site may answer best.

A peat-forming forest was preserved in situ by a 298.34 ± 0.09 Ma volcanic ash fall in the Wuda Coalfield, Inner Mongolia, being called Wuda Tuff Flora, here termed as the Permian Vegetational Pompeii - Wuda Plant Fossil Site. With respect to the geologic and taphonomic similarities to the world-famous Italian UNESCO World Heritage Site of the Roman city of Pompeii, this flora has been also called Chinese “vegetational Pompeii”, well known as a plant lagerstätter, snapshooting a glimpse to the late Paleozoic peat-forming forest. Such a T0 deposit provides an unrivaled chance to reconstruct the taxonomic diversity, vegetation structure and density, and synecological associations.

Through the recent two decades, along with the open-cast mining of the Wuda Coalfield, extensive field research and quantitative investigation on some areas of over 10, 000 square meters have been conducted and yielded a larger collection of fossil material and data of forest community ecology. The completeness and the exquisiteness of plant remains facilitate a thorough systematic study of many taxa of this peat-forming forest. Nearly all the taxa of this forest show both gross morphology and anatomy, and both vegetative and fertile parts, and thus likely to facilitate restoration as whole plants and natural species, which is impossible in most other localities due to the small number and the limited size of specimens. There are seven plant groups forming this peat-forming forest: lycophytes, sphenohytes, progymnosperms, ferns, seed ferns, cycads and coniferophytes. In addition, forest structure and landscape heterogeneity, such as density of individuals, species-area curve and vegetational recovery are all detectable. In brief, long last geological and palaeobotanical investigation and research on the Wuda Plant Fossil Site significantly promote our understanding of the coal-forming plants and forest, providing so far the best answer to the above mentioned mystery of coal formation.

With respect to the high scientific significance and strong common interests, this fossil site has been proposed to be protected to build museum and geopark. Local government has organized meetings to discuss about the conservation, research and exploitation of this site.

Tepuis and quartzite karst of Gran Sabana, Venezuela

boyeon JEON[1]*, test (coastal1803@naver.com)

Abstract

The Gran Sabana is a region in the south-eastern part of Venezuela, located in the humid tropics, just north of the Equator. It is renowned for the occurrence of striking plateaus and mesas, some rising to altitudes of more than 2000 m a.s.l., which host the most spectacular karst phenomena developed in silicate rocks. Geologically it is part of the Guyana Shield, where the basement of Precambrian magmatic and metamorphic rocks is overlain by a thick succession of clastic sedimentary rocks, mainly quartz sandstones and conglomerates, of also Precambrian age. This succession is a few kilometres thick and includes the most resistant quartz sandstones of the Matauí Formation, exposed in magnificent escarpments many hundreds of metres high. The most conspicuous landscape elements are tabular hills (tepuis, mesas), with flattish summit surfaces surrounded by sheer cliffs, rising above the regional planation surface. The tepuis have various dimensions and some form multi-tiered extensive plateaus, tens of kilometres long. Their top surfaces show extraordinary diversity of relief, described as ruiniform. It includes rock walls, towers and pinnacles, separated by narrow corridors and basins. Closed depressions, acting as sinkholes for surface streams, and deep shafts are common. Large, multi-level caves occur inside the mesas. The region hosts some of the longest caves in quartz sandstones globally, with the total lengths of galleries of the order of many kilometres, and several shafts exceed 300 m deep. Rivers originating on the plateaus descend in waterfalls, including the highest waterfall on Earth – Angel Falls (979 m). Part of the area is protected as the Canaima National Park, inscribed as World Heritage property of UNESCO in 1994, including criterion (viii).

Landforms similar to those in limestone karst, but in apparently non-soluble rocks, were long considered as a natural curiosity of little wider significance. Research in the Gran Sabana, initiated in the 1970s, demonstrated the critical role of quartz dissolution in the formation of surface and subsurface landforms, including ruiniform relief, dolines, karren, deep shafts, caves and speleothems. The mechanism of arenization, that is corrosion along grain contacts leading to loosening of the rock mass and making grains available for transport, was elaborated in detail and serves as a model for sandstone/quartzite disintegration. The Gran Sabana is therefore a benchmark locality and global reference site for silicate karst, which inspired many studies focused on sandstone landforms and surface-subsurface connectivity in sandstone terrains undertaken elsewhere.

Inverted landscape of a Plio–Pleistocene phreatomagmatic monogenetic volcanic field: Tapolca Basin, Hungary

Karoly NEMETH[1]*, Saudi Geological Survey (knemeth@geoconservation.org)
Barnabas Korbely[2], Bakony-Balaton Geopark Group, Balaton Uplands National Park Directorate

Abstract

Tapolca Basin is part of the Bakony–Balaton UNESCO Global Geopark and the Balaton Uplands National Park hence its geological landmarks enjoy high degree of conservations status. In the scientific literature it appears as part of the Bakony–Balaton Highland monogenetic volcanic field that is probably more correct to call as Bakony-Balaton Uplands referring its difference from being highland that is an area of land that is at elevation; mountainous land while upland is the area in the interior of a landmass with a generally higher elevation; often hilly, but not generally mountainous, just like the Tapolca Basin. In this area volcanic erosion remnants are closely spaced, and the significant erosion resulted a globally unique, breathtaking landscape that attracted scientific research since the 18th century. Relief inversion is a process where a negative landform becomes a positive one, e.g., a valley becomes a ridge. Relief inversion is particularly common in areas where rheologically contrasting rock types assembled. Relief inversion on volcanic terrains typically occurs when a valley filled by volcanic products that are either more erosion resistant since their emplacement (e.g., lava flow) or became harder than the surroundings through diagenesis (e.g., pyroclastic density currents). Over time, the valley shoulders diminish, and the resistant volcanic successions in the former fluvial networks become the new high ground. While relief inversion is mostly associated with linear valley networks, in volcanic environments craters (e.g., maar) and calderas can also act to capture volcanic products that are more erosion resistant. As a result of the relief inversion, the solidified rock (columnar jointed basalt) of lava lakes, especially those ponded within tuff rings/maars, can resist to erosion for much longer than the hosting pyroclastic edifices, generating inverted hills which are called “buttes” or “witness mountains” (the latter is a Hungarian term). The volcanic successions in the Tapolca Basin provide ample evidence that the volcanism was primarily driven by explosive magma and water interaction to form maar and tuff ring volcanoes. These volcanoes had broad and deep craters that operated as sediment traps or hosted scoria cones, lava flows and in some cases lava lakes. The differential erosion relatively quickly removed the tephra rings around the wide craters and carved into the pre-volcanic fluvio-lacustrine sedimentary layers leaving behind basalt lava and agglutinated scoria successions as hilltops. The volcanoes of Tapolca Basin represent a volcanic flare up between 4.5 and 3 Ma. Erosion made typical volcanic remnant hills marking a geomorphological level like the palaeosurface these volcanoes erupted on. World-class examples of columnar jointed basalt, peperite and diatreme-filling pyroclastic rocks complete the geological wonders of this region. As inverted relief is a unique type of differential erosion, Tapolca Basin is considered one of the best examples of complete geomorphic inversion of a high vent-density phreatomagmatic monogenetic volcanic field on Earth hence it has been selected to be one of the

Second 100 IUGS Geological Heritage Sites.

Suggestion of New Paradigm for UNESCO Global Geoparks

Daekyo CHEONG[1]*, Organizing Committee of IGC 2024 (dkcheong@kangwon.ac.kr)
Sujin HA[2], Pusan National University

Abstract

UNESCO Global Geoparks encourage international cooperation between areas with geological heritage of international value, through a bottom-up approach to conservation, local community support, promotion of heritage and sustainable development of the area. The original Geopark concept arose in the mid-1990s as a response to the need to conserve and enhance the values of geological significant sites in Earth history.

Global Geoparks consist of geological heritages, where science and local communities engage in a mutually beneficial way especially in remoted and low-developed areas. Education at all levels is also at the core of the Global Geopark concept. Geomorphic features and geological formations are key witnesses to the evolution of our planet Earth and are cornerstones for our future sustainable development. From the beginning, Geoparks adopted a “bottom-up” or community-led approach to ensure that an area’s geological significance could be conserved and promoted for science, education and culture, in addition to being used as a sustainable economic growth for indigenous people through the development of responsible ways such as geotourism.

From now on, UNESCO Global Geoparks should change their paradigms, and actively widen their scopes upto some large civilized areas to carry out new goals in addition to economic benefit for local inhabitants. In partnership with big city communities, metropolitan Geoparks will particularly provide wide ranges of chances for education to many visitors including young generations and can maximize popularization of geosciences to regional publics nearby mega cities.

The contribution of UNESCO Global Geoparks and Global Geoparks Network to Geosciences

Maria-Luise Luise FREY[1]*, Global Geoparks Network (frey@terra-outreach.de)
Nickolas ZOUROS[2], Global Geoparks Network

Abstract

As a result of the economic boom of the coal and steel industries after World War II, a structural change began to take place in Europe in the 1960s, led to their collapse in the western industrialised countries. The shift in economic priorities led to new industries with consumer goods and services. Formerly important know-how in the geosciences, for example, was pushed into the background in favour of new disciplines, such as cultural sciences, humanities or environmental sciences, or the establishment of new universities. The overall structure of geoscientific services etc. has undergone a change. Problems like unemployment on the one hand and the development of new fields of work as challenges of a structural change encouraged people to come up with new ideas. From 1998, four European partner regions started the EU-funded project: "Development of Geotourism in Europe" with the aim of developing a European Geoparks Network (EGN) under the auspieces of UNESCO. Haute Provence (F), Lesvos Petrified Forest (GR), Maestrazgo (E) and Gerolstein/ Vulkaneifel (DE) founded the EGN in 2000 and accepted new members (Martini, Zouros & Frey 2003). In 2004, together with eight Chinese national geoparks, they created the Global Geoparks Network (GGN) with the aim of promoting the sustainable development of rural regions on the basis of geoscientific heritage. New ideas are often not taken seriously in their own discipline, are often ridiculed and need time to become known. However, the demand for proof of success is established immediately and the GGN members pick it up. In 2015, UNESCO recognised the 120 members of the Global Geoparks Network and adopted them as the basis of the new UNESCO programme: "International UNESCO Geosciences and Geoparks Programme". It consists of the pillars "International Union for Geosciences" and "Global Geoparks Network association" and is the first "bottom up" programme of UNESCO. Through the regular quality assessment and assurance of the "UNESCO Global Geopark - UGGp" certification by UNESCO and the results of their activities, they impressively demonstrate the importance of geoscientific heritage and its use for sustainable development of rural areas. After 20 years of GGN, an impressive geodiversity is in the public awareness worldwide. Fields of action such as geotourism, geo-education and sustainable development in rural areas are image- and value-shaping components for modern geoscientific work. At universities worldwide, new sub-disciplines and chairs have emerged in geotourism as well as in sports sciences, exercise and health (Gabriel et al 2018) or mechanical engineering new fields of research have emerged through the geopark movement in social and linguistic sciences, didactics and pedagogy (Hlawatsch & Felzmann 2023), as well as in art and philosophy (Mehrpooya & Morovat 2021: 191-202).

By the end of 2024, there will be 215 UGGps with the "UNESCO Global Geopark" label. They

look back on an impressive track record of publicising and promoting the importance of geoscientific heritage in modern society and its new uses actual as well as for future generations. This paper focuses on the achievements of Global Geoparks for the geosciences. The latter

Samcheok Geopark: Promising and aspiring geopark in Korea

Kyung-Sik WOO[1]*, IUCN WCPA Geoheritage Specialist Group (happyman369@naver.com)
Kwang Choon Lee[2], Sangji University
Lyoun Kim[3], Cave Research Institute of Korea
Chong Chul Paek[4], The Korean Association of Natural Heritage Conservation
Junki Kim[5], Samcheokcityhall

Abstract

High geological diversity in Samcheok City is characterized by Precambrian metamorphic rocks of sedimentary and igneous origins, Cambrian to Ordovician marine sedimentary rocks (Joseon Supergroup), Carboniferous to Triassic, marine to nonmarine sedimentary rocks (Pyeongan Supergroup), Cretaceous volcanic rock (rhyolite), plutonic rock (granite) and pyroclastic rock (tuff), Cretaceous terrestrial clastic rocks of alluvial to fluvial origin, and Miocene marine sedimentary rocks of hemipelagic origin with plant and insect fossils. Also, Quaternary travertine formed by limestone karst spring and cave speleothems can be added. High mountain range in the west (Baekdudeagan), coastal erosional and/or depositional landforms along the eastern sea coast, various karst landforms and caves of different genetic processes, and specialized ecological habitats provided by karst springs provide high geomorphic diversity and ongoing processes. Among them, high national geoheritage values of some limestone caves and the lower Paleozoic sedimentary sequence in Seokgaejae area provide the justification to be endorsed as a Korean national geopark. This high geodiversity may well be enough to provide effective geotourism for public geo-education. Twelve geosites are selected based on geoheritage values and their high potential for educational tourism and local sustainable development; (1) Daetjae Baekdudaegan mountain range, (2) Jukseoru fluvial landform, (3) Deokbongsan coastal depositional landform, (4) Chogok coastal erosional landform, (5) Jangho coastal landform and its related ecosystem, (6) Chodanggul Cave and Sohan Valley, (7) Daeiri cave area, (8) Mugeonri moss waterfall, (9) Miin Waterfall and Tongri Gorge, 10) Gagok sulfur hotspring, 11) Deokpung Valley, and (12) Seokgaejae Lower Paleozoic sedimentary sequence and Seokgaejae Cave. Especially various and abundant, ecological, historical, cultural and archaeological features nearby every geosite, together with their close geographic proximity to each local village would make stronger potential candidate for an ideal geopark in Korea.

[Keynote] Global Geoparks Network: 20th anniversary Protecting and managing Earth heritage - Building Sustainable Communities

Nikolaos ZOUROS[1]*, University of the Aegean (nzour@aegean.gr)

Abstract

The Geopark concept was introduced at late 90's aiming to protect and promote Earth heritage sites through the sustainable local development of territories containing abiotic nature of significant value.

The Global Geoparks Network (GGN) was established in 2004, under the umbrella of UNESCO and operates as an international network, providing a platform of cooperation among Geoparks, bringing together government agencies, non-governmental organizations, scientists and experts from all countries around the world in a unique worldwide partnership.

In 2015, the 38th UNESCO General Conference ratified the statutes of the International Geoscience and Geoparks Programme and the UNESCO Global Geoparks Operational Guidelines, introducing the brand UNESCO Global Geopark as a label of excellence for areas that meet certain criteria. Since then the Global Geoparks Network was recognized as the official partner of UNESCO for the operation of the UNESCO Global Geoparks.

In 2024, the GGN includes 213 Geoparks in 48 countries working to protect Geological heritage and promote local sustainable development.

The GGN organizes co-operation and mutual assistance between Global Geoparks and between Global Geopark professionals.

The GGN initiates and co-ordinates Regional Geoparks Networks which will foster international co-operation and promotion of sustainable development.

The GGN represents, advances, and disseminates knowledge in Geodiversity management and other disciplines related to studies in Geo-conservation, Geo-tourism, Geo-education and/or the management and activities of Global Geoparks.

An important component of the Geopark management plan is the support of the local economy. Geoparks create links with local tourist enterprises, restaurants and small hotels in order to provide the necessary infrastructure to meet the needs of the increasing number of park visitors. As a result many new enterprises are connected with the activities of the Geopark.

The Geopark also supports the making of local handicrafts such as the production of fossil casts and souvenirs by local enterprises. These items are on sale in the Geopark shop along with a variety of other locally made products and the Geopark promotes these products to its visitors.

Geoparks also collaborates closely with women's agrotouristic cooperatives and local organic food producers to offer their visitors the opportunity to taste and buy local food products. The catering for all Geopark events (conferences, meetings etc.) is supplied using the local traditional food. The Geoparks organize Agro-touristic festivals, which promotes quality local products, food and drinks. The Women's agrotouristic cooperative found that this festival provided them with an excellent opportunity to promote their products and their success lead to the creation of similar

cooperatives in other villages

Geoparks contribute significantly to territorial development by directly and indirectly creating new jobs. But what is even more important for the employment in the area is the number of other job opportunities which are created in tourist enterprises, small hotels, guest houses, restaurants and other activities connected with the increase of tourist flow in the Geopark area.

Several other local artisans, such as makers of handicrafts and ceramic fossil casts, carpenters, and blacksmiths, are permanent collaborators with the Geopark.

UNESCO Global Geoparks in Belgium - added value and perspectives.

Sophie Verheyden[1], Institute of Natural Sciences, Geological Survey of Belgium
Serge Delaby[2], UNESCO Global Geopark Famenne-Ardenne, Belgium
Jan Walstra[3], Institute of Natural Sciences, Geological Survey of Belgium
Xavier DEVLEESCHOUWER[4]*, Institute of Natural Sciences, Geological Survey of Belgium (xdevleeschouwer@naturalsciences.be)
Jonathan Jacops[5], Geopark Schelde-Delta, Belgium-Netherlands
Walter Jonkers[6], Geopark Schelde-Delta, Belgium-Netherlands
Vanessa M.A. Heyvaert[7], Institute of Natural Sciences, Geological Survey of Belgium

Abstract

Belgium has a rich history of managing its geological subsurface, dating back to the the beginning of the 19th century with the first geological maps covering France and the Netherlands also including the future territory of Belgium. Those geological maps were drawn at the request of Napoleon's government and printed in Paris. After a long period of exploration and industrial exploitations of the subsurface in Belgium, the decline of the coal mining led to a gradual fading for geology away of the forefront of societal concerns. Moreover, young people have limited exposure to geology in schools, despite the pressing contemporary challenges related to raw materials, clean energy, and natural hazards.

In 2014, research conducted in the caves of Southern Belgium, lead researchers from the Geological Survey, together with Mons and Namur Universities to the creation of the Geopark Famenne-Ardenne. This initiative earned the UNESCO Global Geopark designation in 2018. Building on this success, support was given during the creation of the cross-border Geopark Schelde-Delta in Northern Belgium and the Netherlands. It includes participation in the 3-years Interreg project (Be) Leefbare Schelde. This year, the Geopark also secured the UNESCO Global Geopark designation, marking a significant milestone with two such designations for Belgium.

The geoparks has had a profoundly positive impact by raising awareness among the public, including policymakers, about the significance of geology. While there is still progress to be made, these initiatives have fostered a greater appreciation for geoheritage and its role in enhancing our understanding of Earth processes through research. The public, whether residents or tourists, has shown keen interest and curiosity in exploring these territories in novel ways.

The geoparks facilitate the acquisition of resources necessary for improving the identification, characterization, digitalization, study, and management of geoheritage in Belgium. They also serve as platforms for initiating discussions with policymakers regarding specific legislation aimed at protecting this valuable heritage.

The Famenne-Ardenne Geopark offers a unique landscape associated with karstic features, developed on Devonian and Carboniferous folded and faulted limestone rocks. These rocks have undergone significant alterations during warm and humid climate periods with intense karstification. Caves were formed, subterranean meanders and hydrogeological systems such as "swallow-hole / resurgences" can be explained by the underground pathway of rivers sometimes

over 10 km.

On the contrary the Schelde Delta Geopark encompasses a distinctive transnational estuary where the tides of the North-Sea are impacting the course of the river Scheldt. This unique landscape is closely tied to the evolution of the Quaternary valley of the Scheldt river and its estuary. The environment undergoes significant changes influenced by climate change, fluctuating sea level, warming climate conditions, anthropic pollution, and pressure from the development of the nearby port of Antwerp. These dynamics shape this natural area, highlighting the importance of conservation and protection efforts.

A third geopark remains a viable option, as other regions in Belgium can showcase the connection between geology and human activities. UNESCO Global Geoparks play a crucial role in transitioning towards a more sustainable management of territories.

UNESCO's Earth Sciences Activities in Africa: Impacts on sustainable development and capacity building

Asfawossen Asrat KASSAYE[1], Botswana International University of Science and Technology
Özlem ADIYAMAN LOPES[2], UNESCO Earth Sciences and Geoparks Section, Division of Earth and Ecological Sciences (EES), Natural Sciences Sector (SC), Paris, France
Kombada Mhopjeni[3], UNESCO, Natural Sciences Sector (SC), Windhoek, Namibia
Kombada Mhopjeni[4]*, Geological Survey of Namibia (k.mhopjeni@unesco.org)

Abstract

UNESCO, as the the only United Nations organization with a mandate to support research and capacity building in earth sciences, has been supporting the development of African geosciences through its two flagship programs – the IGCP (International Geoscience Program) and the UGGp (UNESCO Global Geparks), within the framework of its leading moto: Earth Sciences for a sustainable Earth and sustainable Societies. Though there is an increasingly impactful geosciences community in Africa, considering the deep-rooted and diverse challenges in the continent hindering the growth of the geosciences, thereby limiting their impact on the sustainable growth of the African society, UNESCO's support is not only crucial but instrumental in helping alleviate these limitations. This keynote will address the impacts of the major initiatives and activities UNESCO has been carrying out in Africa in collaboration with local geoscience institutions including professional societies, universities, geological surveys, and African geoscientists. Emphasis of the keynote will be on ongoing major initiatives and activities, but reference will also be made to past initiatives, such as the African Network of Earth Science Institutions (ANESI), which has been very impactful in creating a database of African Earth Science Institutions and researchers, which further helped in creating and supporting several early career researchers to establish research networks and collaborations among African Earth Science Institutions. One of the major ongoing activities of UNESCO in Africa is supporting the training of Earth scientists form many countries in Africa on geoheritage inventory and development of geoparks in collaboration with the Pan-African Support to Geological Sciences and Technology Africa-EU Partnership (PanAfGeo) and local institutions and geoscientists in Africa as well as supporting fledgling geoparks in Africa through expert missions, which helped to enhance existing aspiring geoparks and to initiate new geopark projects in the continent. UNESCO, through its IGCP-766 project – Fostering Researchers in the Geosciences (FoRGe), has recently conducted a survey of the African geoscience community to identify the needs of the community with the ultimate goal of building geoscience research capacity in Africa. All these and many other UENSCO initiated and supported projects in Africa have been impactful in building capacity of researchers, in creating knowledge networks and in helping establishments of sustainable institutions such as geoparks. In order for these impacts to take root and to ensure that African societies fully benefit from the geosciences, UNESCO will work with member states to own these initiatives and build upon them.

Participatory inventory of geosites as a tool for geoheritage management in the Mixteca Alta UNESCO Global Geopark (Mexico)

Jose Luis SANCHEZ-CORTEZ[1]*, National Autonomous University of Mexico, Institute of Geography (jsanchez@geografia.unam.mx)
Norma López-Castañeda[2], National Autonomous University of Mexico
Xochitl Ramírez-Miguel[3], National Autonomous University of Mexico, Institute of Geography
José Luis Palacio-Prieto[4], National Autonomous University of Mexico, Institute of Geography

Abstract

Geosite inventories are important tools for determining the most important elements of the geodiversity of a territory, and also play a representative role when divulge an area of interest. Specialized literature has standardized the need for geosites to have a preponderant scientific value for their consideration.

However, in the context of geoparks, the efforts are made to ensure that geosites, in addition to their intrinsic interests, have a symbolic relationship with local communities. Geoparks seek to promote the relationship between the population and its environment.

In this sense, in Mixteca Alta UNESCO Global Geopark there is a valuable relationship between indigenous communities and their territory; this strong link unites the local cosmovision with geodiversity, evidencing it in their language, legends, orality, in the name of their communities. This sense of belonging must be encouraged and strengthened.

This particular panorama of the Mixteca Alta Oaxaqueña (Mexico) allowed us to generate a geosite inventory model that takes advantage of this strong social and geological link, for which a participatory inventory was developed that enhances this relationship, being a viable, appropriate and adapted option to the territorial reality.

Although this inventory was generated by local communities, represented by their municipal and communal authorities, the geosites listed and described effectively fulfilled the role of generating a panoramic vision of the main geological and geomorphological interests present in the territory of the geopark. A list of 48 sites was generated, of which 4.2% of the inventoried sites registered to have international importance, while 16.7% had national interest, 37% and 41% had regional and local values respectively.

Of the geosites inventoried through this method, 77.1% had some cultural, archaeological or anthropological value, linked directly or indirectly. But, on the other hand, 100% of the sites covered the geological and geomorphological interests previously prospected in this territory during the detailed geological mapping. 33.04% of the sites showed geomorphological interest, 19.79% petrological interests, 12.17% stratigraphic and sedimentological interests, 11.01% tectonic and structural interests, 9.28% mineralogical interests, 6.09% paleontological interests, 4.93% hydrogeological interests, and 3.77% pedological interests.

In general, this inventory covered a participatory need and also complemented geological-geomorphological information in the Mixteca Alta Geopark.

The Pollino UNESCO Global Geopark (southern Italy): a route in the Ancient Tethys Ocean

Roberto BUCCIONE[1], Department of Sciences, University of Basilicata, viale dell'Ateneo Lucano 10, 85100 Potenza, Italy
Giovanna RIZZO[2], Department of Sciences, University of Basilicata, viale dell'Ateneo Lucano 10, 85100 Potenza, Italy
Luigi BLOISE[3], Parco Nazionale del Pollino, 85048 Rotonda, Italy
Egidio CALABRESE[4], Parco Nazionale del Pollino, 85048 Rotonda, Italy
Giovanni MONGELLI[5]*, Department of Sciences, University of Basilicata, viale dell'Ateneo Lucano 10, 85100 Potenza, Italy (giovanni.mongelli@unibas.it)

Abstract

In the southern Apennines, rocks with distinctive characteristics, known as ophiolitic sequences, outcrop in the Pollino Massif near the border of the Basilicata and Calabria Regions. These rocks represent fragments of oceanic crust, with associated deep-sea sedimentary cover and record an ancient oceanic basin of Jurassic age known as Tethys Ocean. These rocks, which history began about 150-170 million years ago, were involved in the complex orogenic processes that led to the genesis of the southern Apennines. The southern Apennines is a fold and overthrust chain consisting of tectonic units resulting from deformation of the Mesozoic Apulian-African paleo margin. On a regional scale, the different tectonic units, which make up the southern Apennines in the Pollino Massif, are the result of compressional tectonics, which involved, at first, the rocks of the ophiolitic sequence and later, the Mesozoic-tertiary platform terrains consisting of calcareous-dolomitic successions. The geological features of the ophiolitic sequence constitute, therefore, fundamental elements that allow us to reconstruct the main evolutionary stages of this orogen. Pressure and temperature variations, to which ophiolitic rocks were subjected during the geodynamic evolution of the southern Apennines, induced both mineralogical and structural transformations in the original oceanic crust rocks. In the Pollino UNESCO Global Geopark trail, which is 720 m long, is possible to find the evidence of the opening of the ocean basin and its subsequent closure and to observe the origin and evolution of the rock outcrops and to understand the geological and environmental evolution of millions of years. The route is described through a series of stages with specific and detailed signage, where visitors can understand they are walking on the bottom of what was once an ocean. The geotouristic route deals with the rock outcropping at the "Timpa delle Murge" and "Timpa di Pietrasasso" sites, which represent the complete ophiolitic sequence of the southern Apennine area and characterize the landscape of the Pollino UNESCO Global Geopark. During the different stops, visitors will observe the different portions of the ancient Jurassic ocean and touch the different types of rocks of the Tethys oceanic crust which are: (I) the ultrabasic complex, whose dominant rocks are serpentinites; (II) the intrusive complex in which gabbros predominate; (III) the volcanic complex, with a spectacular outcrop of "pillow lavas"; and (IV) the cover of sedimentary rocks consisting of deep-sea deposits. The Pollino Massif ophiolitic sequence attracts visitors from all over the world since rocks that were

once part of an ancient ocean can be seen here and represents cultural patrimony that must be safeguarded, protected, and promoted.

Geopoetics as a new tool for the enhancement of the management of Natural and Cultural Heritage in UNESCO Global Geoparks

Georgius Dimitriadis[1], UNESCO Chair on Geoparks, Sustainable RegionalDevelopment and Healthy Lifestyles
Artur Abreu SÁ[2]*, Department of Geology, University of Trás-os-Montes e Alto Douro (asa@utad.pt)

Abstract

In recent times, there has been an increasing recognition of the significance of intangible assets, such as cultural heritage, on international platforms like UNESCO (UN Resolution 2199: 2015; UN Resolution 2347:2017) and various organizations (WB 22559:2000). This attention signifies a broader acknowledgment by scholars and policymakers of the crucial role played by cultural and geological heritage in driving regional socioeconomic progress. There is a concerted effort to incorporate contemporary discussions on geological culture and development, with a specific emphasis on comprehending prevailing patterns and practices across diverse geographical regions. This shift underscores the necessity of including both tangible and intangible aspects of heritage in endeavours to rejuvenate communities and economies.

Cultural and natural heritage are viewed as dynamic constructs that have been shaped by evolving value systems throughout history. Thus, the selection process for preserving certain objects, monuments, or natural environments is of utmost importance as it shapes cultural narratives and societal consensus about the past and present. In this sense, geological heritage sites hold symbolic importance as many times they represent cultural identities and foster a sense of community.

The management of cultural and natural heritage sites faces the challenge of striking a balance between the growth of tourism and the preservation of site authenticity and cultural significance. In this context, UNESCO emphasizes the significance of managing geoheritage to transmit cultural identity to future generations. In the same way, the Global Geoparks Network, which encompasses areas of geological and cultural heritage, is acknowledged for its potential contribution to human well-being. Within this framework, the concept of 'Geopoetics' highlights the dynamic relationship between humans and the Earth, providing a complementary approach to managing Natural and Cultural Heritage in UNESCO Global Geoparks. In effect, Geopoetics emphasizes geographical consciousness as a means to transcend limiting perceptions and enhance the management of heritage sites. Overall, there is a growing awareness of the interconnectedness between cultural, geological, and human dimensions of heritage, driving efforts to preserve and leverage these assets for sustainable development.

Geoheritage conservation and promotion on a small tropical island: first steps toward a UNESCO Geopark in Guadeloupe, Lesser Antilles

Yves MAZABRAUD[1]*, Université des Antilles (yves.mazabraud@univ-antilles.fr)

Abstract

Guadeloupe is located in the Eastern Caribbean (Lesser Antilles), a recognised biodiversity hotspot. It is an archipelago of six inhabited islands with a surface area of 1600 km2, 16% of which is protected, and a total population of over 400,000. This area is facing a rapid loss of biodiversity, which has led to several conservation measures in recent decades (creation of a National Park and a National Nature Reserve, protection of several forests, RAMSAR areas, Caribbean SPAW Protocol, Man and Biosphere Reserve). These efforts have led to a growing environmental awareness among the population, although much remains to be done. As an active subduction, tropical arc archipelago, Guadeloupe's geodiversity is particularly rich (carbonate platforms, living and fossil coral reefs, mangrove-rich mudflats, terrestrial and submarine thermal springs, various types of volcanic deposits, tropical karst and an active volcano, La Soufrière). Between the diminishing availability of resources (geomaterials and especially water), the multiple geohazards (volcanic, seismic, landslides, tsunamis, floods, hurricanes), the importance of soils for agriculture, and the growing income from ecotourism, the socio-economy of Guadeloupe is partly dependent on an effective geoconservation policy and strategy. Paradoxically, however, the geological heritage suffers from a lack of protection and is sometimes endangered or damaged.

We will present the strategy we have developed to prepare a geopark project and the results obtained so far. We will then present some of the questions and challenges we are facing in order to stimulate a constructive discussion.

University and Geopark: Fundamental Partnership for the Preservation and Promotion of Geological and Cultural Heritage.

Stela Mariana MORAIS[1]*, Universidade Federal do Triângulo Mineiro (stela.morais@uftm.edu.br)
Paula CUSINATO[2], Universidade Federal do Triângulo Mineiro
Thiago da Silva MARINHO[3], Universidade Federal do Triângulo Mineiro
Diogo Nobre SILVA[4], Universidade Federal do Triângulo Mineiro

Abstract

The role of universities in a Geopark, exemplified by the participation of the Federal University of Triângulo Mineiro (UFTM) in the Uberaba Geopark, is multifaceted and of paramount importance for the understanding, preservation, and promotion of the geological and cultural heritage of the region. UFTM offers scientific and academic expertise that is essential for understanding the geodiversity, natural, and cultural history of the Geopark. Collaborating with national and international research groups, the university develops projects and seeks to investigate and document the geological and cultural aspects of the region, contributing to the conservation and responsible management of resources. Additionally, UFTM actively participates in the development and execution of educational and scientific programs aimed at the Geopark. These programs not only inform but also raise awareness among the public about the importance of conserving geological and cultural heritage, promoting a sustainable relationship between the local community and its environment. The university's contribution also extends to the promotion of scientific and cultural dissemination activities for both the local community and visitors to the Geopark. This includes organizing events, exhibitions, lectures, and environmental education activities aimed at sensitizing the public about the importance of conserving geological and cultural heritage and engaging the community in its preservation. Specifically, UFTM plays a fundamental role in the management of Peirópolis Geosite, the main geosite of the Uberaba Geopark, coordinating a variety of activities that encompass teaching, research, tourism, local economic development, scientific dissemination, heritage, and cultural. Additionally, prominent events are regularly held at this location, contributing to the dissemination of knowledge and the promotion of the Geopark. In summary, the active participation of UFTM in the Uberaba Geopark exemplifies the essential role of universities in the conservation, research, education, and promotion of the geological and cultural heritage of a region. This collaboration is crucial to ensure the sustainability and responsible development of the Geopark, benefiting both the local community and visitors. By educating its students and contributing to the production of knowledge and documentation of geological and cultural heritage, the university plays a fundamental role in promoting research, education, and preservation within the scope of the Uberaba Geopark. Collaboration between the university, the local community, and other partners of the Geopark is essential to ensure the sustainability and responsible development of the territory, ensuring that its geological and cultural value is appreciated and protected for future generations.

Strategic Management of Geoparks: Conservation, Development, and Challenges.

Stela Mariana MORAIS[1]*, Universidade Federal do Triângulo Mineiro (stela.morais@uftm.edu.br)
Daniela ROCHA[2], AGA - Associação Geoparque Arouca

Abstract

In the context of preserving geological, biotic, and cultural heritage, as well as promoting sustainable economic development through geotourism, a proposal for the strategic management of geoparks is presented. This work outlines the stages of an integrated and multidisciplinary process, aiming not only at conservation but also at the valorization and promotion of the territory, based on the model used by Geopark Uberaba (Brazil). The idea of creating Geopark Uberaba, particularly regarding its management structure, drew inspiration from the UNESCO Global Geopark Arouca. Both share the model of an Association as the managing entity with the participation of entities serving as anchors in the Geopark. The AGA - Arouca Geopark Association, founded in 2008, is an association formed by entities of both public and private nature, with the Municipality of Arouca serving as the President of the Board, employing a bottom-up participatory working methodology. In the case of Uberaba, the Geopark Uberaba Association comprises the four signatories: the Brazilian Association of Zebu Breeders (ABCZ), Uberaba City Hall (PMU), Brazilian Service of Support for Micro and Small Enterprises (SEBRAE), and the Federal University of Triângulo Mineiro (UFTM). The first step of the model used by Uberaba consisted of forming working groups, representing the diversity of areas of action within a Geopark, including management, geology and geoconservation, education, natural heritage, cultural heritage, economic development, tourism, and communication. Each group had to work on goals outlined based on the UNESCO Geoparks Self-Evaluation Form and develop a specific action plan to achieve them. Leadership, performed by the Management group, played a fundamental role in coordinating and monitoring the progress of all areas of action. It was essential to establish clear communication among the groups, ensuring that short, medium, and long-term priorities were aligned so that resources were allocated efficiently. Progress assessment was conducted using the "101 questions" form, allowing for a comprehensive and careful analysis of the Geopark's performance in relation to UNESCO criteria. This assessment served as a guide to identify strengths and areas that needed improvement, paving the way for the Geopark's candidacy. The main challenges were: 1. Establishing and maintaining a collaborative network from the early stages of the project, promoting an inclusive and participatory approach. 2. Making strategic decisions under conditions of uncertainty and risk, especially during the evaluation process for endorsement. 3. Balancing the technical and political dimensions of the team, recognizing and integrating different perspectives and skills necessary for project success. Conclusion: The strategic management of geoparks is a continuous mechanism of how the conservation of natural and cultural heritage can be integrated into the sustainable economic development of a community. The success of a Geopark is not limited only to obtaining UNESCO

endorsement but also to building local/regional/national/international partnerships and promoting sustainable and responsible tourism, highlighting the importance of participatory and integrated management in conservation and territorial development projects. This model can serve as a reference for other regions seeking to balance heritage conservation with socio-economic development.

Identifying the Relationship Between Geoparks and Local Government Policies

KEYUP KIM[1]*, GeoMecca Engineering (geokey@hanmail.net)

Abstract

UNESCO defines a global geopark as a geological site with special scientific importance, rarity, or beauty and has ecological, archaeological, historical, and cultural values, promoting regional economic development through conservation, education, and tourism. In this study, the consciousness, willingness to pay, regional policy evaluation, and the direction of future regional policy of Cheorwon residents for the geopark were proposed. 1,500 copies of the questionnaire were distributed and 1,011 copies of the recovered effective questionnaire were analyzed. The confidence level is 95% with a sampling error of 0.3% points.

Among the local residents of Cheorwon-gun, 83.9% know about the geological park and 77.3% have visited, but 16.1% do not know it and have low satisfaction. 87.1% of residents think that geoparks are helpful for regional development and improve economic development, cultural status, affection, and pride. Environmental management was cited as a good policy in relation to geoparks. On the other hand, it is worth paying attention to 31.1% of residents who think that there are no good policies. Regional policies that are not good are related to income growth and public relations. Among the residents, 60.2% said they would donate to geopark-related programs. Meanwhile, 51.5% of the residents said they would volunteer and 48.5% said they would not.

The participation and cooperation of residents are necessary for sustainable development. To know this, the willingness to donate or volunteer was determined. Willingness to donate and volunteer was greater, and this is related to more positive groups, more good policies, higher the education level, residing closer to geological attractions, and higherage groups. Geoparks are estimated to bring an average annual economic profit of 7,569 million won per household.

The regional policies related to geoparks obtained through this study are as follows. First, residents must deeply understand geoparks and change their perceptions. Second, promotion policies should be expanded and digitized. Third, there should be an effective economic policy promotion. Fourth, customized policies should be pursued. Fifth, efforts for sustainable development are needed. Sustainable development of ESG management concepts is also required. Sixth, efforts to popularize geological parks are needed.

Geoheritage and Geodiversity in Yazd Province, the Potentials to Develop Shirkouh and Bahabad Geoparks, Iran

Alireza AMRIKAZEMI[1]*, National Iranian Geoparks Network (aamrikazemi@gmail.com)
Saeed Afsarifard[2], Nationa Iranian Oil Company
Soma Sayedyounesi[3], Geoscience Institute of New Age
Kimiya Ajayebi[4], Azad Islamic University of Karaj
Abolfazl Ezzatti[5], Azad Islamic University of Tehran

Abstract

Yazd Province in Central Iran is known for its remarkable geodiversity and diverse nature, complemented by a rich history and culture. From vast sand dunes and deserts to towering mountains and glaciers, this region offers a wide range of natural wonders. Additionally, Yazd Province is home to the rare and unique Zoroastrian community, as well as stunning examples of Islamic architecture from various eras. The local community takes great pride in their distinctive ceremonies and intangible heritage.

Shirkouh Mountain, with an elevation of 4075m, is the highest mountain in central Iran. This mountain is classified as one of the "Ultra Prominent Peaks". The presence of glaciers on this mountain is particularly unique, as they are situated at a latitude of 30 degrees in the middle of a desert. Another remarkable feature in this area is an underground conglomerate formation that functions as a natural dam, storing water. The Bahabad area is known for the best and rarest Liesegang patterns, which have a three-dimensional relief and are significantly larger than normal Liesegangs. Additionally, this area boasts the oldest exposed rocks in central Iran, dating back to the Pre-Cambrian era. Moreover, there are numerous structural, sedimentary, and geomorphological features in these areas.

Zoroastrians have been living in Iran and some neighboring countries for 2000 years. Currently, the largest community exists in Yazd Province, where they have their own temples and ceremonies. One notable temple is the fire temple in Yazd City, where a sacred fire has been burning for over 1500 years. It is known as the Eternal Flame. Each year, thousands of Zoroastrians, both from other cities within Iran and even from other countries, travel to this area as pilgrims.

The gastronomy of this area is unique and derived from desert living. There is a wide variety of natural herbs and vegetables that are used as food or traditional medicine. The indigenous people have a strong understanding of how to treat and remedy ailments using these natural products.

Qanat or Kariz was invented by Iranians to transfer water through underground channels to distant villages. The most famous and longest Qanats can be found in this area. It is a creative method to adapt to life in arid lands with limited access to fresh water.

After considering all the mentioned attractions and potentials, it is clear that there is a great opportunity to establish two geoparks in this province. These geoparks are intended to preserve and promote not only the geological heritage but also other types of heritage. The local community and authorities are highly enthusiastic about achieving sustainable development goals

through the geoparks. Extensive investigation and studies have already been conducted in these two potential areas, and the projects for establishing the geoparks are currently in progress.

[Invited] The master plan of Hantangang transnational UNESCO Global Geopark between ROK and DPRK.

KIL YOUNGWOO[1]*, Chonnam National University (ykil@jnu.ac.kr)

Abstract

The Quaternary Hantangang River Volcanic Field (HRVF) in the central part of the Korean Peninsula hosts unique volcanic landforms associated with fluvial topography. The volcanic field consists of a series of basaltic lava flows, ca. 0.1 to 0.6 Ma old, which originated from two source vents in DPRK (Democratic People's Republic of Korea; North Korea) and flowed along a 110 km long stretch of paleo-river channels to the terminus in the northern part of ROK (Republic of Korea; South Korea). In 2020, UNESCO Global Geopark Secretariat recommended that Hantangang UNESCO Global Geopark of ROK (Republic of Korea) should be expanded into a border area of the DPRK (Democratic People's Republic of Korea) for an enlargement of outstanding geological heritage values. Around Cheorwon-Pyeonggang lava plateau area (ca. 1,530 km2) of Pyeonggang-gun, Sepho-gun, Cheorwon-gun, and Gimhwa-gun in DPRK is a reasonable area to make the Hantangang transnational UNESCO Global Geopark. The Marble Arch Caves transnational UNESCO Global Geopark, located on boundary between British Northern Ireland and Ireland, should be considered as the most suitable preceding model, because both are located in the troubled regions. There are many geological, archaeological, and ecological attractive sites in the Hantangang transnational UNESCO Global Geopark. There are four phases of 10 years for the nomination of the Hantangang transnational UNESCO Global Geopark: first phase, the establishment of preparatory committees and joint researches; second phase, the geosite designation and the visitor program development in the DPRK; third phase the establishment of management plans of two Koreas and geopark center in the DMZ (demilitarized zone); and fourth phase, submission of geopark application and on-the-spot evaluation. If the roadmap, suggested in this paper, is successfully carried out, the Hantangang transnational UNESCO Global Geopark will have the greatest impact on establishing a peace system between two Koreas.

Historical and cultural value of Mount Baekdu as seen through old Korean maps

Sangmyeoung MOON[1]*, Northeast Asian History Foundation (moon@nahf.or.kr)

Abstract

Old maps are works of art that have great pictorial value because they contain both style and artistic flavor, and they also convey information about spaces that we are not familiar with in three dimensions. In particular, the time period and social perceptions of the time when they were created are comprehensively shown through the images, implying the local characteristics and perceptions of the people who lived, observed, and felt at the time.

Baekdu Mountain has been a part of the Korean peninsula not only in history and geography, but also culturally. Our ancestors emphasized Baekdu Mountain on their ancient maps. And they expressed it with various names. Baekdu Mountain has been called by many names, including Bulhamsan, Taebaeksan, Gaemadaesan, Dotasan, Jangbaek, Baeksan, Baekdu, and Gaiminsangsangsan. As a large mountain in Northeast Asia, it's only natural that it has been called by many different names over the course of people's memories.

It has also long been considered a sacred and special place and recognized as Taebaeksan, the mountain where King Dan descended. On the other hand, Baekdu Mountain is not emphasized on the ancient maps of China.

It is often said that Westerners perceived Joseon as the land of ginseng, but this is not the case. Westerners remembered the marten that lived in Baekdu Mountain and remembered Joseon as the land of marten.

Keyword

Old maps, Baekdu Mountain, marten, Taebaeksan, Bulhamsan

[Keynote] Transnational UNESCO Global Geoparks

Patrick James MCKEEVER[1]*, Global Geoparks Network (patrickgsni@yahoo.ie)

Abstract

Since the creation of the Global Geoparks Network in 2004 and the subsequent adoption of the UNESCO Global Geopark designation in 2015, the number of Geoparks has reached 213 in 48 countries. Of these, currently only 5 are transnational, i.e. they are shared by one or more countries. All 5 however are in Europe and are part of the European Union. A similar geographical imbalance is also apparent in UNESCO's two other heritage-related designations, World Heritage Sites and Biosphere Reserves.

This could be due to the significance of funding schemes available for cross-border cooperation in Europe and a long history of such cooperation following the end of the Second World War. Transnational properties, whether UNESCO Global Geoparks, Biosphere Reserves and World Heritage Sites have a fundamental role to play in bringing countries together, furthering international cooperation and fulfilling the mission of UNESCO itself, "Since wars begin in the minds of women and men, it is in the minds of women and men that the defences of peace must be constructed."

Of course there is great potential for the creation of transnational UNESCO Global Geoparks in other areas of the world but in some areas, such as the Korean peninsula, huge challenges remain due to a hard, closed border which does not permit the kind of community cooperation so fundamental to UNESCO Global Geoparks.

UNESCO, Geoparks, Transnational

Expected Effects and Key Strategic Approaches for Promoting a Transnational UNESCO Global Geopark Network in Northeast Asia, Including Baekdusan aUGGp and Hantangang UGGp.

Soo Jae LEE[1]*, Korea Environment Institute (sjlee@kei.re.kr)
Soo Jae LEE[2], Korea Environment Institute

Abstract

1. Overview
Although North Korea and China have been promoting the Baekdusan (Mt Paektu)/Changbaishan region as a UNESCO Global Geopark, China's prior designation as a UNESCO Global Geopark will have significant implications. This presentation explores strategies for promoting peace-based co-prosperity in Northeast Asia through the operation of transnational UNESCO Global Geoparks, in addition to addressing these implications. Furthermore, considering that UNESCO Global Geoparks are operated under international norms, we will examine an approach based on these norms.

2. The need for Baekdusan UNESCO Global Geopark and Transnational Global Geoparks
First, regarding the concern that the name "Changbaishan" will be used more frequently than "Baekdusan", it is desirable for North Korea to conduct a field evaluation of the UNESCO Global Geopark and be designated as soon as possible. It would be beneficial to actively promote the name "Baekdusan" through independent operation for a considerable period thereafter.

On the other hand, if North Korea pursues a Transnational UNESCO Global Geopark (TUGGp), it is necessary to strive for the selection of the name "Baekdusan-Changbaishan UNESCO Global Geopark." However, if this is not feasible due to various factors such as international norms and practices, efforts should be made to revise the UNESCO regulations regarding the use of names. In this case, it is necessary to establish regulations that allow North Korea to use the name "Baekdusan-Changbaishan UNESCO Global Geopark" and China to use the name "Changbaishan-Baekdusan UNESCO Global Geopark."

3. Necessity of Promoting Northeast Asian Transnational Global Geoparks
There are about four potential areas for TUGGps between North and South Korea. If conditions permit, it is necessary to promote these areas as TUGGps to seek peace-based co-prosperity between the two Koreas.

To effectively respond to the Northeast Asian TUGGps, it is necessary for South Korea to immediately start a dedicated organization and related activities. To this end, a "Northeast Asia Transnational UNESCO Global Geopark Forum" should be established to carry out its activities systematically and continuously.

4. Suggestions

The following considerations are necessary for the successful operation of Northeast Asian TUGGp.

- Preparation for Changes in Inter-Korean Political Situation
- Establishment of Sustainable Management Plan
- Securing International Support etc.

5. Conclusion

TNUGGps are essential for pursuing peace-based co-prosperity on the Korean Peninsula and in Northeast Asia. Even if the realistic conditions, such as the inter-Korean confrontation, are not sufficient, it is possible to prepare internally. Therefore, it is proposed to start with the "Northeast Asia Transnational UNESCO Global Geopark Forum." On the other hand, it is necessary to propose a revision of the operational guidelines for Transnational UNESCO Global Geoparks to UNESCO to minimize the side-effects of name usage.

The Designation and Denomination of Transnational Geoparks: A Case Study in East Asia

Jisung KIM[1]*, Hantangang River UGGp (intkim777@korea.kr)
Dongwon CHOI[2], Hantangang River UGGp

Abstract

To establish transnational geoparks, numerous obstacles must be overcome, encompassing not only political boundaries but also language, ethnicity, and historical perspectives.

Among these, language emerges as one of the predominant factors. Despite geographical congruence, many regions experience or have experienced conflicts over differing nomenclatures, even in areas physically identical. Such conflicts commonly arise in disputed territories with artificial boundaries, and they can occur within single political entities devoid of disputes.

The fact that three out of four existing transnational geoparks utilize bilingual naming highlights the challenge of achieving nomenclatural uniformity, surpassing the complexities of political integration.

Examining a prospective transnational geopark in East Asia, consider the case of the Hantangang River UNESCO Geopark in South Korea, where such impediments are non-existent. This region, comprised of a homogeneous ethnic group, remains separated into The Republic of Korea(ROK) and The Democratic People's Republic of Korea(DPRK) for political reasons of less than three-quarters of a century. Both sides utilize the same language and nomenclature, mitigating potential conflicts.

The other case is the Mount Changbaishan UNESCO Global Geopark in China designated recently. It is also a significant candidate for a transnational geopark. North Korea, which shares the identical geological area as Mount Changbaishan(in DPRK, it is called Paektusan), has requested UNESCO to designate its geological area as the "Mount Paektu Global Geopark." However, given the significant overlap in geological boundaries, it would be more appropriate for these areas to be designated as a single transnational geopark rather than separate national geoparks. Hence, the linguistic divergence between the two countries, each with distinct historical legacies, anticipates that consideration of the naming of transnational geoparks will be needed in the future.

Given these complexities, one alternative proposes leveraging geological terminology in geopark nomenclature. Geological terms offer neutrality compared to geographic names that originated from specific languages.

Necessity of Transnational UNESCO Global Geopark in East Asia: Focusing on Baekdu Mountain Geopark and Gangwon Peace Geopark

Donwon CHOI[1]*, Jeju culture promotion foundation (cave4@hanmail.net)

Abstract

Currently, there are no transnational Geoparks in East Asia. However, with the designation of China's Changbaishan Geopark as a UNESCO Global Geopark in 2024, it will share a border with North Korea's Baekdusan Mountain Geopark (Mt Paektu Geopark). This has led to a growing interest in South Korea, particularly due to the historical symbolism of Baekdusan Mountain. This presentation discusses the considerations for the establishment of a transnational Geopark in South Korea's Gangwon Peace Geopark, which currently borders North Korea.

1. Introduction

The establishment of a transnational Gangwon Peace Geopark presents unique challenges and opportunities. While the shared geological heritage of the region provides a strong foundation for cooperation, the political divide between North and South Korea poses significant hurdles. This presentation explores the feasibility and potential benefits of establishing a transnational Geopark in this region, considering both the challenges and opportunities.

2. Background and Issues of the Gangwon Peace Geopark

The Gangwon Peace Geopark was designated as a national Geopark in 2014. Despite its potential, the Geopark faces several challenges, including limited accessibility, lack of public interest, and a shortage of readily accessible geological sites. Furthermore, the designation of the Hantangang River, a key geological feature within the Geopark, as a UNESCO Global Geopark has further reduced the number of internationally recognized geological sites within the Gangwon Peace Geopark.

3. Issues to Consider in Establishing the Gangwon Peace aUGGp

Distance from Neighboring Geoparks: UNESCO recommends a minimum distance of 100 km between existing Geoparks when establishing new ones. However, the Gangwon Peace Geopark is adjacent to the Hantangang River Global Geopark, necessitating a careful approach to address this issue.

4. Key Issues in Establishing a transnational Gangwon Peace Geopark

Naming: The name "Gangwon" is used by both North and South Korea as an administrative district name. Therefore, if the two Koreas operate a transnational Geopark along the current DMZ, the name "Gangwon Peace Geopark" could be used, minimizing naming-related disputes. However, if North Korea requests a different name, a process for renaming would be necessary.

5. Proposal for Establishing a transnational Gangwon Peace Global Geopark

Given the current political situation, the immediate demilitarization of the DMZ between North and South Korea is unlikely in the short term. Fortunately, North Korea has also expressed interest in establishing Geoparks in various regions, as evidenced by their application for Baekdu Mountain Geopark in 2019. Therefore, the following phased approach is proposed:

- Establishment of Individual Geoparks in North and South Korea
- Establishment of the Gangwon Peace Global Geopark by South Korea Alone
- Establishment of a transnational Global Geopark through Expansion

6. Necessity and Expected Effects of the transnational Gangwon Peace Global Geopark

The Gangwon Peace Geopark is a place that bears the scars and history of the Korean War and was the very site of ideological confrontation. Therefore, geo-tourism based on geological heritage can be a region that can attract great interest from both domestic and foreign visitors.

This region is an area where détente is absolutely necessary for sustainable

Magnetic susceptibility measurement using simulated rock samples and application to the stone used in Himeji Castle, a World heritage site

Ayaha EMURA[1]*, University of Hyogo (fern.folium358@gmail.com)
Kyohei Sano[2], University of Hyogo
Norihito Kawamura[3], University of Hyogo

Abstract

As for the characteristics of rocks in Japan, volcanic rocks are commonly used as construction materials. Since ancient times, the technique of stone processing spread among the common people, and stones became ingrained in religious practices and daily life. In Geoparks, the relationship between geology and culture is an important theme. Stones have been carried and used for materials like accessories and buildings, so research on stone materials can tell us the relationship between people from different regions. It is the relationship between people and the earth, which is consistent with the Geopark ideal. In cultural geology in Japan, researchers observe the rock's texture and use magnetic susceptibility for the source identification of building materials and stone structures. However systematic studies have not been conducted on the stability of magnetic susceptibility measurements for rock samples, the relationship between the size of rock samples and magnetic susceptibility measurements, and the relationship between the crystallinity of volcanic rocks and magnetic susceptibility. In this presentation, we talk about the experiment of using simulated rock samples to propose a method for measuring the magnetic susceptibility and discuss the way and example applied to geopark.

Indoor experiments demonstrated changes in magnetic susceptibility when varying the magnetite content in the target object. The presentation also outlines correction methods for the thickness and area of the target object.

Considering these aspects, we think the magnetic susceptibility of the stone material used in Himeji Castle, a cultural heritage site, in Hyogo Prefecture can be compared with previous research findings.

The Journey: IUGS Geological Heritage Sites of Namibia

Helke Brigitte MOCKE[1]*, Geological Survey of Namibia (helke.mocke@mme.gov.na)

Abstract

Namibia has had an interesting geological history starting from the Archaean and lasting until the Cenozoic, spanning 2600 million years of Earth's history. It is also synonymous with various beautiful minerals, gemstones, meteorites, and fossils. Given all this wealth in geoscientific resources, which has received much international scientific attention for more than 100 years many potential geoscientific heritage sites could therefore be nominated as IUGS Geological Heritage Sites. This led geoscientists from the Geological Survey to nominate several sites in collaboration with scientists who have worked here.

The Nama Group of southern Namibia has attracted much research on the first multicellular organisms known as Ediacara, especially answering questions about the evolution of complex life forms. Already in the 1920s Georg Gürich and Paul Range published on the Ediacara from southern Namibia and in the 1960s and 1970s Hans-D Pflug and Gerard Germs respectively added much needed information to the understanding of these enigmatic animals.

In the Cryogenian rare, special geo-historical events called Snowball Earths during which ice sheets covered most continents are recorded in rock formations in Namibia and have been of scientific interest for some time. The exposures at Fransfontein Ridge were critical in framing the Snowball Earth hypothesis and the acceptance of this hypothesis.

The Etosha Pan attracts many tourists annually, but geologically and geomorphologically it has always contributed to much interesting scientific debate. It can be considered one of the largest palaeolake salt pans in the world which supported a diverse Neogene to Pleistocene fossil fauna, of which southern mammoths were part of the wildlife.

In 1962, Dr Charles Koch established the Namib Desert Research Station at Gobabeb. From this time the Namib Sand Sea has received much scientific attention, especially on the formation and evolution of the various dune types. It is estimated that the Namib Sand Sea covers an area of about 34,000 km2.

One of the richest ore deposits of rare minerals in the world is the steeply dipping Tsumeb polymetallic ore deposit which is located in northern Namibia and takes on the shape of a pipe that extends to a depth of 1 700 m. Already in 1906, the first type mineral Otavite of the Tsumeb ore deposit was discovered by Otto Schneider of the Berlin Mining Academy. Not only aesthetic minerals were studied but also ore minerals. This led Dr Hans Schneiderhöhn of the University of Freiburg to develop his own microscope to study ore minerals.

The Fish River Canyon in southern Namibia is the largest canyon in Africa, as well as the second largest in the world. It cuts through rocks that formed over more than 2 billion years ago and exposes the geological history of three major Proterozoic orogenic cycles. The canyon's main geological interests include stratigraphy and sedimentology, igneous and metamorphic petrology, tectonics, geomorphology and active geological processes, and palaeontology.

These are just a few sites that have been nominated for Namibia, and there are many more that have contributed invaluable scientific knowledge to the geosciences.

Inventory and Revision of Paleobiodiversity in the Uberaba Geopark: Challenges and Perspectives

Isadora PIZZI[1]*, Uberaba UGGp (isadora.pizzi@hotmail.com)
Thiago da Silva Marinho[2], UFTM

Abstract

The territory of the Uberaba Geopark comprises the entire area of the homonymous municipality, where two highly fossiliferous units of the Upper Cretaceous (Bauru Basin) are exposed: the Uberaba Formation (Campanian) and the Serra da Galga Formation (Maastrichtian). However, data regarding the diversity of known species are scattered and with few revisions over eight decades of publications, making research in the area and the control of the real paleobiodiversity existing in the Geopark difficult. Therefore, a survey becomes necessary that, in addition to checking the previous data, adds the new discoveries made in the last ten years. Initially, an analysis of the two most recent compilation articles was made, which included fossils from the Serra da Galga and Uberaba Formations. From these two articles, the species were listed and placed in a table in order to undergo checking of their original sources and redescriptions, when available. For this, extensive bibliographic research was necessary to obtain the largest possible amount of available data for all known taxa for the Uberaba Geopark. The relevant information added to the table included: taxon, geographical locality, location coordinates, geological unit, age, accession number, original reference, and revision reference when available. During the analysis of the articles for the survey, various problems were encountered, with the most serious being in the articles of invertebrates, where the description is confusing or even erroneous, not corresponding to the species they claim to describe. There was also a mistake in cataloging the locations, which often did not correspond to reality, since some of the listed species were not found in Uberaba. When possible, the data were corrected based on other articles and consultations with the collection logbook deposited in the Dinosaur Museum of UFTM. Despite the attempt to add as much information as possible to the table, not all data were found. A revision of the descriptions of invertebrates is necessary, as many present errors and/or are incomplete. This work is important because it is the first to bring a complete inventory of the paleobiodiversity of the Uberaba Geopark, which can serve as reference material for researchers and visitors.

Study on Environmental Characteristics of the Eundae-ri water spider(Argyroneta aquatica) habitat in Hantangang River Global Geopark

Jinah MOON[1]*, Kangwon National University (moon88@kangwon.ac.kr)
Heejung Kim[2], Kangwon National University

Abstract

Argyroneta aquatica, a rare species existing as a monotypic genus globally, spends most of its life underwater, creating air bubbles for habitation. This unique lifestyle is exemplified in South Korea solely by the Eundae-ri diving bell spider habitat within the Hantangang Global Geopark. Discovered in Eundae-ri, Yeoncheon County, in 1994, the necessity for conservation of this habitat was recognized, leading to its designation as Natural Monument No. 412. The habitat faces reduction in area due to extreme climate changes and drying conditions around the wetland. Efforts by the responsible local government include creation of artificial wetlands and groundwater extraction to control the water level, aiming to maintain the spider population. Based on monitoring surveys from 2019 to 2023, including data on spider population, pH, dissolved oxygen (DO), depth, geology, topography, and surrounding environmental changes, this study observes the environmental changes within the habitat, assesses its current state, and analyzes environmental factors affecting the spider population. Comparisons between breeding and non-breeding sites reveal lower average water temperatures and DO levels at breeding sites, while average depths and pH levels show similar trends. Given that Argyroneta aquatica typically hunts within a web at water depths of 5-10 cm, areas with depths of 15-20 cm are habitable, whereas those over 80 cm are unsuitable. This study proposes future research directions and management strategies for habitat preservation and maintenance to sustain the spider population.
This work was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (grant numbers 2019R1I1A2A01057002 and 2019R1A6A1A03033167)

Abstract

CoalHeritage for "Conservation and promotion of the Coal Mining Heritage as Europe's cultural legacy" is an EU-cofunded project focusing on former coalmining regions and those that are currently in a transition. Its objectives are to (i) Identify the processes needed to declare coal sites as heritage; (ii) Enhance management in the coal regions in transition, improving health and safety of employees as well as minimizing the environmental impact; (iii) Design and develop a European Visual Map Journal; and (iv) Disseminate information and develop a European network. Thus, this project aims to develop an interregional network for the promotion and conservation of coalmining heritage in Europe and to support local communities in transition.

France experienced coalmining activity for three centuries, with a gradual decline in recent decades. The French State has supported as far as possible the reconversion of the mining regions, whose most famous are Nord-Pas-de-Calais and Lorraine. The reconversion was a necessity to ensure their economic survival, and a policy to preserve mining heritage has developed in both regions, especially at the Wendel Mine Complex (WMC) and the Lewarde Mining History Centre (LMHC).

The WMC (parc-explor.com), one of the largest and most complete complexes of coal mining buildings in Europe, offers leisure-time and cultural activities for visitors who can discover the

miner’s museum, cycle paths and walking trails, and enjoy a large number of activities such as visits to mining towns. The museum invites visitors to discover the history of coal mining in Lorraine while revealing the place occupied by miners. In a modern and attractive presentation, objects, models and multimedia resources immerse visitors in the history of coal, the daily life of the miner and his family, and the social policies of mining companies. The WMC also aims to conserve and highlight collections (nearly 2,000 objects and machines), publications and temporary exhibitions.

Nestled in the UNESCO World Heritage Nord-Pas de Calais Mining Basin, the LMHC (chm-lewarde.com/fr) comprises expansive industrial structures. Since 1984, the centre aims to preserve and display the mining culture ensuring that the forthcoming generations gain insights into this 300-years mining history. The LMHC holds a collection of 15,000 objects representing the mining techniques, ethnology with representations of the miners’ daily lives, and geology with significant petrographic and palaeontological collections. The Centre also aims to raise public awareness of energy issues and improve our understanding of the current challenges about future energy sources.

The Italian Geosite Inventory: a useful tool for knowledge and geoconservation.

Elisa Brustia[1]*, ISPRA (elisa.brustia@isprambiente.it)
Paolo Primerano[2], ISPRA
Mauro Lucarini[3], ISPRA

Abstract

The importance of a Geosite Inventory is mainly linked to the growing need to know geoheritage within the national territory for scientific, educational and geotouristic purposes.
ISPRA, the Italian Institute for Environmental Protection and Research, collect information about "geosites" since the first 2000s when a collaboration project between Geological Survey of Italy and University of Genova started. It was driven from the common desire of the geological community to increase the knowledge of the Italian geoheritage. Presently, the Italian Geosite Inventory (ING) is a public geodatabase published on the ISPRA website, its consultation is open and all the information about each geosite is available. These concern, among other things, the classification of the degree of interest, information about divulgation and the state of conservation.

A map viewer is also available, where is possible to search geosites in a selected area. One of the most important activities carried on by ISPRA in collaboration with the Geological Regional Survey of Italy is the drafting of a document about "Criteria and Definition"; it's a necessary guideline to evaluate correctly every geosite. These guidelines are developed on the basis of the european ones (Wimbledon et al., 1995) and contain the definition of geosite, clarifying the terms "rare", "representative" and "exemplificative". On this basis, all the geosites that have been collected in the first phase of cataloguing of the Geosite Inventory are under a reviewing process, still in progress.
Although some italian regions are moving towards the introduction of regional laws, Italian geoheritage is not now protected by a national one. For this reason, the Geosite Inventory could be a useful tool for territorial planning and geoconservation.

Illuminating the cultural traces in the transition zones: Examples from the Mediterranean region

Nikos PAPADOPOULOS[1]*, Lab of Geophysical Satellite Remote Sensing and Archaeoenvironment, Institute for Mediterranean Studies, Foundation for Research and Technology Hellas (nikos@ims.forth.gr)

Abstract

Time, space and human intervention, are responsible for the conservation of archaeological remains and cultural heritage (CH) in general. The present and future survival of cultural remains is often compromised, particularly when the "space" in which these artifacts are today is hostile, rendering the documentation process a complex and expensive task. The accessibility to information regarding the current-state of now-submerged sites by minimizing the gap of available protocols and procedures for shallow-water CH investigations is nowadays quite important, considering the projected sea level rise due to climatic and geological factors. Thus it is very important to develop ways to explore and promote these under-studied submerged contexts improving at the same time the community awareness and involvement in protection practices.

Recently, geoinformation technologies integrating satellite/aerial remote sensing, photpgrammetry, geophysical prospection and risk assessment modeling have been extensively tested for the non-destructive documentation of littoral and shallow off-shore cultural material either visible or buried below the sea bottom. The complexity and constantly evolving environmental regime encountered in the transition zones posed limitations to implement efficiently such technological advancements in order to reconstruct the archaeoenvironment in these archaeological sites. The resolving capabilities, the spatial limitations, and the actual applicability of these technologies in mapping submerged cultural assets in shallow depth wetland environments was thoroughly investigated through laboratory numerical modelling approaches and extensive in situ implementation in coastal and submerged archaeological sites dating from prehistory to Byzantine times in Eastern Mediterranean.

The possibility to apply well-known methods to under-explored archaeological shallow-water contexts was very important from the methodological point of view and for the obtained results. Although the adaptation of commonly used tools to ultra-shallow depths presented some challenges and required the creation or customization of equipment, the final results support such efforts and provide useful information for the understanding of complex archaeological sites encountered in Eastern Mediterranean. Ultimately, the results of this work can integrated in the strategic framework of developing an effective interdisciplinary research model that could be applied to similar archaeological surveys in coastal or shallow-water environments thus contributing substantially towards the management and promotion of the concealed cultural resources.

Exploration of Characteristics of Pollen Assemblages in Soil Sampes of China

ping wang[1]*, Institute of Forensic Science,China (wp1029@cifs.gov.cn)
hongling guo[2], Institute of Forensic Science,China
hongcheng mei[3], Institute of Forensic Science,China
can hu[4], Institute of Forensic Science,China
jun zhu[5], Institute of Forensic Science,China

Abstract

The application of pollen analysis is in providing associative evidence, assisting to prove or disprove a link between cases, people and objects with places or with other people. The aerodynamic properties and the vast amounts of pollen grains released by many plants result in an airborne “pollen rain” which settles onto soil and other surfaces. In this paper, the pollen in soil was extracted by heavy liquid flotation method. Pollen assemblages were identified under optical microscope. Soil samples were collected from Beijing, Inner Mongolia, Shandong, Fujian and Xinjiang in China, including different regions, different climatic environments and different land use types in this paper.

The results showed that the pollen assemblages in soil samples from different regions were obviously different at a large spatial scale, and the content of the same pollen was different within a small scale. In soil samples with different climate environments and different land use patterns, there were remarkable pollen combination characteristics or marker types due to differences in vegetation cover types, like the pollen of Ephedra and Tamarix in Xinjiang. This study can provide the basis of inferring for geographic information and the environment. The analysis of pollen types as forensic samples can be used for comparison and geolocation purpose, such as to be confirmed or rejected by pollen types or to be identified pollen from diffrent carriers such as soil from soles to search dominant and/or marker pollen. However, the pollen results from the same soil vary across different sampling seasons. Moreover, when inferring information from the types and content of spore-pollen in soil samples, factors such as production, dissemination, sedimentation, and preservation of spore-pollen must also be considered.

Occurrence, Sources, Mechanisms of Enrichment and Possible Human Health Impacts of Fluoride-Bearing Groundwater in the Central Parts of the White Volta River Basin of Ghana

Moses Boakye OKYERE[1]*, University of Johannesburg, South Africa (mosesokyere5@gmail.com)
Hassina Mouri[2], University of Johannesburg
Carla Candeias[3], University of Aveiro

Abstract

Fluoride present in groundwater can affect its quality for domestic purposes, especially drinking and hence pose a risk to the health of the consumers. Therefore, the present study aims to determine the occurrence, sources and mechanisms of the high fluoride content in groundwater, in the central parts of the White Volta River Basin, Northern Ghana. Thirty-six (36) groundwater samples were collected and analysed to identify the hydrogeochemical processes responsible for variations in the groundwater chemistry. The Piper diagram, Gibbs plots, thermodynamic calculations, and multivariate statistical analysis, e.g., Spearman correlation matrix, and factor analysis, were conducted. Also, the study evaluated the human health risks associated with high groundwater F- consumption using the United States Environmental Protection Agency (USEPA, 1989) human health risk assessment model. The F- concentrations in groundwater samples varied from 0.2 to 19.5 mg/L, with a mean of 4.3 mg/L, with ~84% (n = 30) of the samples revealing levels above the threshold value of 1.5 mg/L, proposed by the World Health Organization (WHO, 2017). However, ~8% (n = 3) of the studied samples presented F- levels (0.20 to 0.25 mg/L) below the recommended value of 0.5 mg/L, considered needed for healthy human teeth and bone development. Meanwhile, ~8% of the samples had F- levels within the recommended standards of 0.5-1.5 mg/L (WHO, 2017). The predominant cation and anion in the studied samples were K+ and HCO3-, respectively and the dominant hydrochemical facies were K–HCO3 (33%); Mg – K – HCO3 (25%); K– Mg – HCO3 (11.1%), with other mixed water types. The Gibbs diagram and ionic bivariate plots suggested that groundwater chemistry, in the study area, was primarily controlled by water-rock interaction and ion exchange reactions. Furthermore, the R-mode factor analysis resulted in seven (7) principal components (PCs) having eigenvalues greater than 1 and accounted for a total variance of 82.86 %. The PCs confirmed that the major processes controlling the groundwater chemistry were mineral dissolution reactions, ion exchange processes and minor anthropogenic inputs, possibly from the use of sulfate and nitrate fertilisers. The spatial distribution of F- showed that the high concentrations were observed within the northeastern fringe of the study area, while the lowest levels were observed in the western fringe. The USEPA human health risk assessment revealed that the population including; infants, children, teenagers and adults had high hazard quotient (HQ) values ranging from 1.06 to 27.63. These values exceeded the safe limit of 1.00 recommended by the USEPA to prevent health risks associated with F-. However, children were found as the most hypersensitive population in the area, showing the highest HQ values of 1.56 to 27.63. This implies that most of the inhabitants, especially

children are prone to the health effects of elevated F- in water such as dental fluorosis. Therefore, preventive measures such as defluoridation techniques are suggested to be applied to reduce the high F- in the water content to make it safe for drinking.

Assessment of potentially harmful elements on human health and agriculture of surface and groundwater sourced from the granito-gneissic phreatic aquiferous formations in Bertoua and its environs, east region Cameroon.

SHARON NTUBE NGWESE[1]*, University of Johannesburg, South Africa (ngwese.sharon2@gmail.com)
HASSINA MOURI[2], University of Johannesburg, South Africa
RICHARD AYUK II AKOACHERE[3], University of Buea, Cameroon
CARLA CANDEIAS[4], University of Aveiro, Portugal

Abstract

The purpose of the present study was to determine the potentially harmful elements and their concentrations in the surface and groundwater used for drinking and agricultural purpose in Bertoua and its environs, and to assess their possible health effects on the communities in the area. Ion chromatography (IC) and inductively coupled plasma mass spectrometry (ICPMS) were used to determine the major and trace elements as well as anion concentrations in the 30 surface and groundwater samples during the wet and dry seasons. The results revealed that Al concentrations vary between 0.017 and 1.79 mg/l and remain the same in both seasons, while NO3 is slightly higher during the dry season (2.0 to 705.4 mg/l) than during the wet season (0.0 to 643.5 mg/l). Such concentrations of Al and NO3 are far much higher than the World Health Organisation drinking water guidelines (0.1 mg/l for Al, and 50 mg/l for NO3). The average value for hazard quotient, for non-carcinogenic outcomes of Al was 6.6, with 96 % of the samples >1. The average value for hazard index of NO3- was 20.14 for males, 23.80 for females, and 9.61 for children, all >1, with 100 % for NO3, showing that human consumption of surface and groundwater, according to the United States Environmental Protection Agency guidelines can result in adverse health effects. Piper's diagram classified these waters as CaCl, Ca-Mg-Cl-SO4, CaHCO3, NaCl, and NaHCO3, suggesting the evolution of the water chemistry from ionic exchange. Gibb's diagram showed that rock weathering was the primary control of surface and groundwater geochemical characteristics, with minimal influence from precipitation. Surface and groundwater in the study area were assessed for irrigation suitability using various indices and showed that Na adsorption ratio <10 and Permeability Index >75 was excellent, while Kelly ratio <1 and Mg adsorption ratio <50 was suitable. Agriculture Food and Organisation and Wilcox diagrams showed that water can be used for irrigation. The possible sources of Al enrichment in the surface and groundwater might be geogenic caused by weathering of the granitic rocks, which are the main geological formation in the study area, while nitrate enrichment may be anthropogenic due to the use of fertilizer for agriculture in the area. Based on the results above, the consumption of surface and groundwater with high Al concentration might present a potential health risk to the population in the study area, that can induce serious common health issues such as Osteomalacia and Alzheimer, while high NO3 might trigger methemoglobinemia, colorectal, and thyroid cancer amongst others.

Environmental and Health Risk Assessment of Coal Mining in Moatize, Tete, Mozambique

Micaela Arlete Jose CHAPO COSSA[1]*, University Of Johannesburg (mchapo906@gmail.com)
Kim Dowling[2], RMIT University, Melbourne, Australia
Vicente Albino Manjate[3], National Institute of Mines, Ministry of Mineral Resources and Energy, Maputo – Mozambique
Hassina Mouri[4], Department of Geology, University of Johannesburg, South Africa

Abstract

Tete Province, in the central part of Mozambique, has several natural resources, including extensive coal reserves in the Moatize Coal Basin. In this basin, coal is being exploited by mining companies such as Jendal, Nkondezi Mining and Vulcan Mozambique, with the latter controlling the largest mining concession area of approximately 25,000 ha.

Mining has the potential to release toxic trace elements into the environment through various vectors including dust. Without appropriate controls, the dust may degrade the environment with direct impacts on water, air and soil quality as well as indirect impact on food crops grown in affected soils and irrigated with contaminated water.

The coal field in Moatize is located close to the Zambezi River drainage system incorporating the Revúboè River and its tributaries. This drainage system crosses the district and presents an extensive rivers network that distributes contaminates. This rivers network provides drinking and agricultural water for local communities. Furthermore, the community of Moatize uses coal in homemade brick kilns. Ash resulting from coal burning is disposed of in the local environment without environmental controls, which enables this material to be transported by wind, and rain to riverbeds, resulting in further environmental contamination. It is therefore important to assess the impact of the coal mining in the study area on the environment quality and its possible health impacts on the local communities.

For Environmental Risk Assessment of Coal Mining, preliminary ten water sampling and field assessment revealed mean EC value of 3022 µs/cm, which is above the accepted limits by Mozambican legislation of 50 – 2000 µs/cm. Furthermore, all samples exceeded 5 NTU, the turbidity values set by Mozambican water quality legislation. pH and Total Dissolved Solids (TDS) parameters, were within the limits required by Mozambican water quality legislation (6.5 – 8.5) and 1000 mg/L, and by WHO (6.0 - 9.0), respectively. These preliminary results suggest that the population of Moatize might be consuming poor quality water. Therefore, a detailed, systematic and extensive sampling program (water samples as well as source material from the mining area including mine tailing, soil, ash and dust) is proposed. This will be accompanied by a human perception survey and health investigation program to assess public awareness of water quality issues and potential impacts. It is essential for the long term health of the region that we assess the level of contamination and determine impacts.

The occurrence of potentially harmful elements in gold mine tailings and their possible impacts on the environment and public health with reference to the Welkom goldfields in South Africa - A review

Rinae MAKHADI[1]*, University of Johannesburg (makhadir@ufs.ac.za)
Hassina Mouri[2], University of Johannesburg
Robert Hansen[3], University of the Free State
Kim Dowling[4], STEM college, RMIT university

Abstract

Gold mining activities in the Witwatersrand basin, South Africa have produced over 270 mine residue deposits such as tailings facilities and waste rock dumps that have covered a total area of about 400 km2. Tailings storage facilities may contain high levels of potentially harmful elements (PHEs) that can be released into the air, soil, and water. Such PHEs can be taken up by humans through drinking water, dermal contact, and ingestion of impacted food crops or geophagia resulting in serious adverse health effects.

Many communities live in the vicinity of the Witwatersrand goldfields and are potentially at risk of being affected by PHEs emanating from the tailing's repositories. Extensive research has been conducted in certain parts of the Witwatersrand goldfields to ascertain the environmental and health impacts associated with the tailings. However very limited studies were conducted in the Welkom goldfields, which forms the focus of this study under the form of a PhD research project.

A review of previous studies in the Witwatersrand and Welkom goldfields on the occurrence of PHEs in gold tailings dams, as well as their environmental and public health impacts in comparable parts the world was performed.

This review provided insight into the environmental effects associated with gold tailings dams on the quality of soil, surface, and groundwater resources, as well as food crops and air quality. For example, previous studies in different regions of the Witwatersrand goldfields showed that U, SO4, As, Mn, Cr, Cu and Pb are amongst some of the most common PHEs emanating from the gold tailings dams. These studies have also highlighted that communities near the tailing's dams are prone to adverse health effects possibly linked to the occurrence of PHEs in their environment. A study in Tudor shaft, in the west rand of Johannesburg, South Africa revealed that children were at cancer related risk associated to the exposure of metal and metalloid from gold tailings. Given the environmental similarities between parts of the
Witwatersrand basin and the Welkom goldfields (the study area), it is therefore necessary to conduct a multidisciplinary research investigation in this latter to ascertain and quantify the presence of PHEs in the tailings materials, their mobility to the surrounding environment, pathways, their bio accessibility and bioavailability, impacts on the quality of air, water, soil and

food crops, as well as health of the communities.

Identification of mercury in stream sediment in Yanomami Indigenous Land, Roraima, Brazil

Patricia DURINGER Jacques[1]*, cprm (patricia.jacques@sgb.gov.br)
Eduardo Paim VIGLIO[2], cprm
Daniel d`EL Rei[3], Habitat Geo Consultoria

Abstract

In October 2022, the Geological Survey of Brazil – CPRM carried out an environmental geochemistry campaign in the Yanomami Indigenous Land, located in the Alto Mucajaí Region, state of Roraima in Brazil. The work is part of the project “Impact of Mercury on Protected Areas and Forest Peoples in the Eastern Amazon: An Integrated Health-Environment Approach” (http://dgp.cnpq.br/dgp/espelhogrupo/532438#identificacao), under the led by researcher from the Oswaldo Cruz Foundation (Fiocruz), Paulo Cesar Basta. Geological materials (river water and stream sediment) were collected from 14 points, and the main objective of the Fiocruz project is to carry out a specific analysis of the element mercury to find out whether there is anthropic contamination of the element and whether it is affecting the health of the indigenous population. The project encompasses geological material (river water and stream sediment) and biological material (hair, saliva and fish), as well as clinical, neurological, pediatric and psychological evaluation of the indigenous population residing in the location. The data with the results of the geological material are presented in VIGLIO & JACQUES (2023) in the CPRM environmental geochemistry technical report (https://rigeo.cprm.gov.br/bitstream/doc/23869/3/levant_geoq_mucajai_final_ab.pdf) and in the scientific article JACQUES et al. (2023) (https://www.mdpi.com/2305-6304/11/10/861). In Brazil, the National Environmental Council - CONAMA, is responsible for implementing environmental standards and indicating indicator systems, so CONAMA Resolution 357 of March 17, 2005 was used as a reference for water samples and for the current sediments CONAMA Resolution 454 of 01/November/2012 was used. The river water results do not show mercury values above the maximum limit, however two of the stream sediment samples showed higher values, the limit being 0.17 mg/kg. These are samples PJS009, with a value of 0.344 mg/kg and PJS010 with a value of 1.386 mg/kg. Both were collected near the Fumaça waterfall, where researchers reported that there was an illegal mining dredger. It was not possible to carry out collections upstream, according to initial planning, as the researchers were alerted to the danger related to the presence of ilegal miners. The presence of mercury levels above the limits established by CONAMA resolution 454 in the stream sediments indicates that the region upstream of Cachoeira da Fumaça may also be contaminated. The project's biological analysis data has not yet been published and it is important to carry out a joint analysis of biological and geological data to prove whether or not the local population has been exposed to waste left by illegal mining, present in the region, mainly Mercury contamination in the Mucajaí River affects aquatic biota, more specifically fish, which are consumed by the local indigenous population.

Abstract

In certain tropical and subtropical countries, including Sri Lanka, the problem of Chronic Kidney Disease with undetermined origin (CKDu) is widely recognized and mainly affects the agricultural communities in rural areas. Numerous case-control studies in Sri Lanka suggest CKDu is most likely an environmentally induced disease. Therefore, this study aims to determine the differences in groundwater quality consumed by the CKDu vulnerable community and non-vulnerable population in different climate zones in Sri Lanka. Water samples were collected from the dry zone with CKDu hotspots in Wilgamuwa (n=65), a dry zone with a low disease prevalence region of Hasalaka (n=28), and a CKDu non-prevalence wet zone of Kandy (n=20). In addition to basic field water quality parameters, samples were analyzed for their major anions, cations, and stable isotope compositions (δ2H and δ18O). The groundwater in the wet zone was slightly acidic (median pH= 4.89) and had a lower electrical conductivity (medium EC =172 µS/cm) compared to the locations in the dry zone. According to Na-normalized bivariate mixing diagrams, silicate weathering is pronounced in disease-free areas, while predominantly silicate and carbonate weathering processes occur in dry zone groundwater. Ca-Mg-HCO3 type groundwater is more common in CKDu and low-prevalence regions, while Na+ is predominant in the non-CKDu areas. Interestingly, the average silicon (Si4+) concentration was higher in the CKDu prevalence area (46.14 mg/L) while lower in the disease-free area (8.22 mg/L) and the low-prevalence area (20.5 mg/L) in the dry zone without any significant variation of the lithologies of the regions. Furthermore, 62% and 36% of wells used by CKDu-vulnerable and low-prevalence communities were in the “hard” and “very hard” water categories, respectively. However, only 10% of the wells from the wet zone can be classified as hard or very hard. The fluoride concentration is significantly higher (at $p < 0.05$) in the CKDu area (mean:0.62 mg/L) compared to wells in the low prevalent zone (mean:0.16 mg/L) and the wet zone (mean:0.03 mg/L), indicating the risk of

vulnerability of dental and skeletal fluorosis other than CKDu from the elected community. In addition, the δ18O and δ2H plot for groundwater in the regions with CKDu prevalence and low prevalence of the dry zone showed a slope of 5.4 (δ2H=5.4 δ18O – 3.47) and 6.39 (δ2H=6.39 δ18O + 2.39), respectively. Most groundwater samples were plotted below the LMWL with a slope of 7.71, indicating the modification of groundwater either by mixing with surface water or by evaporation before infiltration. The intersection points of the GWL and LMWL of the two regions of Wilgamuwa (δ2H- (-35.05‰), δ18O – (-5.84‰) and Hassalaka (δ2H- (-34.64‰), δ18O – (-5.795‰) showed the average isotopic composition of the nearest rainfall obtained for the regions - North East Monsoon. In summary, the frequency of CKDu prevalence varies depending on groundwater composition, and continuous monitoring of disease progression in individuals at risk of CKDu could be interesting.

The Potential Traceability of Mineral Commodities using Artificial Taggant Particles

Laurance John DONNELLY[1]*, AHK and IUGS-IFG (laurance.donnelly@ahkgroup.com)
Quentin Dehaine[2], GTK
Ian Corfe[3], GTK

Abstract

Mineral resources have always played a crucial role in the development and advancement of civilisation. As we embark upon the so called 'battery revolution' and green revolution', minerals are likely to continue to remain fundamentally important. However, coinciding with this increasing demand for minerals are increases in crime in the mining, minerals and metals sectors. These include, but are not necessarily limited to illegal mining, illicit trading, theft, adulteration, substitution, fakery, smuggling. The beneficiaries are criminal cartels that legitimise huge profits via sophisticated money laundering schemes. Furthermore, the global flow of mineral commodities and associated regulatory frameworks are economic and political concerns. In Europe, these are driven by critical raw materials (CRMs) requirements, the European Union Battery Regulation and European Union Directive on Corporate Sustainability Due Diligence. A strategy is needed to trace minerals in order to 1) determine their legitimate provenance, to discourage illegal mining and trading, and 2) allow required data to follow minerals throughout their entire usage lifespan. The objective of this paper is to provide an overview of geological methods of traceability, using for example elemental analysis, geochemistry, mineralogy and isotopes. Additionally, this paper provides an overview of the three-year Horizon Europe funded MaDiTraCe (Material and Digital Traceability for the Certification of Critical Raw Materials) project, involving 14 partners and six countries. There will also be a focus on the potential use of artificial taggant particles (ATP) to track mineral commodities through global supply chains. ATPs were initially developed to track explosive additives but were later adapted for commercial and technology goods. Typically, these included clothing, pharmaceuticals, chemicals, drugs, explosives, vehicles and watches. The main taggants used include inks, dyes, spiked pollen and a variety of micron-sized particles or barcodes.

Hazard and exposure assessment in contaminated land investigations and environmental management: The Lavrion case study, Hellenic Republic

ALECOS DEMETRIADES[1]*, IUGS Commission on Global Geochemical Baselines
(alecos.demetriades@gmail.com)

Abstract

The development of an integrated environmental management scheme should constitute the ultimate objective of contaminated land investigations. To develop such a scheme, it is necessary to carry out a systematic investigation, and to evaluate all spatial data and information generated, i.e., maps of (a) geochemical distribution of potentially toxic elements; (b) distribution of metallurgical processing wastes or other types of waste; (c) land use; (d) hazard and exposure assessment, and, of course, to propose effective rehabilitation techniques and their cost. In the decision-making phase, the results of cost/benefit analysis are important, because the cost in relation to the benefit index of recommended rehabilitation methods is evaluated, and remediation of land is accordingly prioritised. Since, in contaminated land investigations in urban areas the end aim is the development of better living conditions for the local population, it is important to communicate both the hazards of land contamination and the benefits of its rehabilitation to the people. The fundamental components of environmental risk assessment (hazard and exposure), the procedure of environmental management, as well as the problems of risk perception and communication, using the Lavrion (Hellas) case study results will be concisely described.

The large quantity and spread of mining and metallurgical processing wastes in the Lavreotiki peninsula and the Lavrion urban area (55 km SE of Athens) caused, together with other morphoclimatic factors (wind, streams, etc.), the contamination of the surface cover by Pb, As, Sb, Cd, Cu, Hg, Zn, etc. The rock geochemical survey determined the possible primaeval soil geochemistry in Lavrion before humans began contaminating it with their activities. Whereas, detailed mapping and chemical characterisation of metallurgical processing wastes, in combination with the geochemical survey of soil cover and house dust, have revealed the extent and intensity of the contamination problem. Despite the alkaline pH of the soil, high carbonate content of flotation tailings, carbonate rock substrate and Mediterranean climate (low rainfall during the winter months), their extreme contamination load is such that leaching of contaminants has been initiated and their downward movement towards groundwater has started.

Exposure effects on the population, due to the local severe environmental contamination, are verified by high levels of Pb in child blood and deciduous teeth. Child blood-lead concentrations, in combination with other variables, such as lithology, soil geochemistry with respect to lead, spatial distribution of metallurgical processing wastes and land use types, were used in the generation of a multi-criteria algorithm to assess the hazard and exposure of children to environmental contaminants.

It is concluded that the multi-element contamination of the ‘soil cover’ in the Lavrion urban area is very high, and presents a non-acceptable risk to the health of the local population, and is potentially hazardous to plants and animals. Consequently, rehabilitating the whole urban area with suitable cost-effective methodologies is considered extremely urgent.

Investigating the relationship between health and the environment using soil and air pollution data in a changing climate.

Jennifer M MCKINLEY[1]*, Queen's University Belfast (j.mckinley@qub.ac.uk)
Shay Mullineaux[2], Queen's University Belfast
Ruth Hunter[3], Centre for Public Health, Queen's University Belfast
Joanna Sara Valson[4], Centre for Public Health, Queen's University Belfast
Bernadette McGuinness[5], School of Medicine, Dentistry and Biomedical Sciences, QUB

Abstract

Soils can reveal the legacy of historical and modern pollution. Urbanisation will have an increasing impact on soils because of climate change. Therefore, soils can be used as 'urbanisation tracers' to determine geogenic and anthropogenic contamination. Research also shows that ultrafine particles (including lead (Pb), Molybdenum (Mo) and Sb) may become blood-borne and translocate to other tissues such as the liver, kidneys and brain. Therefore, urban soils combined with air pollution data may be used as a proxy for the availability of toxins for human intake from environmental pollution. The environment also plays an important role in promoting brain health and preventing dementia through access to green/blue space, and promoting walkability and cyclability. Exposure analysis undertaken as part of the UKRI ESRC SPACE (Supporting Environments for Physical and Social Activity Healthy Ageing and Cognitive Health) project explores how the local environment and pollutants synergistically affect our cognitive health outcomes. Studying long-term health outcomes in the NICOLA cohort, the "Northern Ireland Cohort for the Longitudinal Study of Ageing", comprising 8,000 older people, we can explore how different environmental factors relate to brain health. In this part of the study we use road buffer analysis (testing buffers of different sizes: 300m, 500m, 1000m and 2000m) for an elemental sub composition (comprising As, Cd, Co, Hg, Mo, Pb, Rb, Sb, Se, Sn, Th, U, Al, Ba, Cr, Cu, Fe, Mn, Ni, Sr, V, Zn) of an urban soil geochemistry database of total element concentrations of potentially toxic elements (PTEs). Combined with air pollution data: fine particulate matter (PM2.5), PM2.5 source fraction, PM10 and Nitrogen oxide (NOx), we examine the statistical relationship between cognitive Metrics provided in the NICOLA dataset with environmental toxins to assess how the participants' health outcomes are linked to proximity to transport networks. We also examine the decay rate function of different air pollution particles and the relationship to soils. A compositional balance and multivariate analysis approach is demonstrated to assess the association between the environmental toxins associated with proximity to road networks and the different cognitive health indicators.

Abstract

Understanding the transfer of contaminants from soil to plants, particularly in agricultural products, is crucial in environmental science, especially within the context of risk assessment and the development of sustainable agricultural practices. The estimation of transfer factors (TFs) (Singh et al., 2011), which quantify the adsorbption of elements or pollutants by plants from the surrounding soil, serves as a fundamental parameter in evaluating potential ecological and human health risks, as these elements may enter the food chain (Ozhovan and Kremenetskiy, 2018).

For this study, transfer factors from soil to plants were estimated using bioavailable concentrations (Guarino et al., 2022) of Potentially Toxic Elements (PTEs) identified by Italian law (D.lgs. 152/2006) in agricultural soils and the elemental concentration in primary agricultural products (PAP). These latter are freshly harvested fruits and vegetables, maintaining their integrity and freshness as they have not undergone significant processing and were collected across the entire region through the Campania Trasparente project (www.campaniatrasparente.it).

The study aimed to compare various transfer factors (TFs) among the most numerous vegetal species and potentially highlight different behaviors. A robust multivariate statistical approach, such as Robust Principal Component Analysis (RPCA) (Hubert et al.), was applied to the TFs, and multiple regression analyses were conducted using the stepwise method, with Principal Components (PCs) as dependent variables and soil physical parameters (grain size, organic matter, pH, cation exchange capacity, salinity, electrical conductivity) as independent variables.

Results revealed distinct patterns in the soil-to-plant transfer factors for various elements, emphasizing the role of soil properties, plant species, and environmental conditions. The results indicated that within the Campania region, the highest TFs for most vegetal species are associated with Zn and Cu. Specifically, RPCA indicates a positive correlation between Zn and Co TFs. Furthermore, multiple regression analysis applied to the PCs highlighted that certain soil physical

factors influence TFs across different plant species.

This integrated approach provides a comprehensive understanding of soil-plant transfer processes and the impact of soil physical parameters on TFs in regional cultivations. The study aids in better understanding the impact of soil physical parameters, such as cation exchange capacity (CEC), grain size, organic matter, etc., on vegetal species growth, leading to well-informed decisions regarding crop selection, fertilizer application, irrigation, and other factors.

The Development of Strontium and Oxygen Isoscapes to Determine a Geographical Origin of Human Remains in Korea

Seongshin GWAK[1]*, Mr. (ssgwak@korea.kr)
Yu Ran Lee[2], Dr.
Dongkye Lee[3], Dr.
Byeongyeol Song[4], Dr.

Abstract

Strontium (Sr) and oxygen (O) isotope analyses have been considered as a tool for human provenancing in the field of archaeology, ecology, and forensic science. As one of the alkaline earth metals in rocks, Sr has four naturally occurring stable isotopes: 84Sr, 86Sr, 87Sr, and 88Sr. The radioactive β-decay of rubidium-87(87Rb) produces radiogenic 87Sr with a half-life of 48.8 x 109 years. Bedrocks of different ages and Rb/Sr ratios have variable Sr isotope ratios (87Sr/86Sr) which can be transferred to a human body through food intake including groundwater and local food products. It is expected that 87Sr/86Sr of a human body correlate with environmental samples (groundwater, soil, rocks, plants, etc.) in a specific region. Oxygen is the most abundant element on Earth with three stable isotopes: 16O, 17O, and 18O. It is well known that the oxygen isotope ratio(δ18O) of human bone is related to the consumed sources of oxygen, including food intake and drinking water. In order to obtain useful geographical information of specimens, it is required to have a reference Sr and O isotope ratio map (isoscape) in the region of interest. This study was focused on the construction of Sr and O isoscapes using human tooth enamel taking account of environmental contribution. A total of 156 dental samples were collected from individuals with necessary information including a place of birth and address depending on age group classifications. Each dental sample was then prepared for the determination of Sr and O isotope ratios. Tooth samples were cleaned and ground for Sr and O isotope analyses. For the Sr isotope ratio analysis, the aliquoted ground dental samples were digested with a series of multiple steps for the quantification of Sr concentration using inductively coupled plasma mass spectrometry (Agilent Technologies). 87Sr/86Sr was then determined using multi-collector inductively coupled plasma mass spectrometry (Nu instruments). Another set of aliquoted ground dental sample was then prepared for the O isotope ratio analysis using a gas bench isotope ratio mass spectrometer (Thermo Fisher Scientific). Due to a limited number of dental samples for isoscapes, obtained data for 87Sr/86Sr and δ18O of dental samples were interpolated by inversed distance weighed (IDW), kriging, and spline (RBF-ST) methods using a coordinate-based Geographic Information System(GIS).

[Keynote] Community to Combat Crisis: Steps to engage with our environment and progress to better human and environmental health outcomes.

Kim DOWLING[1]*, RMIT University (kim.dowling@rmit.edu.au)
Philip Warner[2], Albatross Consulting
Macklin Leslie[3], RMIT University

Abstract

The UN Sustainable Development goals assert many principles and measures to attain sustainability and achieve a resilient human society that exists in harmony with our environment. However, humanity continues to address the major threats in a siloed and segmented manner. We make narrowly focused attempts to address the myriad of issues such as climate change, contaminated sites, human hunger, or population growth as individual items with scant regard to linking the components in a holistic systems-based approach. A partnership-centred approach that holistically addresses the significant issues and practices that threaten the survivability of humans is required and we need new ways to engage with our populations that demonstrate environmental connections. Medical Geology gives us a mechanism to consider a systems wide approach that maintains a focus on the human.

We suggest this siloed mentality is a social expression of physical distancing from the natural environmental. It is the result of increased urbanisation where exposure to nature is modified, limited, distorted, or remote. It is compounded by political messaging, expediency, short-term planning focusing on growth, and the ever-increasing demand for and acquisition of goods.

Complex holistic interventions are unlikely to appeal to populations and leaders in our current sociopolitical environment. To address this issue, we must establish new ways of Earth Systems engagement. Human and environmental health requires the reestablishment of the close and clearly defined links between environment and humans. We need to normalise that humans are part of the environment and not just differentiated users of the planet's products and functions. We explore the simple practice of supplementary foraging for food (fungi) and urban vegetable gardens as a way to reengage with environment, improve health outcomes, and establish a direct link between human and environmental health and thereby potentially drive change. The discipline of Medical Geology proved the scaffolding for this exploration.

Coupling of neurodegenerative diseases to element distribution through geospatial statistics

Katelyn Elisabeth Murphy[1], Department of Civil, Environmental and Natural Resources Engineering, Applied Geochemistry, Luleå University of Technology, Luleå, Sweden
Sarah CONRAD[2]*, Luleå University of Technology (sarah.conrad@ltu.se)
Lena Alakangas[3], Department of Civil, Environmental and Natural Resources Engineering, Applied Geochemistry, Luleå University of Technology, Luleå, Sweden

Abstract

Medical geology is a growing field in which elemental distribution from natural and anthropogenic sources are studied, and uptake by humans through exposure pathways such as ingestion, inhalation, and dermal contact are linked to disease development and/or progression (Selinus et al. 2010). This project aims to increase the knowledge of how we are affected by our environment and focuses on neurodegenerative diseases, including Multiple sclerosis and Parkinson's disease (MS and PD), and potential links to elemental distribution in bedrock, soil, sediment, and groundwater. Neurodegenerative diseases have been shown to be linked to an upset in the homeostasis of and interactions between metals in the brain, including Al, As, Cd, Pb, Mn, and Zn (Bredholt & Frederiksen, 2016; Karri et al., 2020; Schofield, 2017). To explore these linkages, soil and groundwater geochemical data from the last 35 years (SGU) will be used in collaboration with municipal level data on neurodegenerative disease rates to determine possible relationships. Geospatial statistics will be carried out using the geographical information software QGIS and statistical software. Statistical methods, including spatial weighting, factor analysis, and multiple regression, will be used to determine any statistically significant correlations between elemental concentrations and disease occurrence. Results from these analyses will be compared with relevant medical studies to assess validity and exposure pathways. These data will then be analyzed to locate areas for further environmental sampling. For example, acid sulfate soils, recently shown to overlap with MS prevalence in Finland, constitute a metal source directly linked to food production and drinking water resources (Åström & Roos, 2022). An environmental forensic approach using a multi-element and multi-isotope approach to pinpoint sources, transport, and exposure pathways to target elements will move medical geology forward. The compiled data will then be presented as a risk assessment mapping tool to ensure that the choice of residence will not jeopardise personal health and open the potential for increased monitoring of residents of potentially endangered areas.

Potential risk of CO poisoning for casual workers exposed to emissions from clamp kiln: a South African perspective.

Lawrence DIKO MAKIA[1]*, University of Venda, South Africa (dikom73@gmail.com)

Abstract

The South African Clay Brick Industry (CBI) is a sector that contributes towards job creation in the country; accounting for about 16921 direct employment. It is unclear if this estimate includes casual workers (CW). The latter, also referred to as non-standard workers, comprises persons employed mostly on temporary, fixed-term, seasonal, casual or for piece-rate work, often associated with peak or comparatively busier work demand related periods. Literature contends that CW are usually paid for results rather than time and do not enjoy the full protection of the South African labour law. The South African CBI makes use of CW, especially during unloading of bricks after firing. In the production of bricks, the CBI mainly employs clamp kiln technology (accounting for 69% of total production). Despite their cost effectiveness, clamp kilns are associated with significant CO2 emissions. Exposure through incomplete combustion of scintle may lead to CO poisoning. Risk of exposure is exacerbated by the economic drivers of demand and supply owing to the housing challenge and associated backlog. The pressure on suppliers often interferes with recommended cooling periods of kilns, prior to unloading of bricks. This predisposes CW to incidental exposures of CO through inadvertent inhalation. This study ascertains the extent to which such exposures may pose health threats to the CW. It further interrogates the legal and policy framework and related ethical issues. The study concludes with recommendations for best practice.

Determining the geographic origin of illegally imported Chinese dinosaur nests retrieved in Australia

Robert William FITZPATRICK[1]*, The University of Adelaide (robert.fitzpatrick@adelaide.edu.au)
Mark Raven[2], CSIRO Mineral Resources
Peter Self[3], CSIRO Mineral Resources
John Long[4], Flinders University
Robert Fitzpatrick Fitzpatrick[5], The University of Adelaide

Abstract

Dinosaur eggs and nests are highly sought after by collectors. China has some of the strictest regulations and laws in the world in protecting rare fossil remains. Despite the very best efforts of authorities there is a thriving black market in illegally acquired dinosaur fossils including teeth, bones and fossilised eggs with huge sums of money being exchanged. Under Chinese law, fossilized dinosaur nests are protected, and both their sale and purchase are banned in Australia. Between 2004 and 2005 the Chinese government asked for Australia's help through the Australian Federal Police (AFP) to stop the illegal trade in fossils. Approximately 6 million Australian dollars-worth of illegally imported fossils from China were seized by the AFP comprising 25 dinosaur eggs & nests and three dinosaur egg pieces. However, the Australian collectors claimed the nests were not Chinese, but rather from legal American fossils.

To prove that these fossils were illegally obtained, visual (e.g. soil Munsell colour) and mineralogical (X-ray diffraction – XRD and Diffuse Reflectance Infrared Fourier Transform Spectral DRIFTS) analyses were conducted on both the questioned fossils seized by AFP detectives and known reference nest fossil samples obtained from museums in Australia sourced from Henan Province, China.

Two questioned dinosaur nest materials from illegally imported samples were compared with four reference samples provided by the Victorian and South Australian museums sourced from Henan Province to determine if the samples have; no, limited, moderate, moderately strong, strong, very strong, extremely strong or conclusive “degree of comparability” of being from a single location.

One questioned sample from the illegally imported nests contained the following 9 out of 9 similar mineral components (semi-quantitative amounts) when compared with the four known reference materials provided by the Victorian and South Australian museums, sourced from Henan Province: quartz and calcite (co-dominant); smectite and albite (minor to sub-dominant); microcline, hematite (red colour), chlorite, mica and dolomite (trace). These samples were also remarkably similar as confirmed in the detail in the XRD patterns (i.e. line broadening).
The morphological descriptors of the samples (Munsell soil colour, consistency, shape of quartz particles, particle size, white coloured calcite-rich concentrations) and mineralogical data (XRD) indicate that the questioned sample has an extremely strong degree of comparability with the four

known reference materials provided by the Victorian and South Australian museums, sourced from Henan Province indicating the strong likelihood that these samples have a common origin and originate from a common geological source or region. In 2008 the collection seized by the AFP was handed back to China at a ceremony at the Chinese Embassy in Canberra. To show their gratitude to Australia's efforts, the Chinese government gave a gift of several important Chinese fossil specimens to two Australian museums.

However, one questioned sample of an illegally imported nest contained sufficiently different mineralogical properties (i.e. palygorskite and ankerite) to the materials provided by the Victorian and SA museums, indicating it was not sourced from Henan Province but likely the USA.

“We Did not Notice This Demon in Our Backyard!”—Introducing a New Source of Geogenic Health Hazard

Kirtikumar Ramkrushna RANDIVE[1]*, Department of Geology, Rashtrasant Tukadoji Maharaj Nagpur University,Nagpur, Maharashtra, India (randive101@yahoo.co.in)

Abstract

Dust, an inevitable inhalation, cannot be avoided by any means in a day-to-day life except without applying preventive measures. The inhalation of certain minerals in fine particulates is a well-established respiratory health risk. It has been known that the occupational exposure to dust particles can result in lung diseases. The situation worsens when these dusts are mixed with high proportions of minerals; such as aluminum oxides, asbestos, coal, cement, limestone, magnesites, marbles, mica, man-made mineral fibers, silica, talc, titanium dioxide and zeolites, etc. The reaction of the lungs to mineral dust depends on the dosage and the nature of the dust inhaled. Most common mineral related disease is silicosis, which is caused due to long term inhalation of airborne particulate crystalline silica.The present study is subject of a peculiar condition in which contemporary soils are remarkably rich in silica fragments. This silica, which is a mixture of crystalline, cryptocrystalline and amorphous forms, also occur in various size fractions including clays, which are dispersed through dust and inhaled by men and animals alike.

In order to access the hazard potential of these silica pebble laden soils, we conducted systematic study which included (i) soil profiles from selected areas in order to understand the depth persistence and control of silica pebbles, (ii) Particle Size Distribution (PSD) analysis of silica pebbles using Image-J software, (iii) Granulometric analysis of soils, (iv) X-ray Diffraction studies of clay and silt fractions, and (v) chemical analyses of soils. It is commonly known that the atmospheric dust contains “environmental” level of mineral dust which is <50µg/m3; whereas in active mining areas this level is of the order of ~10 µg/m3. In the present study area we have recorded alarmingly high levels of mineralized silica which is in the order of ~2-7.5 µg/m3. Such high levels of mineralized silica were not reported earlier from the urban populated areas, and therefore needs immediate attention. We therefore present here a new source of geogenic health hazard.

Role of Critical Minerals in Medical Geology: Applications and Implications

PRATIK PRAVIN GODBOLE[1]*, Post Graduate Department of Geology, RTM Nagpur University, Nagpur, Maharashtra, India (prateek15godbole@gmail.com)
Kirtikumar Ramkrushna Randive[2], Post Graduate Department of Geology, Rashtrasant Tukadoji Maharaj Nagpur University, Nagpur, Maharashtra, India

Abstract

Medical geology, an interdisciplinary field merging geosciences and medicine, examines the intricate relationship between geological materials and human health. This abstract provides comprehensive insights of critical minerals and emphasizes the critical importance of harnessing these minerals for their diverse medical applications. Rare earth elements (REEs), prized for their unique magnetic properties, are essential for magnetic resonance imaging (MRI), enabling precise diagnostic imaging crucial for detecting and monitoring various medical conditions. Gadolinium, a specific REE, serves as a contrast agent in MRI scans, enhancing image clarity and diagnostic accuracy. Lithium, sourced predominantly from geologically distinct regions, is indispensable in psychiatric medications for managing mood disorders like bipolar disorder. Its mood-stabilizing properties make it a cornerstone in the treatment of these conditions, improving patients' quality of life and reducing the risk of relapse. Cobalt, commonly found alongside chromium, is vital for producing cobalt-chromium alloys used in orthopaedic implants. These implants, renowned for their biocompatibility and mechanical strength, are instrumental in joint replacement surgeries, restoring mobility and relieving pain for millions of patients worldwide. Gold nanoparticles hold promise in cancer therapy, serving as effective vehicles for targeted drug delivery and photothermal therapy. Their unique properties enable precise tumour targeting while minimizing systemic side effects, revolutionizing cancer treatment approaches. Silver nanoparticles exhibit potent antimicrobial properties, making them invaluable for medical applications such as wound dressings, catheters, and medical device coatings. Their ability to combat infections reduces healthcare-associated complications and promotes faster wound healing. Titanium, extracted from mineral deposits, finds widespread use in dental implants due to its biocompatibility and corrosion resistance, restoring oral function and aesthetics for patients with missing teeth. Zirconium, derived from zirconium minerals, enhances dental ceramics' durability and aesthetic appeal, ensuring long-lasting dental restorations. Hence, it is essential to explore secondary sources of these minerals to meet growing demand while minimizing environmental impact. Additionally, focusing on the environmental implications of mineral extraction and utilization is crucial for achieving sustainable development and ensuring the continued availability of critical minerals for medical applications. By integrating geological knowledge with environmental stewardship, we can optimize healthcare delivery while preserving our planet's health for future generations.

Mineralogy and morphology of earth materials in vehicle wheel-rims as significant trace evidence in a double murder and arson investigation in Australia

Robert William FITZPATRICK[1]*, The University of Adelaide (robert.fitzpatrick@adelaide.edu.au)
Mark Raven[2], CSIRO Mineral Resources
Peter Self[3], CSIRO Mineral Resources
Robert William Fitzpatrick[4], The University of Adelaide

Abstract

Through two diverse cases involving a double murder and arson investigation, this paper will demonstrate how combined pedological, mineralogical and chemical investigations involving earth materials recovered in vehicle wheel-rims, have been critical in developing reliable information on earth materials, from landscape to microscopic scales, to help in forensic investigations, which were used as evidence in Australia.

Sufficient descriptive (Munsell colour) and mineralogical (X-ray diffraction: XRD) data was acquired on all questioned earth material samples collected from vehicle wheel-rims and control samples collected from materials sampled from surfacing aggregate on road surfaces associated with the crime scenes. This information was used in both a double murder and arson investigation to determine the major similarities and differences between the questioned samples and control samples using no, limited, moderate, moderately strong, strong, very strong or extremely strong "Categories of Comparability" of being from a single location.

Double murder case: A suspect was trying to cover up a murder, whose body was found in a shallow bush grave in the Dandenong Ranges, Victoria in 2011, when he killed a second victim (cyclist) in a hit-run and then torched his car to cover up the crime. The suspect denied ever traveling on the unsealed roads leading to where the body was found. Two questioned earth material samples were recovered from the inside back rim of the suspects vehicle. Control samples were collected at 9 sites that cover road surfaces leading to the bush grave. Based on morphological and mineralogical examination the two questioned samples recovered from the back rim of the suspect's vehicle have an extremely strong degree of comparability to the control sites that cover the road surfaces leading to the crime scene. A jury found the suspect guilty of murder and manslaughter.

Arson case: The Cherry gardens bushfires occurred on in 2021 during a 37 degree centigrade day with a total fire ban declared. The bushfire destroyed 2 homes and blackened 1,700 hectares. A suspect was arrested, and his vehicle ceased and transported to the South Australian Police storage depot. Questioned earth material adhering to the rear inner wheel-rims was recovered from both

wheel-rims on the passenger and drivers sides of the vehicle. The 2 questioned calcareous soil materials from the inside rear wheel-rims of the suspect's motor vehicle had an extremely strong degree of comparability with the 4 control calcareous earth materials sampled from the calcrete surfacing aggregate on road surfaces adjacent to where 4 fires were lit along sections of four different roads. The calcrete road surfacing aggregate material placed on sections of the roads where the 4 fires were lit were also proven to be sourced from a known nearby Quarry. The morphological and mineralogical examination of the 2 questioned materials from the back rims of suspect's vehicle and 4 control samples of calcareous earth materials that cover the road surfaces where 4 fires were lit provided compelling evidence that these samples have virtually identical origins. A jury found the suspect guilty of starting 7 bush fires.

Forensic application of traceability technology in illegal marine sand mining crimes

Ping YIN[1]*, Qingdao Institute of Marine Geology,China Geological Survey
(yinping@mail.cgs.gov.cn)

Abstract

Marine sand is a precious marine mineral resource and an important raw material for construction. With the development of urbanization and the decrease in the supply of sand and gravel resources on land, especially under the influence of strict environmental protection, marine sand has become an important supplement to sand and gravel resources, while the illegal exploitation of marine sand has gradually increased around the world, causing disruption to the legal development and utilization of marine mineral resources. Marine sand is an important part of Marine ecological environment, and illegal mining brings serious harm to marine ecological environment.

Modern Marine geological survey, monitoring, experimental analysis and data processing technology have been widely used in the forensic identification of illegal marien sand mining. Sonar mapping can compare the changes of seabed landform before and after sand mining in detail, and assess the seabed damages. Through the investigation of Marine biodiversity, the influence of sand mining on the change of biological population was detected. By means of mineral composition, particle size analysis, heavy mineral and element analysis and foraminifera analysis, the source information of marine sand can be traced. By combining the results of all physical and chemical analyses with ecological models, it is possible to fully assess the overall impact of illegal sand mining activities on marine ecosystems.

This report introduces the application cases of forensic geological in judicial protection of marine sand resources in China.

Dimensionality reduction for visualizing gold trace element geochemistry through the chain of production in Brazil using UMAP

Angel VERBEL[1]*, Universidade de Brasilia (aaverbelo@unal.edu.co)
Daniel Gregory[2], University of Toronto
Maria Emilia Schutesky[3], Universidade de Brasilia
Liland McInnes[4], Tutte Institute for Mathematics and Computing
Jay Thompson[5], United States Geological Survey
Eric Moreira[6], National Institute of Criminalistic, Brazilian Federal Police

Abstract

The process of producing and selling artisanal gold in Brazil can be broken down into four steps: refining the ore locally, selling it to a trading house, then to an international refinery, and finally using it for various applications. However, irregularities in this chain can result in gold entering at various points. Surprisingly, from 1995 to 2007, artisanal gold introduced irregularly amounted to six times the declared amount produced regularly. Hence, having tools to understand how gold behaves throughout the chain of production would help develop mechanisms to prevent gold trafficking and all the problems it brings with it.

This study was carried out using natural gold samples and gold bars, seized at the deposit and declared to be from it (these bars were produced with that gold ore using amalgamation) and were analyzed via LA-ICP-MS/MS providing trace elemental and Pb isotopic composition. The results were compared by mass balance, taking the average composition of the natural samples as our fresh material. Later, the trace element concentrations were compared using Uniform Manifold Approximation Projection (UMAP), using the compositional data of gold as vectors of probabilities to compare their similarities with Hellinger distance.

Lead Isotopes from the ore showed a wide range ratio (206Pb/204Pb 12.1 to 22.7) which agrees with the analysis of the bars that were seized at the deposit (206Pb/204Pb 12.9 to 19.5). However, gold bars declared to come from there showed a narrower Pb isotopic signature (206Pb/204Pb 15.9 to 18.7). In addition, the UMAP projection of the multinomial probabilities of gold in the compositional space reveals that one of the samples seized at the deposit has a different chemical signature which suggests that it came from a different source.

These findings show that high-resolution in-situ analyses via LA-ICP-MS/MS on gold can track Pb isotopic signature of gold allowing to differentiate gold with a markedly different origin. In addition, the use of UMAP on the results gives us a detailed differentiation of the samples based on their trace element composition unveiling what can be interpreted as smuggled gold in the mine.

Anthropogenic gadolinium in surface and groundwaters of Poland

Irena Agnieszka WYSOCKA[1]*, Polish Geological Institute National Research Institute (irena.wysocka@pgi.gov.pl)
Dorota Kaczor-Kurzawa[2], Polish Geological Institute National Research Institute
Adam Porowski[3], Institute of Geological Sciences Polish Academy of Sciences
Agnieszka Konon[4], Polish Geological Institute National Research Institute
Angelika Szczypczyk[5], Polish Geological Institute National Research Institute

Abstract

Since the first publication on an anthropogenic gadolinium (Gd) in rivers in Germany (1996) detecting a positive gadolinium anomaly in surface waters has been reported in various regions of the developed countries. The gadolinium anomaly is linked, most of all, to the widespread usage of Gd-complexes for enhancement contrast in magnetic resonance imaging. With an increasing tendency in the application of stable Gd-based contrast agents in medical tests all over the world, it can be expected that the contribution of anthropogenic gadolinium to the total Gd concentration in water can reach up to 100%. This phenomenon has been observed mainly in waste and surface water, but due to limitations of analytical methods it is much less recognised for groundwater. Furthermore, there is no regular monitoring of Gd concentration in surface waters that receive the significant load of treated wastewater and no gadolinium threshold value for drinking water has been set in any country.

In this presentation we provide the information on gadolinium microcontamination in different types of Polish waters, including groundwater which is an important source of drinking water. The presented data are the compilation of the 10-year study on rare earth elements in Polish waters. For the data comparison, we apply the estimated background values for gadolinium in European natural waters based on the analysis of datasets produced within two European projects: (1) ‘FOREGS – Geochemical Atlas of Europe’ and (2) ‘Geochemistry of European Bottled water’. We discuss some implications of the anthropogenic gadolinium emission to the environment, such as (1) emerging new Gd species and its prevalence in total Gd pool in natural waters, and (2) the significant change of total Gd concentrations and disturbance on distribution patterns of rare earth elements in natural waters, especially surface waters.

Our long-term study has shown that the anthropogenic Gd fraction in groundwater is generally negligible (below 10%) but it already reaches up to 90% in tap water samples collected in big Polish cities (e.g. Kraków and Warszawa) and up to 95% in the Vistula river samples collected near to the places of treated wastewater discharge.

"RASASHASTRA": AN ANCINET INDIAN MEDICINAL SYSTEM PROMOTING MEDICAL GEOLOGY

Kirtikumar Ramkrushna RANDIVE[1]*, Department of Geology, Rashtrasant Tukadoji Maharaj Nagpur University,Nagpur, Maharashtra, India (randive101@yahoo.co.in)
Pratik Godbole[2], Department of Geology, Rashtrasant Tukadoji Maharaj Nagpur University,Nagpur, Maharashtra, India

Abstract

The Rasashastra uses minerals and metals for cure of diseases. Development of Rasashastra as a separate discipline simultaneously developed with the science of mining and metallurgy in ancient India. Among the inorganic substances used in Indian medicine, the most important is mercury. Pure mercury is consumed in different forms for getting long and disease-free healthy life. Other substances are classified into three categories namely, the Maharasa (means the substance of great importance), which includes mica, tourmaline, pyrite, black bitumen, blue vitriol, selenite and zink ore, the Uparasa, means the substance of secondary importance viz., sulfur, melanterite, hematite, alum, orpiment, realgar and the Sadharana Rasa, means an ordinary or a common substance e.g arsenolite, sal-ammoniac, montroydite, cinnabar, etc. However, the basis of this classification is not clearly known. Reference has been made of seven metals (dhatus), namely Suvarna (gold), Rajat (silver), Aara (brass), Tamra (copper), Vanga (tin), Naga (lead), and Tikshna (steel) in the Rashshashtra. Similarly, use of gemstones for medicinal purpose also finds a mention. The stones are classified in Ayurveda based on their preciousness as, Ratna, means precious, Uparatna, means semi-precious, and Kshudra Ratna, means non-precious stones. The calcium compounds also find special mention in Rasashastra, they are called as Sudha varga in Rasashastra. Their inorganic sources include chalk, selenite, gypsum, talk, quicklime, whereas animal sources include fossils encrinite, norinite, gastropod oyster shells and corals. Mercury is the base of all medicinal formulations of Ayurveda, although considered toxic in the modern medicines. These medicines are prepared in the form of their incineration, pastes and pulps, tablets and syrup. The traditional knowledge has been serving for last 5000 years in India and still used by a large number of populations. However, there are several areas where modern knowledge cannot concur with the traditional knowledge. This could largely be due to poor documentation of the traditional knowledge and other missing links such as selection of particular materials, which almost have no use in the modern medical practices. It is therefore imperative that systematic studies be carried out to bridge the gap between traditional and modern medicinal practices through medical geology.

Olle Selinus (1943-2023): The Founder of Modern Medical Geology

Robert B. FINKELMAN[1], University of Texas at Dallas, United States
Jose A. CENTENO[2], University of Puerto Rico at Mayaguez, Puerto Rico
Hassina MOURI[3], Department of Geology, University of Johannesburg, South Africa
Chaosheng ZHANG[4], International Network for Environment and Health, School of Geography, Archaeology and Irish Studies, University of Galway, Ireland
Anna LADENBERGER[5]*, Geological Survey of Sweden (anna.ladenberger@sgu.se)

Abstract

Few people have had the opportunity to establish a globally recognize discipline. Olle Selinus (1943-2023) is one of those selected few for having established the modern discipline of Medical Geology. Medical Geology is defined as the impacts of geological materials and geologic processes on animal and human health had is modern beginnings with the initiatives of Olle Selinus two decades ago. However, awareness that the natural environment can have both positive and negative impacts on health stretches back to the dawn of time. Early humanoids were aware of the benefits and dangers of geologic materials and they undoubtedly learned this by observing the behavior of various animal species. The earliest writing of virtually all of the ancient civilizations contained detailed recommendations for using a wide range of minerals and rocks to treat various health issues. The term ‘medical geology’ was used as far back as 1849 and during the past 50 years there had been several efforts to develop a discipline along the lines of medical geology but none were successful until Olle Selinus turned his attention to this issue. In 1996 Olle led a Working Group under the auspices of the International Union of Geological Sciences. The name ‘Medical Geology’ was adopted by the Working Group in 1997. Thanks to Olle’s foresight and leadership the discipline of Medical Geology is now firmly established with the formation of the International Medical Geology Association as well as several other regional and national medical geology organizations, More than 40 books on Medical Geology have been produced since Olle’s groundbreaking 2005 Essentials of Medical Geology. Perhaps most importantly, Olle Senius’s efforts have led to countless medical geology studies designed to better understand the health impacts of the natural environment resulting in improved health outcomes globally.

Mineralogical and elemental information for soil geolocation tracing

hongling guo[1]*, Institute of Forensic Science, China (guohongling1234@163.com)
Jun Zhu[2], Institute of Forensic Science, China
Hongcheng Mei[3], Institute of Forensic Science, China
Ping Wang[4], Institute of Forensic Science, China
Can Hu[5], Institute of Forensic Science, China

Abstract

One of the key tasks of soil analysis in forensic sciences is to provide information about its diversities for comparison and geolocation provenance. The evidence value of soil depends on the variation of its characteristics. A research project about soil multivariable examination and geolocation tracing was carried out in China from 2018-2021. A combination of comprehensive techniques was established. These techniques concern the physicochemical information (elemental, mineral and isotope information) in bulk soil, trace pollutants (pesticide residues) in soil, soil spore and pollen features, plant debris fingerprint (microscopic fingerprints of plant species analyzed by scanning electron microscope and optical microscope) analysis in soil, soil microbial DNA test, plant barcoding inspection for soil samples. The combination of these different techniques can improve the accuracy of source tracing of soil evidence. However, in China, soil examination is the duty of trace evidence division. The inspectors prefer to use physiochemical methods first to analyze soil samples. In addition, soil botany and microbial community analysis are time consuming, expensive and require complex statistical analyses. Soil botany analysis, highly skilled inspectors are needed to perform pollen examination. And source tracing analyses of microorganisms and pollen in soil samples are difficult to perform at a large scale. In this study, a total of 80 soil samples were collected from eight Chinese cities (*Fuzhou*, *Guangzhou*, *Wuhan*, *Hohhot*, *Lanzhou*, *Xian*, *Changchun*, *and Beijing*, covering most areas of China). Minerals and elemental analysis were carried out by XRD and XRF. Principal component analysis (PCA) and hierarchical clustering analysis (HCA) methods were performed for dimensionality reduction, elemental marker identification and soils classification to the city they came from purposes. The eighty soils analyzed in this study could be tracked correctly to their city of origin. The K-Nearest Neighbors (KNN) model was done to evaluate the prediction ability based on the soil elemental composition. The results demonstrated that mineralogical and elemental composition can provide powerful information for soil discrimination and source tracing. Till now the comprehensive geological examination methods were applied in 103 cases and promoted in forensic labs in 20 provinces and cities around China.

Forensic Geology in Chile: Foundations of a scientific basis for Justice and Environmental Sciences.

Kristian AGURTO VELASQUEZ[1]*, University of Chile (kmagurtov@gmail.com)
Katja DECKART[2], University of Chile

Abstract

Forensic geology, or geoforensics, is the application of the tools available in geology to the resolution of police cases associated with crime and homicide. It is here that soil analysis plays a fundamental role in providing information that can be useful in narrowing down crime areas, or associating an environmental crime to a group of people.

Given the total absence of professional geologists dedicated to Forensic Geology in Chile, and the lack of a specific scientific method for geoforensic cases and environmental crimes, it is proposed to develop a methodology based on compositional geochemical analysis and isotopy of carbon, oxygen, strontium and lead in soils characteristic of some geographic and geomorphological areas of Chile, considering general physicochemical parameters of the soil such as pH, electrical conductivity and granulometry, together with variables such as climate, humidity and rainfall of the environment. Potentially useful instruments for isotopic measurements will be ICP-MS, IRMS, QEMSCAN and TIMS. Currently, this is the first doctoral research work of its kind in Chile.

The specific objectives are directly related to the 5 variables to be included in the baseline, which are defined as: sampling methodology, standard geochemical data, physicochemical parameter maps and error/confidence ranges. The methodology is expected to be based on the protocol, survey and measurement of different soils of the Metropolitan Region of Santiago, and of geographic and geomorphological zones representative of Chile in urban, peri-urban and rural sectors, for its application in police investigations related to crimes against persons, and in cases of environmental crimes typified in the law.

The hypothesis of this research establishes that the physicochemical parameters of the soil (pH, EC and SOC) allow differentiating two completely equal or different soils, without the need to know whether they are intervened by natural or anthropic factors. In addition, the isotopic concentrations of δ12C and δ13C together with those of δ16O and δ18O contribute significantly to the characterisation of anthropogenic or organic interventions in soils, as well as the concentrations of δ87Sr/ δ86Sr and δ206Pb/ δ204Pb, and δ208Pb/ δ207Pb allow the identification of various sources of anthropogenic and geogenic contamination such as fuels, fertilisers, natural leaching processes and inputs of atmospheric pollutants.

This also connects directly with the environmental crime line, where it is expected to typify particulate matter contamination or non-standard emissions in volcanic, urban (analysing fuels),

agricultural (fertilisers and wildlife input) and large-scale industrial (mining, manufacturing, among others) soils.

The products of this thesis are expected to be: an unpublished database of physicochemical and isotopic parameters of Chilean soils; chemical maps of elemental concentration by geographical area; isotopic maps of C, O, Sr and Pb by: climatic zone, land use and potentially contaminated areas of Chile.

Stefano Albanese[6], University of Naples Federico II - Department of Earth Sciences, Environment and Resources

Abstract

In recent years, intentional illegal burnings have escalated in frequency, emerging as a globally significant issue. Consequently, humans and animals are exposed to potentially toxic elements (PTEs) released during combustion, dispersed by wind, and accumulated in fire ashes (Dimitrios, 2020).

Various studies have indicated that the PTE content in deposited ashes can modify the chemical and physical properties of soil, thereby affecting the development and growth of local microorganisms and vegetation (Raison, 1979). The geochemical characteristics of ashes are contingent upon the nature of the burned material (Dermibas et al., 2003), as well as factors such as combustion intensity, underlying soil composition, and bedrock type.

This study aimed to assess the environmental impact of two fire events that occurred in the Campania region (Southern Italy) during the 2017 summer season at two distinct sites. One fire involved a forest on the slopes of Mt. Somma-Vesuvius, while the other affected a waste disposal site known as Ilside near the city of Caserta. Changes in PTE concentrations in the topsoil were examined.

Specifically, 30 topsoil samples were collected before and immediately after the fire events at both locations, resulting in a total of 60 samples each from the Mt. Somma-Vesuvius slopes and Ilside surroundings. Post-fire samples were collected at pre-existing sampling sites along the main wind directions recorded during the fires.

To investigate potential elemental soil contamination resulting from the fires, the Enrichment Factor (EFs) of selected PTEs was determined and mapped for individual samples. Predominant enrichment of Hg was observed in both areas.

Furthermore, a combined application of multivariate statistics and geospatial analysis was conducted on the calculated EFs.

For the Ilside site, where special waste and e-waste were burned, the association of Hg, Tl, Cu, and Co was identified as the main contributor to data variability. In the Vesuvian area, the association of Hg, Cu, and Cr was found to be significant, likely linked to forest biomass burning.

This study highlights the varying chemical evidence left by fires depending on the nature of the burnt materials. Additionally, it demonstrates that even burning biomass from natural areas can introduce PTEs into the environment, potentially increasing the existing level of environmental hazard.

A Study on Discrimination Capability of Soil for Forensic Comparison based on Statistical Approach in South Korea

Yu Ran LEE[1]*, National Forensic Service (urain94@korea.kr)
Seongshin Gwak[2], National Forensic Service
Siwon Kim[3], National Forensic Service

Abstract

Forensic soil analysis can play an important role in various crimes including thefts of agricultural products, homicides, and illegal disposal of waste. The comparison and differentiation of soil samples between suspects or objects to a crime scene is crucial in crime investigation. Soil exhibits various elemental compositions based on its location and depth due to the different weathering process of rocks and geological formation periods. Since the formation of soil is largely affected by surrounding environmental factors including climate, topography, and biology, it is important to understand characteristic elemental compositions of soil in different region for forensic soil analysis. In this study, 5 distinct regions in South Korea were selected for soil sample collection because its varied topography, climate, and geological history. Soil samples were collected in plastic bags (approximately 500 g) from the surface(topsoil) and the depth of 0.3 meter at 9 points with 1-meter interval in each region. The collected soil samples were then dried at room temperature for 3 days and then sieved to separate them into particle size of between 200 and 63 μm, and below 63 μm for analysis. Colorimeters, x-ray diffraction (XRD), and x-ray fluorescence (XRF) were employed to differentiate and characterize each soil sample. In order to provide objective discrimination value in forensic soil analysis, various statistical approaches were applied.

Tracing the geographical origin of bottled water collected in South Korea via isotopic and elemental analyses

Byeong-Yeol SONG[1]*, National Forensic Service (songby10@korea.kr)
Dong-kye Lee[2], National Forensic Service
Yu-Ran Lee[3], National Forensic Service

Abstract

The production of bottled water requires a forensic discriminant technique that enables the identification of the brands or accidents caused by intended contaminants. The bottled water poisoning crimes have drawn much attention, and such crimes may recur in the future. The water is colorless and odorless, and thus it is difficult to detect contaminated water through visual observation. Thus, bottled water can be easily exploited for poisoning, and a method for tracing their origin is currently required. In this study, a total of 27 brands of bottled water samples were analyzed to determine stable oxygen isotopes, strontium isotopes, major and trace elements. The geographical origin of the water was traced based on the climatic and geographical characteristics of the location from where water was sourced, which was assumed to be reflected in the bottled water. Furthermore, we investigated whether this method can be applied to identify bottled water products. The results demonstrated that the characteristics of the bottled water, including the oxygen stable isotope ratios, reflect the latitude and altitude of bottled water source in South Korea, from the high-latitude region to the coastal regions. In addition, the results indicated that excellent discrimination was achieved using strontium isotopes to identify source areas with different types of bedrock, complex underlying lithologies, and ocean areas in South Korea. A statistical method based on discriminant analysis was applied to measure trace elements, and the results effectively reflected the characteristics of water–rock interactions (cross-validated classification probability: ≥92%).

Igor Gennadievich Spiridonov[5], Institute of Mineralogy, Geochemistry and Crystal Chemistry of Rare Elements
Yurii Alexandrovich Sharoijko[6], Institute of Mineralogy, Geochemistry and Crystal Chemistry of Rare Elements

Abstract

GIS used in the practice of multi-purpose geochemical work significantly increase the reliability of research results that require visualization of their content. The cadastres, thematic databases and banks of primary geochemical information accompanying cartographic data make it possible to clarify the Clarke concentration of chemical elements in bedrock, evaluate the natural regional and local geochemical backgrounds of all studied components of the geological environment and solve a complex set of geological and environmental problems. In particular, ecological and geochemical maps display the areas and territories with abnormally high concentrations of chemical elements with an assessment of the degree of environmental contamination in relation to the functional zoning of the study area according to the nature of its economic use.

The achieved high level of reliability of multi-purpose geochemical research allows today, using medical statistics data and multi-scale cartographic materials, to replenish databases on regions that are problematic in terms of the presence of environmental problems, and to reliably delineate the administrative boundaries of areas where endemic and environmentally-related diseases occur.

In combination with situational design using GIS, it becomes possible to determine the landscape and geological-geochemical parameters of the areas of hotbeds of endemic and environmentally-related diseases associated with the problems of pollution of environmental components with toxic chemical elements, to establish the possible causes of their occurrence, to assess the risk and forecast their further spread, create scientific and methodological foundations for medical and environmental monitoring of territories.

Based on the analysis and synthesis of geochemical mapping data, including the results of reprocessing materials from past years using modern procedures, the possibilities of delineating areas of environmental and medical risk with substantiation of the causes of occurrence and forecast for the spread of disease foci caused by geological factors of natural and technologic origin have been demonstrated.

Occurrences of potentially toxic elements such as uranium (U) and molybdenum (Mo) in the Karoo ground-and-surface waters near Beaufort West, Western Cape, South Africa: a possible health threat to the local population?

Okuhle POTO[1]*, University of Johannesburg, South Africa (okuhlepoto@gmail.com)
Bastien Linol[2], Nelson Mandela University, South Africa
Hassina Mouri[3], University of Johannesburg, South Africa
Gaathier Mahed[4], Nelson Mandela University, South Africa
Thomas Muedi[5], Council for Geoscience, South Africa

Abstract

This study investigates the degree of ground-and-surface water contamination from uranium (U) and molybdenum (Mo) in the Rietkuil river catchment (114 km2) and Leeugamka Dam near Beaufort West and associated health risks to the local communities. Twenty water samples were collected in the study area from the mine pit and surface water sources in September 2018 during the wet season and July 2019 during the dry season, respectively. Hydro-chemical analysis revealed abnormally high concentrations, up to 6760 g/l for U and 266 g/l for Mo, in the mine pit compared to other sampled localities, suggesting active leaching of these chemical elements, most likely by rainfall from the rocks exposed by previous mining activity in the pit. Conversely, the concentrations of these elements in surface water upstream and downstream of this mine pit and exposed stockpiles during both sampling seasons are generally low and within acceptable limits (U ≤ 30 µg/l; Mo ≤ 70 µg/l) determined by World Health Organization (WHO) and South Africa National Standards. However, spatial analysis shows a progressive increase in U and Mo concentrations downstream from the mine water sample, most likely due to transportation nearly 10 km from the defined source in the mine pit. While concentrations of these elements in all groundwater locations were also within acceptable limits, comparing U against standard limits of 20 g/l suggested by Health Canada, two groundwater samples surpassed this limit with concentrations reaching up to 27 g/l. Moreover, the chemical form of U in groundwater samples occurring as uranyl hydroxide can have serious health implications. These results indicates that drinking from groundwater sources close to the mine pit in the Riekuil drainage is not safe for drinking purpose for both humans and animals. However, a detailed health investigation is necessary in order to assess the current health issues associated with the revealed high concentration of such elements in the study area as well as their possible short and long terms implications.

New insights into the geological occurrence, morphology and toxicology of New Zealand erionite minerals

Janki Prakash Patel[1], University of Auckland
Martin Brook[2]*, University of Auckland (m.brook@auckland.ac.nz)
Alessandro Francesco Gualtieri[3], University of Modena and Reggio Emilia
Sonia Scarfi[4], University of Genoa
Melanie Kah[5], University of Auckland
Ayrton Hamilton[6], University of Auckland
Serena Mirata[7], University of Genoa
Vanessa Almonti[8], University of Genoa

Abstract

The presence of volcanic processes in New Zealand has led to the formation of diverse minerals that originate from volcanic activity, including a category of aluminosilicates referred to as zeolites. One such notable zeolite is erionite, which typically crystallizes through hydrothermal alteration or diagenesis of volcanic rocks, forming mainly in tuffs and basalts. Erionite possesses a fibrous crystal habit, similar to asbestos. And as with asbestos, erionite exposure has also been linked to cases of malignant mesothelioma- A significant epidemic was discovered in the Cappadocia region of Turkey in the 1970s. While undisturbed erionite fibers are not considered harmful to human health, the International Agency for Research on Cancer (IARC) has designated erionite as a Group 1 carcinogen due to its hazardous potential when disturbed or inhaled. Consequently, research is ongoing in New Zealand, employing various experimental and analytical techniques to detect and identify the occurrence of erionite. Some of the methods being utilized include Electron Microscopy, X-Ray Fluorescence, Electron Microprobe Analysis, micro-Raman spectroscopy, and X-ray powder diffraction with the Rietveld Method. These techniques aid in the characterization and identification of erionite in different regions of New Zealand. Notable findings so far include woolly erionite discovered in vesicles of rhyolitic rock at Mount Somers in the Canterbury region of the South Island, asbestiform erionite found in the Waitakere Group Volcanics in the Auckland region of the North Island and acicular bundles of erionite fibers found in tuff from the Timber Bay Formation in Kaipara. Toxicity tests have also been conducted on two of the erionite samples (Mount Somers and Kaipara) with results indicating that NZ erionite signifies an acute toxic potential especially in relation to non-carcinogenic fibers such as wollastonite. Due to the potential adverse health effects linked to erionite exposure, this research aims to develop an understanding of erionite occurrence, towards mitigating any environmental hazards exhibited this mineral.

WATER QUALITY FOR HUMAN CONSUMPTION IN THE CONTEXT OF ABANDONED ARTISANAL GOLD MINING

Marina THIMOTHEO[1]*, University of Campinas - UNICAMP (marina.thimotheo@gmail.com)
Ricardo Perobelli BORBA[2], University of Campinas - UNICAMP
Francisco Wohnrath TOGNOLI[3], Federal University of Rio de Janeiro - UFRJ

Abstract

Artisanal mining of metallic elements in gold mines is still carried out today without adequate environmental regulation, frequently causing hard impacts and irreversible damage to human life and associated ecosystems. The study area is located in southern Brazil, in the Lavras do Sul municipality, where gold prospects occur in quartz veins derived from hydrothermal fluids percolating in volcanogenic crystalline terrains. In this region, there was artisanal extraction of Au-Cu-Ag mines for almost three centuries, until the beginning of the 1980s, without decommissioning and environmental remediation. Nowadays, some of these areas are contaminated, but they are used for agricultural activities and pastures. This study evaluated the water quality produced in homemade and groundwater wells used for human consumption, verifying the possible relationship with byproducts of abandoned mining. Two field campaigns were carried out, totaling 34 water and 10 soil sampled points. Quantification included alkalinity, Cl-, NO3- and SO4-2 and potentially toxic metals (Al, Ba, Cu, Cr, Fe, Mn, Ni, Zn, Hg, As, Cd and Pb), determined by an Inductively-Coupled Plasma Optical Emission Spectrometry (ICP OES). The soils were mineralologically characterized by X-ray Diffraction (XRD). The water analytical results were compared with the standard references to evaluate their portability by Brazilian environmental legislation. The assessment of the chemical composition is based on the interactions between the aqueous and minerogenic phases through hydrogeochemical modeling using the PhreeqC program, version 3.7.3, llnl.dat database. Considering the two campaigns, the results show that 64% of the samples present at least one element with values above the maximum determined by the legislation. However, most elements that make samples inappropriate for human consumption are Al and Fe, essentially contained in the particulate phase. Among the potentially toxic elements, Cd, As and NO3- are detected above the maximum of 0.003 mg/L, 0.01 mg/L and 10 mg/L, respectively, in 27% of the total samples. The hydrogeochemical modeling indicates that the minerals are in equilibrium in the aquifer, except arsenopyrite, which may be a potential source of As for the waters. Primary minerals contribute to chemical composition. However, exogenous factors prevail. It is concluded that the NPK-based fertilizers used for many years influenced the dynamics of toxic metals, both in the sorption of these elements and in their desorption, much more than the interactions of water with ores or mining waste. Therefore, the control of the chemical composition of water is strongly influenced by current human activity, which is agriculture. The byproducts of mining activities 40 years after their completion do not significantly influence the quality of these waters and, therefore, the impacts on public health today.

Frequency dependence of internal mechanical losses in rocks in the low-frequency range

Aleksandr Sergeevich VOZNESENSKII[1]*, NITU MISIS (al48@mail.ru)
Vladislav Sergeevich Salyukov[2], NUST MISIS
Yaroslav Olegovich Kutkin[3], NUST MISIS

Abstract

The study of internal mechanical losses in rocks and the patterns of their changes under cyclic deformations and loadings of varying duration, frequency and intensity are considered. Internal mechanical losses are estimated either by the quality factor Q, or by the inverse value - the mechanical loss coefficient Q-1. In rocks, they manifest themselves under cyclic loads resulting from earthquakes, blasting or the effects of various machines, leading to fatigue phenomena and subsequent destruction. The fatigue properties of rock materials are usually studied using cyclic load–unload tests, and the evolution of deformation and damage reflects their weakening characteristics. Studying the fatigue properties and failure mechanism of rocks, which is characterized by the Q-1 coefficient, is crucial for predicting the long-term stability of mining engineering structures. This study involves determining losses depending on the frequency of mechanical impacts. One of the models for describing such a dependence is the Rayleigh model, which takes into account two components. One of them characterizes the increase in losses with increasing frequency of exposure. The second component characterizes their increase with decreasing frequency. Mechanical losses in rocks under low-frequency periodic impacts have not been sufficiently studied. The purpose of the study was to experimentally establish the patterns of change in the loss coefficient Q-1 in the low-frequency region of periodic impacts for various rocks. The experiments used samples of gabbro and dolerite in the form of a rectangular parallelepiped with dimensions of 120x40x40 mm. The samples were cyclically loaded during bending according to a three-point scheme on a press in a deformation mode. The tests were carried out using a specially designed device for cyclic loading according to ISRM recommendations, which allows minimizing friction in the supports, as well as measuring deflection directly on the samples. The load was measured with a strain gauge dynamometer, and the beam deflection was measured with LVDT transducers. The sample was loaded at a given speed to a value of 0.2 MPa, after which a cyclic load occurred in the range from 0.2 MPa to 0.3 MPa (8 cycles), then the sample was loaded to a value of 0.4 MPa, after which a cyclic load occurred in the range from 0.4 MPa to 0.5 MPa (8 cycles). The sample loading rates were: 0.05, 0.075, 0.1, 0.25, 0.5, 0.75, 1 mm/min. Frequencies were defined as the reciprocal of cycle durations. As a result, hysteresis loops were obtained for each sample at each loading rate. The loss coefficient was estimated through hysteresis loops. To plan the experiments, as well as to interpret their results, modeling of the entire process of sample deformation was carried out using the finite experiment method in the COMSOL Multiphysics environment. As a result, it was found that in the frequency range under consideration there is a minimum Q-1, with a frequency

deviation in both directions from which the loss coefficient increased. The work was carried out with financial support from the Russian Science Foundation, grant No. 24-27-00103.

The engineering geology of London's raised reservoirs with a summary of ground investigation risks and recommendations, citing techniques used at three sites

Hollie Elizabeth FISHER[1]*, AtkinsRealis (hollie.fisher@atkinsrealis.com)

Abstract

In London and the immediate Thames Valley area, there are thirty raw water reservoirs supplying water services to nine million customers in the capital. The majority of these reservoirs are retained by a soil embankment dam with a traditional puddle clay core that extends down to the underlying London Clay Formation bedrock. These reservoirs were built without filters or drains downstream of the puddle clay core which together with the age (up to or over a century old) make them more prone to internal erosion problems. Non-intrusive geophysical surveys are regularly carried out to identify areas of excess leakage or seepage, with remediation works being carried out afterwards.

London is situated within the London Basin formed during the Alpine Orogeny and comprises a faulted succession of Paleogene sediments. Locally derived soils were typically used for constructing the embankments, including London Clay Formation derived Puddle Clay, and embankment shoulder material largely comprising a combination of granular River Terrace Deposits and cohesive London Clay Formation.

Ground investigation through puddle clay cores is notoriously challenging with a number of key risks; this presentation uses three projects as case studies to provide a summary of the ground conditions and associated risks which may be expected at the various reservoir sites around the capital. This presentation also summarises the various techniques used for investigating the dams to mitigate these risks and support the construction and remediation of the structures, with a particular focus on the requirements of British Standards and best practice, and the practicality of using these techniques in the field.

The Engineering Geology of Havant Thicket Reservoir – The first to be built in the United Kingdom in over three decades

Hollie Elizabeth FISHER[1]*, AtkinsRealis (hollie.fisher@atkinsrealis.com)

Abstract

Havant Thicket Reservoir shall comprise a 160hectare, naturally flooded reservoir bounded by a 3km long, 20m high soil dam and the natural bowl-like topography of the site. Havant Thicket Reservoir is the first reservoir to be built in the UK in over three decades and will be constructed in Hampshire, England; currently the project is in its pre-construction phase with earthworks due to commence in 2025. This reservoir is a nationally strategic asset securing reliable drinking water for the water-stressed Southeast England. In addition, the scheme will maximise the community and environmental benefits of a new reservoir - creating a vibrant new wetland habitat and leisure facilities for local communities.

The site of the reservoir is directly underlain by a classic succession of Hampshire Basin geology, formed during the Alpine Orogeny, and comprising a faulted succession of Paleogene and Cretaceous sediments. Due to the southerly dip of the topography and strata associated with the Bere Forest/Chichester syncline, the bedrock strata form a rough geological ‘feather-edge’ meaning the site is home to range of daylighting strata.

Overlying the site are superficial peri-glacial ‘Head’ deposits containing relic shear surfaces. The investigation into the presence and condition of these features are key for the design of the soil dam as these could present potential significant risks to the project, including embankment failure and the loss of water and flooding of adjacent land. As well as significant geohazards being present at the site, there are also a number of opportunities due to the favourable ground conditions; these include use of the bedrock (primarily London Clay Formation) for the construction of the embankment dam itself.

This presentation aims to provide a summary of the regional and local geology of the site (a major factor for the selection of the site for this nationally important scheme), and a review of the identified geohazards and their investigation.

Crack Propagation Analysis Through Digital Image Correlation in Volcanic and Plutonic Specimens Under Brazilian Tensile Tests

Chamran KAZEMI[1]*, Universitat Politècnica de València (ckazemi@upv.es)
Akbar CHESHOMI[2], University of Tehran
Víctor MARTÍNEZ-IBÁÑEZ[3], Universitat Politècnica de València
María Elvira GARRIDO[4], Universitat Politècnica de València
Carlos HIDALGO SIGNES[5], Universitat Politècnica de València
Álvaro RABAT[6], Universidad de Alicante

Abstract

The mechanical characteristics of rocks stand as pivotal parameters across multiple engineering domains, including petroleum, mining, civil, and environmental engineering. Among these attributes, the phenomenon of crack propagation holds paramount importance. This intricate process encompasses the initiation point, trajectory of extension, and morphological features within rock specimens. The Brazilian test emerges as a widely employed technique to induce cracking. In this method, compressive stress is applied diametrically to disc-shaped samples, inducing a tensile stress regime, perpendicular to the compression according to ISRM and ASTM standards. Consequently, the samples experience failure in the diametrical direction towards the loading jaws .. Diverse methodologies exist for evaluating crack extension in rock samples subjected to the Brazilian test. This study aims to leverage Digital Image Correlation (DIC), to discern the initiation and evolution of strain fields and cracks sans physical contact with the samples. A comprehensive dataset comprising 10 rock samples representing two main lithological groups of volcanic and plutonic rocks was utilized to assess the influence of varied parameters such as grain size, presence of pre-existing cracks, matrix composition, indirect tensile strength, and ultrasonic pulse velocity on crack trajectory. The outcomes of the investigation unveil intriguing patterns. Specifically, samples with grain sizes akin to sand tend to exhibit indentation influencing the crack propagation pattern. Conversely, irrespective of grain size, samples lacking a matrix predominantly display curvature patterns. Moreover, a decrement in indirect tensile strength correlates with cracks adhering more closely to standard trajectories (straight and diametral connecting loading jaws). Notably, the primary crack trajectory is highly influenced by the surrounding pre-existing cracks, unless the tensile strength of the lithology is substantially low. The Digital Image Correlation is a powerful mean to measure the full-field strain development in objects, and this study intends to focus on its applications within crack detection in igneous rocks.

Shear behavior and deformation mechanisms of reactivated ancient landslides soil in the Nepal Himalaya

Bharat Prasad BHANDARI[1]*, Tribhuvan University (bharat@bharat.com)

Abstract

The reactivation of old landslides has emerged as a major problem in the Nepal Himalayas in recent years. A significant number of individuals have resided atop the historical accumulation of landslide debris for a long time and are currently confronted with the threat of reactivation. This study examines the shear behavior and deformation mechanism of fourteen reactivated landslides in the Sidhupalchwok District, Nepal. Between 2020 and 2021, fourteen distinct ancient landslide deposits were reactivated in the study region during the monsoon season. The remolded soil samples from all fourteen reactivated landslides were obtained from the field. The multistage direct shear test of unsaturated soil was conducted by enabling separate regulation of matric suction. The curve depicting the relationship between shear stress and horizontal displacement was derived for each soil sample. The shear strength parameters of all soil samples were evaluated. The samples exhibit cohesion values that span from 5 to 10, whereas the angle of internal friction varies between 21 and 27. The soils exhibited a plasticity index ranging from 3 to 7. Out of all the samples, eleven are loose and non-compact, while three samples are in a dense state. The findings of the gradation study indicate that the soils are characterized as Clayey sands (SC) with a relatively low plasticity index and a low cohesion. The average rainfall amount in the monsoon period from 2015 to 2023 ranged from 1400 mm to 2200 mm. The rainfall amount in the early monsoon period increased dramatically from 2019. The unconsolidated soils with low cohesion and a low plasticity index deformed due to the 7.8 magnitude Gorkha earthquake and subsequent aftershocks, causing the landslide reactivation during the early monsoon season.

Engineering-geological characteristics of pyroclastic deposits from paroxysmal eruption of Shiveluch volcano in 2023 (Kamchatka Peninsula)

Mariya NIKULINA[1]*, Lomonosov Moscow State University, Faculty of Geology, Department of Engineering and Ecological Geology (mariya.nikulina.2002@mail.ru)
Julia Frolova[2], Lomonosov Moscow State University, Faculty of Geology, Department of Engineering and Ecological Geology
Olga Girina[3], Institute Of Volcanology And Seismology FEB RAS

Abstract

Pyroclastic deposits are the most common volcanic products. They cover large territories in areas with high volcanic activity (e.g., the Kamchatka Peninsula in Russia, Indonesia, and the Philippines). The significance of their engineering-geological study relates to the planning and development of engineering projects and economic infrastructure on these territories, as well as the growth of tourism in volcanic areas. It is well known, that pyroclastic deposits (especially the finest-grained fractions, such as ashes) have a number of undesirable properties that complicate construction. These include settling, shrinking, swelling, and in the case of freezing, extreme heaving of soils. Additionally, dangerous geological processes such as mudflows, landslides, and dust storms may also be associated with pyroclastic deposits.

The paroxysmal explosive eruption of Shiveluch volcano (Kamchatka peninsula, Russia) in April 2023 led to the formation of pyroclastic flows. Their length reached 10-15 km. During the field work in August 2023 we studied pyroclastic deposits and collected six samples over the area of pyroclastic flow. The samples were studied both at the micro and macro levels. Dispersion of soils varies from fine and very fine sands with a significant amount of coarse grain material (15-20%) to clayey soils with a small number of inclusions. The finest fractions, even with low moisture, are capable of grains aggregation. The aggregates are generally spherical in shape, but irregularly shaped aggregates are also present. Point and coagulation types of contacts are formed between the grains. According to X-ray analysis, plagioclase (up to 75%) and cristobalite (up to 23%) predominate in the composition of pyroclastic deposits. Quartz, pyroxene, and hornblende are present in smaller amount.

The bulk density varies from 1.44 to 1.57 g/cm^3 in undisturbed deposits. The grain density ranges from 2.64 to 2.74 g/cm^3. The porosity of the soils varies between 42 and 47%, with a porosity coefficient between 0.73 and 0.9.

The plasticity for fine-grained soils varies, with a plastic limit (PL, %) in the range of 20 to 21%. The liquid limit (LL, %) is 26 to 29% and the plasticity index (PI, %) varies from 6 to 8%. According to plasticity chart in ASTM D2487-17, some samples are classified as silty clays (CL-ML), while others as lean clays (CL). In terms of consistency index (Ic, %) fine-grained samples can be classified as very stiff and very soft-stiff (ISO 14688-2—2017). The strength and deformation characteristics of the samples are also different, and depend not only by soil dispersion, but also by grain habitus. The presence of thin material as a filler for the pyroclastic flow increases the strength of deposits (all other things being equal).

Influence of anthropogenic factors on landslide activity in the Moskva river valley (Moscow, Russia)

Pavel Novikov[1]*, Lomonosov Moscow State University (pasha-nov@mail.ru)
Oleg Zerkal[2], Moscow State University, Moscow, Russia
Olga Barykina[3], Moscow State University, Moscow, Russia
Igor Averin[4], "Engineering Geology" LLC, Moscow, Russia

Abstract

Moskva River valley is located in the European part of Russia, in the central part of East European Platform. It is one of the most densely populated areas of the country, and a large part of Moscow agglomeration is situated within the Moskva River valley. The territory is characterized by subhorizontal bedding of terrigenous-carbonate strata of the Carboniferous deposits and sandy-clayey deposits of the Jurassic, Cretaceous and Quaternary ages.

The first settlements in the valley of the Moskva River date back to the 1st millennium B.C., but until the 20th century the main anthropogenic impact on landslide masses consisted in planning and terracing of certain areas (e.g. Vorobyovy Gory, Khoroshevo-I). Since the 20s of the XX century, large-scale measures on economic development of territories, including landslide areas, have started to be implement.

Despite the fact that landslide processes in the Moskva river basin have been studying since XX century influence of some of anthropogenic factors were being underestimated for a long time. Among the anthropogenic factors of landslides, both those related to the purposeful impact on the landslide masses and those related to the indirect impact of human activity have been identified.

There are 2 two main types of landslides 1). Shallow slides associated with Quaternary glacial, glaciofluvial, alluvial and deluvial deposits, 2). Rotation slides associated with Jurassic clayey sediments.

For the first type of landslides such methods as forest planting, surface drainage, flattering and benching significantly reduce activity of shallow slides. On the site “Vorobyovy Gory” after mitigation measures only several landslide events are known. In contrast, human-induced river and gully erosion lead to intensification of such processes. An example is the site "Rublevo-Arkhangelskoye” the coastline of which is characterized by the impact of small landslides of about 30%.

For rotational slides the greatest impact on stability reduction is caused by slope loading and undercutting, as well as leakage from water-bearing utilities. Activities, which increase factor of safety are: building counterforces and anti-erosion measures (e.g. concrete embankments). Erosion control measures reduce water flow influence on slopes with no respect to volume and shape of landslides. At the same time efficacy of counterforces, is not so obvious. There are well-known cases when loading of toe part of the slopes had only temporary effect (“Vorobyovy Gory”, “Khoroshyovo-II”, “Kolomenskoye”).

For human activity analysis of spatial-temporal aspects is crucial. Immediate effect of landslide

control measures was significant up to complete cessation of deformations. However, after 20-30 years signs of movements on some sites were identified. It could be explained by complex inner structure of such large landslides and rapid changes in anthropogenic impact over time.
In comparison with shallow slides, anthropogenic influence assessment for rotational slides is a complex task. In the end, types and rate of technogenic impact drastically change in space and time, combination of multiple factors could have both positive and negative effect on slope stability.

Effects of heating-LN2 cooling on the Brazilian tensile strength of rock materials

BIKASH KUMAR KUMAR RAM[1]*, INDIAN INSTITUTE OF PETROLEUM AND ENERGY VISAKHAPATNAM INDIA (bikashramgeo@gmail.com)
DEEPAK AMBAN MISHRA[2], INDIAN INSTITUTE OF PETROLEUM AND ENERGY VISAKHAPATNAM INDIA
Rajeswar Das[3], INDIAN INSTITUTE OF PETROLEUM AND ENERGY VISAKHAPATNAM INDIA

Abstract

Evaluation of the effects of temperature on physical and mechanical properties of rock has key implication towards safe and sustainable development of various rock engineering projects such as extraction of geothermal energy and coal/shale gas, nuclear waste repositories, drilling and blasting etc. The rocks, which have experienced very high temperatures in such engineering sites, very often undergo rapid cooling treatments either to increase the permeability of the hot dry rock masses or cool the vicinity of the high temperature rock formations. In the recent past, liquid nitrogen (LN2) cooling has gained considerable attention as a substitute for conventional water-based cooling techniques. LN2 has also become common as a potential fracturing agent to construct enhanced geothermal system. However, this cryogenic cooling process significantly deteriorate the strength of the rock. Therefore, a comprehensive understanding on physical and mechanical properties due to heating and LN2 cooling is required to build sustainable and economical design of deep underground engineering projects and optimize the drilling parameters. In this investigation, the effects of LN2, and air-cooling methods were used in order to study the influence of different heating-cooling treatments on the physical properties and Brazilian tensile strength of the sandstone and basalt. The prepared specimens were heated in a muffle furnace at 100°C, 200°C, 300°C, 400°C, 500°C, 600°C and subsequently cooled in two different cooling conditions i.e. under normal room temperature and in LN2. It has been found that the sandstone possesses a general decline in Brazilian strength with a slight increase in strength between 300°C and 500°C. The Brazilian strength further decreases and becomes ~45-46% with the induced quenching after heating above 600oC. However, in case of basalt it is observed that the Brazilian strength increases ~11-21% with reference to untreated specimens at thermal treatments of 100°C in both the cooling methods. In thermal treatments above 200°C the Brazilian tensile strength of the basalt gradually decreases with higher drop in

case of LN2 cooling. This study infers that the mineral content and inherent texture plays a vital role in the development of thermal induce stress and pertaining its effects on the physical properties of different rock materials which influence the strength of the rocks.

Sensibility analysis of the parameters "Factor of Safety" and "Probability of Failure" in Slope Stability

Rubén Eduardo ROMERO MAYMA[1]*, IAEG Peru (rromerom@uni.pe)

Abstract

In many projects of roads and surface mining, an important challenge to solve is the assurance of the stability of the designed slopes. However, the common analysis is principally focused on the realization of a deterministic approach with the calculus of the Factor of Safety (FoS). In this job, was considered the estimation of the Probability of Failure (FoS) that uses the variability (Media and Standard Deviation) of several variables involved in the deterministic approach, as the cohesion or friction angle. It was realized taking in account data of slopes in Peru. The zones considered was a road (Ica), and two open pits (Moquegua and Lima). With the data, the FoS and PoF were calculated rigorously comparing diverse calculus methods like limit equilibrium (analytical) or shear strength reduction (numerical). The softwares Dips, Slide, Rocplane, Swedge, FlacSlope, Phase2 and SBlock were used. It is to obtain the most representative values of FoS and PoF. So, having these two parameters, was conducted a sensibility analysis via statistical correlations. The relationship varies with the change degree of confidence of the standard deviation, the statistical distributions used and the function analyzed. Taking in account all the possible analysis and comparisons, the better distributions to analyze these variables are the normal and, in less grade, the exponential distribution. And between all the functions the most adequate is the "Function error" because it stablishes a great determination coefficient in comparison with another functions. The established relationship is consistent and is useful to know better about these methods. In general, it is a good idea to foster the use of probabilistic approaches in future slope stability projects to avoid the uncertainty that a deterministic approach can generate.

INTERPLAY OF COHESIVE-ORGANIC SOILS AND DISPERSIVE BEHAVIOR: SHAH ALAM'S SUSCEPTIBILITY TO WATER PONDING

NOR SHAHIDAH MOHD NAZER[1]*, UNIVERSITI KEBANGSAAN MALAYSIA
(shahidahnazer@ukm.edu.my)

Abstract

Flash floods, especially in urban areas like Shah Alam, may result from a combination of factors including heavy rainfall and inadequate drainage. The localized nature of these floods and their impact on infrastructure, including roads and vehicles, underscores the importance of flood preparedness and the need for comprehensive flood mitigation strategies. However, one often overlooked factor is the presence of cohesive-organic and potentially dispersive soils, which complicate water absorption and runoff management. This research explores the intricate relationship between the physical properties of cohesive soils, their dispersive characteristics, and the resulting impact on water ponding. Cohesive-organic soils in Shah Alam, peat primarily composed of fine clay particles, exhibit high water retention capacities due to their small size and surface charges, leading to inherently low permeability. This characteristic slows water infiltration during heavy rainfall, contributing to increased surface runoff. Additionally, when these soils display dispersive behavior—where clay particles are prone to separation and suspension in water due to high sodium concentrations—the risks are compounded. Soil dispersion can lead to erosion, sedimentation in drainage channels, and reduced structural integrity of slopes, further obstructing effective water management and exacerbating flood conditions. Therefore, effective management and mitigation efforts incorporating the aspect of water ponding from dispersive behavior of cohesive-organic soil are essential to reduce the vulnerability of these areas to flooding and its associated impacts.

Keyword

cohesive-organic soil, dispersive, water ponding, flood, peat

Damage Evolution Mechanisms of Granite Rock under Cyclic Loading: X-Ray Computed Tomography and Digital Volume Correlation Technique Analysis

Shangtong YANG[1]*, China University of Mining and Technology / University of Strathclyde, UK (6538@cumt.edu.cn)
Qinxin HU[2], University of Strathclyde
Xiaozhao Li[3], China University of Mining and Technology, Xuzhou, China

Abstract

Understanding the damage evolution mechanisms under cyclic loading, leading to brittle failure of rocks, can shed light on estimating and predicting the life-cycle reliability of rock structures and rock engineering. In particular, microscale fracture evolution is a key to understanding and elucidating the macroscopic engineering properties of rocks, especially the fracture propagation and damage behavior. In this study, cyclic uniaxial compression tests were performed on granite rocks together with X-Ray Computed Tomography (XCT) and Digital Volume Correlation Technique (DVC) analysis. The quantitative statistics of cracks reveals the dynamic closing, opening, nucleation and self-propagation of micro-cracks. Evidence of micro-cracks coalescence and crack clustering to achieve failure has also been demonstrated. The strain fields reveal the relationship between the strain localization and crack behavior and reflect stress concentration zones under different damage level. Damage evolution is dominated by nucleation at initial cycles and transit to self-propagation and coalescence as the cycles increased. DVC results show that distortion has the highest correlation to cracking. Apart from the strain localization, damage evolution process tends to cause larger deformation in the undamaged zones, which is completely different to the monotonic loading scenario. The results implicate that the stress transfer is the main mechanism for fatigue damage.

Comprehensive studies of the engineering geological behavior of red clay soils in Bangladesh

Md Shohel RANA[1]*, Institute of Mining, Mineralogy and Metallurgy (IMMM); Bangladesh Council of Scientific and Industrial Research (BCSIR), Joypurhat 5900, Bangladesh (shohelrana@bcsir.gov.bd)
Tamanna Tasnim[2], Department of Geological Sciences, Jahangirnagar University, Dhaka 1342, Bangladesh
Hossain Md. Sayem[3], Department of Geological Sciences, Jahangirnagar University, Dhaka 1342, Bangladesh
Md. Emdadul Haque[4], Department of Geological Sciences, Jahangirnagar University, Dhaka 1342, Bangladesh

Abstract

Red clay soils are widely distributed over the Madhupur Tract, Barind Tract, and Lalmai Hills areas of Bangladesh, covering an area of 12800 km2 (8.67% of the total area of the country). These tracts are comparatively more populated than neighboring areas due to their stable landscape. The growing cities, e.g., Dhaka, Gazipur, Narayanganj, Tangail, Bogura, Naogaon, Joypurhat, Dinajpur, and Lalmai area of Cumilla, are located over this unique variety of residual soil. These areas are urbanized rapidly, which expands laterally as well as vertically. The red clay soils serve as a shallow foundation layer in these areas for low to moderately load-bearing superstructures. Therefore, the aim of this research is to evaluate the engineering geological properties of red clay soils that were collected from the Barind Tract (the largest Pleistocene Terrace) in two boreholes by combining the light cable percussion drilling method and the standard penetration test (SPT) method. The lithology of the investigated soil reveals that it is reddish brown to yellowish in color, mottled, and occasionally contains manganese tints and iron concretions. The field SPT values indicate that the ground condition of the soil is mainly stiff to hard. The red clay soils are fine-grained, composed predominantly clay-sized particles (42% to 59%), with lower amounts of silt (26.31% to 36%) and sand (14.5% to 30%). Mineralogically, the soils mainly composed of illite (77% to 89%) over kaolinite (11% to 23%) with a small amount of smectite. The liquid limit values range from 33.75% to 52.7%, plastic limit values from 13.88% to 21.27%, and plasticity index from 16.36% to 32.26%. According to the British soil classification system, clay soils are characterized as low- to high-plasticity inorganic clay and classified as CL to CH. The activity (0.42 to 0.73) value suggests the soil is inactive. However, the high linear (11.07% to 16.64%) and volumetric shrinkage (24.34 to 36.19%) values reveal that these soils are critical in nature, with a shrinkage ratio of 1.82 to 2.03. The soils exhibit medium to high swell potential based on the plasticity index and clay content plot. The 3D swelling test results indicate that the rate of swelling strain normal to the bedding plane is greater than the rate of swelling strain parallel to the bedding. In terms of consolidation, the soils are overconsolidated with an overall lower settlement, stiff to hard consistency, medium to very low compressibility, medium to low plasticity, and low permeability. Despite having a poor index and swell-shrink characteristics,

the consolidation behavior suggests that this soil is suitable for low- to moderately load-bearing superstructures. This engineering geological information is valuable for stakeholders, including land developers, urban planners, policymakers, geotechnical engineers, and the local population, aiding in informed decision-making for construction and development in these areas.

Successful Replacement for Slope Stability Enhancement in Group-housing Site

BYUNG DON RO[1]*, Architecture Safety Center, Gangseo-Gu, Seoul, Korea (engeo@naver.com)

Abstract

In the case of a cut slope, when exposed for a long period of time in the air, weathering progresses rapidly, and rock mass or shallow sliding on the surface layer often occurs. In particular, slopes with frequent joint or crack are likely to gradually be destroyed because sliding may occur between each nail or rock bolt installation point when reinforced only with nails or rock bolts.
As a common countermeasure to this, cover with shotcrete while installation of rock bolt or soil nail. However, due to the nature of the material, rigid surface-reinforcing such as shotcrete cause cracks easily, ductile deformation within the slope surface cannot be allowed, and there is a possibility of falling out due to seepage in the back surface. It also has the disadvantage that greening is difficult and the landscape is poor. In the case of ductile surface-reinforcing, it is difficult to apply to steep slopes, and there are restrictions due to the strength of the material itself (geotextile or geo-membrane), so it is particularly difficult to apply it to rock slopes. A flexible surface-reinforcing, which combines the advantages of rigid and plastic method, while allowing a certain amount of displacement within the slope supports, so it has excellent applicability on soil and rock slopes, and can be applied in combination with nailing. Furthermore, in terms of environmental friendliness, it is possible to plant planting and greening slopes, and also minimizes maintenance costs. Currently, the development trend of slope stabilization methods around the world is an environmentally friendly construction method and can be restored to a natural state, and research and development is being carried out in the direction of minimizing future maintenance costs.

Paleostress from healed microcracks and fluid inclusions in granites in the northeastern and southwestern areas of the Ogcheon folded belt, South Korea

Seong-Seung KANG[1]*, Chosun University (kangss@chosun.ac.kr)
Bo-An Jang[2], Kangwon National University
Taeyoo Na[3], Korea Institute of Geoscience and Mineral Resources
Jeongdu Noh[4], Jeonnam Research Institute

Abstract

In the northeastern and southwestern areas of the Ogcheon folded belt, where Mesozoic granites are distributed, measurements were taken of healed microcracks and fluid inclusions within the granite bodies to elucidate the paleostress field that acted upon these areas. The predominant orientations of healed microcracks in the northeastern and southwestern areas of the Ogcheon folded belt are as follows: N50°W for the Inje granite, N30°W for the Jecheon granite, N55°W for the Wolaksan granite, N5°W for the Sobaeksan granite, N30°W for the Daebo granite, and N70°W for the foliated granite. The homogenization and trapping temperatures of fluid inclusions, along with the estimated formation periods of healed microcracks, are 170-290°C, 260-390°C, and 209-149 Ma for the Jecheon granite; 165-290°C, 250-400°C, and 176-160 Ma for the Inje granite; 165-375°C, 230-570°C, and 116-88 Ma for the Wolaksan granite; 155-280°C, 210-410°C, and 92-84 Ma for the Sobaeksan granite; 150-310°C, 380-550°C, and 120-166 Ma for the foliated granite; and 150-320°C, 380-440°C, and 183-166 Ma for the Daebo granite, respectively. Consequently, during the Mesozoic era, the predominant maximum horizontal stress direction in the Korean Peninsula was NW-SE, with secondary influences from N-S and E-W directions. Moreover, it is thought that the direction of these maximum horizontal stresses rotated from NW-SE to N-S around the mid-Cretaceous period. The directions and formation periods of healed microcracks in the study area align well with the Mesozoic orogenies of the Korean Peninsula. The Daebo orogeny, occurring from the Jurassic to early Cretaceous, primarily influenced the Jecheon granite, Inje granite, Wolaksan granite, foliated granite, and Daebo granite in a NW-SE direction, while the Bulguksa orogeny, from the mid to late Cretaceous, mainly influenced the Sobaeksan granite in a N-S direction.

Comparative analysis of slope stability assessment using LightGBM and CatBoost

Jeongdu Noh[1], Jeonnam Research Institute
Dahye Kim[2], Chosun University
Youngshin Park[3], Chosun University
Seong-Seung KANG[4]*, Chosun University (kangss@chosun.ac.kr)

Abstract

Machine learning prediction models, LightGBM and CatBoost, were utilized to assess the stability of slopes. The slope prediction models were classified into three types: Case-1 composed of 9 numerical data, Case-2 composed of 22 categorical data, and Case-3 composed of 31 mixed numerical and categorical data. Model results for each analysis stage were evaluated and analyzed based on training performance, prediction performance, and variable importance. Analysis using the LightGBM model for slope stability prediction showed that the AUC values were 0.681 for Case-1, 0.766 for Case-2, and 0.783 for Case-3. While training and test data showed similar learning performances in Case-1 and Case-2, overfitting was observed in Case-2. In terms of prediction performance, the precision, recall, F1-Score, and accuracy for training and test data were 73% and 68% for Case-1, 79% and 77% for Case-2, and 84% and 78% for Case-3, respectively. Variable importance was in the order of slope length, upper slope gradient, and slope gradient for Case-1; rock type, surrounding terrain for Case-2; and soil layer depth, upper slope gradient, slope gradient, slope length, slope height for Case-3. In the analysis using CatBoost, AUC values were 0.672 for Case-1, 0.777 for Case-2, and 0.794 for Case-3. Similar to LightGBM, Case-1 showed similar learning performance between training and test data, but overfitting was evident in Cases 2 and 3. Prediction performance metrics such as precision, recall, F1-Score, and accuracy for training and test data were 70% and 67% for Case-1, 86% and 78% for Case-2, and 90% and 79% for Case-3, respectively. Variable importance was in the order of soil layer depth, upper slope gradient, slope height for Case-1; discontinuity orientation, side shape, surrounding terrain for Case-2; and soil layer depth, discontinuity orientation, side shape, discontinuity type for Case-3. LightGBM did not show prediction imbalance across the three interpretation methods and exhibited similar training performances between training and test data. Numerical data showed relatively higher importance, with rock type and surrounding terrain being significant among categorical variables. CatBoost, except for Case-1, showed more significant overfitting in training data compared to LightGBM. Categorical data showed relatively higher importance in variable significance, with soil layer depth being the most significant, followed by discontinuity orientation, side shape, and discontinuity type among categorical variables. Consequently, LightGBM could be considered the most stable model for predicting slope stability, while CatBoost could be considered the most accurate model for this purpose.

A comparative study of cation exchanges in 'extreme types of clay minerals' to modify the swelling index of the foundation soil underlying the civil engineering structures

Sudipta SARKAR[1]*, Retired Deputy Director General from Geological Survey of India (sudiptaashish@yahoo.co.in)
Ashish Sarkar[2], Retired Associate Professor from Pandit Deendayal Petroleum University, Gandhinagar, India

Abstract

Essential components of the soils are phyllosilicates in the form of clay minerals, a product of chemical weathering of other silicates. While weathering of basic and ultrabasic rocks produce smectite group of clay minerals, feldspar rich rocks produce kaolinite. The geotechnical properties of smectites and kaolinite are vastly different. Presence of various groups of clay minerals in the soils are responsible for wide variation in the foundation property of the soil, which in turn control the stability of the civil engineering structures (CES) erected on it. Among the other geotechnical properties, swelling index is a very important and a very significant geotechnical parameter determining the stability of the CES. While, under the influence of water, kaolinites do not swell much; montmorillonite, a significant member of smectites, swells 'infinitely' causing instability to the CES.

The swelling index of the soil containing clay minerals can be effectively modified by treating it with the chlorides of different cations resulting in the 'cation exchange' in the structures of the clay minerals. But the process of cation exchange in the soils containing both smectite and kaolinite becomes tricky as these clay minerals respond differently to the different cations. To address this problem, a series of experiments were carried out in the present study. In order to determine and understand the amount of cation exchange vis-a-vis modification in the geotechnical properties of soil samples, a total of 36 aliquots of each montmorillonitic and kaolinitic soil were treated with CaCl2, MgCl2, NaCl, and KCl with 0.5N, N, and 2N concentrations and were cured for periods of 7, 15, and 21 days following standard procedures. Swelling Index of the untreated (soaked in double distilled water) montmorillonitic and kaolinitic soils, and each of the total 72 treated samples were determined following the standard procedures. Ammonium Acetate and double distilled water extracts of each of the treated montmorillonitic and kaolinitic soil samples have been analysed in the ICP-ES system following the standard procedures to understand the cation (Ca++, Mg++, Na+, and K+) exchange behaviour in each of the treated montmorillonitic and kaolinitic soil samples.

The experimental data reveal that while treatment with different cations in treated montmorillonitic soil results in lowering in swelling index at the combination of 2N concentration and lower curing period in general with all the cations, the best reduction in swelling index

(~15%) is obtained at the concentration of 2N with a curing period of 15 days. Interestingly, barring only one sample (at 2N MgCl2 with 7 days curing period), all other (35 samples) treated kaolinitic soil samples show enhancement of swelling index from 11 to 53%. The results depict that if the foundation soil of the CES contains substantial amount of kaolinite along with montmorillonite, cation treatment should be avoided, even though the cation exchange proves to be an effective method of lowering the swelling index of montmorillonite.

Rockslides and Rock Avalanches in the Upper Part of Mzymta River Valley (Caucasus, Russia)

Oleg V. ZERKAL[1]*, Moscow St. University, Geological Department (igzov@mail.ru)
Alexander A. PONOMAREV[2], "EngZashita" Ltd., Sochi, Russia
Andrey A. PONOMAREV[3], "EngZashita" Ltd., Sochi, Russia
Olga S. BARYKINA[4], Moscow St. University, Geological Department

Abstract

The valley of the Mzymta River, which flows into the Black Sea, is located in the southwestern part of the Caucasus (Russia). The Caucasus mountain system is a collisional orogen that was formed on the southern border of the East European Platform as a result of the interaction of the Eurasian and Arabian lithospheric plates. The geological section of the Mzymta River valley is composed of Lower Jurassic terrigenous flysch (right side, lower part of the left side) overlain by Middle Jurassic volcanogenic-terrigenous strata (middle and upper parts of the left side). The regional tectonic suture (the Main Caucasus thrust) is located slightly to the north (~4 km).

The present-day valley of the Mzymta River in this area has a complex character. Its left side is formed by the Aibga Ridge with a relative height of up to 1.5-1.7 km. The right side of the valley is formed by a series of lower ridges (Achishkho, Pseakhako and others) with a relative height of less than 1.0 km. The valley of the Mzymta River is an alternation of narrow linear sections, where the channel has a V-shaped form with sharp drops in elevation, and relatively wide sections of the trog type, with the presence of several floodplain terraces. The studies have shown that the present-day appearance of the Mzymta valley is associated with the wide development of large-scale rockslides and rock avalanches, the frontal parts of which reached the valley bottom or overlapped it.

Based on the results of mapping (aerial photographs and satellite image analysis, field investigations), six rock avalanches with volumes ranging from 145 million m3 to more than 310 million m3, 31 rockslides and rock avalanches with volumes ranging from 10 million m3 to 95 million m3, and several hundred smaller landslides have been described in the Mzymta River valley. The rockslides, typically formed in terrigenous flysch, are located in the middle and lower parts of the valley sides. The source areas of rock avalanches are located in the tributary part of the Aibga Ridge, within the area of distribution of Middle Jurassic volcanogenic deposits. The frontal parts of rock avalanches reach the Mzymta River channel and often extend to the opposite side of the valley. Due to the insignificant width of the channel part of the valley, the dynamic impact of rock avalanches provoked displacement of "counter" rockslides from the opposite side of the valley. This is one of the peculiarities of the development of rockslides and rock avalanches in the upper part of Mzymta river valley.

A Basic Study on the Development of Trenchless Excavation Technology and Construction Method

YONG BAEK[1]*, KICT (baek44@kict.re.kr)
JIN HWAN KIM[2], KICT
JONG HYUN LEE[3], KICT

Abstract

Hydrogen is essential as a future energy industry, and it is expected that the supply of hydrogen energy will be activated. In order to secure localization of hydrogen pipe network construction technology in consideration of the characteristics of demand and production sites such as hydrogen cities, the current status of excavation technology is re-examined according to the characteristics of the ground field. It is necessary to develop construction technology roughly into an excavation method and a trenchless excavation method in accordance with the characteristics of the domestic ground. Therefore, the current status of the excavation technology used in Korea was investigated and analyzed, and the applicable method was suggested according to the characteristics of the domestic ground. Develop a trenchless excavation method for domestic hydrogen pipe network construction by deriving improvement plans or suitable technologies for the applied technology in accordance with the strengths and weaknesses of each ground characteristic. It is to localize the trenchless excavation method by improving the localization and the inefficient operation plan. In the case of weathered rock or abnormal ground, there is a possibility of excavation work, but in the case of hard rock, there may be a problem with the construction speed, so the ground characteristics may be a problem. It is necessary to develop management technology for the stability of construction during the construction process. For maintenance, this study introduces maintenance technology and sensing technology in a visible and intuitive manner using a contactless sensor. The collected data can be acquired and analyzed through a transmission system. By incorporating customized communication equipment and technology into regional characteristics, the focus was on safety during construction. In addition, the data of the construction process can be used from the beginning of the work to the operation by leading to maintenance and operation. The utility of this study is to safely construct the hydrogen pipeline and secure highly efficient equipment design and construction technology for safe hydrogen transfer in the city. In addition, it is intended to lead to localization and practical use of development technology, thereby reducing the cost of building the hydrogen pipeline.

Investigating physico-chemical and mechanical properties of Cretaceous sandstones within Khorat Cuesta, Northeastern, Thailand

Prachya Tepnarong[1]*, School of Geotechnology, Institute of Engineering, Suranaree University of Technology (prachya@sut.ac.th)
Anisong Chitnarin[2], School of Geotechnology, Institute of Engineering, Suranaree University of Technology

Abstract

Clastic sedimentary rocks within the UNESCO Khorat Geopark in Nakhon Ratchasima Province, northeastern Thailand are examined for physical, chemical and mechanical properties. The natural exposures on the western border of the Geopark area including Phra Wihan (PW), Phu Phan (PP) and Sao Khua (SK) Formations were investigated. At each locality, primary and secondary structures were inspected, rock types were initially identified, then the representative samples were collected. The polished sections were prepared to classify the rocks, physical characteristic such as grain size, texture, type of gravels, cementing materials were also defined. Sets of rock samples were prepared to determine their mechanical property following ASTM. Rock samples belonged to the Phra Wihan and Phu Phan Formations which exposed naturally as a double cuesta were classified as fine- to coarse-grained sandstones and conglomeratic sandstones. Rock samples of the Sao Khua Formation represented a valley between the double cuesta are consisted of very fine-grained sandstones, conglomerates, and calcrete. PW and PP samples tend to have lower density but higher porosity than SK samples, and range between weak to strong rock types. SK samples have high density, low porosity, and are assigned to strong to very strong rock types. It is found that Point Load Strength Index and Slake Durability Index of the rocks correlate well with the density, therefore; SK samples are stronger and more durable than PW and PP samples. Rock strength does not pertain with silica and clay mineral contents but refers to percentage of calcite. Calcite cementation and deposition in SK samples should play important role in weathering and development of the Khorat Cuesta.

Evaluation of operating cost and economic feasibility of a limestone open pit mine in Korea

Dong-Kil LEE[1]*, Korea Institute of Geoscience and Mineral Resources (ldk@kigam.re.kr)
Jae-Ho Lee[2], Korea Institute of Geoscience and Mineral Resources
Ji-Whan Kim[3], Korea Institute of Geoscience and Mineral Resources
Yong-chan Cho[4], Korea Institute of Geoscience and Mineral Resources

Abstract

As difficulties in securing ore production are expected due to a decrease in the ore reserves in the mining area under development, a preliminary feasibility assessment was conducted for a mine planning to develop a new ore body in adjacent mining area under development. For this purpose, a final pit was designed based on a grade block model of the ore body, and a production schedule planning for 11 million tons per year was established. Based on the established production plan and engineering mine design, a preliminary feasibility assessment over the entire life of the mine was assessed as of 2020. As a result of comparing the cost of Korea's limestone open pit mines investigated after the evaluation point and the cost evaluated in 2020, the unit operating cost of this study was found to have an error of -1.9% compared to the domestic average cost, and an error of -8.8% compared to the cost of the mine. In this study, it was evaluated that the mine mines limestone itself, but in reality, the mine mines limestone by outsourcing it to other companies. It is considered that this error occurred for this reason. The development of a new mining area in this mine showed good economic feasibility with a discount rate of 4.5%, an net present value (NPV) of KRW 174.2 billion, a internal rate of return (IRR) of 59.2%, and a B/C ratio of 1.30 based on present value. As a result of a sensitivity analysis, it was found that the main factor affecting economic feasibility was the price of ore.

Case of Rockmass Classification in the Submarine Ground Where Marine Investigation is Difficult Due to Rapid Current

Seong-Woo MOON[1]*, Chungbuk National University (msw2080@naver.com)
Jeong-Eum Lee[2], Chungbuk National University
Se-Jeong Ju[3], Chungbuk National University
Yu-Jin Ha[4], Chungbuk National University
Yong-Seok Seo[5], Chungbuk National University

Abstract

This study carried out to conduct rock mass classification in sections that have been drilled without cores, connecting the mainland and an island in the southwestern part of the Korean Peninsula. The sea of the study area has the fastest current (up to 6.5m/s) in the Korean Peninsula, making marine drilling surveys using barge difficult. Additionally, the inclined drilling for the submarine pipeline installation is kind of a drilling type, not a boring type that can recover samples, and only the fractured rock fragments can be recovered as slimes. For these reasons, it is difficult to conduct directly rock mass classification.

Therefore, the types of rock masses distributed around the study area were first identified using geological surveys of land outcrops and the results of drilling surveys conducted near land and the coast. After mechanical properties of rocks were then acquired through core observations, ultrasonic tests, and unconfined compressive tests, and rock classification was performed on the sections of rock cores that could be observed. After that, gamma-ray logging was conducted at regular intervals in the submarine pipeline (inclined drilling) section, and the gamma-ray results were compared to the results of rock classification. For the submarine ground where it was difficult to carry out rock classification through visual observation, the rock classification of the submarine ground was performed by matching the gamma-ray values and the distribution of rock masses (inferred from the results of drilling surveys on land and the coast).

Experimental study on mechanical properties of pore-filling and fracture-filling clayey silt hydrate-bearing sediments

Yiming LI[1]*, jilin university (1192718979@qq.com)
Wei Guo[2], Jilin university
Yuan Wang[3], Jilin university
Rui Jia[4], Jilin university

Abstract

The filling characteristics of hydrate have significant influences on the mechanical properties and failure mechanisms of sediments. In this study, two typical filling characteristics of hydrate were selected, which were pore-filling and fracture-filling (layered) in clayey silt sediments, the mechanical response characteristics of pore-filling hydrate-bearing sediments (PFHBS) and fracture-filling hydrate-bearing sediments (FFHBS) were compared and analyzed through a series of triaxial tests. The results show that PFHBS and FFHBS exhibit significant differences in mechanical properties under identical conditions. The stress-strain relationships of clayey silt sediments with varying hydrate saturation are influenced by the filling characteristics of the hydrate. The enhancement effect of hydrate on the strength parameters of the sample at the same saturation increment is influenced by the filling characteristics. The failure strength, Young's modulus, and shear strength indexes of FFHBS surpass those of PFHBS under identical hydrate saturation conditions, while FFHBS exhibits a greater volume expansion than PFHBS. The number of fracture layers in FFHBS exhibits a positive correlation with the strength parameters of the sample, yet intensifies the phenomenon of volume expansion. In addition, the filling characteristics of pore hydrate and fracture hydrate determine that the sediments exhibit different strength enhancement and shear mechanisms. The results provide valuable references for the selection of target hydrate reservoir sites and the design of safe exploitation in various target areas.

Engineering geological studies and expected support design during the construction of diversion tunnels, Renukaji Dam Project, District Sirmaur, Himachal Pradesh, India

TRIPTI BABA[1]*, Geological Survey Of India (tripti.baba@gsi.gov.in)
Prashant Ilamkar[2], Geological Survey Of India

Abstract

Renukaji Dam Project envisages construction of a 178m high rock fill dam across Giri River, near Dadhau town, Sirmaur district, Himachal Pradesh, India. The main components of the projects are three circular (10.50m finished diameter) diversion tunnels of 1355.46 m, 1549.76 m and 1448.90 m lengths, a surface power house of 40 MW capacity located on the right bank and a 550m long chute spillway on left bank of the Giri River.

The proposed diversion tunnel would pass through the repetitive sequence of rocks of pink shale followed by pitted, crumbly, cavernous limestone and bedded limestone of Krol Group and carbonaceous slates and bleached shales of Infra Krol Formation due to folding in nature. These are expected to behave as weak tunnelling media & would offer little stand up time. However, drill hole data drilled along the alignment of the diversion tunnel have established the presence of adequate rock cover above the tunnel grade having very poor to poor RQD. The project area also bounded by two major thrusts viz., Main Boundary Fault (MBF) exposed in the d/s and Renukaji Thrust in the u/s of the propose dam axis due to which rocks can be seen as folded, highly jointed, sheared and fractured at many places along the DTs.

Rock mass rating (RMR), Rock mass quality (Q), Geological Strength Index (GSI) systems, Weathering Grade and UCS as per IS Code were used for empirical rock mass quality determination, site characterization and expected support design.

According to the field based studies, tunnel stability problem expected in the carbonaceous shale/siltstone/phyllite and limestone bands observed in bedded form forming synclinal closure near to the proposed dam axis. The expected support system, suggested by empirical methods, was given but the performance of suggested support system must be evaluated by means of numerical modelling during the construction of the diversion tunnels. Reducing the width of the tunnel should also to be considered depending on the discharge and storage capacity of the river/reservoir.

This paper presents the results of surface engineering geological investigations along proposed DTs and recommendations rendered accordingly during the field studies. These include engineering geological mapping, intensive discontinuity surveying, drill hole logging and empirical field tests.

Review on geological and engineering aspects of gypsum solubility and dissolution in the Arabian Gulf coast

Sungbin YIM[1]*, KEPCO E&C (sbyim@kepco-enc.com)
Joohyeon YI[2], KEPCO E&C
Hyunseok YUN[3], KEPCO E&C
Yongwoo NOH[4], KEPCO E&C
Jihwan SHIN[5], KEPCO E&C

Abstract

Evaporitic geology, hot and arid climate, fluctuating relative humidity, and alkaline environment governs the evolution of gypsiferous rock formation in the Arabian Gulf coast. In this area, gypsum beds are interspersed within the Miocene and Eocene sediementary formations. Unusually, small opening and network of small-diameter passages with cavities are developed within gypsiferous rock formation.

Calcium sulphate generally occurs naturally as two different forms of anhydrite (CaSO4) and gypsum (CaSO4·2H2O) in the local formation. Hydration of anhydrite and dehydration in gypsum lead to alternating volume changes, thereby posting serious engineering problems.

The engineering properties of gypsum and anhydrite change as a consequence of groundwater pressure and heat. The two basic problems cause the subsidence due to the solubility characteristics of gypsum and heave due to the hydration of anhydrite. Generally, gypsification of anhydrite is associated with up to 63% swelling and dehydration of gypsum to form anhydrite results in a maximum volume reduction of 39 % (Zanbak and Arthur, 1986).

Especially, gypsum is susceptible to rapid dissolution wherever there is active circulation of water that is unsaturated with respect to calcium sulfate.

CaSO4·2H2O+H2O → Ca+SO4-2+3H2O

In underground system, chemical solution trends to occur along existing discontinuities, e.g. joints and faults. Thus, until a late stage of development, karstic gypsum terrains usually have cavity patterns related to the discontinuity geometry. Karst features in the gypsum usually consist of a network of small-diameter passages (Culshaw and Waltham, 1987). If gypsiferous rock is massive and jointed, large openings are created along preferential flow paths (Karacan and Yilmaz, 1987).

Many studies have been undertaken on the solubility and dissolution of gypsum in the context of construction engineering and karst processes. In this study, the dissolution characteristics of gypsum are reviewed through both field observations and literature studies.

Mainstreaming urban geoheritage as a tool for environmental education and geotourism in local administrations

Juana VEGAS[1]*, Geological Survey of Spain (IGME-CSIC). Spain (j.vegas@igme.es)
Andrés Díez-Herrero[2], Geological Survey of Spain (IGME-CSIC). Spain

Abstract

In 2022 there will be more than 8 billion people on our planet and currently around 56% of the world's population lives in cities. For millions of people the little 'nature' in urban environments, together with gardens, zoos and parks are the only option for real contact with biodiversity and geodiversity. Geoheritage and geodiversity are also present in many cities and form part of their skyline, with rock outcrops in streets and squares, which may contain fossils in the case of sedimentary rocks. The wide variety of ornamental rocks on building walls and interiors are also a resource at our disposal. The movable geological heritage in collections and museums allows us to enjoy elements that are accessible to all audiences (including people with disabilities). Not forgetting the rock gardens in some cities. The relationship between the geology and the historical-artistic buildings is highly remarkable, through the location of the quarries from which the raw materials were extracted, the traditional trades, the foundations of monumental buildings, and even legends, children's stories and miraculous with a geological background. This social reality shows the great potential of urban geoheritage as an asset for the promotion of environmental education, geotourism and the health of people living in or visiting cities.

A paradigmatic case in the integration of geoheritage in land-use planning, environmental education programmes and urban geotourism is the city of Segovia (Spain). Due to its position on the Iberian Peninsula (SW Europe), Segovia's geological record covers the last 600 Ma of Earth's history. A detailed inventory of the municipal district was compiled that containing 94 geosites, where four of them are collections of minerals, rocks and fossils (movable geoheritage). An assessment method of the geoheritage for environmental education and geotourism in the urban areas was designed, including six main criteria that specifically assess aspects of environmental education, geohazards, global change and geotourism. The potential users of environmental education in the city have also been considered: students of primary, secondary and university education, families in their leisure time, visitors and people with disabilities. This assessment of the geoheritage is a novel design worldwide, and this is the first time that it has been implemented and applied to a city. This model can be replicated in any other urban area. Understanding Segovia's geological past and present through environmental education and geotourism generates more resilience among people when tackling important issues in our society such as climate change and its effects on the urban ecosystem and people.

The monitoring of land subsidence and groundwater level in the southeast Kanto groundwater basin, Japan

Atsushi KAGAWA[1]*, Research Institute of Environmental Geology, Chiba
(kagawaa2016@gmail.com)
Kunio FURUNO[2], Former Institute of Environmental Geology, Chiba

Abstract

The Kanto groundwater basin is composed of Pleistocene marine sediments, Kazusa group and Shimosa group. The number of observation wells for monitoring groundwater level condition in the basin was 375 in total as of 1982 and 471 as of 2020. Chiba Prefecture is located in southeast part of the basin; and as of 2020 land subsidence has been monitored by 159 wells and 1075 benchmarks. Based on continuous monitoring, the mechanism of land subsidence is now reasonably well understood.

Kazusa group contains brine groundwater including natural gas and iodine. Heavy land subsidence occurred in 1970s and was due to gas production. Since that time, groundwater-pumping regulations have been strictly enforced in the Tokyo Bay area. Therefore, the pumping is now limited to the marginal area of the basin. Shimosa group has been extensively pumped, mainly for public water supply, agricultural and industrial use. Groundwater in the aquifer fell to its lowest level at the coastal industrial zone of Tokyo metropolis in the 1960s to early 1970s. National government and local governments then regulated groundwater using. Annual pumped volume of the southern Kanto groundwater basin was 4.0 million m3/day in 1973 and 1.6 million m3/day in 2020. After that, the recovery of the groundwater level was monitored according to the pumping up control. Recently, the lowest groundwater level in the lower aquifer has been around 10 m below sea level.

Our general hydrogeologic investigations now show that we can reasonably pump groundwater in the Kanto Basin without causing undue land subsidence. Nevertheless, groundwater pumping requires constant monitoring for sustained use.

Characterizing Groundwater Drought-Induced Land Subsidence Dynamics in Economic Hub of State of Gujarat, India

Anuradha Karunakalage[1]*, Indian Institute of Technology Roorkee (anuradha_s@es.iitr.ac.in)
Mohammad Taqi Daqiq[2], Indian Institute of Technology Roorkee
Marc-Henri Derron[3], University of Lausanne
Ravi Sharma[4], Indian Institute of Technology Roorkee
Michel Jaboyedoff[5], University of Lausanne

Abstract

The economic capital of the state of Gujarat, Ahmedabad, exhibits a semi-arid climate prone to droughts, with a variable surface water supply. The city experienced significant municipal and industrial expansion, alongside meeting the demand from the neighbouring agricultural areas reliant on groundwater irrigation. Groundwater in this region is stored within a complex aquifer system characterized by alternating layers of coarse and fine-grained sediments, with the latter acting as aquitards. Hence, fluctuations in groundwater levels can possibly be associated with the deformations of the land surface to both the elastic and the inelastic deformations in the underlying strata. State-of-the-art remote sensing techniques highlighted land subsidence as a prevalent occurrence in cities across the northwestern region of India, and the land surface deformation in Ahmedabad was first unveiled in 2021. However, the influence of groundwater drought on land subsidence in Ahmedabad and the relative compaction and its nature among the subsurface strata have not been discussed in any previous scientific work. The present study observed maximum vertical subsidence rates of 9.1 cm/year in the southeast and 7.2 cm/year in the western parts of the city between October 2017 and March 2020, utilizing the Small Baseline Subset (SBAS) technique in Interferometric Synthetic Aperture Radar (InSAR). Building upon these findings, the study aims to identify the period of initial compaction occurrence and its nature and estimate the spatial distribution of deformation type in the city. Additionally, it seeks to establish correlations between land subsidence and groundwater drought events to understand the dominant spells of drought-induced compaction. The anticipated information and findings of this study hold potential benefits for simulating long-term compaction processes within fine-grained layers, its interplay with the coarse-grained sediments, and offer comprehensive insights for water management and urban development authorities to mitigate the risk of infrastructure damage.

Abstract

With cities growing, the pressure on the urban subsurface has become a significant challenge in urban development. Limited understanding of subsurface conditions can lead to costly conflicts and damages during construction. The data Exchange between geological surveys, municipalities and urban planners may help to mitigate these risks and potentially prevent spending large amounts of funds on remediation works.

Geological surveys often possess extensive amount of archival data on the urban subsurface, encompassing various geoscientific domains. However, these data are not usually used during the urban planning or the decision-making processes by the municipalities. The absence of direct data links and user-friendly visualization tools hinders effective communication between geoscientists and urban stakeholders. The Geoscientific City Model (GeoCIM), conceptualized by European Urban Geology experts within EuroGeoSurveys (EGS), offers a promising solution to this challenge. It envisions a 3D subsurface model that facilitates seamless data exchange, bridging the knowledge gap between disciplines.

This study presents a pilot 3D GeoCIM for the city of Liberec, Czech Republic. The core objective was to create a user-friendly platform for the Liberec municipality to access and utilize pre-processed and visualized subsurface data held by the Czech Geological Survey. The 3D model integrates newly interpreted archival data with existing sub- and on-surface information from the city (engineering networks, technical objects) and historical underground structures (shafts, tunnels, bunkers, cellars) documented by the Museum of North Bohemia. Such comprehensive data integration helps uncover potential conflicts that could arise during urban planning projects.

The model was built using MOVE software with emphasis on the shallow subsurface providing detailed insights into crucial features like underground water level, tectonic faults or artificial deposits. To ensure convenient access for the municipality, a free, open-source 3D viewer was built on QGIS and Python platforms. This tool allows the municipality to directly query subsurface data at any point on the surface, thanks to a condensed grid-based layer.

This pilot project demonstrates the potential of GeoCIM as an effective tool for integrating

valuable subsurface data into the urban planning process. By bridging the gap between geoscientific knowledge and practical urban development, GeoCIM can foster informed decision-making, minimize conflicts, and contribute to resilient and sustainable city growth.

Abstract

Damage caused by liquefaction and fluidization was seen at the Tokyo bay reclaimed land on the 1987 east off Chiba Prefecture Earthquake and the 2011 off the Pacific Coast of Tohoku Earthquake. The damage was concentrated in multiple bands about 500m wide extending northeastward. Elucidating the cause of this problem geologically can contribute to planning cities that are resilient to disasters. For this reason, we have investigated by continuous borings and dynamic cone penetration tests in more than a dozen sites where liquefaction and fluidization have occurred. Here, we will summarize the results of these surveys and examine the distribution of damage based on the base distribution of the Holocene formation and the seismic amplification status of the Holocene formation measured by underground seismometers.

Almost of the Tokyo bay reclaimed land were filled by the sand pump system from the mid-1960s to the mid-1980sThe reclamation material was supplied by dredging alluvial and shallow-marine late Pleistocene strata on the sea bottom of adjacent the Tokyo bay.

The results of geological surveys in and around areas where liquefaction-fluidization phenomena were observed are summarized as follows regarding liquefaction-fluidization.

1. Most of the liquefied strata are sand layers.
2. No liquefaction was observed in most of the shell layer, shelly sand layer, and mud layer.
3. Liquefaction-fluidization is observed when the shelly sand layer is overlain by a well-continuous mud layer laterally.
4. Beneath the reclaimed layer, thick alluvial layers are distributed in a belt-like manner in some areas, and liquefaction-fluidization phenomena are observed in such places, whereas this phenomenon is rarely seen in areas where the alluvial layers are thin.
5. On the 2015 West off Ogasawara Irands Earthquake (Mg: 8.1), we compared the accelerations of a seismometer installed in a reclaimed land where the Holocene formation is thick and a seismometer installed in an adjacent reclaimed land where the Holocene formation is thin. The

acceleration at the base of the Holocene formation is the same. However, the acceleration at the ground surface where the Holocene formation is thick was about 1.5 times that where the Holocene formation is thin.

From the above, it is estimated that in the Tokyo Bay reclaimed land, the shaking during an earthquake was amplified in the thick band-like Holocene formation, the sand layer in the reclaimed layer liquefied and fluidized, and the damage was concentrated within that band. In this way, when planning urban development in coastal reclaimed areas, it is important to consider the facies distribution of the reclaimed layer, the thickness of the Holocene formation, and the amplification of seismic motion caused by this.

[Keynote] Safe Urbanization in an Alluvial Terrain (Bangladesh): In the Reality of Seismic Risk and Climate Change

A K M Khorshed ALAM[1]*, Formerly Geological Survey of Bangladesh
(khorshed2024@gmail.com)

Abstract

Bangladesh, a Holocene fluvio-deltaic sedimentary terrain in South-Asia and located in one of the active tectonic regions of the world with a rich archaeological heritage, is the home of nearly 170 million people and a density of 1150 per sq km. Due to the complex regional tectonics and geology the country experiences frequent seismic shaking, and it also faces other natural hazards and impacts of man-made climate change owed to its low elevations. With rapid economic development and population growth in Bangladesh rapid urbanization is going on, occasionally unplanned. At present the urban population is 31.66% which is expected to rise to 80% by 2050. Moreover, the situation would be aggravated and challenging because of the climate migrants imposing pressure on scanty land resources. Hence safe urbanization and planned development activities are essential in the reality of seismicity, land resource and climate change.

During the last about two hundred and fifty years nine >7.0 magnitude earthquakes occurred in this region which changed landforms in many instances, although casualty and damage to infrastructure within the country were low because of low population and weak infrastructures. The country is shaken occasionally by medium to strong earthquakes originated in and around it. However, based on the available earthquake data seismic zoning map of the country was prepared, updated and included to building code. A number of activities such as comprehensive investigations for safe urbanization, geo-information for urban development, and geo-information for urban planning and climate change adaptations have been implemented. Still, investigations for identification of potential seismic sources, characterization of geodynamics and related researches are carried on by different organizations and academic institutions.

Although, people of the country is greatly dependent on its scarce land resources for food and shelter. But, geoscientific data plays pivotal role not only for safe urbanization but also for optimum utilization of land resources. Anyway, for effective seismic risk reduction actions, a better understanding of the complex interplay of regional tectonics and geology is essential. Through this judicious and sustainable use of land and other natural resources, food security, safe and resilient infrastructure and sustainable human settlements, combat climate change and its impact, social justice and gender equality, peace and global partnership can be achieved, vital for the population living in this region. Here the tectono-geologic characteristics and geotechnical properties and their roles in urban safety, combat climate change impacts, needs of its inhabitants and sustainability of resources, and challenges to reach the goals will be discussed.

Young-Seog Kim[7], Pukyong National University

Abstract

We conducted a tunnel stability analysis utilizing data acquired from the paleoseismological survey to assess the impact of the fault on the tunnel. Through a trench survey conducted in the central part of the Ulsan fault zone, we confirmed the Quaternary faults and obtained paleoseismological data, including displacement and the timing of the most recent earthquake event. To evaluate the seismic safety of the tunnel within the construction area under dynamic loading conditions, we performed dynamic analysis using Midas IT's GTS-NX program. Analysis of ground displacement and stress over time using nodes and elements surrounding the tunnel revealed significant ground stress occurring around the 3.8-second mark, corresponding to the peak ground acceleration. Ground displacement exhibited noticeable differences in both left and right directions based on the fault zone in both static and dynamic analyses. The maximum tunnel displacement induced by dynamic loading was approximately 2.86 cm. Regarding stress distribution, the greatest stress along the X-axis was observed in the lower tunnel, while the smallest was in the upper tunnel. Along the Y-axis, the highest stress occurred in the left tunnel, with the lowest in the upper tunnel. Additionally, the maximum shear stress was highest in the left tunnel and lowest in the lower tunnel. The maximum axial force (member force) of the rock bolt was approximately 74 kN, occurring at the intersection point of faults, which was lower than the allowable tensile axial force (load capacity) of 88.6 kN. Similarly, the bending compression stress (member force) of the shotcrete followed the order of side (approximately 5.7 MPa) > bottom (approximately 5.5 MPa) > ceiling (approximately 2.7 MPa), with a maximum of about 5.8 MPa on the side part. This was below the allowable bending-compressive stress (load capacity) of 8.4 MPa. Upon assessing the seismic safety of the tunnel concerning dynamic loading, it was determined that the load capacity of the tunnel's rock bolt and shotcrete members exceeded the force generated by the earthquake. These results are deemed valuable as fundamental data for analyzing the impacts of faults on tunnels in future studies.

August 2022 monsoon thunderstorm impact on the sedimentation in a tectonically active small catchment; case study of Saydoon dam reservoir, Southern Iran

Arash Barjasteh[1]*, Khuzestan Water & Power Authority (KWPA) (barjasteh@hotmail.com)

Abstract

Saydoon dam site in the eastern part of Khuzestan Province, Iran is located in Izeh Fault Zone of of the active Zagros Fold-Thrust Belt. The present-day configuration of the drainage system in this zone is mainly controlled by transverse faults including formation of linear valleys, landslides, rupturing of rocks and changing water tables in the area. The dam will be constructed over the Saydoon River with a 13.3 km length and a catchment area of about 78.8 km^2. Although the Province is classified as an arid-semi arid region, the dam site region has an average annual rainfall of 790mm. The intense rainfall from the August 2022 monsoon thunderstorm striped away the surficial weathered argillaceous rocks causing significant increase of the bed load sediment within the reservoir area. It also triggered a rock fall near the end of the reservoir mainly composed of calcareous blocks. The exposed rocks are mostly composed of marly and shaly layers of Pabdeh Formation of Eocene Age. It is mostly composed of Marlstones (71%) and marly Limestones (18%) and petrographic analysis indicated that its clay content is about 35 to 45 percent. Most of the bed rock along the river banks is covered by quaternary alluvium deposits that are soft, uncemented and erodible. A paleo-landslide is seen nearly in the middle of the reservoir with a surface area of about 12km^2. Regarding to the August 2022 monsoon event, a re-assessment and calculation of sediment load within the reservoir area is necessary for the project.

Abstract

The risks posed by surface fault rupture to buildings and infrastructure have been recognised for decades, but Fault Displacement Hazard Analysis (FDHA) is a relatively new field. Other earthquake hazards often spatially coincide with zones of permanent, coseismic ground deformation near surface rupturing faults. Recent case studies have highlighted that coseismic landslides and floods may be exacerbated by tectonic and seismological factors associated with faulting. The 2016 Kaikoura earthquake in New Zealand is an important case study for investigating near-fault multi-hazards. Off-fault deformation zones spanned hundreds of metres and discrete fault displacements were in some places distributed on traces >2 km across strike, highlighting the complex kinematics of faulting and its hazard implications. Coseismic landslides clustered near surface rupturing faults and there is evidence that rock mass damage and/or uncharacterised seismic site effects within fault damage zones influenced the distribution of slope failures. Landslide susceptibility models may be improved by including a fault deformation zone width variable, where possible. Both fault rupture and landslides affected rivers draining some of the highest ranges outside the Southern Alps. In several places, fault rupture caused instantaneous avulsion of streams and in one instance diverted a major braided river. The avulsion event and attendant flooding could have been anticipated using simple hydrodynamic models and pre-event paleoseismic data, lidar, and hydraulic constraints. The results of these studies demonstrate linkages between traditional seismic source characterization and multi-hazard models that reduce the consequences of earthquakes on people and property.

Landslide susceptibility assessment based on multi-sources data in the Three Gorges Project reservoir area

Ningtao WANG[1]*, Wuhan Center,China Geological Survey (wnt113@126.com)
Runqing Ye[2], 13469992966

Abstract

Landslides result in enormous property damages human casualties, congested river valley and causing shipping disruptions in the Three Gorges Project reservoir area. Landslides are controlled and influenced by many temporal and spatial factors, is a difficult point to landslide susceptibility mapping. Comprehensive understanding of landslides should be based on multi-source data acquisition, information extraction and system analysis. This paper selects landslide-prone area which is from Zigui to Badong as the study area, explores landslide information extraction and hazard analysis based on multi-source data accumulated systematically, focused on the research topic of integration between remote sensing and non-RS information, such as geological map and DEM, for landslide investigation and hazard analysis. Ten thematic maps for landslide susceptibility mapping, including controlling factors and influence factors, were created from the multi-source data, namely geotechnical map, slope map, slope structure map generated from geological map and DEM, and land cover and its changes map, NDVI, NDWI and object-oriented images features extracted from remote sensing images. The Support Vector Machine (SVM) is employed to create landslide prediction map (landslide or no-landslide area with a value of 0 and 1 respectively) and landslide susceptibility map (with a value range 0 to 1), which are useful for landslide hazard control and protection.

Michel Jaboyedoff[6], Risk Group, Institute of Earth Sciences, University of Lausanne

Abstract

Areas affected by rockfalls require an in-depth understanding of the evolutionary processes that govern these events. This study investigates the case of Koto Panjang, a local quarry located beside a cross-provincial road. Geologically, the area consists of the Bohorok Formation, which is characterised by pebbly mudstone. Three different rockfall events in 2015, 2016, and 2017 severely disrupted vehicular traffic, highlighting the inherent risks of collapse.

To estimate rockfall volume, a multi-temporal approach was employed, leveraging historical and primary data. A comprehensive dataset of images from 360° street view panoramas (2015-2021) was processed using the "decompose equirectangular panorama" method and Agisoft software to generate detailed point clouds. Comparative analysis with recent UAV data revealed significant volume changes, reaching a 5.27×10^3 m^3 at specific locations between 2015 and 2021. Furthermore, kinematic structural analysis, incorporating direct measurements and 3D point cloud data, identified prevalent direct toppling and wedge failure mechanisms as the primary drivers of rockfall events.

This study demonstrates the effectiveness of combining historical data with cutting-edge technology in reconstructing landscapes affected by rockfall. By elucidating the temporal evolution of rockfall retreat, this approach has the potential to significantly improve risk prediction and mitigation strategies, ultimately protecting public safety and ensuring uninterrupted transport in vulnerable areas.

The role of brittle rock mass fracturing in alpine slope instabilities

Reinhard GERSTNER[1]*, Insitute of Applied Geology, Department of Civil Engineering and Natural Hazards, University of Natural Resources and Life Sciences, Vienna (reinhard.gerstner@boku.ac.at)
Christian ZANGERL[2], Insitute of Applied Geology, Department of Civil Engineering and Natural Hazards, University of Natural Resources and Life Sciences, Vienna

Abstract

Tectonic structures such as faults, joints, or shear bands are a decisive factor influencing rock slope stability, as their reactivation can provide kinematic feasibility for specific failure mechanisms. However, natural rock slope failures can also involve the formation of new, brittle, landslide-induced fractures. Combining both the reactivation of structures and the formation of new fractures in numerical investigations is challenging and remains a topic of ongoing research. To this end, we present a synthetic rock mass approach to model the initiation of four active rock slope instabilities in the European Alps. The landslides addressed in our study are located in similar geological settings characterized by highly schistose, anisotropic, fractured metamorphic rock masses. However, the landslides differ regarding their failure mechanisms and volumes, ranging from 30,000 to several million m3.

Using the 2D distinct element code UDEC, we applied a synthetic rock mass approach that we refer to as 'asymmetric Voronoi logic'. In the approach, we consider the schistose metamorphic rock mass as a matrix of small polygons characterized by an elongated axis, i.e. asymmetric Voronoi elements. By aligning the elongated axes according to the orientation of the schistosity planes, we represent the rock mass anisotropy related to schistosity. Finally, we implemented field-related discontinuities into the matrix of small Voronoi elements. Assigning a Mohr-Coulomb contact law to the discontinuities and the contacts bounding the Voronoi elements allowed us to model the development of any failure geometry.

We derived the model input from comprehensive investigations comprising geological mapping, lithological analysis, discontinuity characterization, and rock mechanic testing. Data from several remote sensing techniques, such as synthetic aperture radar, multitemporal terrestrial laser-scanning, and unmanned aerial vehicle photogrammetry surveys, enabled us to identify the rock slope failure mechanisms and validate the UDEC model results.

By the asymmetric Voronoi approach, we successfully modelled the initiation of all four landslides on rock slopes ranging from 200 m to 1,500 m in height. The models accurately reproduced complex detachment surfaces involving reactivated geological structures and newly formed fractures along the Voronoi contacts. The resulting failure geometries, e.g. step-path or complex toppling failures, were consistent with our field observations. These results confirmed that pre-existing geological structures and brittle rock mass fracturing processes control the

mechanics of the investigated rock slope failures. In accordance with our geological landslide models, the numerical model also reproduced characteristic landslide features, e.g. minor scarps, uphill-facing scarps and retrogressive tensile fractures. Thus, our asymmetric Voronoi approach proved to be a feasible method to model the initiation of landslides in complex geological settings and further contributes to our understanding of landslide mechanics.

Abstract

Damage induced by the 2016-2017 seismic sequence to building and infrastructural heritage in Central Italy was locally associated with the major evidence of surface faulting. This confirmed the relevant impact that surface faulting processes can have in urbanized areas and amplified the need to consider them in reconstruction planning, promoting Seismic Microzonation studies focused on capable faults. The presence of capable faults that produced dislocation of the ground surface at least once over the past 40.000 years (cf. Italian Civil Protection guidelines), is, in fact, one of the exclusion criteria for post-earthquake reconstruction.

In 2020-2022, the Italian Government Extraordinary Commissioner for post-earthquake reconstruction funded a program of studies to better characterize known and suspected capable faults affecting urbanized zones in the epicentre area, including several villages located along the NE, E and SE borders of the Rieti Quaternary intermountain basin.
Extensional tectonics that affected the western flank of the eastward migrating Apennine chain during the Quaternary, combined with regional uplifting, have controlled the formation and evolution of the box-shaped Rieti basin. During the Early Pleistocene, the NNW-trending normal fault located along the eastern edge acted as a master-fault, controlling progressive deepening of the half-graben, and the deposition of thick sequences of fluvial deposits, from early alluvial fan (Fosso Canalicchio Synthem) to late alluvial plain (Monteleone Sabino Synthem) facies. The E-W oriented structures along the northern and southern margins of the basin acted as transfer structures linked to the eastern border fault. Early Pleistocene deposits were displaced a few hundred meters, with a further deepening of the Rieti basin and northward diversion of the Velino River hydrographic network, also affecting the evolution of the Marmore Falls system.
Field observations and extensive geophysical prospections along the E master fault and the N and S transfer faults driven the opening of 17 new paleoseismological trenches that yielded 52 radiometric dates. We recognized evidence for Late Pleistocene and Holocene paleoearthquakes along the investigated faults. We identified five time windows, each ranging from 500 yr to more than 5 kyr, during which surface faulting events occurred along the NNE-trending master fault and the transfer faults of Rieti basin. We discuss whether the events recognized in the various trenches located along the three different faults correspond to a single ca. M6.5 earthquake, or multiple M6.0 earthquakes that occurred in succession in the different segments of the local tectonic architecture. In fact, the threshold for coseismic surface faulting in the Rieti Basin is ca. M6; no significant surface rupture occurred during both the June 28, 1898, Santa Rufina (M5.5), and December 31st, 1949, Rivodutri (M5.4) earthquakes along the S and N transfer faults, respectively. We argue that these new results allow us to better constrain the tectonic evolutionary style of the Rieti Basin, recognize the possible presence of seismic cycles and define the current seismic hazard.

Bruno Pace[7], University of Chieti - Pescara, Department of Engineering and Geology, Italy

Abstract

The Probabilistic Fault Displacement Hazard Analysis (PFDHA) plays a crucial role in evaluating the likelihood of surface fault displacement during seismic events, which has significant implications for infrastructure systems such as pipelines and lifelines. Recent seismic activities have underscored the importance of fault displacement as a major contributor to damage. This research expands upon existing PFDHA models by introducing innovative approaches and widening the dataset to include various seismic events, thereby offering a more comprehensive assessment of distributed ruptures (DRs) associated with both reverse and normal faulting. Leveraging the SURE 2.0 database, which categorizes DRs into primary (Rank 1), simple (Rank 2), and triggered (Rank 3), logistic regression models are utilized to evaluate the likelihood of DR occurrence. Factors such as earthquake magnitude, proximity to the principal fault, faulting style, and DR location are considered as predictive variables. Furthermore, a fault displacement model is developed to estimate the median throw on DRs based on these parameters. The findings provide valuable insights into the characteristics and probability of DRs, with implications for PFDHA applications. The study introduces a decision-tree algorithm aimed at aiding PFDHA practitioners in selecting the most appropriate models based on their geological expertise. This research contributes to an enhanced understanding of fault displacement hazard analysis and presents a flexible framework for its implementation across diverse geological settings.

ABSTRACT
Slope stability challenges persisted throughout South Korea's history, driven by the rising demand for engineered cut and fill slopes in construction projects. To address these issues, a deep understanding of analytical methods, investigative tools, and effective stabilization techniques was crucial. Notably, South Korea's rapid infrastructure expansion since the 1960s, driven by a growing population, necessitated the development of a robust transportation network, especially highways. As mountains covered approximately 70% of the country's land, highway construction resulted in substantial slope excavations on either side of these roadways. This study aimed to "Evaluate the Relationship between Catchment Area Capacity and Constructed Slope Failure Probability," specifically focusing on the connection between catchment area size and slope failure probability. It investigated how the intensity and duration of precipitation data in South Korea related to the moment of slope failure. The study findings revealed that during the rainy season from June to September, slopes with larger catchment areas were more prone to failure due to continuous and heavy rainfall. Consequently, areas with larger catchment regions experienced a higher concentration of slope failures as precipitation events increased.
However, when examining the moment of failure, the study considered 188 slopes with known failure dates. Three distinct groups of slope failures were identified based on the rainfall pattern leading to the failure. The majority, 66.3% (124 failed slopes), experienced failures as rainfall

intensity decreased during the rainy period. These slopes were characterized by higher elevation, larger catchment areas, intense weathering, and elongated catchments. The analysis suggested that while precipitation played a role in slope failures, it interacted with other factors like elevation, catchment size, catchment shape, and weathering, leading to varying patterns of failure.
Therefore, the distinctive characteristics of these three groups of failed slopes demonstrated that precipitation was not the sole cause of slope failure; rather, it influenced slope failure by interacting with other factors such as elevation, catchment area size, catchment shape, and weathering.
