We also discuss the position of the family Alienopteridae. These share these characters, supporting a sister group relationship between Alienopteridae and Umenocoleidae, as proposed by (Luo et al., 2022). We propose these characters as new apomorphies for the Umenocoleoidea. We also remove the genera *Vitisma* and *Permoponopterix* from this superfamily and move the Permian *Permoponopterix* to the Protelytroptera group.

Abstract

Mesopsychids, a long-probosid mecopteran group, associate with the pollination of Mesozoic Gymnosperms. Thought study of the genus Mesopsyche spans over 100 years, only isolated wings have been discovered. Mesopsyche is redefined as a monotypic genus currently housing only one species, Mesopsyche triareolata. The other species previously classified under Mesopsyche are reassigned to the newly established genus Turbidapsyche gen. nov., distinguished by 3-branched Sc compared to the numerous Sc branches Mesopsyche. Herein, we present descriptions and illustrations of new material from the middle part (late Ladinian) of the Middle-Upper Triassic Yanchang Formation, assigned to the newly erected genus. The first Mesopsyche species reported from the Tongchuan entomofauna is revised based on S. Additionally, we erected two new species of Turbidapsyche gen. nov. based on their wing size, shape, and especially the colored patterns. Turbidapsyche orientalis gen. et sp. nov. is characterized by the distinctly shrunken wing base and dense colored markings along anterior wing, while Turbidapsyche sparsa gen. et sp. nov. is distinguished by its relatively larger wing size and the sparse colored spots situated at the forks, areas of crossveins, and apical longitudinal veins. Although hindwings of Turbidapsyche gen. nov. are described and illustrated, they are not formally assigned to any specific species. The species of Mesopsyche also Turbidapsyche are full discussed. The wing color patterns of Turbidapsyche exhibit regional differentiation, with numerous colored spots observed in China, transparency in Kyrgyzstan, and full pigmentation in Ukraine. Based on previous paleomagnetic research conducted in Tongchuan area, we derive a palaeolatitude of 21° in the Middle Triassic. Turbidapsyche distributed along the north of Palaeotethys, near similar palaeolatitude, suggesting inhabitation of comparable climates and perhaps specific ecological requirements or limited dispersal capabilities.

The review of Protopsyllidioidea in China

Minmin Xu[1]*, tate Key Laboratory of Paleobiology and Petroleum Stratigraphy, Nanjing Institute of Geology and Paleontology, Chinese Academy of Sciences, Nanjing 210008, China (mmxu@nigpas.ac.cn)
Diying Huang[2], State Key Laboratory of Palaeobiology and Petroleum Stratigraphy, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing 210008, China

Abstract

Protopsyllidioidea, an extinct insect group within the suborder Hemiptera, are characterized by the basal fusion of R with the common stem M + CuA. The superfamily Protopsyllidioidea comprises four families, Permopsyllidiidae, Protopsyllidiidae, Protopsyllidioidea Postopsyllidiidae, and Paraprotopsyllidiidae, spanning from the Artinskian to the Late Cretaceous.

To date, eight species have been described from China, including: Sinopsocus oligovenus Lin, 1976 (upper Middle Jurassic Haifanggou Formation at Beipiao, Liaoning Province), Poljanka hirsute Yang, Yao & Ren, 2012 (upper Middle Jurassic Haifanggou Formation at Daohugou, Inner Mongolia), Poljanka strigosa Yang, Yao & Ren, 2013 (Daohugou), Poljanka strigosa Yang, Yao & Ren, 2013 (Daohugou), Subaphidulum sinica Xu, Hakim & Huang, 2023 (lower Middle Jurassic Yan'an Formation at Yan'an Shanxi Province), Sinopsocus yananensis Xu, Hakim & Huang, 2023 (Yan'an Formation), Poljanka curticapillata Lü, Luo & Yao, 2023 (Daohugou) from the Jurassic Yanliao biota, and one species Paraprotopsyllidium shouchangense Hakim & Huang, 2023 (Lower Cretaceous Shouchang Formation at Zhejiang Province) from the South China.

Research on the evolution and distribution of Protopsyllidioidea is crucial for understanding the insect transition from the Yanliao biota to southern China and eventually to Myanmar. These fossils also serve as important indicators for stratigraphic correlation in the Middle Jurassic due to their abundant occurrences and morphological diversity.

Fossil insects from China: a review

Diying HUANG[1]*, State Key Laboratory of Palaeobiology and Petroleum Stratigraphy, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing 210008, China (dyhuang@nigpas.ac.cn)

Abstract

The study of fossil insects in China can be traced back to 1928, when C. Ping described some Cretaceous fossils from the Laiyang Basin in Shandong Province. Since the establishment of the People's Republic of China, two pioneering palaeoentomologists, Yongchong Hong and Qibin Lin, published new papers on fossil insects in 1965. Hong described dragonfly fossils, namely Sinaeschnidia heishankowensis, from Inner Mongolia, while Lin described two species of Haglidae also from Inner Mongolia. From the 1970s onwards, palaeoentomology gradually became a recognized field within paleontology in China.

Since the beginning of this century, palaeoentomology has experienced rapid development in China, with abundant publications by Chinese scholars. These publications mainly focus on two significant Mesozoic exceptional preservation sites: the Early Cretaceous Jehol biota and the Middle Jurassic Daohugou biota. Approximately 800 insect species (belonging to 24 orders) have been described from Daohugou, representing one of the most diverse palaeoentomofaunas in the world.

Carboniferous insects from China are well-known from the Xiaheyan locality in Zhongwei County, Ningxia. The insects from the Kaiping Basin were first reported by Mathieu in 1939, initially consisting of a few cockroach-like wings. This locality holds special interest for early insect evolution, as recent years have seen the collection of many new and diverse insects. Carboniferous insects are also sporadically found in the Benxi Formation of North China and the lower parts of the Taiyuan Formation.

Permian insects from North China are relatively scarce. The Late Guadalupian Yinping Biota from Chaohu City, Anhui Province, in Central China stands out as the most representative site for Permian insects in China, containing a plethora of insects from the orders Mecoptera, Hemiptera, and Orthoptera.

Triassic insects in China have been discovered in various scattered localities. The most significant Triassic entomofauna is represented by the latest Middle Triassic Tongchuan biota in Shaanxi Province, where at least 16 insect orders have been identified. While the insects from the Tongchuan Biota hold potential importance, currently only mecopterans have been relatively well-studied in this biota.

Early Jurassic insects are relatively rare in China, yielded mainly in the western parts such as Xinjiang, as Early Jurassic strata are largely absent in the eastern and central regions. The Middle-Late Jurassic Yanliao Biota can be subdivided into initial, early, and late stages, each yielding a wealth of fossil insects. These include specimens from the Yan’an Formation, Daohugou biota, and Linglongta biota, from bottom to top, respectively.

Early Cretaceous insects are also prevalent in China, with the Jehol Biota being a prominent example. This biota is believed to be distributed across Northeast China, Northwest China, Central China, and the Southeast coastal areas of China. It appears to be widely distributed, ranging from approximately 135 million to 118 million years ago, although further study is needed to understand its detailed relationships.

Cenozoic fossil sites in China are notably represented by the Miocene Shanwang entomofauna, as well as ambers from Fushun in Liaoning Province and Zhangpu in Fujian Province. Recently, we have also gathered a significant number of insect fossils from

Abstract

Terrestrial ecosystems acquired their modern structure during the Early Cretaceous. Many species that shape the world we know today emerged and radiated from this period, referred to as the Cretaceous Terrestrial Revolution (Jouault et al., 2024). It is admitted that the Early Cretaceous with its significant global warming, is also the period that witnessed the appearance of most orders of flowering plants (or at least the beginning of their radiation, Barba-Montoya et al., 2018) accompanied with the key families of pollinators within insects (flies, butterflies, beetles and bees; Condamine et al., 2016). Simultaneously, the patterns of the modern-like groups of animals appeared and diversified, outnumbering for some of them former existing species. From this period, while important modern fish groups appeared in the marine environment, including the diverse spiny-rayed fishes (nowadays one third of all vertebrate species), the early diverging ray-finned fish (sturgeons and gar relatives) thrived in freshwaters (Guinot & Cavin, 2016). Non-avian dinosaurs and birds both underwent an extraordinary phase of evolutionary radiation during the Early Cretaceous (Nebreda et al., 2021); while many modern placental mammalian taxa also emerged during this period (Springer et al., 2003).

Dysodiles are sedimentary rocks formed by the superposition of finely laminated millimetric layers and are characterized by their richness in organic matter and well-preserved fossils (Cordier, 1808). Dysodiles are found in different lacustrine deposits in various areas of Lebanon, from the early Barremian. However, their documentation was restricted to a few old references mentioning their presence and their richness in fossils (Botta, 1831; Fraas, 1878; Janensch, 1925; El Hajj et al., 2019, 2021). Afterward, dysodiles were totally forgotten until recently, when extensive geological fieldwork led to their (re-)discovery in Lebanon. We focus herein on dysodiles from the Bkassine locality (South of Lebanon) from the lower Barremian sandstone formation, which deposited when Lebanon was located in the north-eastern part of the Gondwana

supercontinent. These dysodiles are found nearby volcanic deposits suggesting a close relation between volcanism and their deposition and/or preservation.
We present here new information on a fossil assemblage found in the dysodiles. To date, these layers allowed the collection of several tetrapods (anourans, chelonians, lizards, and possibly archosaurian remains), a rich “fish” assemblage encompassing a dozen of coelacanths, possible polypteriforms and small teleosts, pulmonate gastropoda, diverse aquatic related insect assemblage, plant debris (macroflora and palynomorphs) including ferns, algae and spermatophytes, but also ostracods and a concentration of various coprolites. Here, we provide a preliminary reconstruction of the associated depositional environment: a freshwater lake found nearby volcanic edifices, surrounded by a typical Early Cretaceous flora (open forest and savanna-like environment), where lived various lineages of early diverging actinopterygians, and some more derived teleost fishes that will later represent the core of modern ichthyofauna. This fossil setting is important on a local and a worldwide scale as the studied environment and its biota could be compared to the coeval lacustrine shales and limestones of East (Jehol in China) and West Eurasia (Bernissart in Belgium, Las Hoyas in Spain), as well as of the

The oldest Gondwanan record of durophagous shark Strophodus Agassiz, 1838 (Hybodontiformes) from the Kachchh Basin, western India

Suraj Arjun Bhosale[1]*, Indian Institute of Technology Bombay (suraj.bhosale@iitb.ac.in)
Nibedita Rakshit[2], Indian Institute of Technology Bombay
Abhishek Natarajan[3], Indian Institute of Technology Bombay
Gaurav Chauhan[4], Department of Earth and Environmental Science, K. S. K. V. Kachchh University, Bhuj, India
Mahesh Thakkar[5], Birbal Sahni Institute of Palaeosciences, Lucknow, India

Abstract

The hybodont sharks were one of the most dominant groups of chondrichthyans during the Mesozoic. The genus Strophodus was one of the most successful hybodont sharks that covered marine to coastal, occasionally high salinity niches in the pantropical basins and had adapted an unique dentition for their durophagous diet. Although the European basins are enriched with the genus fossil record, the distribution in the Gondwana basins is scarce and patchy. The hybodont shark Strophodus is reported for the first time from the
Mesozoic sequence of the Kachchh Basin, western India. This record marks the earliest appearance of Strophodus in Gondwana. The southwestern Tethys basins, Kachchh and Jaisalmer, show a diverse assemblage of the genus occupying coastal to marine settings and feeding mainly on invertebrates. It also sheds light on the link between Gondwana and Laurasia with faunal exchange/interchange and confirms the wide cosmopolitan distribution of Strophodus. The migration initiated from western Tethys through the marginal marine part of northern Gondwana and then reached southwestern Tethys. However, a robust palaeobiogeographic reconstruction of the genus requires new findings from the Early−Middle Jurassic Gondwana basins. The present study from the Kachchh and Jaisalmer basins indicates that hybodont sharks, and especially Strophodus, show great species diversification and distribution, negating the previous consensus of a decline of these sharks in the Middle Jurassic. This study is a contribution to the scarce record of the Mesozoic chondrichthyan fauna of the Kachchh Basin and Gondwana.

Abstract

Korea is renowned for its Cretaceous vertebrate ichnology, featuring a remarkable variety of well-preserved vertebrate tracks, numerous sites with these occurrences, and abundant strata with tracks in the Cretaceous deposits. Professor Martin G. Lockley has conducted research in Korea numerous times, collaborating with Korean scientists on diverse vertebrate ichnofossils in locations such as Goseong, Haenam, Yeosu, Hwasun, and Jinju, leading to significant publications. These collaborations have yielded notable outcomes, including a special issue of Ichnos titled “Tracking on the Korean Cretaceous Dinosaur Coast: 40 years of Vertebrate Ichnology in Korea” (2012, vol. 19, issue 1-2) and 2023 Symposium on Mesozoic Terrestrial Ecosystems (MTE) in Korea, with several other international symposiums.

The initial discovery of a dinosaur track in Korea was made in 1992 at Deokmyeong-ri, Goseong, with the first dinosaur tracksite excavation occurring in 1996 at Uhangri, Haenam. This excavation also revealed the first pterosaur tracks in Asia. The variety of dinosaur tracks identified includes theropods, ornithopods, and sauropods, featuring distinguished ichnogenera such as *Hamanosauripus ungulates*, *Koreanosauripus cheongi*, *Dromaeosauripus hamanensis*, *D. jinjuensis*, *Ornithopodichnus masanensis*, *Caririchnium kyoungsookimi*, *C. yeongdongensis*, *Brontopodus pentadactylus*, *and Dromaeosauriformipes rarus* all originating from Korean discoveries. These tracks have supported various research studies on ecology, behavior, and soft tissue impressions, such as revealing pedal skin textures, demonstrating the theropod’s agility by analyzing their rapid acceleration phase, and gregarious behavior of ornithopods through the parallel trackways.

A significant achievement in 1996 for Asian paleontology was the identification of pterosaur tracks in the Uhangri Formation of the Haenam Basin, with *Haenamichnus uhangriensis*

being acknowledged in 2002 as potentially the largest pterosaur tracks, possibly related to azhdarchids. Further findings have expanded the catalog of pterosaur tracks from various Cretaceous deposits, including *Pteraichnus koreanensis* and *P. gracilis* from the Hasandong Formation and Jinju Formation, respectively. To this day, approximately 20 tracksites, such as Hwasun, Jinju, Gunsan, and Ulsan, have been recorded, with ongoing research efforts.

This extensive ichnofossil record establishes Korea as a pivotal site for Mesozoic vertebrate research, leading to its inclusion on the tentative list for UNESCO World Heritage and as geosites within the UNESCO Global Geoparks in Korea. Professor Martine G. Lockley's collaborative work on Korean vertebrate tracks has significantly influenced the paleontological field and the cultural industry, including museums, expos, documentary films, and movies.

The earliest calcareous peyssonneliacean red algae fossils from Ordovician: systematics, evolutionary and paleoecological significance

weiling ZHUANG[1]*, Northwest university (201921090@stumail.nwu.edu.cn)
lijing Liu[2], Northwest university
Juan Braga[3], Universidad de Granada
Robert Riding[4], University of Tennessee
yasheng Wu[5], Institute of Geology and Geophysics, Chinese Academy of Science

Abstract

Peyssonnelialeans are a taxon of crustose red algae that grow on rocky or microbial substrates and are the taxon of Rhodymeniophycidae that can deposit aragonite crystals in their cell walls. The Rhodymeniophycidae is one of the most diverse taxa of the Florideophyceae in the Rhodophyta. Molecular clock analysis suggests that Peyssonneliales diverged from their sister group Gigartinales within the Rhodymeniophycidae clade at about 300 Ma. Until now, however, the earliest known undisputed fossil Peyssonneliales are from the Lower Cretaceous (Albian, 113-110.5 Ma). Here we report the earliest peyssonelialean algal fossils, one new genus *Paleopolystrata* gen. nov. and two new species, *Paleopolystrata tarimensis* sp. nov, *Paleopolystrata coarsewirensis* sp. nov. They occur in the Upper Ordovician (~450 Ma) reef facies of Lianglitag Formation in the Tarim Basin, Northwest China. *Paleopolystrata* had a pseudoparenchymatous organization consisting in a single system of dividing filaments showing a feather-like arrangement in longitudinal section. Its preservation suggests that the skeleton was originally composed of aragonite that is now replaced by calcite. The crustose habit, the pseudorparenchymatous organization and the aragonite calcification are characteristic of Peyssonneliales. The record of *Paleopolystrata* advances the fossil record of the large subclass Rhodymenophycidae by 340 Ma.

Additionally, they possess significan paleoecological importance and can form reef-building communities with diverse green algae (*Vermiporella*, *Aphroporella*, etc.), *Solenopora*, stromoforaminifera, cyanobacteria for constructing reef skeletons and providing growth substrates for crinoids, bryozoans, etc. They play an important leading role in the process of reef building. Peyssonnelialeans not only exhibit barrier deposition and bonding effect of calcareous algae, but also has a strong wave resistance structure and a new function of leading the construction of lattice reefs, indicating that the dominant reef-building community in the late Ordovician was the addition of calcareous red algae, which explains the complexity of reef-building community composition during the process of GOBE. It holds immense significance for understanding Paleozoic forms of reef building and ecosystem evolution.

Jae-Il Park[5], Animal Facility of Aging Science, Korea Basic Science Institute
Hye-Yeon Jung[6], Animal Facility of Aging Science, Korea Basic Science Institute

Abstract

Carettochelyidae is a crown group that includes the extant pig-nose turtle, *carettochelys insculpta*. Before the family radiated to Asia, Europe, and North America in the Eocene, the oldest fossil of this group was first recorded in the early Paleocene of Asia. Although fossil records of basal pan-carettochelyids were discovered in the Cretaceous of Asia, they were unearthed by fragmentary shells and distinguished from Carettochelyidae by a highly reduced cruciform plastron and the presence of plastral scute. Unlike other Cretaceous fossil records of Asia, the specimen in this study is the oldest definite Carettochelyidae from the Hasandong Formation (the Early Cretaceous) of South Korea. It comprises the almost preserved shell and post-cranium components revealed by micro-CT scanning between the shells. It belongs to Carettochelyidae given the following characteristics: (1) distinct ornamentation that consists of vermiculated ridges; (2) a low midline keel; (3) a single suprapygal; (4) ten pairs of peripheral; (5) an intermediately sized cruciform plastron; (6) the presence of carapace scutes; and (7) the loss of plastral scutes. By discovering the Early Cretaceous Carettochelyidae, we identify that the family already appeared in the mid-Cretaceous and that the crown group existed with the stem group together in Asia. Also, it implies the possibility that their occurrence and divergence took place before the Early Cretaceous in accordance with the result of the molecular phylogenies indicating that pan-carettochelyids originated in the Middle to Late Jurassic.

DISCOVERY AND GEOLOGICAL SIGNIFICANCE OF PHOSPHATIZED ANIMAL RESTING EGG FOSSILS IN THE CHANG 73 MEMBER, YANCHANG FORMATION, ORDOS BASIN

Dexiang GAN[1]*, Northwest University (1007529279@qq.com)
Lijing LIU[2], Northwest University
Jin Dong[3], Research Institute of Petroleum Exploration and Development

Abstract

During the Middle and Late Triassic, the Ordos Basin experienced a warm and humid climate, creating a suitable environment. In sedimentary period of the Chang 73 Member of the Yanchang Formation, there was a significant expansion in lake basin development, leading to the deposition of large, thick and high-quality source rocks. The composition and abundance of planktonic algae in the Chang 73 Member and the establishment of complex ecosystem of continental lakes to the exploration of high productivity of the lake during this period have garnered much attention. Many planktonic algae and animal fossils were discovered in the Chang 73 Member of the Yanchang Formation. Phosphatized spheroidal microfossils with regular morphology were previously thought to be green algae. In this study, the fossils have a large diameter, generally 120-μm, with some reaching up to 300 μm. They have a clear and obvious membrane wall structure, and irregular polygonal impressions can be seen on the outer wall of the membrane, which are quadrilateral, pentagon and hexagon structures like football, while no division is seen inside the fossils, and they are filled with uniform phosphate. These results indicate that the cellular structure of 8-part division and 16-part division formed by early cleavage in animals, supporting their interpretation as dormant eggs or embryos of animals. A new genus and species, *Yanchangparapandorina inornata* gen. et. sp. nov., was established through an extensive comparison with with the fossil and living animal eggs, which may be fossils of the eggs of an aquatic arthropod. The analysis of fossil morphology and taphonomy indicates that these nimal dormant egg fossils were formed in the shallow burial stage of early diagenesis, when the organisms'cells and tissues have not decomposed, and the fluid rich in phosphate has mineralized and permeated, which can preserve the division stage of the fossils. The identification of animal dormant egg fossils from the Chang 73 Member clarifies the confusion existing in the previous studies on the planktonic algae fossils in the Yanchang Formation. This discovery has provided new insights into the species diversity within the continental lacustrine ecosystem of the Ordos Basin during the Middle and Late Triassic periods. In addition, the large number of phosphatized dormant egg fossils may be related to the massive influx of volcanic ash, and their discovery is of great significance for the analysis of the various paleoenvironmental parameters at the bottom of the lake basin during the deposition period of Chang the 73 Member, such as oxidation and reduction state, phosphorus nutrient level, heavy metal, salinity, and temperature.

New discoveries of the fossil lampreys from the Yanliao and Jehol Biotas, North China

Feixiang Wu[1]*, Institute of Vetebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences (wufeixiang@ivpp.ac.cn)
Philippe Janvier[2], Muséum National d'Histoire Naturelle, UMR 7207, CP38, 8, rue Buffon 75231, Paris Cedex 05, France
Chi Zhang[3], Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences
Mee-Mann Chang[4], Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences

Abstract

Lampreys, one of two living lineages of jawless vertebrates, are hailed as a model for vertebrate evolutionary research. They have been in existence for at least 360 million years; however, they left a meager fossil record, and their evolutionary history remains elusive. The fossil lampreys from the Middle-Late Jurassic Yanliao Biota and Early Cretaceous Jehol Biota were superbly preserved and illuminate the evolution of the feeding apparatus, the life cycle, and the historic biogeography of the group. The best-known fossil lamprey from the Jehol Biota, Mesomyzon mengae has a feeding apparatus adapted for blood-sucking habit. Whereas the fossil lampreys' from the Yanliao Biota have an extensively toothed feeding apparatus that differs radically from that of their Paleozoic and Cretaceous kin but surprisingly resembles the living Southern Hemisphere pouched lamprey, which foreshadows an ancestral flesh-eating habit for modern lampreys. Based on the revised petromyzontiform timetree, it is argued that modern lampreys' three-staged life cycle might not be established until the Jurassic when they evolved enhanced feeding structures, increased body size and encountered more penetrable host groups. The study also places modern lampreys' origin in the Southern Hemisphere of the Late Cretaceous, followed by an early Cenozoic antitropical disjunction in distribution, hence challenging the conventional wisdom of their biogeographical pattern arising from a post-Cretaceous origin in the Northern Hemisphere or the Pangean fragmentation in the Early Mesozoic.

Early Cambrian evaporite deposits in the North China Craton and their event stratigraphic, paleogeographic, and paleoenvironmental implications

Wentao ZHENG[1], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing 210008, China
Xiaopeng WANG[2], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing 210008, China
Bin WAN[3]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing 210008, China (binwan@nigpas.ac.cn)
Ke PANG[4], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing 210008, China
Qing TANG[5], School of Earth Sciences and Engineering, Nanjing University, Nanjing 210023, China

Abstract

Evaporites are climate-sensitive sedimentary deposits with event stratigraphic, paleogeographic, and paleoenvironmental significance. The Early Cambrian is characterized by early evolution of animal and extensive evaporite deposits at the end. Widespread evaporite deposits were developed in the lower Cambrian succession in the North China Craton (NCC), which could provide critical constraints on the age of evaporite-bearing strata, the reconstruction of paleogeographic evolution, and the paleoenvironmental change of the NCC during the Early Cambrian. In this study, we systematically synthesized the geographical and stratigraphic distributions of the Early Cambrian evaporite deposits in the NCC based on field collections and published data. The results show that the Early Cambrian evaporite deposits in the NCC mainly include gypsum, halite pseudomorph, and gypsum breccia. They have been found in two sets of reddish layers and geographically distributed in the Jiao-Liao-Xu-Huai region and western Henan region. Integrated evidence of biostratigraphy, chemostratigraphy, and detrital zircon chronology constrains the age of these evaporite deposits within the Cambrian Series 2, Stage 4 (ca. 514–509 Ma). Consequently, these late Early Cambrian evaporite deposits represent drought events that can act as regional event stratigraphic markers to constrain the age of the evaporite-bearing strata near the Great Unconformity and also suggest that the paleogeographic position of the NCC in the Cambrian Stage 4 may be located between 20◦N–30◦N near the western Gondwana with northwest-southeast orientation. Additionally, the hot-arid paleoclimate evidenced by evaporite deposits may be the environmental factors for the decline of benthic organisms in the NCC in the late Early Cambrian.

Taxonomy and taphonomy of fossil fish scales from the Lower to Middle Miocene of eastern part of Shimane Prefecture, Japan

Mami HAMADA[1]*, Shimane University (n22d203@matsu.shimane-u.ac.jp)
Toshiaki IRIZUKI[2], Shimane University
Akira TSUJIMOTO[3], Shimane University
Yoshitaka YABUMOTO[4], Kitakyushu Museum of Natural History and Human History

Abstract

Fossil fish scales have been found from the Lower to Middle Miocene Josoji Formation in the eastern part of Shimane Prefecture, southwestern Japan. The Josoji Formation was formed in a deep–sea environment during the opening of the Sea of Japan from approximately 18 to 16 Ma. However, to date, no taxonomical and morphological studies on fossil fish scales have been conducted.

Considering the aforementioned factors, this study was conducted to identify taxonomic groups of fossil fish scales from the formation based on a comparison with scales of extant fishes and the transition of fossil fish assemblages during the opening of the Sea of Japan. Furthermore, geochemical and microfossil analyses of the sediments were conducted to reconstruct the paleoenvironment of the sea bottom where the fish scales were deposited.

Several well-preserved fossil fish scales were found in laminated black shale from 11 sites of the Josoji Formation.

Various types of fossil fish scales were recognized at these sites. Based on their morphological observations, seven families, namely, Clupeidae, Myctophidae, Macrouridae, Gadidae, Halosauridae, Sparidae, and Scombropidae were identified for the first time.

The results of the analysis of total organic carbon, total nitrogen, and total sulfur contents of rock samples indicated a poorly oxygenated paleoenvironment. Furthermore, several specimens of fossil benthic foraminifera were found in black shale. Upper bathyal species such as Uvigerina cf. proboscidea were dominant. Therefore, the occurrence of well-preserved fossil fish scales can be attributed to their preservation in upper bathyal reducing sea bottoms.

Regarding the temporal changes in fossil fish assemblages, fishes of the family Clupeidae entered the Sea of Japan during the early transgression that began approximately 17–18 Ma. Subsequently, deep-sea fishes, such as the family Myctophidae and Macrouridae, also moved into the Sea of Japan and became dominant, increasing the diversity of fish assemblages.

Phylogeny of the Trigonioididae

Seong Young YANG[1]*, #1805/102 the sharp Seocho Apt., Seochojungangro 2gil, 21 Seocho-gu, 06720 Seoul Korea (youngi2x0@nate.com)

Abstract

Since the genus Trigonioides was reported by Kobayashi and Suzuki from the Cretaceous Formation of Korea in 1936, several species have been reported from the non-marine formations in various places including Japan, China, Southeast Asia, Russia and U.S.A. as well as in Korea. Therefore, it has been the subject of much attention among the non-marine bivalve fossils. Trigonioides the type genus of Trigonioididae shows the characteristics of crenulated hinge teeth and V-shape surface ornamentation. In particular, the genus name was given because the hinge structure is very similar to schizodont trigonia, a famous standard fossil of the Mesozoic Era.

Kobayashi(1955) presented the idea that Trigonioides which lived in the marine environments, was partly confined to continental environments due to the early to middle Cretaceous Sagawa Orogeny in Japanese islands and evolved in non-marine environments. Meanwhile, observing the specimens of Trigonioides suzukii from Wakino formation Japan, Cox(1955) suggested that part of the hinge structure of Trigonioides also appears in Unionacea, so it cannot be concluded that it necessarily evolved from trigonia.

A lot of many fossils belonging to Trigonioididae have been reported from the Cretaceous Gyeongsang Group in Korea. That is, the subgenera of it Trigonioides (s. s), Nippononaia, Koreanaia, Wakinoa were found from the single sedimentary basin. Thus we can say safely the stratigraphic relative positions of these subgenera.

From the stratigraphic relations of the subgenera, the phylogeny of the family can be read as following: the angle of V-sculpture is gradually decreased from about 450 to 120, the surface ornamentations covering is from the whole discs through antero-posterio and umbo part to postero-umbo part only. And the hinge structure is changed also lamellar unio type through striation wakinoa type to crenulation trigonioid type, From this phylogeny we can say that the Trigonioididae evolved from the unioinacea not trigoniacea

New insights into pterosaur cranial anatomy: X-ray imaging reveals palatal structure and evolutionary trends

He CHEN[1]*, School of Ecology, Sun Yat-sen University (chenhe6@mail.sysu.edu.cn)
Shunxing JIANG[2], Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences
Alexander W. A. KELLNER[3], Department of Geology and Paleontology, Museu Nacional/UFRJ
Xiaolin WANG[4], Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences

Abstract

Among the least studied portion of the pterosaur skeleton is the palate, which tends to be poorly preserved and commonly only visible from one side (the ventral portion). Even in well-preserved specimens, the bones tend to be fused, with the limits of individual palatal elements obscured. To shed new light on this region, we employed advanced X-ray imaging techniques on the non-pterodactyloid Kunpengopterus (Wukongopteridae), and the pterodactyloids Dsungaripterus (Dsungaripteridae), Hongshanopterus (Istiodactylidae), and Hamipterus (Hamipteridae). Our analyses revealed the presence of sutures between palatal bones in Dsungaripterus and Kunpengopterus, which resulted in different interpretations of the relation between palatine, ectopterygoid, and pterygoid. Those new results led to a new identification of the palatal openings. In addition, our study shows six main observations such as the variation of the angle between the two rami of the palatine and the variation in the relative sizes of the palatal openings. We also point out that the presence of a maxillopalatine fenestra (previously identified as postpalatine fenestra), is unique within Diapsida. Although much more work needs to be done, we showed that advanced X-ray imaging techniques open a window for understanding pterosaur cranial anatomy and provide a new perspective for investigating the evolutionary history of these flying reptiles.

Tracing Palaeo-Gaseous Mercury Variations through Fossil Plants: Preliminary Analysis of Mercury Concentration Data in Extant *Ginkgo* and Extinct Ginkgoaleans

Li Zhang[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (lizhang.pb@gmail.com)
Yongdong Wang[2], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Micha Ruhl[3], Trinity College Dublin, The University of Dublin
Emma Blanka Kovács[4], Trinity College Dublin, The University of Dublin

Abstract

Vegetation leaves have long been considered a significant receptor of gaseous mercury (Hg) in the atmosphere, offering the potential to passively monitor palaeo-atmospheric Hg concentrations. Despite this potential, the idea has been discussed very little. In this study, we conducted Hg measurements on two *Ginkgo* leaf collections: one containing leaves from ten sampling sites across China, and the other comprising leaves collected monthly for one year in Nanjing. The results revealed that the foliar Hg concentrations in this study (an average of 61 $ng \cdot g^{-1}$, N = 272) were higher than those observed in previous *Ginkgo* leaf samples collected from Ireland or the USA. Additionally, the leaf age and atmospheric Hg concentration were found to be two primary factors impacting foliar Hg content in *Ginkgo*. These results prompted further investigations into fossil ginkgoaleans. Hg concentrations in fossil cuticular samples (avg. 585.5 $ng \cdot g^{-1}$) were observed notably higher than those in modern *Ginkgo* leaves (avg. 61 $ng \cdot g^{-1}$) and sediments from the same layers (avg. 113 $ng \cdot g^{-1}$). Considering possible Hg migration during fossilization, we suggested that the elevated Hg concentrations in fossil cuticles were attributed to both the retention of Hg in leaves and the loss of leaf content during fossilization. Based on 23 fossil ginkgoalean samples from 6 beds of the Dameigou section (spanning from the Early to the Middle Jurassic), Qaidam Basin, China, we detected a Hg anomaly through Hg concentrations in fossil cuticles during the presumed palaeo-volcanic event (the Karoo-Ferrar Large Igneous Province). This preliminary test suggested that variations in Hg concentrations in fossil cuticles could potentially reflect the gaseous Hg changes in the palaeo-atmosphere triggered by palaeo-volcanism, highlighting the possibility of using fossil plant cuticles as a Hg proxy of the palaeo-atmosphere.

Mesozoic Climate change and CO2 concentration variation - paleobotanical evidence from China

Yongdong WANG[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (ydwang@nigpas.ac.cn)

Abstract

The Mesozoic (252 myr – 66 myr) is characterized by a hot Greenhouse climate. It contains a series of geological and environmental changes, such as active volcanic activities, major changes in paleogeography, rapidly increased CO2 concentrations, sea level rise, oceanic anoxic event, flora and fauna turnovers at Triassic/Jurassic boundary, and Cretaceous/Paleogene boundary.

As one of the primary greenhouse gases, CO2 plays a major role in global warming, which affects the surface temperature of the Earth. Reconstruction of atmospheric CO2 using proxies is crucial for understanding the Mesozoic “Greenhouse”. However, at present, CO2 concentration data are less common before the Cenozoic, thus it can be difficult to reliably connect changes in the Earth’s environment with changes in paleo-atmospheric CO2.

Palaeobotanical proxies based on the stomatal features of leaf cuticles show great application value for reconstructing the deep time CO2 level in recent decades. In recent years, several fossil localities from China have been further studied, such as the Upper Triassic Yanchang Formation and the Middle Jurassic Yan’an Formation in Huating County, eastern Gansu Province, nothwestern China, the Lower Jurassic Xiangxi formation in Zigui County, western Hubei Province, South China, and the Upper Triassic Hongweikeng Formation in Nanling region, border of Guangdong and Hunan Province. Based on Ginkgo, Ginkgoites and Sphenobaiera leaves, our estimated paleo-CO2 values are 1962 ppm in the Late Triassic, 900-1200 ppm in the Early Jurassic, and 1320 ppm in the Middle Jurassic.

To test the congruence of paleo-CO2 estimates, all three methods applied to different Ginkgoalean fossil species collected from the same fossiliferous bed. Considering the potential effect of guard cell size to the mechanistic method, the result demonstrates that a likely occurrence of polyploidy in Sphenobaiera huangii may result in underestimated paleo-CO2 when applying mechanistic method due to an increase in the size of the stomatal complex.

In our ongoing research, the fossil leaves in taxa such as Pachypteris, Anthrophyopsis, Pterophyllum, Ptilophyllum, Ginkgoites and Baiera from the new localities in Nanling region also show potential for plant carbon isotope analysis and palaeo-CO2 reconstruction. They will provide climate evidence from south coastal of China during the Carnian age, Late Triassic.

The linkage between Carnian Pluvial Episode and volcanism recorded by mercury anomalies in South China

Qing LI[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (qingli@nigpas.ac.cn)
Micha Ruhl[2], Trinity College Dublin, The University of Dublin, College Green, Dublin 2, Ireland
Emma Blanka Kovács[3], Trinity College Dublin, The University of Dublin, College Green, Dublin 2, Ireland
Dong Yong Wang[4], Nanjing institute of Geology and Palaeontology, Chinese Academy of Sciences

Abstract

The Carnian Pluvial Episode (CPE) is used to describe the dramatic climate changes and geological phenomena due to intensely increased rainfalls that occurred during Carnian in late Triassic. These phenomena include the carbonate platform crisis, terrigenous clastic input, biotic turnover, sea level changes, negative carbon isotope excursions, and so on. However, the cause of the increased precipitation of Carnian Pluvial Episode is still uncertain. Some researchers think that volcanism, especially Wrangellia Large Igneous Province (LIP) is the main driver, while others think that monsoon is the trigger.

To explore the cause of CPE, we used mercury (Hg) enrichments and mercury/total organic carbon (Hg/TOC) ratios to evaluate whether there exists enhanced Hg loading and whether the increase of Hg coincides with the carbon cycle and hydrological perturbations across the CPE in South China of the eastern Thethys. Our studied profile is represented by the Luojiagou section located at the Zigui Basin, in Hubei Province, which is a foreland basin on the northern margin of the Yangtze Plate in South China. In the Zigui Basin, the Mesozoic sequences are well developed and successively exposed with marine to continental outcrops. Our recent study proved that four negative carbon isotope excursions are presented in the Luojiagou section of the Zigui Basin. Here, we analyzed the mercury concentrations and Hg/TOC ratios from the CPE sequence with transitional facies in the Luojiagou section of Zigui Basin. The Hg/TOC ratios recorded in the studied section display four peaks and have good correlations with the four negative carbon isotope excursions. After reviewing the global mercury concentration perturbations during CPE, we found that the Hg/TOC ratios exactly coincide with the negative carbon isotope shifts, no matter in marine or non-marine sedimentary strata. Hence, our new evidence proved that CPE has a strong correlation with the volcanic activity that was responsible for biological extinctions in Carnian.

The Mesozoic vegetation of Madagascar and the Jurassic vegetation of the Mahajanga Basin, northwestern Madagascar

Vivi Vajda[1]*, Swedish Museum of Natural History (vivi.vajda@nrm.se)
Sylvain G. G. RAZAFIMANDIMBISON[2], Swedish Museum of Natural History
Nicolas RAKOTOSOLOFO[3], Mahajanga University
Hery L RANARIJAONA[4], Mahajanga University

Abstract

The rich biodiversity and endemicity of Madagascar are often attributed to its prolonged isolation as a continental island since the Mesozoic era. Having once been part of the Gondwana supercontinent, Madagascar began its separation from continental Africa and the Indian subcontinent approximately 160 million years ago. Consequently, the flora of Madagascar has been historically perceived as primarily remnants of an ancient Gondwanan vegetation, diverged due to continental drift. Noteworthy examples of endemic plant lineages on Madagascar, such as Takhtajania perrieri (Winteraceae) and Podocarps, exemplify groups with ancestry dating back to the Gondwanan era. This study presents findings resulting from a collaborative endeavor involving paleontologists, geologists, and botanists from the Swedish Museum of Natural History and Mahajanga University, Madagascar.

The geological history of Madagascar plays a pivotal role in elucidating the origins of its flora and fauna, as the island severed ties with continental Africa during the Jurassic period, approximately 165 million years ago, leading to its subsequent evolutionary isolation. While paleobotanical investigations are scarce, primarily conducted in the 1960s and 1970s by Appert, who characterized Upper Jurassic (Oxfordian) assemblages from the Manamana massif in southwestern Madagascar, they provide crucial insights. These studies revealed a predominance of dipteridaceous ferns and conifers of genera including Brachyphyllum, Elatocladus, Cupressinocladus, Cyparissidium, and Araucarites, alongside minor occurrences of "seed ferns" within the impression floras.

Palynological analyses conducted on Jurassic outcrop sections within the Mahajanga Basin unveil well-preserved palynological assemblages showcasing a distinctly continental character. The older assemblage is notably dominated by fern- and lycophyte spores, including Cyathidites, Baculatisporites, Dictyophyllidites, Ceratosporites, and Retritiletes, whereas the younger counterpart is characterized by a prevalence of gymnosperm pollen, constituting approximately 70% of the composition. Notable spore genera within the gymnosperms include Classopollis, Araucariacites, Perinopollenites, and Callialasporites. Based on the identified taxa, the studied assemblage is assigned to the Early Jurassic (Pliensbachian–early Toarcian) Corollina torosa Zone as delineated by Helby et al. (1987). These findings underscore striking similarities between the flora of Madagascar and contemporaneous floras elsewhere, such as those in Sweden and Australia, suggesting a remarkably homogeneous global vegetation pattern during the Late Jurassic period.

Atypical element accumulation in fossil leaves from the end-Triassic of Northern Hemisphere

Susan NEHZATI[1]*, Diamond Light Source (susan.nehzati@diamond.ac.uk)
Kajsa G.V. SIGFRIDSSON CLAUSS[2], MAX IV
Vivi VAJDA[3], Swedish Museum of Natural History

Abstract

Intense volcanic activity and continental break-up during the formation of the Atlantic [1] undoubtable affected the elemental balance in the environment during the end of the Triassic. We analyzed the metallome of a number of fossilized plants, both foliage and stems for naturally occurring, but also anomalous levels of toxic metals and metalloids to delineate the conditions of plants during this specific time interval. X-ray absorption spectroscopy (XAS) analysis of sedimentary successions across the Triassic-Jurassic (T-J) boundary showed anomalous levels of various elements with differing chemical forms in the fossilized leaves compared to those in the host sediments.

Several elements are non-essential to plants and in fact toxic to many plant species. Furthermore, some of the elements are highly volatile components of volcanic emissions and hydrothermal brines. Plant biology with respect to elemental accumulation has been largely studied by other workers with growing knowledge on uptake, transport and accumulation mechanisms of specific chemical species [2,3]. Together, this provides a unique opportunity to explore the hypothesis that elevated levels of other elements may have been present signifying the difficult natural terrain caused by massive geological activity over 200 million years ago. Using XAS and X-ray fluorescing imaging (XRF) we report distinctive accumulation patterns which may strengthen the idea that dispersal of specific elements may have been the driving factor in the mass extinction of life.

First fossil foliage record in the red beds from the Upper Jurassic in the Sichuan Basin, southern China

Yongdong WANG[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (ydwang@nigpas.ac.cn)

Abstract

The terrestrial red beds are extensively developed in the Upper Jurassic system of the Sichuan Basin, southern China, where few fossils had been documented. Recently, abundant silicified woods were found in the central Sichuan Basin, but no foliage fossil has been recorded from the same strata. Here we report the first leafy shoot fossil collected from the red beds of Upper Jurassic Penglaizhen Formation in the Shehong City, central Sichuan Basin. Based on careful comparisons with potential Mesozoic conifer fossils, it has been assigned to Pagiophyllum. The generic classification agreed with the paleo-vegetation features of the Penglaizhen Formation which were represented by gymnosperms of Araucariaceae (Agathoxylon-type woods) and Cheirolepidiaceae (Brachyoxylon-type woods). The non-coexistence between the leafy shoot fossil and the large amount of petrified woods depicted a unique process of the fossil preservation, which may be affected by the paleo-flood events of this area. The occurrence of genus Pagiophyllum, as well as the predominated Classopollis pollen from the Penglaizhen Formation indicated that the Shehong City and nearby regions were under a hot and semi-arid climatic condition during the Late Jurassic. The ecological system of this place was considered with more complexity allowing huge gymnosperms trees as well as some megaherbivores dinosaurs to be survived in the central Sichuan Basin area in the Late Jurassic Epoch.

Early Jurassic plants response to the Toarcian Ocean anoxic event in the Ordos Basin, China

Yunfeng LI[1]*, Research Center of PaleontologyStratigraphy, Jilin University
(liyunfeng@jlu.edu.cn)
Changlu Zhang[2], College of Earth Sciences, Jilin University

Abstract

The ecological effect of global warming is a hot topic in today's scientific community. The early Toarcian Oceanic Anoxic Event (T-OAE, ~183 Ma) was characterized by abrupt global warming, enhanced weathering rates, expansion of anoxic conditions, elevated extinction rates, potential increase in atmospheric methane concentrations and the worldwide ac-cumulation of organic-rich sediments. It is an important comparative model for the study of this scientific problem. Studies on this event are mainly limited to Marine ecosystems at present, while studies on terrestrial ecosystems are rare. The response of fossil plants to this event is still unclear. The Early Jurassic Fuxian Formation in the Ordos Basin is a natural archive for studying the response of plants to the Early Jurassic Toarcian oceanic anoxia event, with well-developed strata, well-defined stratigraphic ages, well-preserved diverse fossil plants. Paleontologists ascribe the Fuxian Formation to the late Early Jurassic (Toarcian) through the characteristics of fossil assemblages. The preliminary study shows that the flora of the Fuxian Formation in the Ordos Basin is composed of cycas, czekanowskiales and conifers. The declining plant diversity, the increasing proportion of thermophilic plants, and a high content zone of Classopollis show a positive response of the terrestrial ecosystem to the Early Jurassic Toarcian ocean anoxia event.

Preliminary report on pterosaur track from the Cretaceous Jindong Formation, Gyeongsang Supergroup, Goseong County, South Korea

Hyeokpyo JEON[1]*, Chinju National University of Education (jhp9712@naver.com)
Kyung Soo Kim[2], Chinju National University of Education

Abstract

The Cretaceous Jindong Formation, which is the uppermost formation of the Hayang Group, the Gyeongsang Supergroup, is best-known for abundant vertebrate track assemblages and multiple track-bearing layers in the Gyeongsang Basin lake deposits of South Korea. Especially, the Deokmyeongri tracksite (formerly the Deongmyeong-ri tracksite), once called the Samcheonpo tracksite (Dukmyeongri section), where the first dinosaur footprints were discovered in Korea is the lower part of the Jindong Formation. The tracksite have yielded abundant dinosaur and bird tracks on the fine-grained volcaniclastic sediments associated with sedimentary structures such as ripple marks, desiccation cracks, raindrop impressions and cross-bedding.

In October 2021, the second author discovered the small to medium-sized pterosaur tracks and trackways reported herein from the Deokmyeongri tracksite of the Jindong Formation in Deongmyeong-ri, Hi-myeon, Goseong County, Gyeongnam, South Korea. Although it is well-known that the dinosaur and bird tracks are very abundant in the Jindong Formation, pterosaur tracks of the Jindong Formation have been rarely reported. The newly discovered assemblage of pterosaur tracks consists of at least 80 manus tracks attributed to small to medium-sized ichnotaxon. No pes tracks have been identified. Manus-only pterosaur track assemblages are not rare and could be interpreted to reflect differential registration depths of manus and pes and/or suboptimal preservation condition. The small-sized sauropod and the medium-sized theropod trackways registered on the same surface represent the contemporary vertebrate ecosystem during the Cretaceous Jindong lake period.

Neocomian ammonites from Talesh region (NW Alborz Mountains, Iran)

MAHMOUDREZA ---------- Majidifard[1]*, Research Institute for Earth Sciences in Geological Survey of Iran (m_majidifard@yahoo.com)
SIMA ------ SHAMS[2], Reyhane High School

Abstract

The study area is restricted to the Talesh Mountains in the north-western Iran. The research records several specimens of the Berriasian to Valanginian ammonite from the Lower Cretaceous Kolur Formation exposed near at east of the village of Shal in the Alborz Mts in northwest Iran. At the study section, the thickness is about 270 m. The sediments consist of alternations of thin- to medium-bedded limestone and argillaceous limestone containing numerous ammonite beds. The Kolur Formation conformably overlies the Shal Formation. Its upper boundary with the Cretaceous rocks is conformably. The Kolur Formation contains ammonites, but no detailed studies have been carried out so far. Based on the present study, the age of the formation is early Berriasian to late Valanginian.

An Berriasian to Valanginian ammonite fauna is described for the first time from the Iran (Alborz Mountains). The formation, consisting of alternation of thin to medium limestone and argillaceous limestone with numerous ammonite beds and comprise the families fauna (Phylloceratidae, Lytoceratidae, Haploceratidae, Neocomitidae, Olcostephanidae, Berriasellidae).

Some of the taxa are recorded for the first time from Iran: Phyllopachyceras infundibulum, Phyllopachyceras winkleri, Lytoceras subfimbriatum, Haploceras (Neolissoceras) grasi subgrasi, Pseudosubplanites fasciculatus, Olcostephanus (Olcostephanus) atherstoni, Olcostephanus densicostatus, Campylotoxia campylotoxa, Berriasella subcallisto, Strambergella aff. Carpathica, Neocomites teschenensis, Fauriella cf. floquinensis, Tirnovella cf. allobrogensis, Tirnovella cf. alpillensis and Fauriella gauthieri.

Palaeobiogeographically, these taxa are common in European and North African Tethyan successions.

Yuki Tomimatsu[4], Fukuoka University
Lisa Santello[5], University of Padova
Yixing Du[6], Chengdu University of Technology
Xin Jin[7], Chengdu University of Technology
Angela Bertinelli[8], University of Perugia

Abstract

Microfossils are important components of sedimentary rocks used for palaeontological, biostratigraphic, palaeoenvironmental and palaeoclimatic investigations. They are usually extracted from rocks by using an acid solution, depending on the rock lithology. A new method using common NaOH (sodium hydroxide) has been developed to extract radiolarians and conodonts by digesting cherts (micro- and cryptocrystalline quartz) instead of the standard technique based on HF (hydrofluoric acid). Hydrofluoric acid (HF) has traditionally been used to extract microfossils from siliceous deposits (radiolarian cherts), but this acid is currently strictly regulated due to environmental and human health concerns. Different concentrations of sodium hydroxide solution (1, 2, 3, 4, 5 mol/L NaOH) have been tested at different temperatures as an alternative chemical to HF. This NaOH method allowed to collect undamaged different kind of microfossils, such as conodonts, radiolarians, teeth and dermal scales, the minerology of which is still preserved (e.g. conodonts in biogenic apatite). The use of soda is thus recommended, is less hazardous, easier to handle and has less impact on the environment and human health than HF. This method can thus be widely used for research, teaching and resource exploration of radiolarian fossils, even in institutions where HF cannot be used due to chemical restrictions.

Study of Quaternary Radiolaria from the Core ABP-06, Station II, Section 1, Central Indian Ocean

DEEKSHA BOHRA[1]*, Kumaun University, Nainital (deekshabohra2@gmail.com)
Girish Kumar Sharma[2], Delhi University

Abstract

A comprehensive study is carried out on the core ABP-06, Station II, Section 1 from Central Indian Ocean. 50 samples of 1 metre length were taken at a depth of 5,179m of Latitude 11°35'37.4"S and longitude 75°10'10.9"E. Lithologically, the studied core consists of fine grained clayey material (siliceous ooze) with white lensoid patches and having radiolaria and sponge spicules in traces.

The samples were disaggregated and boiled with dilute hydrogen peroxide. Then sieved through 63μm mesh stainless sieve and thorough washing was done with running water to clean the radiolaria shell. The final wet residual material is dried in an oven and used it to prepare the glass slides with the help of Canada balsam.

50 radiolarian species are identified and their distribution in the core are described. Taxonomy of 10 stratigraphically important taxa are described in detail. Based on the first morphotypic occurrences (Bm), last appearance (Tm) and consistent abundance of taxa, two radiolarian biozones are recognized namely *Buccinosphaera invaginata* zone and *Collosphaera tuberosa* zone. On the basis of this and radiolarian assemblage, the core belong to Upper Quaternary age. Three reworked species viz. *Spongaster pentas*, *Heliodiscus echiniscus* and *Acrosphaera spinosa echinoides* are present from very rare to rare. Two upwelled species -*Lamprocyrtis nigriniae* and *Tetrapyle octacantha* show their presence throughout the column and one cold water species - *Stylodictya validispina*, is also present in the study carried out so far. It is also interpreted that this area is having upwelling zone and basin is having the cold water currents from the Antarctic region.

Rowan C. Martindale[8], University of Texas at Austin

Abstract

The Pliensbachian/Toarcian boundary event (~184.2 million years ago) and the Toarcian Oceanic Anoxic Event (TOAE, ~183 million years ago) represent two of the most severe environmental perturbations of the Early Jurassic Epoch, leading to marine ecosystem disruption and biotic crises. Previous work on the Early Jurassic biotic crises has regarded warming-induced anoxia as the primary driver for the extinctions, and the two events (i.e., the stage boundary and early Toarcian) are often considered to be causally linked. Recent studies, however, show elevated extinction rates in well-oxygenated basins, such as the Iberian Basin in Spain, and the High Atlas Basin in Morocco. Furthermore, subtle differences in environmental conditions (such as, warming or eutrophication) between the two events have been identified at multiple localities. So far, there have been no quantitative studies on the Early Jurassic macrofauna from Morocco; thus, the extinction dynamics (e.g., ecosystem functioning and recovery), as well as the exact causes of the extinctions in the marine level-bottom communities in this low latitude locality, remain unclear. In this study, we report the occurrences of late Pliensbachian-Toarcian marine invertebrate taxa from the Central High Atlas Basin of Morocco and their associated functional groups. We collected macrofaunal samples from the late Pliensbachian- Toarcian strata, capturing the boundary event and the TOAE, followed by taxonomic identification and functional group assignment. Assessing functional diversity (i.e., how organisms operate in a community) provides data about how marine communities changed in response to environmental stressors (e.g., increased temperature or eutrophication) and what factors dictated survival versus extinction. The functional groups of the macrofauna are documented based on their inferred lifestyle, and niches assigned based using the Bambachian ecospace model. Preliminary results show that bivalves are the most functionally diverse, with eight different functional groups. Unattached epifaunal carnivores and unattached deep-infaunal suspension feeders cross the stage boundary event but disappear at the onset of the T-OAE. Similarly, the facultatively-unattached, epifaunal, suspension feeders appear after the onset of the TOAE, while byssate epifaunal suspension feeders are present throughout the late Pliensbachian-Toarcian interval. The differential survival of functional groups is likely due to the causal mechanisms of the two events. This new paleontological data from tropical, shallow-water macrofaunal communities is critical to our understanding of the extinctions across these two events because most of the comparable data has been collected from deeper-water, extratropical

shales. In addition, this study provides important data about the patterns of biotic change in tropical marine communities and how these communities recovered from significant global events like those we are facing now.

V.V. Shesa Sai[4], Geological Survey Of India
Vidhya Sivadas[5], Geological Survey Of India
Vandana Umredkar [6], Geological Survey Of India

Abstract

Paleontological study on fossil remains of Temnospondyl skeletal elements have been carried out within the Middle Triassic sedimentary rocks of Denwa Formation of Upper Gondwanas in Satpura Basin, Madhya Pradesh, India, as part of the Annual programme of Geological Survey of India, Central Region. With the successful rate of survival, the early amphibians Temnospondyli were one of the clade along with the extant Lissamphibia and Amniota, that survived into the Late Triassic and beyond. The study area was near Tekapar village in Hoshangabad District of Madhya Pradesh, where fragmentary bone fossils and partially preserved skeletal elements of Temnospondyl were found out. The fossil bearing beds here are mainly a 1m thick gritty sandstone horizon within a sandstone- siltstone-purple sandstone sequence. The cranial elements comprise of the ornamented skull roof bones, part of maxilla and mandible with uni- bi-serial teeth while, the post-cranial elements include intercentrums, partial limb bones, femur, partial bone of pelvis and fibula of temnospondyl were also collected and studied. A few skull bones near orbital zone together with that of posterior part are well preserved. Partially preserved occiput at the back of the cranium is found with ossified wall. The occiput is preserved along with the squamosal and quadrate of the skull lying below the postparietal. The mandible bones are long, slender with serrated and tightly ossified sutures. It preserves well differentiated splenial, postsplenial and angular plates. The skull roof bones are moderately thick (max. 1cm.), pitted at places and show intricate network of ridges and grooves on external surface. Near squamosal area, honeycomb pattern is observed. Osteological studies of the recovered bone fossils of the temnospondyl from the present study area indicate a close similarity to the Mastodonsaurus giganteus from the Middle Triassic (Lettenkeuper: Longobardian) of Germany. Associated fossils recovered from the area are of archosaur (Shringasaurus indicus) and conifer plant wood, apart from small coprolites of varied origin. Presence of associated fossils, sedimentary association and bone structures of the temnospondyl suggests that the animal was mainly thrived in an alluvial and lacustrine environment in a relatively warm climate.

A new research on ultra-large ichthyosaur-Himalayasaurus tibetensis

Qinghua SHANG[1]*, nstitute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences (shangqinghua@ivpp.ac.cn)
Chun Li[2], Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences
Wei Wang[3], Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences

Abstract

Himalayasaurus tibetensis was an ultra-large ichthyosaur (Marine Reptile) that lived during the Norian, Late Triassic. This fossil was first discovered in 1960s and subsequently named by Z.M. Dong (1974). It was a member of the Shastasauridae, with a body length reaching up to 15 meters (Motani and Dong, 1999).

Due to the limitation of the scarcity and unprepared materials, the understanding on the species' morphological features and ecological behaviors are still limited. Meantime, because of the remoteness of the collection time and the brevity of the initial descriptions, the fossil's precise stratigraphic position and paleoenvironment are yet to be determined also.

The original holotype specimen (IVPP V 4003) was re-prepared revealing additional anatomical information, particularly regarding the teeth. Combined with the previous one tooth in situ and new revealed three out-of-situ teeth, the shape of the teeth of the Himalayasaurus tibetensis was considered as uniform. Meanwhile, the shape of the tooth roots is similar to other supergiant ichthyosaurs, but the shape of the crowns is highly specialized. The mesial and distal sides of the teeth are edged, while the labial-lingual sides are strongly compressed, resulting in a short dagger-like shape. The crown morphology is relatively similar to Thalattoarchon saurophagis (Fröbisch et al., 2013), but the size of the teeth is much larger than that of T. saurophagis. These newly exposed teeth indicate that the size (length and height) of their tooth root is even larger than that of an Ichthyosauria indet. species (PIMUZ A/III670), which found in the Alps (Sander et al., 2022).

In addition to the vertebrae, a separately preserved neural arch was also discovered, which is similar in size to the neural arch of Shonisaurus popularis found in the western United States, and has a similar shape to Shastasaurus altispinus (Merriam, 1908). This further confirms that Himalayasaurus is an ultra-large shastasaurid ichthyosaur.

Currently acknowledge on ultra-large ichthyosaur are either toothless or possess conical teeth. Himalayasaurus tibetensis is the only species with tightly packed, large teeth with dagger-shaped crowns, earning it the rightful title of a top predator cruising in the Late Triassic Paleo-Tethys.

It was worth to mention that, in 2023, on the original fossil locality, the Tulong region, Nielamu County, Tibet, a detail field investigation was realized on the Late Triassic well exposed strata. Several fragment skeletal fossils were found within a lenstic calcareous siltstone. This confirming that the fossils originated from the middle parts of the Qulonggongba Formation. From the view of the lithology and combine with the invertebrate fossil, such as bivalves and ammonites, the environment was a shallow marine, where located the northern margin of the Gondwana.

New Pachymeridiidae (Insecta: Heteroptera: Pentatomomorpha) fossils from the Jinju Formation (Lower Cretaceous), South Korea

Jun-Hyeok JANG[1]*, Department of Science Education, Gongju National University of Education, 27 Ungjinro, Gongjusi, Chungcheonnamdo, Souh Korea. (okok2073@gmail.com)
Nozomu OYAMA[2], 2 Centre de Recherche en Paléontologie-Paris (CR2P), MNHN-CNRS-Sorbonne Université, Paris, France/ The Kyushu University Museum, Higashi-ku, Fukuoka 812-8581, Japan
Gi-Soo Nam[3], Department of Science Education, Gongju National University of Education 27 Ungjinro, Gongjusi, Chungcheonnamdo, Souh Korea.

Abstract

Pachymeridiidae is an extinct family-level clade of Heteroptera, known with 43 fossil species until now. They are distinguished from other pentatomomorph bugs by the forewing costal fracture and absence of pulvillus under the claw. Pachymeridiidae fossils are known from Germany, England, Russia, China, Kazakhstan, and Mongolia, spanning from the Late Triassic to the Lower Cretaceous (Barremian).

The Jinju Formation (Albian), is mainly known for extremely diverse vertebrate trackways from trackmakers including dinosaurs, pterosaurs, crocodylomorphs, turtles, lizards, frogs, and hopping mammals, but also bears striking remains of both terrestrial and aquatic insects. Among them, most of the heteropteran fossils remained unstudied. Only a single species of fossil heteropteran with a definitive systematic position has been reported until now from this stratigraphic unit. Here, we present multiple types of new pachymeridiid heteropteran fossils from the Jinju Formation. Each type is morphologically distinguishable from others, mainly based on its size, general outline, manner of forewing venation, and markings on the wing. We suggest these morphotypes may represent new taxa, based on a unique combination of characters. These fossils are the first occurrence of this family-level clade within the formation and expand our understanding of post-Jehol Group aged insect fossil assemblage from East Asia.

CENOZOIC BIOSTRATIGRAPHY APPROACH FROM EQUATORIAL CARBONATE PLATFORM OF BRAZIL

Orangel AGUILERA SOCORRO[1]*, Universidade Federal Fluminense (orangelaguilera@id.uff.br)
Dayana Alvarado[2], Federal University of Pará
Olga Oliveira De Araújo[3], Federal University of Rio de Janeiro
Ricardo Tadeu Lopes[4], Federal University of Rio de Janeiro
Giovanni Coletti[5], University of Milano Bicocca

Abstract

The off-shore Cenozoic succession of the Pará-Maranhão Basin of the Brazilian equatorial margin in the Atlantic Ocean is studied from PETROBRAS core 1-MAS-16 (Ilha de Sanatana Formation) to investigate skeletal and foraminiferal assemblages during the Oligocene-Miocene interval, one of the fundamental moments in the environmental evolution of our planet. Biostratigraphic and paleoenvironmental analyses of these sedimentary records are often based on the study of foraminiferal assemblages. Foraminifera-based biozones are widely employed in the oil industry to support drilling processes that, alongside petrophysical prospecting, define interval favorable for exploiting hydrocarbon resources. New, faster, and more accurate methods based on microCT analyses have emerged as a valuable high-output tool to obtain high-resolution microfossil records for biostratigraphy and paleoenvironmental reconstructions. The results allowed to clearly constrain the Oligocene – Miocene interval and divide it into four foraminiferal assemblages and seven biofacies useful for both paleoenvironmental reconstructions and stratigraphic correlations (assemblages dominated by nummulitids and lepidocyclinids in the Rupelian; assemblages dominated by *Heterostegina* (*Vlerkina*) *antillea*, lepidocyclinids, and primitive miogypsinids in the Chattian; assemblages dominated by *Heterostegina* (*Vlerkina*) *antillea*, lepidocyclinids, and miogypsinids other than *Miogypsinoides* and *Miogypsinella*, in the Aquitanian; assemblages dominated by advanced miogypsinids in the Burdigalian; post Early Miocene assemblages characterized by the lack of abundant lepidocyclinids and miogypsinids). The paleoenvironmental analysis indicates a common pattern of relative sea-level oscillations with the nearby Foz do Amazonas Basin, highlighting a common behavior of this part of the equatorial passive margin during the Oligocene – Miocene interval. The comparison between the succession of skeletal and foraminiferal assemblages of the investigated core and other successions of the Southern and Central American areas indicated the presence of stratigraphically relevant foraminiferal assemblages that could be useful for improving the correlation between the various Cenozoic successions of the American region. The overall resilience of most of the large benthic foraminifera taxa to the Oligocene – Miocene transition testifies once more to the adaptability of this group of carbonate producers.

Abstract

The paleobiota of the Tamengo and Guaicurus formations of the upper Corumbá Group (Ediacaran-Cambrian boundary strata, Brazil) was limited, until recently, to only a few species, with most publications dedicated to the study of Cloudina lucianoi (Beurlen & Sommer, 1957) and Corumbella werneri Hahn et al., 1982. Our recent systematic sampling, accompanied by palynological and ichnological analyses, revealed a paleontological diversity that can be considered quite rich for the Ediacaran - Cambrian transition. The number of species from the Ediacaran - Cambrian boundary strata in Brazil is updated, including a total of twenty-six species from the Tamengo and Guaicurus formations at five sections in the Corumbá and Ladário regions: Corcal and Laginha quarries, Porto Sobramil, Porto Figueiras and Ecoparque Cacimba. In addition, paleoecological and paleoenvironmental inferences are presented based on the occurrence of this fossil assemblage and an updated lithostratigraphic description of the upper Corumbá Group. Cloudina carinata, has been documented in terminal Ediacaran successions in Spain, Siberia, as well as the Tamengo Formation at the Porto Figueiras section of Brazil. Cloudina hartmannae, considered a synonym for Cloudina lucianoi, and Cloudina carinata from the Tamengo Formation offer an important tool for paleobiogeographic and biostratigraphic correlation of the Tamengo Formation and other coeval successions in Paraguay, Spain, Uruguay, Argentina, United States, Canada, Namibia, South Africa, Oman, Russia, and China. The paelobiota from the Tamengo Formation is composed of numerous biomineralizing metazoans: Cloudina lucianoi, Cloudina carinata, Corumbella werneri, sponge spicules, and putative sponge gemmules. Four ichnospecies (Gordia marina, Pilichnus cf. P. dichotomus, Didymaulichnus lyelli and Multina minima) are present in the upper Corumbá Group. Three macroalgal fossil species were identified in the upper Corumbá Group: Vendotaenia antiqua from the Tamengo Formation, and Eoholynia corumbensis and Tawuia dalensis from the Guaicurus Formation. The species diversity of the upper Corumbá Group fossil assemblage was complemented by the occurrence of organic-walled microfossils, including Chuaria circularis, Arctacellularia januarensis, Leiosphaeridia ternata, Leiosphaeridia crassa, Leiosphaeridia jacutica, Leiosphaeridia

minutissima, Leiosphaeridia tenuissima, Leiosphaeridia obsuleta, Bavlinella faveolata, Bambuites erichsenii, Synsphaeridium sp., Jacutianema sp., Lophosphaeridium sp., Ostiama microcystis and Navifusa. A dramatic change in paleoenvironmental conditions between the Tamengo and Guaicurus formations possibly contributed to the 95% taxonomic turnover between the two formations. Among all of the Tamengo species, only the ichnospecies Multina minima continues to be present in the Guaicurus Formation. This local disappearance could represent the Ediacaran-Cambrian extinction. The transition from the Tamengo to the Guaicurus Formation is marked by a stratigraphically rapid drop in FeHR/FeT, recording a shift to more oxic bottom waters. The Tamengo Formation represents an environment with anoxic bottom waters, with fragments of biomineralized organisms that lived on shallower, probably mildly oxygenated surface waters, and that were then transported down-slope. Similar to coeval successions (e.g., the Nama Group in Namibia), recently published data support the hypothesis that late Ediacaran biomineralized organisms lived in a thin oxygenated surface layer above a relatively shallow chemocline. The Guaicurus Formation, on the other hand, records an expansion of oxic conditions to deeper waters during a sea level rise.

Pranav Pandya[6], Department of Biology, Shri R.R. Lalan College

Abstract

Past two decades has witnessed a renewed interest in the Neogene (mainly Miocene) interval of the Kachchh (=Kutch) region owing to its potential to yield numerous records on fishes, reptiles, birds, marine and terrestrial mammals. However, the vertebrate (mainly Piscean fauna) records from the early Miocene (Aquitanian) are quite scanty. The current investigation reveals the most diverse assemblage of shark fauna, to date, from the Aquitanian (~21 Ma) Khari Nadi Formation at Kotada locality, Kachchh Basin. The shark fauna includes genera Galeocerdo, Hemipristis, Carcharinus, and Sphyrna represented by at least seven species. Jaccard similarity coefficient data suggests that the recorded shark assemblage is quite dissimilar to the previously known Middle Miocene (~14 Ma) assemblages of Palasava (JI: 0.28), western India. Overall, the fauna from the Miocene interval of the Kachchh region reveal intermittent palaeobiogeographic connectivity with the Mediterranean Sea. Interestingly, the recorded elasmobranchs faunal assemblage from Kotada comprise the first record of Galeocerdo mayumbensis from India, which has been previously recorded from the Miocene (Aquitanian) Belgrade Formation (USA), early Middle Miocene Pirabas Formation (Brazil), Miocene Maradah Formation (Libya), and Miocene of northwest Madagascar. The records hint at intermittent palaeobiogeographic connections of western India with Madagascar, and Mediterranean during the Miocene.

Traces of Predatory Drilling Behavior on Middle to Late Pliocene Mollusc Fossils from Santo Domingo, Ilocos Sur, Northern Philippines

David Cabahug POLICARPIO[1]*, National Institute of Geological Sciences; University of the Philippines (dcpolicarpio4@up.edu.ph)
Allan Gil Fernando[2], National Institute of Geological Sciences; University of the Philippines
Tomoki Kase[3], National Museum of Nature and Science

Abstract

A recently described Middle to Late Pliocene fossiliferous massive sandstone unit in Santo Domingo, Ilocos Sur, northern Philippines was found to contain abundant mollusc shells with circular to elliptical drill holes. The majority (72%) of the drill holes analyzed were found on the surface of different species of conid gastropods. Most of the drill holes exhibit wider exterior openings (1.59 to 4.24 mm in diameter) compared to the interior holes (0.97 to 2.31 mm). Based on their morphological characteristics, the drill holes were classified mainly as *Oichnus ovalis* Bromley, 1983 (circular to elliptical drill holes with conical interiors and linearly grooved surfaces) and *Oichnus paraboloides* Bromley, 1981 (circular to elliptical outlines parabolically tapering inwards with smooth interiors). The drill holes on the surface of the conid shells are concentrated along the top of the body whorl, typically along the left side of the shell. The traces are attributed to naticid gastropod predatory behavior, which probably function as tertiary consumers in the study area's ancient ecosystem. This is supported by the abundance of several species of naticid gastropod within the fossil assemblage. While the holes can also be attributed to octopus predatory behavior, no octopod remains were found which is most likely due to their poor preservation potential. High predator success rate (89%) is inferred based on the high abundance of drill holes that completely penetrate the shell. *Oichnus ovalis* ichnofossils were observed to have two distinct scraping directions, suggesting reorientation of the prey during the drilling process. Larger prey shell specimens were observed to contain drill holes with larger diameters.

Response of foraminifers to the Hangenberg mass extinction during the Devonian-Carboniferous transition in South China

Yang SHEN[1]*, China University of Geosciences (Beijing) (shenybj@126.com)
Huixin TANG[2], China University of Geosciences (Beijing)
Zidong YU[3], China University of Geosciences (Beijing)

Abstract

The Devonian-Carboniferous global Hangenberg event is one of the most significant mass extinctions in the Phanerozoic eon. There has been an important shift in the global ecosystem, resulting in about 50% of all genus-order marine animal extinctions. Foraminifers, as a class of single-celled protozoa, are at the bottom of the food chain. Their response to major extinction events implies key information affecting the stability of the ecosystem, leading to great significance for research on them. However, the study on the response of foraminifers to the Hangenberg extinction event is lacking in the world till now. This study will focus on this issue. There are several well-preserved Devonian-Carboniferous sections in South China, among which the Huilong section in Guangxi is the representative section of the shallow water platform facies. The Devonian-Carboniferous boundary was located between the Etoucun Formation and the Yaoyunling Formation, and the Hangenberg event occurred immediately below the boundary in the Huilong section. Research results have shown that the Huilong section contains abundant and diverse foraminifers from the Famennian to the Tournaisian, and the foraminiferal biostratigraphic sequence is clear. In ascending order, they are the Quasiendothyra communis zone, the Quasiendothyra kobeitusana zone, and the Bisphaera zone. In the Quasiendothyra kobeitusana zone, before the Hangenberg event, the foraminifers are characterized by the large volume and complex morphology, such as the development of double-walled Quasiendothyra kobeitusana and Quasiendothyra konensis. After the Hangenberg event, the foraminifers of the Bisphaera zone are mainly small single-chambered foraminifers with simple structures, and characterized by a large number of Bisphaera, occurred from the top of the Etoucun Formation to the bottom of the Yaoyunling Formation. Based on the study of the features of foraminifers before and after the Hangenberg event in the Huilong section, it is confirmed that foraminifers were clearly affected by the Hangenberg event, which led to the almost complete extinction of large and complex foraminifers. The study also shows that foraminifers suffered the “Lilliput effect” in the Hangenberg event and were significantly reduced in body sizes across the extinction horizon.

This study was supported by the National Natural Science Foundation of China (grant 42172037, 41702023).

Bone Histology of the Sabertooth and from Brazil

Virginia Silva Maciel[1]*, Postgraduate Program in Geodynamics and Geophysics - PPGG/CCET (virginiamaciel13@gmail.com)
Claude Luiz de Aguilar Santos[2], Câmara Cascudo Museum, Federal University of Rio Grande do Norte (UFRN). Natal, Brazil
Tito Aureliano[3], Diversity, Ichnology and Osteohistology Laboratory (DINOlab), Department of Geology, Federal University of Rio Grande do Norte (UFRN). Natal, Brazil
Aline Marcele Ghilardi[4], Diversity, Ichnology and Osteohistology Laboratory (DINOlab), Department of Geology, Federal University of Rio Grande do Norte (UFRN). Natal, Brazil

Abstract

Climate change in the Quaternary has had a major impact on mammal populations over the last 50,000 years. Among the groups most affected are the large felids. It is essential to study adaptive variations in saber-toothed cats and surviving taxa of large felids to understand the impact of environmental pressures on extinction. In this study we describe the femoral histology of the largest sabertooth taxon, , and compared it with a fossil cougar, , both from Pleistocene deposits of equatorial Brazil to discuss the impact of the paleoenvironment on the paleoecology of both taxa. MCC-868V is a femur of . (total length = 350 mm). MCC-991V is a fragmentary femur of . (reconstructed total length = 307 mm; simple scaling). The presence of an EFS (External Fundamental System) in MCC-868V, the abundant presence of remodeled bone tissue, especially in the middle and inner portion of the cortex, and the three generations of secondary osteons, suggest that the individual was a young adult at the time of death (Type F bone tissue, HOS-11). MCC-991V also has an EFS, advanced secondary remodeling, and four generations of secondary osteons (Type G bone tissue, HOS-13), suggesting that it is an adult. The high rate of bone remodeling suggests that both specimens had ideal environmental conditions for their development into adulthood. Body size in large carnivores seems to be more directly related to the availability of resources than to climate. The histology of extinct cave bears suggested that those individuals that inhabited higher altitudes tended to be smaller and grow slowly due to slow bone resorption during hibernation. Therefore, we suggest that . must not have faced great difficulties in feeding in the face of constant environmental changes throughout the Quaternary as it is a smaller generalist carnivore compared to . , a specialist carnivore. This factor might help explain the survival of . and the decline of . . Future studies in the histological variation in panther populations from different biomes will be key for detailing environmental pressure in large felid populations.

Pleistocene-Holocene Molluscan Fossil Assemblage and Paleoenvironment Analysis of the Damortis Uplifted Marine Terrace Sequence in Santo Tomas, La Union, Philippines

John Paul Martinez Mondala[1]*, National Institute of Geological Sciences, University of the Philippines Diliman (jmmondala@up.edu.ph)
Allan Gil Fernando[2], National Institute of Geological Sciences, College of Science, University of the Philippines Diliman, Quezon City, Philippines
David Policarpio[3], National Institute of Geological Sciences, College of Science, University of the Philippines Diliman, Quezon City, Philippines
Tomoki Kase[4], 3-27-1 Rokkakubashi, Kanagawa-ku, Yokohama, Kanagawa, Japan 221-8686

Abstract

An uplifted marine terrace sequence in Damortis, Santo Tomas, La Union, Philippines reveals a molluscan paleocommunity consisting of 39 families, 68 genera, and 98 species from a total of 1000 mollusc specimens collected. Two ichnogenera have also been documented to occur in the specimens. The uplifted marine terrace succession, which spans the Pleistocene to Holocene interval, exhibits four (4) sedimentary units, namely (1) the west-dipping sandstones of the Pleistocene Damortis Formation; (2) conglomerate layer; (3) an uplifted Holocene coral reef; and (4) an interpreted tidal flat layer. This succession represents a change of depositional environment, reflected in the molluscan paleocommunity, throughout the Late Quaternary Period.

Based on sedimentological and paleontological analyses, the Damortis Formation is inferred to have been an intertidal to subtidal siliciclastic beach environment with low molluscan paleodiversity. The assemblage consists mostly of infaunal and burrowing corbulid, mactrid, and ungulinid bivalves and mud-bottom dwelling turreted gastropods such as turritellids and terebrids, as well as ringiculid micromolluscs. The conglomerate horizon and the uplifted coral reef horizon reflect a patchy reef paleocommunity that is high in molluscan paleodiversity with abundant predatory drillholes represented by the ichnogenus *h*. The patchy reef assemblage is inferred to have transitioned to a rocky shore assemblage subsequent to uplift due to the presence of rocky shore-dwelling species such as sp. No molluscs were observed in the uppermost tidal flat horizon, interpreted to represent a choked and low energy environment, possibly due to interseismic subsidence of the area after uplift. Result of Q-Mode multivariate cluster analysis supports the very distinct vertical/temporal molluscan assemblage change, as well as the change in the relative abundance of the mollusc species throughout the sequence.

Thermal maturity and taxonomic insights from palynomorph coloration: Preliminary results for the immature sediments of the Cretaceous, Yezo Group

Maho HAYAKAWA[1]*, Graduate School of Science, Hokkaido University
(fastriver10000@eis.hokudai.ac.jp)
Hideto Nakamura[2], Faculty of Science, Hokkaido University
Masashi A. Ikeda[3], Faculty of Science, Hokkaido University
Ken Sawada[4], Faculty of Science, Hokkaido University
Reishi Takashima[5], The Center for Academic Resources and Archives, Tohoku University Museum, Tohoku University
Hiroshi Nishi[6], Institute of Dinosaur Research, Fukui Prefectural University

Abstract

The color tones and brightness of palynomorphs in sedimentary matrices serve as indicators for the thermal maturity of organic matter (OM), as demonstrated by indices including the Thermal Alteration Index (TAI) and Palynomorph Darkness Index (PDI). The TAI, while utilizing both brightness and color tone information, relies on subjective visual matching to a standard gauge, resulting in lower numerical precision. Conversely, the PDI offers a more precise quantitative measure, albeit without incorporating color tone information. Meanwhile, the color of palynomorphs might also encode other types of information, such as taxonomic and ecological variety of source plants, as well as differences in diagenetic processes, because palynomorph color within a single sedimentary rock shows significant variation. This study aims to decipher such information by quantitatively assessing changes in hue and brightness in Cretaceous pollen fossils against maturity, highlighting the potential of these characteristics as novel paleontological indicators.

Utilizing image analysis, we quantitatively assessed the brightness and color tones by calculating PDI and hue values for pollen fossils extracted through acid and alkali treat ments from Turonian and Campanian mudstone samples of the Late Cretaceous Yezo Group in Hokkaido, Japan. The analysis targeted Classopollis sp. and bisaccate pollen for conifers, and tricolpate pollen for angiosperms, evaluating the implications of plant taxa on the observed changes. Analyzed sedimentary rock samples have been studied previously for biomarker maturity indices showing advanced thermal maturation in older samples.

Initial findings indicated that at the immature Campanian stage, conifer pollen exhibited slightly higher PDI and lower hue (darker and redder tones) compared to angiosperm tricolpate pollen. As the analysis extended to the older Turonian sample, a shift towards darker and redder hues was observed across all pollen groups. However, the magnitude of this shift in PDI and hue was more pronounced in conifer pollen than in angiosperm pollen, underscoring significant taxonomic differences in the response to thermal maturation.

Considering the inherent colorlessness of modern conifer and angiosperm pollen walls, the observed variations in coloration might suggest lineage-specific differences in the concentration of potential molecular sites within the pollen walls that susceptible to post-depositional alteration to

become chromophores. Previous UV and IR spectroscopic study on modern pollen and spores demonstrated variations in sporopollenin components between ferns and seed plants, providing corroborative evidence for the taxonomic differences in structural and composition of pollen walls that may lead to the observed variations in color withing the visible spectrum.

OPal: Open Palaeontology – a community-driven diamond open access journal with preregistration

Harriet Bethany B. DRAGE[1]*, University of Lausanne (harriet.drage@unil.ch)
Joseph N. Keating[2], University of Bristol
Morten Lunde Nielsen[3], Independent researcher outside academia, now working in government, Denmark
Farid Saleh[4], University of Lausanne
Thomas W. Wong Hearing[5], University of Leicester

Abstract

We are establishing a new diamond open access journal, OPal: Open Palaeontology. OPal's scope will cover all aspects of palaeontological research and the journal will have a flexible publishing model with a range of publication types, preprinting, and transparent peer review. The founding principles of OPal directly address concerns that the current academic publishing landscape is systemically unfit for purpose, dominated by a few large publishing houses that extract substantial profit from public resources for little return value, remove copyright from authors, and hinder innovation. Traditional publishing models bake-in gatekeeping practices controlling who and what is published; single-blind peer review has long been suggested to suppress original thought, be biased against marginalised groups, and be ineffective at improving the quality of flawed work. There is also increasing recognition of a reproducibility crisis in science, partly driven by pressure to publish novel work in high-impact journals. The result is systemic inaccessibility, opacity, and lack of accountability – all supported by the academic publishing system. But all is not lost: there is a wealth of established and emerging good practice across the academic publishing landscape, and OPal will draw on these across its publishing model. OPal's ethos is rooted in financial accessibility, transparency, and accountability in academic research. OPal's model draws on established and emerging good practice from across the academic publishing landscape, including diamond open access to mitigate financial inaccessibility, interactive and transparent peer review procedures, and research preregistration integrated with article publication. We also propose a flexible approach to publishing research at various stages of intellectual development and in different formats. We hope that OPal will help transform our understanding of how palaeontological research can be rigorously assessed and published. Here, we put out an open call for those interested in working with us on this new journal. In particular, we seek people interested in working on the OPal editorial board to manage journal editorial processes and those wishing to act as handling editors. We particularly encourage early-career researchers, those working in non-academic positions, and people working outside Europe and North America to get in touch!

METHODOLOGICAL DEVELOPMENT FOR EXTRACTING THREE-DIMENSIONAL SPECIMENS OF CLOUDINA LUCIANOI (BEURLEN E SOMMER, 1957)

Ana Carolina Valadares Maciel de Oliveira[1], University of Brasília
Dermeval Aparecido Do Carmo[2], University of Brasília
Matheus Denezine[3], University of Brasília
Martino Giorgioni[4], University of Brasília
Rodrigo Rodrigues ADORNO[5]*, Geological Survey of Brazil (rodrigo.adorno@sgb.gov.br)
Shuhai Xiao[6], Virginia Tech

Abstract

This study presents a new 3D method for calcareous skeleton Cloudina lucianoi (Beurlen & Sommer, 1957) extraction. These skeletons occur in limestone matrix of Nama Group, Namibia and Corumbá Group, Brazil, Ediacaran sections. This work improves morphological analysis and provides insights into phylogenetic affinities. New protocols for samples preparation and 3D calcareous skeletons extraction from limestones matrix is presented. Cloudina lucianoi is an Ediacaran fossil attributed to the phylum Cnidaria or Annelida. The studied material came from outcrops of the Tamengo Formation in Mato Grosso do Sul of Brazil and from the Nama Group in southern Namibia, both sections are attributed to the uppermost Ediacaran. The extraction of Cloudina lucianoi specimens from limestones consisted of a series of physical and chemical procedures aiming at separating skeletons from the rock matrix. The samples were submitted to a chemical treatment comprising two methods: Solution Drip System (SD) and Immersion System (SI). Different concentrations of acetic acid (1.8% and 4%) were used in both systems in order to evaluate the effectiveness of different acid concentrations in disaggregating the studied samples. The attacks under both SD and Si modalities took place simultaneously in order to observe the reactions and evaluate the effectiveness of the disaggregation process. The results of this treatment of the samples are promising, with the recovery of three-dimensional Cloudina lucianoi specimens, internal molds and external surface of the skeletons. These specimens allow the observation of important morphological features, such as the funnel-in-funnel construction, lamellar structure of funnel walls, and annular striations on outer funnel walls. In a preliminary analysis, the drip system with a 4% diluted acid solution has proven to be more effective. A geochemical analysis (EDS) of samples from the Tamengo Formation and the Nama Group revealed a lower magnesium carbonate (<2%), although the skeletons have a significantly higher amount of magnesium (>15%Mg), which appears to provide greater resistance to acid attack when compared to the calcium carbonate matrix. This different Mg concentration appears to be related to the differential disaggregation of the matrix allowing the separation of the skeletons in 3D. In conclusion, the integration of thin section observations and morphological characterization of chemically extracted three-dimensional skeletons can provide key morphological information about some of the earliest known animal skeletons.

Growth behaviour and palaeoecological role of microproblematica Palaeoaplysina in the Late Carboniferous to the Early Permian of Svalbard

Juwan JEON[1]*, Department of Earth and Environmental Sciences, Korea University, Seoul, 02841, Republic of Korea; The Institute of Basic Science, Korea University, Seoul, 02841, Republic of Korea (juwanjeon@korea.ac.kr)

Abstract

Late Carboniferous to Early Permian reefs are mostly devoid of large, massive reef-building organisms, but are instead dominated by relatively small organisms such as calcareous algae, sponges and bryozoans. During this period, Palaeoaplysina, an enigmatic fossil with a presumed biological affinity to hypercalcified sponges, is the key builder of these buildups. The palaeogeographic distribution of Palaeoaplysina is concentrated in the northern margin of Pangea, thus in positions regarded as higher latitudes, but extends into the subtropical-tropical range. The classic locality for the well-preserved Palaeoaplysina is in the Broggerhalvoya Peninsula, Spitsbergen Island, Svalbard, in the Wordiekammen Formation (Moscovian–Sakmarian), where it forms a biostrome up to 5 m thick and extends laterally for a few kilometres. This study re-examines the growth behaviour of Palaeoaplysina and discusses its palaeoecological role. Palaeoaplysina characteristically possesses platy growth morphologies with its unique cellular microstructure of skeleton and canal systems. Individuals are about 20 cm wide and 2 to 3 mm thick, with their edges thinning toward the margin. Densely stacked skeletons of Palaeoaplysina form platy bands up to 6 cm thick alternating with layers of peloidal wackestone to packstone. Pores of Palaeoaplysina are orientated side-upwards, indicating their in-situ preservation. Downward-growing epibionts, such as bryozoans and benthic foraminifera below platy Palaeoaplysina, are interpreted to indicate the presence of small primary cavities. Taken together, these observations indicate that Palaeoaplysina, which grew over the seafloor with its palaeoecological role of stabilising substrates by binding, constructed a transient reef community, as stromatoporoid-grade hypercalcified sponges did prior to the Late Devonian mass extinction, culminating at a time when large, massive reef builders were largely absent during the Late Carboniferous to Early Permian interval.

Glossifungites : Tracing the Subterranean Artistry of Ancient Ecosystems from the Baisakhi Formation of Jaisalmer Basin, Rajasthan, India

ANSHUL HARSH[1]*, Jai Narain Vyas University, Jodhpur, Rajasthan, India
(anshulharsh11295@gmail.com)

Abstract

The ichnospecies *Glossifungites* is describes from the coastal plain distributary deposition of the upper Jurassic sedimentary sequence of the Lanela Member of the Baisakhi Formation, Jaisalmer basin, India. This trace fossil is restricted to a single stratigraphic horizon and constitutes a typical firmground ichnoassemblage of the *Glossifungites* ichnofacies. This abstract delves into the allure of *Glossifungites*, exploring its significance as a trace fossil and bioglyphs the valuable insights it provides into the behaviors of long-extinct organisms. *Glossifungites* trace fossils, characterized by the presence of scratch imprints, passive fill, a tongue-shaped structure, and distinct morphological features, represent enigmatic biogenic structures. *Glossifungites* serves as a geological canvas, portraying the subtle nuances of burrowing and tunneling activities that once shaped the sub-surface landscapes. Well-preserved specimens have been recovered from the whitish to brownish medium to fine-grained ferruginous sandstone of Lanela scarp section. These *Glossifungites saxicava* and *Glossifungites gingrasi* trace fossils bearing Lanela Member is located near Kathodi village about 72 km away from Jaisalmer city. The producer have been identified as suspension filter-feeding, possibly crustaceans like animal, probably mayfly burrows which supports the assertion that burrowing mayflies traces. The *Glossifungites* provides a way to distinguish bioturbation by marine-recruited fauna from that produced by freshwater fauna in the rock record. The trace fossils represent an environmentally stressed benthic community in a marginal marine setting. Based on the *Glossifungites saxicava*, *Glossifungites gingrasi* and associated trace fossils assemblages, this study suggests fresh water shallow marine environments for the Lanela Member of the Baisakhi Formation.

Miocene vertebrates of Kutch, Gujarat, India: An implication on Indian-Asian post collision faunal diversification and paleobiogeography

Kongrailatpam Milankumar SHARMA[1]*, Department of Geology, Central University of South Bihar, Gaya, India (milankumar.sharma@gmail.com)
Nongmaithem Amardas Singh[2], Department of Geology, Central University of Punjab, Bathinda, India
Rajeev Patnaik[3], Department of Geology, Panjab University, Chandigarh, India
Ningthoujam Premjit Singh[4], Biostratigraphic Division, Wadia Institute of Himalayan Geology, Dehradun

Abstract

Globally, Miocene time is significant for its intense tectonism as a continuation of collision tectonic of Indian and Asian plate taken placed during the Eocene time. These events and subsequent tectonism are considered to be associated with changes in climate, geodynamic shifting of Indian-Asian-African plate and changes in resultant paleogeographic set up such as the upheaval of the mighty Himalaya, formation of Landbridge between Africa and Eurasia., migration and diversification of fauna, etc. The Miocene deposits of Kutch are divisible into three formations namely Early Miocene Khari Nadi Formation, Middle Miocene Chhasra Formation and Late Miocene Sandhan Formation. These deposits are known for its diverse assemblage of vertebrates including fishes, reptiles, lizards, amphibian and mammals. The present paper tries to discuss the paleobiogeographic significance of Miocene vertebrates from Kutch and its correlation with those of correlatable formations. These deposits are also known for its diverse assemblage of vertebrates including fishes, reptiles, lizards, amphibian and mammals. The early Miocene Khari Nadi Formation of Kutch yielded fossil fishes (Chondrichthyes and Osteichthyes), reptiles (tomistomid crocodiles) and mammals (Deinotherium sp., Gomphotheriidae indet. and Brachypotherium sp.). Certain chondrichthyan and osteichthyan fishes, reptiles (Lizard, Snake and Crocodiles) and mammals, etc. were reported from the middle Miocene Chhasra Formation of Palasava locality. Piscean (chondrichthyan and osteichthyan) remains such as Carcharhinus brevipinna, C. falciformis, C. cf. leucas, C. aff. perezi, Carcharhinus sp., Negaprion sp., Aetobatus sp., Myliobatis sp., Dasyatis probsti, D. rugosa, Himantura menoni, Pastinachus sp., and Taeniurops sp., teleost of the families Bagridae, Channidae, Characidae and Cyprinidae, and mammals such as Sanitherium, Sivameryx, Brachypotherium, Zygolophodon, Gomphotherium, and Deinotherium are known from Palasava sites. The late Miocene Sandhan Formation of Tapar locality also yield certain mega-mammals (Deinotherium, Gomphotherium, Listrodon, Zygolophodonts, etc) and micromammals assemblages, reptiles, amphibians, lizards, etc. and elasmobranch such as Myliobatis, Aetobatis, Dasyatis, Pastinachus, Himantura and Pristis, etc. The early Miocene elasmobranchs from Kutch shows close affinities with those from Mediterranean Sea suggesting a well connection of Tethyan seaway passages till the early Aquitanian and the presence of the remnant waterbody connecting the Mediterranean Sea and Indo-Pacific. Similarly, in the Indian Ocean region Miocene fauna of Kutch shows close similarity

with those of Baripada Beds, Orissa, Bhuban Formation of Mizoram, Gogha Coast, Piram Island and Madagascar. A short-lived reopening of the marine pathway between Indian and Mediterranean Sea is suggested by the good similarity index of Middle Miocene elasmobranch comparing with their counterparts in the Mediterranean Sea. However, a much higher faunal affinity with those of Eastern Pacific indicates a gradual shift in migration path through the Pacific Ocean to Indo-Pacific region after the permanent Landbridge was formed. A closer affinity of late Miocene terrestrial mammalian fauna of Kutch with those of Africa, Europe and Indo-Pakistan may be due to Miocene dispersal across the ‘Gomphotherium Landbridge’.

Discovery of the *Fictovichnus from the Fatehgarh Formation of Barmer Basin from India*

PAWAN KUMAR[1]*, Jai Narain Vyas University, jodhpur, rajasthan, india (pawanvaishnav932@gmail.com)

Abstract

The Cretaceous deposits within the Fatehgarh Formation of the Barmer Basin, Fatehgarh, are composed of calcareous to ferruginous sandstone, wherein two distinct ichnospecies of insect trace fossils were found: *Fictovichnus gobiensis* and *Fictovichnus aragon*. *Fictovichnus gobiensis*, are 18-30 mm in length and 8-10 mm in width, presenting ellipsoid casts with a smooth surface. One end is rounded, whereas a truncated tunnel protrudes from opposite end. *Fictovichnus aragon* exhibits a rounded end on one side and a pointed end on the other, with dimensions of 9-20 mm length and 6-10 mm width. The study area is located near the Sandha village, which lies about 15km from Fatehgarh. This trace fossil is reposited in two stratigraphic horizon and constitutes a typical firmground ichnoassemblage of the *Fictovichnus* facies. These both species are deposited in a gregarious nature parallel to the horizon. Well-preserved specimens have been recovered from the yellowish to brownish medium to fine-grained ferruginous sandstone of sandha village section. Possible producers of *Fictovichnus gobiensis* are coleopterans, whereas *Fictovichnus aragon* was probably produced by pompilid or sphecid wasps. In the contact with the matrix, specimens show micritic layers, interpreted as the remains of the original silky wall constructed by the wasp larva In both ichnospecies. Based on presence of the *Fictovichnus gobiensis*, *Fictovichnus aragon* and associated trace fossil assemblages, this study proposes continental shallow marine environments for the Sandha Section of the Fatehgarh Formation.

Microconchid-cement reefs from the Visean of Belgium

Jeong-Hyun LEE[1]*, Chungnam National University (jeonghyunlee@cnu.ac.kr)
Jaegab Seol[2], Department of Geological Sciences, Chungnam National University
Mar Simonet Roda[3], Research Institute of Natural Sciences, Chungnam National University
Juwan Jeon[4], The Institute of Basic Science, Korea University

Abstract

Microconchids are a type of problematic tubeworm that flourished from the Ordovician to the Jurassic. Reefs formed by microconchids have been rarely described, as these organisms were more commonly secondary framework builders within microbialites from the Devonian to the Triassic. In this paper, we describe microconchid-cement reefs from the Anhée Formation (Upper Visean), southern Belgium. The reef appears as small domes, approximately 20 cm in diameter, within the middle of the Anhée Formation at the top of 4th-order parasequences. The reef is composed of microconchids encased in a few-millimeter-thick layer of isopachous fibrous cements, creating an overall branching, clotted-like fabric. Although various corals, brachiopods, trilobites, and molluscs have been identified in the formation, they are absent from the reef, with the exception of rare bivalves and foraminifera, which are also encased in cements. Surrounding the microconchids and enclosed by cements, minor peloidal to clotted micrite is observed. The spaces between the cement layers, which can be up to a few centimeters wide, are filled with micrite, peloidal packstone, and cement. It is inferred that these microconchid-cement reefs likely flourished at times when other benthic animals struggled to survive. The extensive precipitation of abiotic cement during the Carboniferous would have contributed significantly to supporting the overall structure of the reef.

PERSEPHONE – Autonomous Exploration and Extraction of Deep Mineral Deposits

Marko KOMAC[1]*, INTRAW (m.komac@telemach.net)
Vitor Correia[2], INTRAW
Eberhard W. Falck[3], INTRAW
George Nikolakopoulos[4], Lulea Tekniska Universitet

Abstract

The continuous effort and increased demand of the raw materials are directing mining companies to excavate minerals at greater depths, especially in Europe, where shallow-seated deposits have either been depleted, are non-economic to exploit, or represent environmental protection and societal obstacles. This trend is challenging the current mining operations and the existing traditional technologies towards the objective to retain profitability, while achieving the latest Green Deal environmental vision and securing workers safety. A key enabler, to address these challenges and to foster a sustainable development of the mining industry, is the development and deployment of innovative technologies for resource efficient extraction of mineral raw materials in the EU, as well as near-mine exploration for critical raw materials in currently not extracted ore bodies at existing or in closed or abandoned mines.

PERSEPHONE, a 3-year project funded by the EU, is addressing these challenges by developing pioneering technologies that push the limits of the EU mining industry. This includes autonomous and integrated near mine exploration capabilities to access deep deposits of critical raw materials in hard-to-reach deep occurrences and in abandoned mines. The overall concept and vision of PERSEPHONE aims to reduce the size of mining machines, which are currently adapted to the human scale, and to embed risk-aware, autonomous navigation of machinery and full digitalisation of the extraction process by digital twin creation. The key enabling technologies are expected to be validated at TRL 5. Additionally, the project is introducing novel approaches to on-line near-mine exploration core analysis and overall integration of at face data gathering and analytics to steer the mine development. Thus, it helps to foster the Green Transition by targeted extraction and reduction of waste generated from deep mining operations. The vision is a low-visibility and low-impact mine with near-zero human presence in highly hazardous areas.

The overall goal of PERSEPHONE is to digitalise and automate the extractive value-chain by creating energy-efficient autonomous drilling machines with advanced perception capabilities for navigation, face-drilling, core extraction, and at the face geochemical analytics. The digitalisation will enable a data-driven digital twin creation and geological modelling as means of enhanced decision support and optimal extraction planning. In turn this will enable near real-time assessment of resources and reserves to aid more realistic financial and investment decision making.

Gallium distribution and enrichment in skarn iron deposits: Insights from the Zhuchong deposit, Eastern China

Wang FANGYUE[1]*, Hefei University of Technology (fywang@hfut.edu.cn)
Liang Xian[2], Hefei University of Technology
Zhang Long[3], Hefei University of Technology

Abstract

Global gallium (Ga) is mainly mined from bauxite deposits and sediment-hosted zinc deposits, but rarely from skarn deposits. The Middle-Lower Yangtze River Valley Metallogenic Belt (MLYB), eastern China, is an important skarn iron ore producer, where skarn iron deposits are often associated with critical metals such as Ga and Co. The Zhuchong iron deposit is a typical high-grade skarn iron deposit with Ga enrichment in this belt. This deposit contains 50 Mt Fe ore @ 50.1%, and ~ 1718t Ga metal with an average grade of 33.62 g/t. However, the distribution and enrichment mechanism of Ga in this deposit remain unclear. Our study indicates that the Ga at Zhuchong is mainly enriched in the magnetite ore layer with Ga concentrations of 39.1~70.9 ppm (Avg. = 54.4 ppm). The average Ga contents in hydrothermal minerals, from the highest to the lowest, are as follows: epidote (121.9 ppm), magnetite (71.9 ppm), garnet (33.2 ppm), diopside (8.70 ppm), sphalerite (4.52 ppm), chalcopyrite (1.01 ppm), pyrrhotite (0.38 ppm), and pyrite (0.04 ppm). Whole-rock chemical mass balance calculations suggest that magnetite is the predominant mineral hosting gallium within the Zhuchong deposits. Magnetite can be categorized into three types: massive magnetite within magnetite ore (57.2-140 ppm, average = 88.7 ppm) > disseminated magnetite in skarn (10.7-62.6 ppm, average = 24.4 ppm) > veinlet magnetite in altered diorite (7.58-27.3 ppm, average = 20.9 ppm). This study indicates that the dominant substitution mechanism for the incorporation of Ga into magnetite is $Ga^{3+} \leftrightarrow Fe^{3+}$, and that the enrichment of Ga in magnetite at Zhuchong is mianly controlled by temperatures. During the development of the skarn iron deposit, it is crucial to focus on investigating the gallium (Ga) occurrence within magnetite, as this insight will enable the maximization of resource utilization.

Carbonatites and their potentiality for Niobium mineralisation in Central block of eastern Ambadungar: Indicated Resource for critical mineral

Prabhakar LAKRA[1]*, Geological Survey of India (prabhakar.lakra1@gsi.gov.in)
Bijay Kumar DAS[2], Geological Survey of India
Shilpa P Mandlik[3], Geological Survey of India
Sudhangsu Sekhar Dutta[4], Geological Survey of India

Abstract

The Ambadungar Carbonatite Complex (ADCC) forms a part of large alkaline sub provinces in Deccan Flood Basalt Provinces, Gujarat, India. The ADCC comprises different variant of carbonatites like, carbonatite breccia, calico-carbonatite, ferro- carbonatite, siliceous carbonatite and fenites. Worldwide carbonaitite are well known for potential source of REE mineralisation. In the ADCC, REE bearing variants of carbonatite also contains appreciable amount of rare metals (Niobium) which have received considerable attention in view of its vital importance and military applications. During field season 2021-22 for the first time GSI has successfully encountered carbonatites beneath the basalt of Deccan Traps at a vertical depth of 85 m and established indicated resources in the central block of eastern Ambadungar Carbonatite Complex for Niobium @ 0.02% cutoff grade. Based on the subsurface exploration work and analytical results of core samples, PCS samples, petrological samples, XRD and EPMA studies resource was finalized. All the ten vertical boreholes intersected carbonatite zone with niobium mineralisation in the central block of eastern Ambadungar area during this exploration activity. The resource was estimated for niobium minerals by extended area, LVS and cross section method at 0.02%cut off is 81 MT with average grade of 0.05% in the above block.The objective of this paper is necessarily brief owing with the established resources for Niobium beneath the Deccan Traps of ADCC in the state of Gujarat under critical mineral commodities.

FUTURAM: Developing methodologies for mining waste characterisation

Anna LADENBERGER[1]*, Geological Survey of Sweden (anna.ladenberger@sgu.se)
Ronald Arvidsson[2], Geological Survey of Sweden
Roger Hamberg[3], Geological Survey of Sweden
Stefan Sädbom[4], Lovisagruvan AB
Teemu Karlsson[5], GTK
Tero Korhonen[6], GTK
Erik Ronne[7], Boliden
Björn Wiberg[8], Geological Survey of Sweden
Christina NYSTEN[9], Geological Survey of Sweden
Per NYSTEN[10], Geological Survey of Sweden

Abstract

FUTURAM is a HORIZON EUROPE Research and Innovation project and one of its main objectives is to map the supply of Critical Raw Materials (CRM) obtained from recycling of six waste streams: batteries, electrical and electronic equipment, vehicles, mining waste, slag and ash, and construction and demolition waste. The project has 29 partners from 11 countries, encompassing geological surveys, universities, NGOs and research institutes as well as industrial partners.

Majority of the data required to understand effective management of raw material supply is available, but scattered amongst a variety of institutions, including government agencies, universities, think tanks, and industry, and need to be harmonised to be fit for use in Secondary Raw Materials (SRM) availability assessment.

FutuRaM aims to build state-of-the-art methodologies and harmonised datasets for mining waste initiated by the ProSUM and ORAMA projects and now with improved data from national and research projects. Furthermore, improvements in reporting practices are developed to communicate the viability of SRM recovery projects based on the United Nations Framework Classification for Resources (UNFC). FutuRam also considers economic, technological, geopolitical, regulatory, social, and environmental factors to further facilitate the future SRM recovery projects.

FutuRaM has an ambition to integrate SRM and CRM data available in the six waste streams to model current stocks and flows of the major CRMs. This is then utilized for scenarios of potential availability of future CRMs.

Mining waste case studies of tailings and waste piles have been chosen in Sweden, Finland, Serbia and France. Case studies of mining waste characterization have been designed to provide methodologies for stock and flow assessments, such as exploration techniques, waste characterization, waste processing and extraction technologies. recoverability processes, stakeholder interactions and even policy legislation. Site-specific case studies are also used to test the applicability of the UNFC methodology approach.

In Sweden, tailings in Laisvall, Adak and Kristineberg mines were drilled in the autumn 2022. The

sample aliquots have been sent for chemical analyses and SEM-based automated mineralogy was performed with help of QEMSCAN technique.
The waste piles in Håkansboda historical cobalt mine were sampled in the spring 2023. The randomly collected rock chips were sent as a series of bulk samples for chemical analyses and in situ mineral composition of the selected rock types was carried out with the microprobe. A larger, ca 100 kg composite sample was used for beneficiation tests at Geological Survey of Finland.
Preliminary results from tailings indicate that very high primary commodity contents (e.g., Cu, Pb and Zn) in tailings do not guarantee high amounts of associated trace metals identified as CRMs, e.g., In, Ge or Ga. At Håkansboda historical mine, the spatial distribution of metal high concentrations is heterogeneous and high metal concentrations can be found in the neighborhood of very low contents. This implies that pre-requisite knowledge of the primary ore composition and genesis may help to target the right waste sites for recovery projects as well as the detailed surveys are necessary to adequately evaluate the mineral potential and economic value of the waste.

Geochemical characterization of Rare Earth Elements and Rare Metal Potentials, Neoproterozoic, Peralkaline rhyolite of Malani Igneous Suite, Jodhpur, District, Rajasthan

Mukesh Kumar MISHRA[1]*, Geological Survey of India (mukesh.mishra@gsi.gov.in)
Mukesh Kumar Mandal[2], Geological Survey of India
Bijan Jyoti Barman[3], Geological Survey of India
Rohan Das[4], Geological Survey of India

Abstract

Geochemical characterization of Rare Earth Elements and Rare Metal Potentials, Neoproterozoic, Peralkaline rhyolite of Malani Igneous Suite, Jodhpur, District, Rajasthan

The acidic volcanic rock exposedin and around Tena village of Jodhpur district Western Rajasthan is considered as a part of Malani Igneous Suite of Neoproterozoic Age has resulted in enrichment of Rare Earth Elements (REE) and Rare Metal (RM).The analytical result of core samples and bed rock samplesshow encouragingvalue of total REE ranging from 2636 ppm to 5445 ppm with the mean value 3893 ppm, and rare metal such as Nb and Y. The maximum value of Nb is 605 ppm and Y 1231 ppm.The main REE bearing mineral phases hosted by acid volcanics are bastanesite, REE bearing ilmenite (titanium oxides), britholite (phosphate), parisite (carbonate), monazite (phosphate) and allanite (silicates).

The peralkalinefelsic volcanic magmatism predominantly contains a pink and grey coloured rhyolite, with a calc-alkaline affinity. The rhyolite showaphinitic to porphyritic texture and contains an assemblage mainly of glass and phenocryst of k-feldspar, quartz, hornblende and biotite. Sericite, muscovite and epidote is present as secondary mineral and allanite, zircon and apatite occur as accessory minerals. The opaque minerals (hematite and magnetite) are abundant. The inverse correlation of major oxides, especially CaO, Fe2O3, TiO2, Al2O3 and MgO against SiO2 suggest a magmatic differentiation of the parental melt. Whereas, alkalies K2O and P2O5 shows scattered trend against SiO2, probably suggesting the mobile nature of potash may be due to post-crystallization processes / fluid activity in the area. The chondrite normalized Rare Earth Elements (REE) patterns exhibits the highly fractionated LREE and nearly flat HREE and distinctive negative Eu anomaly. Spidergrams show similar peaks in which Nb negative Pb positive and Ti negative anomalies are observed. All these trace elements characteristics indicate feldspars, titano-magnetite and apatite fractionation and influence of some crustal component in these studied rocks.

Unlocking the Exploration Potential of Critical Minerals in South Korea

Robert SMILLIE[1], Iondrive Ltd
Manuel Knorsch[2], RSC Ltd
Andrew Kim[3]*, Korea Metal Resources (andrew.kim@kmres.co.kr)
Hyosang Kim[4], Korea Metal Resources
John Ju[5], Korea Metal Resources
Michael Gazley[6], RSC Ltd

Abstract

Southern Korea is commonly considered “resources poor” in contrast to the northern Korean Peninsula. Recent and ongoing exploration by ASX-listed junior explorer Iondrive Ltd (ION), leveraging published South Korean government research and regional data sets, is rapidly changing this long-held view. A minerals system approach across the whole country narrowed down the most prospective areas following a review of the tectonic history, geology, structures, academic papers, government reports from the Korea Institute of Geoscience and Mining (KIGAM), geochemistry, geophysics, radiometrics, and historical mining activities. Focus was set on narrowing down the search space for REE carbonatite and alkaline intrusions and LCT pegmatite mineralisation. Two of the high priority projects are described below, with the Li project now under Joint Venture with KoBold Metals Ltd.

The Hongcheon carbonatite is the only mineralised carbonatite described in South Korea. The Hongcheon REE carbonatite dykes are 20–50 m wide, ~2,500 m long, and intrude Precambrian basement gneiss along the deep-seated Hongcheon Fault (Kim et al., 2016). The area surrounding the Hongcheon carbonatite along the Hongcheon Fault is highly prospective due to the presence of Th and magnetic anomalies, fenite alteration in outcrop along the Hongcheon river, continuity of the Hongcheon Fault, and sparse outcrop. SAU recently discovered mineralised REE carbonatite and ironstones within its licence areas along strike of the Hongcheon Fault up to ~6 km south of the known Hongcheon deposit.

LCT pegmatites at the Boam mine were mined for Li from 1945–1963. Analogous the Hongcheon carbonatite, the vicinity around the Boam Li mine is underexplored and further outcropping pegmatites within SAUs application licences (bordering the mine) were not analysed for their LCT affinity. The Uljin pegmatite swarms at Boam contain lepidolite and spodumene and intrude the Cambrian Janggun Limestone Formation (Choi et al., 2014). Iondrive's exploration licence applications cover metasediments including widespread amphibole gneiss surrounding the Boam Li mine, which are a favourable host rocks for LCT pegmatites. Further, the local Tonggo Granite is a fertile granite for producing Li mineralisation due to its low K/Rb (36.6) and Nb/Ta (2.6) ratios (Oh et al., 2022).

These two underexplored areas signify the immense REE, Li and other critical minerals potential

in South Korea and with further exploration the potential for securing new sources of future facing commodities.

Kaisheng Xia[4], Faculty of Materials Science and Chemistry, China University of Geosciences, Wuhan430078, China
Zhen Yang[5], State Key Laboratory of Geological Processes and Mineral Resources, University of Geosciences, Wuhan430074, China
Qishun Fan[6], Qinghai Institute of Salt Lakes, Chinese Academy of Sciences, Xining810008 China

Abstract

Current lithium (Li) salts are produced dominantly from brines in the world due to the low cost of extraction, therefore, the brine Li resource exploration and development are favored by investors. The lowest industrial usage level of Li in brine is 50 mg/L in China. In order to explore more Li-rich brine resources, it is significant to do further research on the types and characteristics of reservoirs, ore-forming conditions and enrichment mechanisms of the brine Li deposits. Up to now, there are already determined four types of brine Li deposits in China, that is, modern salt-lake brine type, confined underground brine type, oilfield brine type, and finally geothermal brine type. The first type predominates in both Li reserves and Li contents, and their reserves have been basically verified, nevertheless the latter three types are explored and appraised in a lower degree. The second and third types are sometimes considered as one thing, and the second type is relatively more deserved to explore in the future. Modern salt-lake brine deposits are nearly distributed on Qinghai-Tibet Plateau, including Qarhan, Taijinaier and Yiliping salt lakes in Qaidam Basin, and Zabuye salt lake in northern Tibet etc. The first-type brine Li deposits were formed by the similar conditions and mechanisms: dry climate, replenishment of hot & warm spring waters that usually have a high Li content of n mg/L, and sustained evaporation in the Plateau environment. In many large-scale evaporite-bearing basins in China, such as Tarim, Qaidam, Sichuan and Jianghan basins, the waters separated from oil-water mixture fluids stored in pre-Quaternary strata usually contain some levels of Li, usually equal to or lower than 50-100 mg/L. On the other hand, the pure brines of confined aquifers in the petroleum-bearing strata or the no-petroleum basins contain relatively higher Li contents. Li in brines may be derived from interaction between the subsurface brine and the basalt/mudstone at temperatures of >120°C in the basins. The enrichment processes of Li in brines include: 1) brine evaporation in salt lake; 2) long time interaction between connate water and wall rocks in deep strata; 3) interaction of secondary brines (formed by atmospheric deep-circulation water dissolving ancient salt rock) with wall rocks having abnormal high Li background.

Shahrokh Rajabpour[5], University of concepcion, Chile

Abstract

The world-class Angouran non-sulfide-sulfide Zn-Pb deposit is a significant zinc resource in Iran, situated in the Takab metallurgical province in northwestern Iran. The deposit contains verified and estimated pre-mining resources comprising 7.2 *million tonnes of sulfide ore with grades of* 21.08% *Zn*, 2.1% *Pb, and* 110 *g/t Ag, and* 17.4 *million tonnes of oxidized carbonate ores with compositions of* 22% *Zn and* 4.6% *Pb. This deposit is hosted within Late-Precambrian to Cambrian schists and metamorphosed carbonate rocks, overlain unconformably by a Neogene volcanic and sedimentary sequence. In this region, the Precambrian basement and the subsequent young Mio-Pliocene magmatism play a crucial role in controlling the metallogeny of Zn-Pb, Au, and Fe polymetallic mineralization. New La-ICP-MS analysis on different generations of sphalerite and galena, reveals notable discrepancies in the concentrations of some critical elements such as cadmium, germanium, gallium, cobalt, and indium among the different generations. Particularly, the early stage of sulfides displays significant levels of these elements, distinct from the subsequent generations. Moreover, the average concentrations of silver and stibnite within the galena are notably high, reaching* 678.56 *and* 884.52 *ppm, respectively. The geochemical variations in critical elements between the first stage of sulfides and the subsequent stages represent compelling evidence for their distinct origins.*

The Critical Metal Potential of Pb-Zn Deposits in the Canning Basin: A case study of Goongewa, Lennard Shelf

Jenna McGovern[1]*, University of Queensland (jenna.hoy@uq.edu.au)
Steven Micklethwaite[2], Sustainable Minerals Institute, University of Queensland
Karen Connors[3], Sustainable Minerals Institute, University of Queensland
Gregory Webb[4], School of Environment, University of Queensland

Abstract

The global demand for the metals germanium (Ge) and gallium (Ga) has skyrocketed in recent years, leading to them being classified as critical metals. Despite the high demand and growing number of uses for these rare metals, an understanding on where and how Ga- and Ge- endowed deposits form is still relatively poor.

The Canning Basin in Western Australia is host to several known carbonate-hosted Pb-Zn deposits, which are thought to have formed at low (70°-110°C) temperatures, during compaction-related fluid mobilisation along structures such as fault zones. These deposits share characteristics with Mississippi Valley-Type (MVT) Pb-Zn deposits, and they have been previously classified as such. In other parts of the world, low temperature sphalerite in 'MVT'-like settings has been linked to enrichments in metals such as gallium and germanium, as well as indium (In). Though, no such analyses have been published on the base metal deposits in the Canning Basin (Lennard Shelf region or the Admiral Bay deposit).

Based on the above research gap, this study first documents the Ga and Ge content of samples from the Goongewa Deposit on the Lennard Shelf, then investigates the geochemical controls and mineralogical hosts influencing the concentration of critical metals. Several deposits within the Lennard Shelf have already been mined, but the waste material left behind could contain significant enrichments in these metals. It was found that at least one particular generation of sphalerite contained significant Ga enrichments. This presentation will present these findings and their implications for critical metal exploration in the wider Canning Basin and discuss the potential for trace metal associations to be used as a vectoring tool in similar geological settings, under cover and at depth. We will also examine the genetic drivers of metal enrichment in this under-studied, critical metal endowed region.

ECONOMIC COOPERATION BETWEEN SOUTH KOREA AND UZBEKISTAN ON CRITICAL METALS.

NAVRUZBEK JAHONGIR UGLI JURABEKOV[1]*, UNIVERSITY OF GEOLOGICAL SCIENCES (n.jakhangirovich@gmail.com)
Arofat Baxtiyarovna Xaydarova[2], UNIVERSITY OF GEOLOGICAL SCIENCES

Abstract

South Korea and Uzbekistan can develop economic cooperation in the field of critical metals. Critical metals are key elements for the production of various high-tech products, including electronics, automobiles, energy systems and drones. Both of these States have significant reserves of some critically important metals, and their cooperation can be mutually beneficial.

Uzbekistan is one of the world's largest gold producers, and also has resources of rare earth metals such as neodymium used in the production of high-power magnets. South Korea, on the other hand, is one of the leading manufacturers of semiconductors and electronics in the world and requires supplies of critical metals for its industry.

Within the framework of economic cooperation between South Korea and Uzbekistan, it is possible to conclude long-term agreements on the supply of critical metals. South Korean companies can invest in the development of Uzbek deposits and technological processes for the extraction and processing of these metals. In turn, Uzbekistan can gain access to new technologies and South Korean experience in the production and use of critical metals.

Such cooperation can contribute to the diversification of Uzbekistan's economy and promote its industrialization and modernization. It will also allow South Korea to ensure a stable supply of critical metals for its industry.

However, successful cooperation requires good infrastructure, legal and financial support, as well as the establishment of reliable trade relations and protection of investors' rights. The development of these aspects may be key to the successful implementation of the partnership between South Korea and Uzbekistan in the field of critical metals.

Phoscorite as a possible source for phosphate and REE: A first report from Chaitma Alkaline Province, Korba district, Chhattisgarh.

NIBIN G TOM[1]*, GEOLOGICAL SURVEY OF INDIA (nibintom80@gmail.com)
TAPAN MOHARANA[2], GEOLOGICAL SURVEY OF INDIA

Abstract

Phoscorite is an exotic ultramafic rock that could serve as a repository for magmatic phosphate and rare metals, usually in association with REE-bearing carbonatites. The Chaitma Alkaline Province is a WNW-ESE trending tectonic domain in the southern part of Central Indian Tectonic Zone, hosting apatite diopside phoscorite (ADP) and syenite between Kadaihpara and Hathibari, Korba district, Chhattisgarh. The poly-deformed and poly-metamorphosed marginal terrain preserve granulite grade rocks and intrusive granitoids. Phoscorite-syenite and pyroxenite extend up to 1.5 km as discontinuous mapable units (250 m wide) in a vast expanse of hornblende granite and exhumed metamorphic rocks. A total of three compressional deformation episodes viz., D1 and D2 resulted in anatexis under amphibolite to granulite facies conditions. The mineral assemblage and reaction sequence indicate a clockwise P-T-t path, typical of collision orogen. The overall path was punctuated by underplating of magma manifested by sills/ dykes.

ADP is vari-textured and comprise of diopside, apatite (11 to 22%), actinolite, epidote, allanite, sphene, zircon and xenocrystic garnet. Biotite is developed along profuse mingling domain with syenite veins. Primary apatite is intercumulus to augite. Allanite-Ce, britholite-Ce, bastnasite-Ce, parasite-Ce and synchisite-Ce form moat around apatite; veins traversing plagioclase, actinolite and inclusion in biotite. Metamict zones are associated with higher modal biotite occurrence. Generally, phoscorite is intrinsically associated with carbonatites and syenite as reported around the world. In case of Chaitma, carbonatites are not associated. However, calcite occur in interstices associated with syenite veins.

High concentration of P2O5 (up to 5.2%), Ba (0.7%; RBa-tREO:0.61), Sr (0.5%) and REO (up to 0.5% tREO) are reported in bedrock samples of Chaitma phoscorite. Chaitma ADP also analyzed 1.86 to 11.62% MgO; 0.43 to 1.57% TiO2; 1.70 to 6.32% K2O; 5.53 to 16.73% CaO; [La/Sm]N range from 0.08 to 133.97 with a moderate negative Eu-anomaly. A total of 65 channel samples around Chaitma and Nunhapara yielded up to 0.3% tREO across 3m zone extending 400m. The phophatic zone assaying 4% over 2m marginally offsets the REO zones (R=0.40 to 0.57). Regolith samples (up to 1m) also analyzed 0.3% tREO (Max. 0.5%). Ore zones show coarse-grained phoscorite (diopside cumulate) with coarse needles of apatite (up to 3cm long), epidote and sphene.

Chatima Phoscorite melts are either derived from upper mantle during D2 deformation that were subjected to mingling and/or melt hybridization over a protracted period by subsequent mantle and /or crustal melts, possibly leading to phosphate-REE-Ba-Sr enrichment. This ADP unit exposed along the southern CITZ could be explored as a new source for LREE and phosphates, similar to Koppal phoscorite, Dharwar Craton of Southern India and Beldih occurrence in Puruliya,

Singhbhum Craton in Eastern India.

Chaitma Phoscorite could be preferred to phosphorite explored in the Mesoproterozoic Chhattisgarh Basin, Central India in terms of grade enhancement and intrinsic value due to co-occurring REE. Further, apatite, LREE-phosphate and carbonates could also be targeted in regolith zones over phoscorite making it an attractive proposition.

The study of Critical Raw Materials in the Czech Geological Survey

Michal Poňavič[1], Czech Geological Survey
Anna VYMAZALOVA[2]*, Czech Geological Survey (anna.vymazalova@geology.cz)

Abstract

Like other European countries, the Czech Republic supports intensive research on Critical Raw Materials (CRM) through research projects. One example is the Ministry of the Environment's "Environment for Life" programme. Within this programme, the Czech Geological Survey is working on one of the most important research project: „SS02030023 Rock Environment and Natural Resources RENS“. This project is divided into four research themes: Mineral Resources, Karst Groundwater, Geologic Hazards-Ground Instabilities, and Geologic Hazards-Mine Subsidence Districts.

Research on mineral resources is focused on the study of CRM, i.e. ore and mineral raw materials that are or might be of economic importance for the Czech Republic or the EU. Among the raw materials being studied, fluorite, graphite, lithium, manganese, copper, nickel, uranium, tungsten, gold and feldspar are of particular importance for the Czech Republic. Potentially important are the rare earth elements and germanium.

The study is focused on the research of newly discovered occurrences in our territory, and on further investigation of mineralogical, geochemical, physical and chemical properties of raw materials and the technology of their processing.

The research of newly discovered types of mineralization is mainly focused on the search and identification of Au-W raw material sources in the Moldanubic area (mainly historical districts); the evaluation of occurrences of rare earth elements in heavy minerals; the study of CRM in skarn ores; and the study of Ni mineralization in mafic and ultramafic rocks.

An important part of the study is the verification of the basic parameters for technological treatment of CRM with a particular focus on production of minimum waste and the development of new, environmentally friendly and low-energy methods of their treatment. The attention is mainly focus on germanium, graphite, lithium, tungsten, REE and gold.

Financial support through the project „Rock Environment and Natural Resource (RENS)”, No SS02030023 from the state support of the Technological Agency of the Czech Republic (Environment for Life Programme) is gratefully acknowledged.

A review of China’s resources of lithium in coal seams

chao LIU[1]*, 01068999005 (1971076064@qq.com)
Zhao Ting[2], CAGS

Abstract

Lithium gains an increasing importance in new energy vehicles and stationary energy storage, and development and utilization of lithium mines has attracted great attention around the world. In addition to the traditional lithium resources,lithium resources in coal seams have great potential in industrial application. Therefore, how to develop and utilize them is strategically significant for guaranteeing supply of lithium resources in China and promoting clean energy transformation. This paper summarizes the metallogenic ages, occurrence,enrichment factors, availability of lithium resources in coal seams in China. Conclusion are obtained as follows. i. coal-hosted lithium deposits discovered in China so far mainly occur in the Carboniferous-Permian strata of North China.They are less concentrated in smaller range in the Permian strata ofQilian-Qinling. ii. In China, coal-hosted lithium is mainly enriched in aluminum-bearing minerals. Lithium in coal seams mainly occurs in the inorganic matter, and some occurs in the organic matter. iii. Lithium enrichment in coal seams is caused by stable supply of aluminum and lithium-bearing minerals and special structural and geological factors. iv. According to China’s national standards on grades of lithium content in coal seams, the metallogenic belts of lithium in coal seams at the southern foothill of Yin Shan and in Qilian-Qinling have the potential of lithium development and extraction, covering Junger mining area in Inner Mongolia, and Pingshuo and Ningwu mining areas in Shanxi.

New developments for minerals discovery in the 21st century

Sandra Occhipinti[1]*, Commonwealth Scientific and Industrial Research Organisation
(sandra.occhipinti@csiro.au)
Discovery Program[2], Commonwealth Scientific and Industrial Organisation

Abstract

The mineral resources industry faces numerous challenges, including uncovering new deposits and extracting metals from diminishing ore grades. The most significant hurdle is orchestrating a global energy transition and addressing climate change while balancing mineral discovery, supply, and demand. This balance shapes commodity prices, employment rates, and research and development prospects. The demand for lithium (Li), copper (Cu), nickel (Ni), and critical minerals has surged, emphasizing the need for prompt action. Challenges present opportunities for collaboration between mineral resources companies, universities, and organizations like Australia's CSIRO. Our team is dedicated to addressing the major challenge of securing sustainable energy and resources for future generations. Collaborating across industry, government, and academia, we apply fundamental research to solve sector-wide issues, leveraging multidisciplinary teams.

Harmonizing expertise across key geoscience fields, regolith, geophysics, geochemistry, mineral mapping, and mineral systems, our emphasis lies in delving into the scientific aspects of emerging advancements (representing the "R" in R&D). Over recent years, we have revamped the applications of this scientific knowledge and incorporated new technologies, including software and machine learning (ML) approaches (constituting the "D" in R&D). These technologies, whether released or under development, are being made universally accessible, reflecting our commitment to global benefit.

To find mineral deposits we need to define new areas of exploration interest. Applying innovative processing techniques for mapping depth-to-basement utilizing geophysical data, plays a crucial role in defining this for practical exploration. These models not only accelerate exploration programs but also furnish comprehensive crustal profiles and images of the Mohorovičić discontinuity (MOHO), offering valuable insights into crustal development and the identification of metal transport zones.

Our teams are leveraging new satellite systems for determining Rare Earth Elements (REE), lithium and nickel prospectivity through mineral mapping. We use ML to interpret results effectively, facilitating the translation of mineral maps into ore deposit vectoring tools. In Australia, we are developing techniques to analyze the distribution of critical minerals, like REE, in both modern and ancient landscapes for further resource discovery.

At CSIRO, we are advancing geochemistry techniques, employing indicator minerals, whole-rock analysis, and mineralogy to detect footprints leading to mineral deposits. Our innovative tools, such as Ultrafine+®, 'Indicator minerals for nickel' (IM4Ni), and ML applications for rapid mineralogy, enhance exploration. We recently introduced a novel approach to delivering lithology

intervals using downhole hyperspectral data (MyLoggerTM). Integrating these data with geophysics and petrophysics is crucial for building robust models that delineate mineral deposits. This presentation will provide examples of these R&D outputs and demonstrate CSIRO's focus to translating scientific advancements into accessible applications, particularly in decision support. We provide greater certainty in mineral exploration and enhance planning for future metal extraction processes, meeting the global mineral challenges through innovation, collaboration and new technological solutions.

The evolving potential of the Australian REE ecosystem

Ignacio Gonzalez-Alvarez[1]*, CSIRO (The Commonwealth Scientific and Industrial Research Organisation) (ignacio.gonzalez-alvarez@csiro.au)

Abstract

Population growth and technological progress in the last 50 years have increased global demand for mineral resources by 400%. The fluid geopolitical, energy and technology context has made Rare Earth Elements (REE) some of the most strategic mineral resources for the near future.

The global economic reserves of REE have been estimated at 120,000 kt. The largest reserves of REEs are located in China (37%), Vietnam (18%), Brazil (18%), Russia (10%), India (6%) and Australia (3%). Whereas, the actual production is dominated by China (63%), the USA (12%), Myanmar (10%) and Australia (9%). The demand for Dy and Nd, as examples, is projected to increase by >2600% and >700%, respectively, within the next 25 years.

Rare Earth Elements are not rare and are not from Earth. REE form by supernova nucleosynthesis, and the concentration in the upper continental crust and Post-Archean Australian Shale average values are ~150 ppm and ~185 ppm, respectively (excluding Sc and Y). In addition, common wisdom proclaims that REE are immobile under most surface processes, which has been widely proven incorrect. The challenge is not only about finding REE, but also about detecting these deposits in geopolitically favourable areas, with acceptable extraction and concentration costs, minimal environmental impact, and positive social engagement.

Rare Earth Elements deposits can be classified as those associated with (i) magmatic and hydrothermal events at high temperatures (High-T), or (ii) weathering and sedimentary processes at low temperatures (Low-T). Carbonatites are presently one of the most prospective host rocks among these deposit types. Although, ion-adsorption REE deposits are showing signs of soon becoming a significant global source of REE.

From the view of REE exploration, detecting the presence and reducing the uncertainty about where to look for REE-mineralized host rocks, sedimentary environments or weathered landscapes would be a significant step forward. Defining the mappable proxies for mineralization and identifying the most favourable geological (High-T REE deposits) or landscape settings (Low-T REE deposits) is a fundamental framework for which we do not yet have clear answers. How to recognize fertile signs, as well as a deposit's geochemical and geophysical footprint? For example, the small size of carbonatite outcrops and footprints (~3 km2) makes them a difficult target. In addition, the limited availability of regional datasets with appropriate data density makes data analytical techniques challenging in most regions. Effective targeting requires a data analytics approach – combining geometrical, spectral, lithological, geochemical, and geophysical data sets

with knowledge about landscape evolution.

New paradigms are needed. Australia's potential for new discoveries of Low- and High-T REE deposits is massive. With a continental scale, deeply weathered cover blanket overlying most of the surface, the possible latent amount of Low-T REE deposits is phenomenal. Australia has the ability to become a fundamental supplier of REE for most leading technology global domains. However, this will be determined by how Industry, Government Research Institutions, and Universities integrate their efforts, support the REE exploration industry, and facilitate discoveries within the Australian context, and globally through key international collaborations.

Discovery of Ion-Adsorption Rare Earth Element Deposits by Geochemical Exploration in Southwestern China

ZHOU JIAN[1]*, Institute of Geophysical and Geochemical Exploration, Chinese Academy of Geological Sciences (zhoujianbisword@126.com)

Abstract

Rare Earth Elements (REEs), especially Heavy Rare Earth Elements (HREEs), are essential for high-tech industries and modern society. Geochemical methods are used to explore and delineate the targets of HREE-enriched deposits. A total of 9 REE-enriched geochemical provinces were delineated throughout China by Mapping Chemical Earth Program-China Geochemical Baselines project. The targets with 3.5 of LREE/HREE, similar to the ion-adsorption HREE-enriched deposits discovered in South China, located in Honghe, Yunnan province, southwestern China, were selected for follow-up geochemical surveys at scales of 1:250 000 and 1:50 000. A giant ion-adsorbed REE deposit with an average REE grade of 0.14% has been discovered by a drilling program. The ore bodies hosted in regolith range in depth from 2 m to 13 m, which developed from the parent rocks of Indosinian and Yanshanian granites and Proterozoic gneiss and leptynite, and are distributed at gentle slope areas. This is the first discovery of ion-adsorption REE deposits containing LREE (La, Ce, Pr, and Nd) and HREE (Gd, Tb, Dy, and Y) with economic and scientific value in south Yunan, China. This finding shows that global-, regional- to local-scale geochemical surveys by using wide-spaced, low-density, and high-density sampling to provide high-quality data of 16 rare earth elements is a cost-effective method to delineate targets for ion-adsorption HREE deposits.

Detailed exploration targeting of LCT pegmatite deposits in the central-part of Rajasthan, India

Alok PORWAL[1]*, IIT Bombay (aporwal@iitb.ac.in)
Rajenderan Kalimuthu[2], NISER

Abstract

Given the recent surge in green technologies and battery metals, rare element LCT pegmatites play a crucial role in providing sustainable supplies of lithium (Kesler et al., 2012; Dill, 2015). As a result, these pegmatites are being explored and mined worldwide. Significant LCT pegmatite deposits, like those found in Tanco (Canada) and Greenbushes (Australia), hold valuable reserves of this metal (Partington et al., 1995; Steiner, 2019). Currently, new deposits are being explored globally. This study reports the results of a project-scale exploration targeting study for LCT pegmatites in the central part of Rajasthan, Western India. A project-scale mineralization model based on the field geological, petrological, geochemical and spectroscopic data was developed to identify the sources, pathways and the controls on the emplacement pegmatites. In addition to multivariate statistical techniques, Compositional Data Analysis techniques were applied to the geochemical data in order to identify the possible sources of the pegmatite fluids and also the vectors to lithium enriched zones within the LCT pegmatites. The study also explored the possible metallurgical techniques for extraction of lithium from lepidolite micas. The results helped in demarcation of the targets for exploratory drilling. This is the first study focused on systematic exploration of lithium bearing pegmatites in India.

A Preliminary Overview of the Metallogenetic Provinces of Southern Angola

Enrique Merino Martínez[1]*, Instituto Geológico y Minero de España (IGME-CISC)
(e.merino@igme.es)
Maria João Batista[2], Laboratório Nacional de Energia e Geologia (LNEG)
Iván Martín Méndez[3], Instituto Geológico y Minero de España (IGME-CISC)
Daniel de Oliveira[4], Laboratório Nacional de Energia e Geologia (LNEG)
MariCarmen Feria[5], UTE-PLANAGEO (IGME/LNEG/Impulso)
Carla Fortes[6], Laboratório Nacional de Energia e Geologia (LNEG)
Catia Prazeres[7], Laboratório Nacional de Energia e Geologia (LNEG)
José Luis García Lobón[8], Instituto Geológico y Minero de España (IGME-CISC)
Jose Manuel[9], Instituto Geologico de Angola (IGEO)

Abstract

The distinct mineralisations found in the Republic of Angola make it an area of significant interest due to its metallogenic potential. These occurrences often have a spatial distribution and form mineral associations related to specific geological areas and environments. However, given the growing global demand for mineral resources, it is crucial to comprehend a country's regional mining potential. This knowledge is essential for effective territorial planning and future exploration and research of its resources. For this reason, the Government of the Republic of Angola, through the Ministry of Natural Resources, Oil and Gas (MIREMPET) and the Geological Institute of Angola (IGEO), implemented the National Geological Plan of Angola (PLANAGEO, 2014-2022). The main aim of PLANAGEO was to establish a detailed and comprehensive geological framework, facilitating a thorough interpretation of the identified geophysical and geochemical anomalies, as well as the geological processes responsible for the recognised mineralisations.

The UTE PLANAGEO consortium, comprising the Geological and Mining Institute of Spain (IGME), the National Laboratory of Energy and Geology of Portugal (LNEG), and the Spanish company Impulso Industrial Alternativo (IIA), conducted numerous geological, geophysical, and geochemical mapping surveys in the southern region of the country, covering an area of around 480,000 km2. One of the most important results of the project was the Metallogenetic Map of Southern Angola at a scale of 1:1,000,000. This map provides a summary of the mineral resources of the country and proposes, for the first time, a preliminary approach to the distribution of metallogenetic provinces in the southern region of Angola. These regions are characterised by mineral resources of potential interest, clearly defined and associated with a geological context, that may or may not be genetically related.

The southern region of Angola comprises five major metallogenic provinces, with metallogenic eras ranging from the Neoarchaean to Cretaceous times: i) the metallogenetic province of Au-Fe, mainly related to BIF-type deposits; ii) the metallogenetic province of Cr-Ni-PGE, associated with distinct Proterozoic mafic to ultramafic bodies; iii) the polymetallic metallogenetic province of the Kunene Complex (KC); iv) the metallogenetic province of Cu, related to various hydrothermal

mineralisation events and the Copper Belt of the Lufilian Arc, covered by the Kalahari Basin; v) and the metallogenetic province of Nb-Ta-REE, represented by Cretaceous alkaline-carbonatite structures and selected granite pegmatite fields.
Hence, this work presents an assessment of the metallogenetic potential of the southern region of the Republic of Angola, discussing the various mineral resources within a regional geological context. Although this work focuses on mineral resources that involve natural processes of concentration and/or whose deposits represent an anomaly in the crust, it also includes the potential interest for the exploration of industrial rocks and minerals and ornamental rocks. The primary aim of the metallogenetic map is to offer fundamental knowledge for future mining research planning and to promote the socio-economic development of the country based on the sustainable use of its natural resources. This will favour intra- and inter-community trade relations and have a direct benefit on the economic development of the country.

Uranium Exploration targeting in the Mineral System Approach

Patrick LEDRU[1]*, University Lorraine (patrick.ledru@univ-lorraine.fr)

Abstract

As a High-Field Strength Element, uranium is present in a wide variety of deposit types. The extreme mobility of uranium in oxydizing conditions has strong control on mineralization distribution and preservation. Thus, the footprints are highly diversified and the application of ore deposit models often inappropriate as the genetic models may be unknown or poorly constrained. The mineral system provides an innovative approach that has already been documented on unconformity-related uranium deposits and can be generalized to other environments like sedimentary basins.

In order to explore mineral systems, critical elements for the source, the architecture, the energy source and the trap can be defined by identifying the significant geo-objects and processes, favorable ingredients and spatial proxi. For example, in unconformity-related deposits, the source geo-objects are radioelement-rich lithologies in the basement and the basin, brines and interaction between superficial and deep-source fluid being favorable ingredients while geochemical assessment of lithologies and fluid inclusion constitutes a proxi for targeting at the regional scale. The energy source is critical as fluid flow in inherited or reactivated permeable structures (the process) requires thermal and mechanical gradients that can be traced by fluid-rock interaction (the favorable ingredient), absolute and relative geochronology and detailed mineralogical and structural analysis defining the footprint (the spatial proxi).

The translation of these critical elements to an exploration strategy requires a multiscale approach using different methods of investigation: planning and reconnaissance exploration at the regional scale, follow-up and detailed exploration at the camp and prospect scales, advanced exploration at the deposit scale. In the case of sandstone-hosted uranium deposits, the knowledge of the hydrological and hydrogeological systems will be envisaged at an early stage at the regional and camp scale as it will condition the feasibility of in situ recovery in low-grade uranium enriched permeable strata. At the prospect and deposit scales, ore body delineation, resource estimation and monitoring of the water table will be requested for the valorization of resources into reserve following detailed and advanced exploration.

This systemic approach benefits directly of our ability to integrate in a stable georeferenced data system historical data, information resulting from a combined knowledge and data-driven project generation, geological, geophysical and geochemical datasets collected at all stages of exploration and geomodels processed on the fly. The concept of common/shared earth model aims at reconciling all data sets in 3D geometrical model in which the ore deposit and its properties are defined. Keeping in mind that the first evaluation of the critical elements and spatial proxies may be revised depending of the exploration results and that each new drill hole or geophysical model will reduce the uncertainty of this model is a paradigm shift for exploration. Recent recognition of the role of nuclear energy in in the energy mix has boosted uranium exploration project generation

and several case studies based on GIS-based prospectivity approaches and machine learning illustrate this approach.

Indonesian Critical Mineral and Energy Transition

Muhammad Wafid AGUNG NOVIANTO[1]*, Geological Agency, Ministry of Energy and Mineral Resources, the Republic of Indonesia (m.wafid@esdm.go.id)

Abstract

Indonesia stands at the forefront of addressing the surging global demand for critical minerals essential for diverse sectors such as defense, aerospace, and renewable energy. With abundant reserves of key minerals like nickel, bauxite, and copper, alongside the promising potential of natural hydrogen, Indonesia is strategically positioned to capitalize on this burgeoning demand. Through proactive measures aimed at fostering an investment-friendly ecosystem, such as the Critical Minerals Accelerator Initiative and strategic international collaborations, Indonesia is poised to emerge as a dominant force in the critical minerals market. These initiatives not only aim to boost economic growth and job creation but also underscore Indonesia's commitment to meeting global mineral demands sustainably.

Concurrently, Indonesia's Geological Agency is spearheading efforts to explore and harness green energy commodities crucial for the country's energy transition. By prioritizing the evaluation of resources like iron sand, manganese, natural hydrogen, and rare earth elements, the agency is dedicated to translating discoveries into optimized resource extraction. Through a multifaceted approach encompassing targeted exploration endeavors, synergistic partnerships with industry stakeholders, and the application of cutting-edge exploration methodologies, Indonesia is steadfast in its mission to fortify the resilience of its mineral and coal resources. These endeavors not only contribute to the nation's energy security but also align with broader global clean energy imperatives.

By investing in strategic initiatives, bolstering international partnerships, and prioritizing exploration and extraction optimization, Indonesia is charting a course towards becoming a global leader in critical minerals. These concerted efforts not only promise to stimulate job creation and economic prosperity but also reinforce Indonesia's standing as a key player in the global marketplace. As Indonesia navigates challenges such as supply chain vulnerabilities and technical complexities, its unwavering commitment to sustainable mineral resource management remains paramount, ensuring a prosperous and resilient future in the ever-evolving global landscape.

Geochemical vectors to LCT pegmatites: the compositional data analysis approach.

Bijal Chudasama[1]*, Geological Survey of Finland (bijal.chudasama@gtk.fi)

Abstract

Exploration of LCT (Lithium-Cesium-Tantalum)-pegmatites is challenging because of their non-distinctive signature in standard geophysical datasets such as airborne magnetics, electromagnetics and gravity. Geochemical data, therefore, is an important exploration dataset for targeting REE deposits related to LCT-pegmatites. These encompass elemental analysis of surface and/or bedrock samples using different analytical methods such as XRF, ICP-AES/MS. However, the multi-elemental analytical data obtained contains detections of elemental concentrations relative to each other. Hence, geochemical data is compositional in nature and therefore contains a constant sum constraint. Although, multivariate statistical analysis of analytical geochemistry data serves as an important tool for geochemical characterization of a region and subsequent identification of geochemical vectors; due to the compositional nature of geochemical data, there occur spurious correlation effects and negative bias relationships between the analyzed elemental concentrations. Hence standard statistical multivariate data analysis methods, based on assessing correlations in a Euclidean space fail to represent the true relations between the elements.

In this study, based on a large-scale whole rock geochemical data, we present a critique of conventional Euclidean distance, and recommend multivariate statistical analysis of whole compositions as well as sub-compositions associated with Li, Cs and Ta (a) in real space based on log-ratio-based transformed data obtained from compositional data procedures and (b) in simplex space using simplical metrics. Multivariate statistical methods based on log-ratio transformations and simplical metrics equitably map the proportionality relations of the compositions and sub-compositions in compositional datasets. Mathematical implications of the above procedures and their manifestation in the statistical results is deduced. Finally, the study identifies anomalies for geochemical characterization of (i) elements with respect to the host lithological units of LCT pegmatites and (ii) elemental signatures vectoring to LCT pegmatites, that have significance towards exploration of critical metals hosted in LCT pegmatites. The geochemical anomalies show correlations with regional structures, indicating underlying structural controls on pegmatite emplacement. This review and analysis have implications for LCT pegmatite exploration globally.

Critical-metal related alteration mineral mapping using hyperspectral data: A new approach using ensemble of Support Vector Machines and Extreme Value Theory

Sandeepan DHOUNDIYAL[1]*, Indian Institute of Technology Bombay (sdhoundiyal@iitb.ac.in)
Alok Porwal[2], Indian Institute of Technology Bombay

Abstract

Hyperspectral data have been instrumental in the identification and mapping of a wide variety of hydrothermal alteration minerals. However, despite their utility, the hyperspectral data remains underutilized due to the significant manual intervention necessary in traditional methods of analysis.

Recently, a variety of machine learning-based methods have been developed to map minerals from hyperspectral data. However, these methods are limited by the need for complex pre-processing or manual feature selection. Furthermore, these algorithms are designed for closed-set mineral identification, which assumes that only the classes seen during training would be encountered during testing/mapping. This is a significant limitation, as a classifier needs to accurately detect samples from previously unseen classes ('outliers') to both mitigate false positives and facilitate the detection of previously unreported minerals in an area.

Therefore, a novel method for identifying minerals from AVIRIS data under an open-set classification regime is proposed. The proposed algorithm then uses an ensemble of Support Vector Machine (SVM) classifiers, each trained over a random subset of fifteen AVIRIS bands, to identify alteration minerals under a closes-set regime. Thereafter, class-wise Weibull distributions (fitted over true positives from the validation set for which the ensemble had the least confidence) are used to predict the probability of an unknown spectrum belonging to an unknown class based on its average distance from the separating hyperplane (the decision boundary learnt by the SVMs).

This algorithm is tested over labelled spectra from the AVIRIS where it performed better than existing machine-learning methods for identifying minerals from hyperspectral data.

The pre-processing consists of (i) denoising; (ii) continuum removal; and (iii) l2-normalization. It facilitates

mineral identification by eliminating variance in the data due to illumination conditions and physical
factors (such as abundance and grain size) while enhancing compositional information.
In its current iteration, the trained model can identify a large variety of clay, silicates and carbonate
minerals (including but not limited to olivine, pyroxenes, phyllosilicates, carbonates, and sulfates), and can
be used to accurately map minerals from AVIRIS data. It may also be used to classify other hyperspectral
datasets.

Cassiterite trace element discrimination plots for critical mineral exploration

Avish Avnith KUMAR[1]*, James Cook University (avish.kumar@jcu.edu.au)
Ioan Sanislav[2], Economic Geology Research Centre, James Cook University
Huiqing Huang[3], Advanced Analytical Centre, James Cook University
Paul Dirks[4], Economic Geology Research Centre, James Cook University

Abstract

Cassiterite is a weathering-resistant mineral which can incorporate a variety of trace elements into its crystal structure. To differentiate cassiterite from different sources, trace element data were collected from seven tin fields worldwide. Laser ablation-inductively coupled plasma- mass spectrometry (LA-ICP-MS) was used to measure trace elements from twelve deposits in the Herberton Mineral Field, Australia. These results were combined with published data from six other tin fields, including the Andean Sn belt in South America; the Karagwe Ankole belt in Rwanda; and, from China, the Kangxiwa–Dahongliutan pegmatite field, the Youjiang basin, the Nanling belt and the Da Hinggan Range belt. These deposits in the dataset were categorized into four types: 1) greisen and veins; 2) skarns; 3) Li-Cs-Ta pegmatites; and 4) polymetallic veins. The trace element dataset was analysed using basic descriptive statistics, principal component analysis (PCA), and cluster analysis. Cassiterite grains from greisen and vein deposits are characterized by high concentrations of Ti (avg. 1751 ppm) and moderate concentrations of Al (avg. 97 ppm), whereas cassiterite grains from skarn deposits generally contain lower concentrations of Ti and Al. The cluster analysis allowed us to define compositional boundaries in the trace element dataset. These boundaries differentiate cassiterite grains from different sources. Relative enrichment of Al and Ti in cassiterite was observed in rocks altered by greisenization reactions. This is common in greisen and vein, and skarn deposits. Hence, the Ti vs. Al diagram can be used to differentiate cassiterite grains derived from greisen and vein, and skarn deposits. The Sb vs. V diagram was identified to be useful in differentiating cassiterite grains from polymetallic veins. Zirconium and Nb concentrations are useful in identifying cassiterite grains sourced from LCT pegmatite deposits. The discrimination diagrams developed in this study through cluster analyses indicated that cassiterite grains sourced from different deposit types can be differentiated based on their trace element geochemistry. Thus, cassiterite geochemistry (e.g., stream sampling) can be used in exploration to identify deposit types and provide insight into mineralization processes that are present in a region.

Regional-scale exploration targeting of Rare Earth Elements associated with carbonatite-alkaline complexes: a comprehensive prospectivity study in northwestern India

Malcolm Aranha[1]*, Oulu mining school, university of Oulu (malcolm.aranha@oulu.fi)

Abstract

Rare earth elements (REEs) are vital for future industrial growth and are found concentrated in rare igneous rocks called carbonatites, often associated with alkaline complexes. India hosts around 30 carbonatites, categorised into four domains based on their spatio-temporal and tectonic associations -– (1) Northwestern domain (Indo-Seychelles-Madagascar split and the passage of greater India over the Reunion hotspot, producing the Deccan LIP); (2) Northeastern (breakup of Greater India from Australia-Antarctica driven by the Kerguelen mantle plume that also produced the Rajmahal-Sylhet LIP); (3) Southern (comprising of two sub-domains – Paleoproterozoic sub-domain related to extension due to relaxation after the SGT-Dharwar accretion and the Neoproterozoic sub-domain related to the fragmentation of Rodinia); and (4) Southeastern domain (fragmentation of Columbia).

India's REE production mainly relies on secondary monazite-bearing beach placers, but the potential of sourcing REEs from carbonatite-alkaline complex-related deposits remains largely untapped. This study in India's Northwestern carbonatite domain utilises Fuzzy Inference Systems (FIS) and Self Organising Maps (SOM) to assess REE prospectivity. FIS, a supervised, knowledge-based AI technique, identified targeting criteria for REE deposits using a conceptual mineral systems model. The main components of the mineral systems model are: (1) pockets of metasomatised subcontinental lithospheric mantle (SCLM) which form fertile source regions for REE-bearing fluids; (2) extensional geodynamic settings; (3) permeable lithospheric architecture for tapping REE-enriched fluids from the SCLM and focusing them to near-surface levels, and (4) post-emplacement tectonic regime that preserves the deposits. Spatial analysis tools mapped these criteria to assess prospectivity at different probability and confidence levels, considering systemic uncertainties via Monte Carlo simulations and stochastic uncertainties through subjectively defined confidence values. REE prospectivity was mapped at three probability levels, draped over a confidence layer. SOM, an unsupervised machine learning algorithm, autonomously analysed geophysical and topographical datasets to identify prospective areas, corroborating FIS results. The SOM workflow eliminated human bias and time-consuming, labour-intensive data pre-processing by not using any interpreted, processed or manually generated data; instead, it relied on the algorithm to identify crucial features to delineate prospective areas.

Primary findings of the study include recognising REE-fertile domains in India based on common tectonic and spatiotemporal relations among carbonatite-alkaline complexes and validating SOM as a reliable, efficient tool for prospectivity modelling, particularly in unexplored regions. The study pinpointed several high-prospective areas in the Northwestern Domain, recommending detailed ground exploration at Kamthai-Sarnu-Dandeli and Mundwara and its immediate

surroundings. Further exploration suggestions were made for the Siwana ring-complex region and adjacent areas.
This research presents a comprehensive, mathematically-driven prospectivity analysis for REE deposits associated with carbonatite-alkaline complexes, offering a systematic two-fold approach applicable to similar geodynamic settings globally.

Exploration targeting of northern Finland for CRMs hosted in ultramafic-mafic orthomagmatic intrusions

Malcolm Aranha[1]*, Oulu mining school (malcolm.aranha@oulu.fi)
Hanna Silvennoinen[2], Sodankylä Geophysical Observatory
Shenghong Yang[3], Oulu mining school

Abstract

Orthomagmatic mafic and ultramafic intrusions are valuable sources of critical raw materials (CRMs) such as nickel (Ni), cobalt (Co), platinum group metals (PGMs), vanadium (V), and copper (Cu) which are in high demand for modern industries and considered strategically important by the European Union. Given the projected increase in demand and potential shortages, local production of these materials is essential.

Northern Finland is recognised for hosting such CRMs in two types of ultramafic- mafic intrusions: conduit-type deposits, rich in sulphides of Ni-Cu-(PGM)-(Co), and layered mafic intrusion type, with relatively lower sulphide content and containing PGM-Cr-V-(Co)-(Ni)-(Cu). This study employs computer-based prospectivity analyses for both deposit types, utilising Fuzzy Inference Systems (FIS), a knowledge-based artificial intelligence technique.

The FIS models rely on generalised mineral systems models for each deposit type to identify targeting criteria. For conduit-type deposits, the mineral system model includes (1) Primitive, mantle-derived, magnesium-rich rocks (ultramafic and mafic rocks), serving as metal sources; (2) trans-lithospheric faults and chonoliths acting as magma pathways, locally enhanced by varying compressional/extensional tectonic regimes; and (3) dilatational zones of high, fracture-related permeability and localised structures that physically trap the mineralising fluids; along with abundant sulphur-rich crustal rocks serving as chemical traps, providing external sulphur required to form immiscible sulphide melts. Layered mafic intrusion-type deposits have similar mineral systems models but differ in the trapping mechanism within the cratonic lithosphere, where they form large magma chambers forming a layered sequence of ultramafic to mafic rocks due to fractional crystallisation under low regional stress and limited magma-induced sagging. Reef-style mineralisation between the lower ultramafic zone and the upper mafic zone and among mafic rocks is typical; however, contact style or marginal style at the base of the intrusion is also known to occur.

Spatial proxies representing critical processes of each mineral system were mapped from various geoscientific datasets in the form of GIS predictor maps. This study has attempted new innovative predictor maps utilising previously underused datasets such as three-component seismic models. All predictor maps, including the innovative ones developed in this study, were incorporated into the FIS models to generate prospectivity maps. The results effectively distinguish between the two deposit types and highlight promising regions for further exploration, demonstrating the approach's utility in targeting CRM-rich areas.

Abstract

Currently, there is an urgent need to strengthen the mineral resource base for rare metal production in the region. Subsoil users are becoming more interested in rare metal objects from Kalba-Narym metallogenic zone in Eastern Kazakhstan due to the growing demand for rare metals globally, especially lithium. One of the promising areas is the practical assessment of “non-pegmatite” rare metal mineralization (Ta, Nb, Be, Li, Sn, etc.) associated with albitized and greisenized granites. Reassessment of a special type of lithium-bearing albite-spodumene pegmatites associated with small intrusions (plagiogranitoids) and dikes of the Kunush complex is also relevant. Similar objects are found in the Karagoin-Saryozek ore zone and are characterized by tantalum-poor and spodumene-rich content. The unconventional type includes both greisen-quartz vein mineralization (Sn, W), superimposed on small intrusions of plagiogranites, and dikes of the Kunush complex under the influence of rare metal-bearing granites of the Kalba complex. All these types can be an additional source of rare metals and should be considered in geological exploration practice.

The main criteria for forecasting and searching for albite-greisen (apogranite) type of tin-tantalum-lithium mineralization were determined during the investigation: 1) favorable geological and structural position of the formation of rare metal objects (supra-intrusive zones, apophyses and domes of hidden granite massifs, recorded by geological and geophysical data); 2) intensive changes in sedimentary rocks in the supra-intrusive zones of hidden granite domes (brecciation, exfoliation, albitization, tourmalinization, fluoritization, sulfidization and quartzification); 3) spatial-genetic connection of lithium-bearing albitite-greisen metasomatic rocks with phase II granites of the Kalba complex based on the gradual transitions established between them; 4) close absolute age of granites of the second phase and lithium-bearing granites; 5) intensive metasomatic transformation of granites (albitization, greisenization, fluoritization, qurtzification) with the introduction of F, Li, Sn, Ta and other elements; 6) mineralogical searching indicators of mineralization (albite, zincvaldite, lepidolite, topaz, fluorite), lithogeochemical anomalies of Li, Rb, Cs; 7) the areal nature of the distribution of rare metal mineralization (Li, Sn, Ta), which increases the prospects of rare metal lithium-fluoride granites in general.

In regional terms, considering the belt distribution of rare metal structures and deposits, it is

advisable to study reserve territories located on the flanks of the Kalba-Narym belt and significantly covered by a cover of loose Meso-Cenozoic sediments. These areas are promising for identifying hidden and buried deposits of various geological and genetic types, including unconventional types of raw materials. To implement forecasts and increase the efficiency of geological exploration work at the present stage, it is necessary to increase the depth of geological study of the territory in the most important mining areas of Kalba and other territories.This research has is funded by the Science Committee of the Ministry of Science and Higher Education of the Republic of Kazakhstan (Grant N°APAP23484205).

Giovanni MONGELLI[6]*, Department of Sciences, University of Basilicata, viale dell'Ateneo Lucano 10, 85100 Potenza, Italy (giovanni.mongelli@unibas.it)

Abstract

A recent resource challenge is to guarantee supplies of Critical Raw Materials (CRMs) that perform essential functions in modern engineered materialss, but are subject to short-term supply risks or concerns about long-term availability. According to the latest European Commission Report on CRMs the definition of CRMs applies to several elements, including REE. In the last decade efforts have been devoted to assess the distribution of CRMs in the Iranian karst-type bauxite deposits with a peculiar focus on the distribution of REE. The Iranian bauxite deposits that are deposited within karstic depressions and sinkholes of underlying carbonates, belong to the Irano-Himalayan karst-type bauxite belt, and are similar to the Mediterranean-type bauxites. Mineralogical and geochemical studies on the northwestern Iranian karst bauxite deposits revealed the intense, long-term weathering of parent rocks, mainly of a mafic protolith, generally associated with warm periods of the middle-late Permian, Permo–Triassic, middle-late Triassic, and late Triassic-early Jurassic as wel. This study employs machine learning algorithms to predict contents of REE and Y , as well as the subsets of light REE (LREE: La-Sm) and heavy REE (HREE: Eu-Lu). The prediction models utilize major elements and geochemical indices, specifically the Chemical Index of Weathering (CIW) and the Chemical Index of Alteration (CIA). The dataset underscores the distinct fractionation behavior between LREE and HREE, necessitating separate prediction models. For LREE predictions, the optimal input features indicate a strong and positive correlation between all major elements and CIW (R^2 = 0.85). Conversely, for HREE predictions a strong positive correlation between major elements and CIA (R2=0.82) is observed. Interestingly, the optimal input combination for predicting REE and Y contents is consistent with LREE predictions, emphasizing the dominant influence of LREE on overall trends (R^2 = 0.87). Customizing input features to specific REE subsets enhances prediction accuracy and also acknowledges the distinct behavior and correlations between LREE and HREE. The study underscores the significance of incorporating geochemical indices for predicting REE contents and for considering the role of geological processes during bauxitization. These insights contribute

to the development of robust prediction models, the significance for efficient resource evaluation, exploration, and the understanding of geochemical parameters controlling REE distribution in different geological settings.

LocatOre: Mineral Exploration and Vectoring Software

Stephen Alexander COOKE[1]*, University of Tasmania (SA.Cooke@utas.edu.au)
Matthew J CRACKNELL[2], University of Tasmania
Michael J BAKER[3], University of Tasmania
Lejun ZHANG[4], University of Tasmania
David R COOKE[5], University of Tasmania
Ivan BELOUSOV[6], University of Tasmania

Abstract

LocatOre is a new software platform we have developed that enables analysis and estimation of the locations of magmatic heat and fluid sources of porphyry copper deposits. LocatOre employs knowledge-driven and data-driven approaches to logarithmic linear regression to help predict ore-body locations.

Proximitor equation (knowledge-driven) based trace element chemistry of hydrothermal alteration minerals are analysed to generate 2-D and 3-D models that assess converging distance to heat and fluid source estimates. The software attempts to determine the likely location of the source intrusion that supplied the hydrothermal fluids responsible for the mineralisation. Generation of randomly placed “potential” heat sources allows for mass-testing (data-driven) by identifying the most likely location of an ore-body based on the regression of distances from each ore sample to the relevant mineral concentrations of those samples. These heat sources can be filtered according to their R2 values to highlight those where a strong correlation exists between the two variables. Forward-feature-selection searches can be conducted to identify the most influential elements to the heat regression process.

LocatOre enables the manipulation, interrogation, 3-D visualisation, and interpretation of geochemical data obtained from rocks and minerals with the end goal of helping improve mineral exploration success. It is designed for ease-of-use such that users who may have otherwise struggled with geochemistry vectoring calculations can perform them easily and rapidly to identify potential exploration targets. Furthermore, interactive visualisation enables users to understand how these targets may fit in to the broader context of the study site in question with an accessible and intuitive control scheme.

The characteristics and use of calcrete as a sample medium for gold exploration in the Karibib area

NAILOKE SHALI[1]*, Osino Gold Exploration and Mining Pty Ltd (nailokeshali24@gmail.com)

Abstract

Calcrete are secondary carbonates dominantly composed of calcite and dolomite formed as a result of climatic fluctuations in semi-arid and arid regions. Several studies in Australia have shown significant occurrences of gold in calcrete which have proven calcrete sampling to be applicable in exploration. In Namibia, the use of calcrete as a sample medium for gold exploration has never been applied before and only now it is being tested by Osino Resources Corp in the Karibib area. The Karibib area is covered by extensive calcrete cover and using calcrete to find gold deposits can be a potential method to establish gold occurrences. Through geophysical anomalies, Osino Resources discovered a new gold trend, now termed as the Karibib Fault, located south west of Twin Hills prospect, one of Osino Resource's gold prospects. Several methods have been proposed to guide in exploration of tracing gold along this gold trend. The methods include soil sampling which revealed a gold anomaly and this was followed up by a calcrete sampling programme and results showed presence of gold concentrations within the calcrete. Nonetheless, the occurrence of gold in the calcrete along the newly discovered Karibib Fault is not well understood and more studies are required to establish the controlling factors of gold mineralization in this area. This project is aimed to show how sampling calcrete as an exploration technique can be used to facilitate the discovery of gold deposits in calcrete covered terrains and to establish how gold values vary with each type of calcrete. Classification of calcrete is necessary in order to interpret the occurrences of gold in calcrete. As part of this study, field work was carried out and this includes pit mapping and sampling, which was necessary to map out the types of calcrete and compare the gold values in each type of calcrete. Mapping of surface calcrete outcrops was used to identify the different types in the area and come up with a conclusion on the environment of formation. Drill core logging and sampling was employed to identify the different types of calcrete and see how gold values vary with depth and with each type of calcrete. Based on observations and geochemical results obtained during this study, calcrete has proven to be a suitable sampling medium for gold exploration in the Karibib area and other calcrete covered terrains. From the geochemical and lithological logging results, the distribution of Au in the area varies with different types of calcrete and there is no strong relationship between the variation of Au and depth.

GEOLOGICAL INVESTIGATION OF THE CHIMBIYA NIOBIUM-TANTALUM (Nb-Ta) ANOMALY IN KASUNGU DISTRICT, CENTRAL MALAWI.

Chrispin Ngwata[1]*, Geological Survey of Malawi (chrispinngwata@gmail.com)
James Mwambananji[2], Geological Survey of Malawi

Abstract

Abstract
This paper describes the results of a geological investigation into a prominent Niobium Tantalum (Nb-Ta) that was identified in Chimbiya village in Kasungu district, central Malawi. The anomaly was revealed by the results of the 2018/2019 geochemical stream-sediment sampling campaign which was conducted under the Geological Mapping and Mineral Assessment Project of Malawi (GEMMAP). Radiometric map of the area also showed anomalous Potassium (K) and Uranium (U) signatures like that of the famous Kanyika Nb-Ta deposit to the north of the area. The paper has been outlined as follows: introduction, outline of the regional and local geology, geochemistry (lithological, soil, and stream-sediments), discussions, conclusion, and recommendations. Annexes contain the U and K radiometric maps of the area. The main objective of the study was to identify the possible Nb-Ta orebody by tracing the source of the anomalous values. This was achieved by conducting a geological mapping and geochemical (stream sediment, soil, and rock) survey of the area. In geological mapping, some rock samples were analysed using the Spectro xepos X-Ray Fluorescence XEP05. The results were grouped into major oxides and were used for rock classification using the Total-alkali Silica (TAS) criteria of Cox et al., (1979) for intrusive rocks. Geochemistry survey involved collecting samples from sediments in active streams at some planned locations (confluences of first order steams) as these were deemed to be representative of the catchment area. A total of 10 samples were collected and these comprised 9 stream sediment samples and one soil sample. The latter was taken from the centre of a uranium anomaly. These were also analysed using the XRF. Geological mapping of the area revealed that the underlying lithology is predominantly supracrustal rocks of a metasedimentary nature. Intrusive rocks were restricted to metasyenite in the northeast and metadolerite in the same vicinity. Analytical results from rock chip samples revealed that Nb and Ta have elevated concentrations in the metasyenite lithology. The stream sediment sampling analysis results also indicated that the samples with the highest values for Nb and Ta were collected from streams that are spatially associated with the Kamwala hill metasyenite body. In conclusion, the geological investigation ascertained that the source of the Nb-Ta anomaly was the metasyenite body which was also found to be the source of the prominent U anomaly in the area. These observations raise the possibility that the mineralization on Kamwala hill could be like, and/or related to the Kanyika orebody to the north. It is therefore recommended that detailed geological mapping of Kamwala hill be undertaken. This should be done concurrently with a ground radiometric survey since the metasyenite has a distinctive K and U signature.

Abstract

Archean Holenarsipur schist belt (HSB) comprises of linear ultramafic-mafic enclaves containing subordinate clastic sediments and BIF enclosed by tonalite-trondhjemite-granodiorite (TTG) gneisses. This schist belt is known to host Ti-V magnetite, PGE, gold and Ni occurrences. Recent discovery of polymetallic (Zn-Cu-Pb) mineralization from Kattaya area provides new dimension for mineral exploration in the area. This polymetallic mineralization is reported along the alteration zone at the contact of amphibolite of HSB and TTG gneisses. For understanding the petrogenetic significance of mafic ultramafic rocks in the HSB some of the samples from Bachihalli and Hulihalli area were analyzed for major oxide and trace elements. These rocks especially talc-tremolite schist are showing komatiitic affinity. Interestingly apart from relatively high Ni (up to 1972 ppm), Co (up to 112 ppm), Cr (up to 2917 ppm) and V (up to 200ppm) concentration Zn is also recorded in considerable amount i.e. up to 680 ppm, which is unusual considering their ultramafic lineage. Detailed Petrographic and Scanning electron microscopic studies revealed this rock containing fine disseminated sphalerite associated with both oxide and silicates confirming the Zn source. Two distinct association of sphalerite is present in the rock (1) as inclusion within the Cr-Magnetite and (2) as inclusion in the retrogressed chlorite. The presence of sphalerite indicate Zn rich environment of mafic ultramafic rocks as it is clear from the inclusion of sphalerite associated with Cr-magnetite, followed by remobilization due to hydrothermal activity, which is evident from chlorite-sphalerite association. This study is significant and opens up new avenues for future exploration in the early Archean rocks of HSB and other similar terrains. Further studies are required to understand the genetic linkage between the Zn in the mafic ultramafic rocks and the polymetallic mineralization in the Kattaya area.

Analysis of Lithium-Bearing Pegmatite Mineral System in the Alvand Plutonic-Metamorphic Complex, Western Iran

Majid Keykhay-Hosseinpoor[1]*, Indian Institute of Technology Bombay (IIT Bombay)
(majidkeykha@iitb.ac.in)
Alok Porwal[2], Indian Institute of Technology Bombay (IIT Bombay)

Abstract

This study aims to explore the mineralization processes of lithium-bearing pegmatites within the Alvand Plutonic-metamorphic complexes in the pegmatite province of western Iran. Situated in the Sanandaj-Sirjan metamorphic zone, a key Tectono-stratigraphic division predominantly comprising Upper Paleozoic to Mesozoic meta-sedimentary sequences, this area has undergone significant deformation during the Mesozoic and Cenozoic tectonic activities. Despite their relatively small volume, the pegmatitic bodies in this region are noted for their significant variability in texture and mineralogical composition. Although lithium-bearing pegmatites have been recognized in the Alvand complex, their genetic links to other pegmatites and associated granitoids remain underexplored. This area presents a significant potential for lithium exploration within pegmatite dykes, which could serve as critical lithium sources. The pegmatites are found in various settings within the plutonic bodies, including interior, marginal, and exterior zones. The Petrological traits of the dykes intersecting both plutonic and metamorphic terrains manifest characteristics akin to both lithium–cesium–tantalum (LCT) and niobium–yttrium–fluorine (NYF) families of pegmatites, indicating the occurrence of complex geodynamic processes in the region. Petrographic analyses reveal that the lithium-bearing pegmatite veins undergo a transition in both texture and mineral composition from the contact zone with the metamorphic country rock (wall zone) to the central part (core zone). In the wall zone, these veins showcase a quartz-rich granitoid composition which gradually evolves into granite, alkali granite, trondhjemite, and quartzolite as it approaches the core zone. This core zone is characterized by the presence of quartz, alkali feldspar, muscovite, spodumene, beryl, and tourmaline, highlighting the significant variation in mineralogical composition across the vein. This study addresses the mineralization system of lithium-bearing pegmatites in the Alvand complexes, offering insights into their potential for economic exploitation and targeted lithium exploration.

Possibility of lignite coal deposits of South Korea as an unconventional REE deposit; preliminary case study of Gyeongju-Yeongil coal field

Woohyun CHOI[1]*, Kyungpook National University (choi313047@gmail.com)
Changyun PARK[2], Kyungpook National University

Abstract

Although global energy trends are shifting towards more eco-friendly and renewable sources, coal and thermal power generation remain primary energy sources for many countries. In addition to its role in energy production, coal is gaining attention as an unconventional source of rare earth elements (REEs).

South Korea's coal deposits consist mainly of anthracite, with some additional lignite deposits in the Northern Gyeongsang province. Previous research has shown that younger and less coalified coal deposits tend to contain higher concentrations of REEs. Therefore, we targeted the Gyeongju-Yeongil lignite coal field for our study.

The Gyeongju-Yeongil coal field comprises two main coal-bearing layers: the upper coal-bearing layer (UC) and the lower coal-bearing layer (LC). The UC is covered by an andesitic tuff layer, with shale formations below the coal seams. The LC consists of a bentonite formation with a coal seam in the middle. Most of the coals in this area are lignite with partial subbituminous. This type of coal deposit, with tuffaceous characteristics, is known to have high concentrations of REEs. X-ray diffraction (XRD) analysis revealed quartz, feldspar, kaolinite, montmorillonite, and zeolite as the major mineral phases in the coal seams and adjacent layers. However, identifying REE-rich mineral phases (e.g., monazite, xenotime, goyazite) was challenging using XRD and EPMA observations, indicating that the majority of REEs are likely absorbed into other mineral phases rather than existing in independent forms.

ICP-MS analysis of rock and coal samples showed elevated concentrations of certain elements in the coal layers. Samples from the UC exhibited over 300 ppm (up to 550 ppm) of total rare earth and yttrium elements (REY), which is the minimum concentration considered economically viable for development. Among the REY elements, light rare earth elements (LREEs) such as lanthanum to neodymium and yttrium showed the highest enrichment. Additionally, significant concentrations of vanadium (V; ~172ppm), barium (Ba;~1034ppm), zinc (Zn; ~172ppm), copper (Cu;~109ppm), rubidium (Rb;~133ppm), strontium (Sr;~410ppm), and zirconium (Zr;~323ppm) were observed.

These preliminary research findings suggest that lignite layers in Korea have the potential to be developed as unconventional REE deposits. However, further detailed research is needed to determine the actual distribution and origins of REY elements within the coal layers.

Jose Manuel[13], IGEO-Angola

Abstract

The Republic of Angola has a very diverse and interesting range of minerals determined by their geological and/or geotectonic environments, spanning from the Upper Archaean to more recent times. This makes Angola significant for potential mineral deposits. Over recent decades, exploration and mining activities have led to the discovery of economically valuable deposits of various elements, such as Fe, Au, Li, REE, and diamonds, some of which are currently active.

The National Geological Plan of Angola (PLANAGEO) was a project developed in Angola during the last decade. The UTE PLANAGEO consortium, formed by the Geological Surveys of Spain (IGME) and Portugal (LNEG) and the Spanish company Impulso Industrial Alternativo (IIA), was in charge of the geological, geophysical, and geochemical studies undertaken in the SW region of the country, in an area equivalent to ca. 476.500 km2.

One of the most important objectives of PLANAGEO was the improvement of the geological and mineral resource knowledge of the country. This project integrated regional aerogeophysical mapping (magnetic and radiometric) and innovative geological mapping carried out both at regional scale (44 maps at 1:250,000 scale) and 15 maps at 1:1000,000 scale in key, selected areas, which included raw materials and mineral resources prospecting at 1:50,000 scale.

Three different clusters were defined in order to explore different raw materials in selected regions from the SW part of the country, regarding their interest in metallic mineral resources: cluster 1, for gold and iron; cluster 2, for REE and niobium-tantalum; and cluster 3, for base metals and platinum group elements. These regions were studied by using conventional geochemical exploration techniques (i.e., rock, soil and stream sediments sampling) and by using the most innovative state-of-the-art methodologies (i.e., in situ geochemical analyses by portable X-Ray Fluorescence equipment).

The combined examination of geological, geophysical, and mineral resources information and the geochemical exploration surveys performed in the selected areas has assessed and identified the mineral potential of the various geotectonic terranes of SW Angola. This information has served

to produce not only distinct geological and geothematic maps at different scales, but also to identify the mineral potential of the country. The various mineral associations detected and investigated in SW Angola were used to group selected geological domains or in certain geological environments, leading to propose a preliminary delimitation of the metallogenic provinces that shape the SW portion of the country. As a result, new mineral potential targets have been created in the region.

Structural control on gold mineralisation in the Ngubevu area (South Africa) inferred from micro-scale to regional-scale spatial analysis

Nolukholo Sinovuyo Busakwe[1]*, University of Free State (sinovuyobusakwe@gmail.com)
John Emmanuel Muico Carranza[2], University of Free State

Abstract

The Ngubevu area in the Mfongosi Group in the Natal thrust front shear zone (Tugela Terrane) is weakly mineralised and is under-explored but it hosts structurally-controlled epigenetic gold mineralisation in five abandoned mining sites (Buffalo River, Golden Dove, HMS, Golden Eagle and Champion River). This study aims to establish a link between micro-scale spatial distributions of ore minerals, local-scale structural features at and around mineral deposits and regional-scale geological structures to infer structural control across different scales in the Ngubevu area. Thin section-scale to micro-scale spatial distributions of sulphide minerals (sphalerite) in oriented quartz vein thin sections were examined using point pattern, Fry, fractal, and shape analyses. The results show a non-random and a clustered ore mineral spatial distribution. The rose diagrams of Fry points of sulphide minerals in thin sections indicate significant NNE–SSW to NE–SW, NE–SW to ENE–WSW, and NNW–SSE to WNW–ESE trends. These trends are similar to the NNW–WNW and NNE–ENE trends determined by shape analysis of sulphide minerals in thin sections of vein material samples in Ngubevu area. These trends correspond to the orientations of local- to regional-scale N- to NNE- and ENE-trending D1 and D2 deformation shear–zone structures. The results of fractal analysis suggest that ore minerals in the area have bi-fractal characteristics with two fractal dimensions of 0.521 – 1.051 at a scales less than 0.2 cm and 1.253 – 1.550 at scales greater than 0.2 cm. This study confirms (a) that there is link between spatial patterns of mineral deposits across different scales and (b) that local- to regional-scale structural controls of mineralisation can be deduced from thin section-scale to micro-scale analyses of ore mineral distributions. These findings have implications for mineral exploration in poorly explored frontier regions of terranes that are geologically permissive for mineralisation.

Geology and Copper-Sulphide mineralisation within the Mutale area, Soutpansberg Group, South Africa

Thangeni Mphanama[1]*, University of Venda (thangeni95@gmail.com)
Humbulani Rejune Mundalamo[2], University of Venda
Jason Samuel Ogola[3], University of Venda

Abstract

The Mutale Copperfield, situated within the Vhembe District of Limpopo Province, South Africa, represents a significant geological site within the Soutpansberg Group. Spanning an area of approximately 320 square kilometres, this region has been historically renowned for copper mining activities from the early 1900s until the 1970s, particularly around the Mutale River area. More than 30 known occurrences of copper mineralisation persist within near-vertical quartz veins and fractures within the Soutpansberg Group's lavas and sediments.

This study investigates the geology and copper-sulphide mineralisation within the Mutale Copperfield. Fifteen samples from waste rock dumps, obtained through grab sampling method from three distinct workings, underwent X-ray Diffraction (XRD) and X-ray Fluorescence (XRF) techniques at the University of Venda's Mining and Environmental Geology Laboratory. The XRD analysis revealed the presence of various sulphide minerals including chalcocite, bornite, malachite, covellite, and native copper. However, only one sample exhibited a copper concentration above the typical economic grade of 1%, measuring at 1,412 wt%. The remaining samples displayed copper concentrations ranging from 0.537 to 0.01 wt%. Although waste rock dump samples imply low copper concentrations overall, a more precise evaluation of the deposit's copper content can be achieved by sampling directly from ore faces or examining core logs.

Identifying target areas for copper mineralization using ASTER and geochemical data in Musina Area, Limpopo Mobile Belt, South Africa

Humbulani Rejune MUNDALAMO[1]*, University of Venda (humbulani.mundalamo@univen.ac.za)
jason Sammuel OGOLA[2], University of Venda
Klaus Maas[3], Hochschule Ostwestfalen-Lippe, University of Applied Sciences

Abstract

The study focused on the structural and geochemical investigation through integration approach of the remote sensing data and soil geochemistry study within and around the copper-sulphide deposits in the Musina area, located in the Central Zone of the Limpopo Mobile Belt of South Africa. The Messina copper deposits are located in the eastern part of Limpopo Province near the border with Zimbambwe.

Different research methods have been applied in the current study so as to identify the area with high copper mineralization for further exploration purposes. This included fieldwork, remote sensing data acquisition, laboratory work, and data analysis and interpretation. Application of ASTER imageries and Arch GIS 10.4.1 was conducted for mapping structural features and alteration zones. Fieldwork involved soil geochemical survey for anomalous concentration determination of copper sulphide metals. A total of 295 soil samples were collected for laboratory investigation.

Data analysis and interpretation of laboratory results involved the use of: Desktop ArcGIS 10.4.1 for geochemical data interpretation as well as ENVI 5.1 and ArcGIS 10.4.1 Softwares for remote sensing data. Remote sensing data interpretation revealed spatial distribution and intensity of epidote alteration within the study area and in places coincided either with the known copper deposits or structural features. Soil geochemical survey revealed geochemical anomalies for Pb, Zn, Cu, As and Ni over the known copper deposits in the area as well as over six other areas that have not been associated with any sulphide mineralisation. The locations where intensity of epidote alterations, structural features and high concentration levels of metals coincided led to the identification of target areas for future mineral exploration in the Musina area.

Reconnaissance Phase of Chromite Potential in Iran

SHAFIGHEH TARKIKORDEDEHI[1]*, Master (shafighetarki62@gmail.com)

Abstract

Abstract

Chromite ore is the only source of chromium, which is of high value in making alloys and preparing special steels. The collection of ophiolitic rocks in Iran has been greatly expanded and developed, and they are often placed in different geological time and place positions with other tectonic units.

The Geological and Mineral Exploration Organization of the country, as the trustee of exploration, is following up the task of identifying new potential areas for mineralization. The project of finding the potential of chromite in Iran has been started in the identification phase since May 2016 by the exploration site of the Applied Research Center of the Geological and Mineral Exploration Organization of the country.

Different layers of information were used to conduct office studies and introduce the potential areas of chromite mineralization, which include digital geological data (lithology) 1:100000 And if not, 1:250,000 maps, remote sensing information layer, indices layer and suitable mines and environments for chromite mineralization with a scale of 1:1,000,000 prepared by the Geological and Mineral Exploration Organization of the country were used. The most important discovery criterion in the phase of identifying and searching for chromite mineralization is the geological layer (lithology and structure), which was used as the main layer due to the specificity of the spatial expansion and distribution of rock units related to chromite mineralization.

According to the metallogenic belts of chromite in Iran, the most important axes include the Esfandaghe-Faryab-Haji Abad axis, which includes from the east of Minab in Hormozgan province to the Kerman region, the eastern axis of Iran (Birjand-Nehbandan), which extends from Birjand in South Khorasan province to Iranshahr. It is drawn in the province of Sistan and Baluchistan the southeastern belt of Iran (or Sistan-Makran), which is the largest concentration of chromite deposits and deposits in this axis in the west of Fanuj in Sistan and Baluchistan province, and the Sabzevar-Torbat Heydarieh ophiolitic belt, which is the largest concentration of chromite mineralization in the north of Sabzevar. And north of Torbat - Heydarieh.

By processing the above layers of information in the present project, areas prone to chromite mineralization were introduced. Based on this, suitable 1:100,000 sheets (114 sheets) were analyzed and processed for information layers separately. Based on geological data and suitable environments for chromite mineralization, three priorities were introduced, the first priority includes rock units of dunite, serpentinite, serpentinized donite, harzburgite, and serpentinized harzburgite. The second priority includes peridotite and serpentinitized peridotite rock units and the third priority includes ultrabasic rocks and colored mixtures. Prone rock units were introduced as hosts of chromite mineralization with an area of 6084 square kilometers. Among the identified potential rock units, in general, an area of 3462 square kilometers of first-class chromite potential

area was introduced for the whole country.

Quantitative Data for Geochemical Exploration of critical elements: The Contribution of Handheld LIBS

Naila MEZOUED[1]*, Georessources, Université de Lorraine (naila.mezoued@univ-lorraine.fr)
Cécile FABRE[2], CNRS, GeoRessources, Université de Lorraine
Jean CAUZID[3], CNRS, GeoRessources, Université de Lorraine

Abstract

Geochemical data are essential in mining operations. However, acquiring this information typically involves: selecting samples from the deposit, transporting the fragments, and thorough analyses using conventional analytical methods in laboratories. A lengthy and costly process that significantly delays strategic decision-making. The Laser-Induced Breakdown Spectroscopy (LIBS) technique and its ability to decipher the chemical composition of a sample by creating a plasma on its surface using a high-energy laser, shows great potential to provide an on-site solution to generate reliable qualitative, quantitative, and mineralogical information on geological materials (ref).

In this context, the handheld LIBS was used to predict the concentration of critical elements targeted for extraction (Li, Cs, Be) in the Beauvoir granite. A rare metal leucogranite, in the northern part of the French Massif Central, characterized by high content of Li, Rb, F, Cs, Nb, Ta, Be, and Sn, currently under study for lithium extraction. The aim was to focus on raw and unprepared samples, including whole core portions measuring up to 4 meters, to minimize the technical constraints required in the field. Reference samples were selected to represent best the variability of the granite samples and an analytical strategy was developed to address the method constraints. The calibration models were built using different spectral parameters and statistical approaches. Then, a comprehensive comparative analysis was conducted to determine the optimal protocol for each element studied. To meet the company's needs, signal variation over successive measurements, and the minimum number of analyses required to maintain a representative LIBS signal of the whole rock composition, were investigated.

The predicted concentrations are consistent with the reference geochemical values obtained through standard techniques (Li => RMSE=0.062 wt% MAE=0.081 wt% Bias=0.064 SEP=0.078 wt%), confirming the ability of the handheld LIBS device to produce relevant geochemical data in a short period, within minutes, directly at the exploitation site, and on unprepared rock sections.

Ore deposits of critical minerals in Indian granitic pegmatites

Yamuna Singh[1], University of Hyderabad
Yamuna SINGH[2]*, University of Hyderabad (yamunasingh1957@gmail.com)

Abstract

The granitic pegmatites of India constitute a potential source for diverse types of ore deposits of critical and strategic minerals in various geographic regions. Systematic exploration revealed localisation of ore minerals of Nb, Ta, Be, Li, Sn, U, and associated ores of Rare Earth Elements (REEs), Th, Bi, Cs, Mo, W in various pegmatite belts of India. Several granitic pegmatites have been commercially mined for Nb, Ta, Li, Be, Sn, U, and other associated ore minerals. Ore minerals of Nb and Ta record a large mineralogical speciation followed by Li ore minerals. Ubiquitous appearance of economic grade Be ore mineral as beryl in pegmatites of almost all the regions is remarkable. The grade of pegmatite ore is low to medium to very high, with moderate to high volumes of individual ore-bearing pegmatites. Most of the mineralised pegmatites bear spectacular imprints of metasomatic alterations and attendant ore concentrations. The ore-bearing pegmatites carry signatures of ‘Rare Earth’ and ‘Beryl’ types of pegmatites, with sub-types of ‘Complex Pegmatite Type’ (CPT), namely, ‘Lepidolite’ sub-type, ‘Spodumene’, ‘Amblygonite’ and ‘Petalite’ sub-types. The ‘Rare Element’ class of pegmatites carry signatures of ‘LCT’ (Lithium Cesium Tantalum) and ‘NYF’ (Niobium Yttrium Fluorine) types of pegmatites. Presence of ore-bearing pegmatites of more than one ‘Family’ together suggest involvement of more than one petrogenetic processes in their formation and ore grade concentrations.

New age data for the rare metal pegmatites of the East Sayan rare metal belt

Anna IVANOVA[1]*, Institute of Precambrian Geology and Geochronology, Russian Academy of Sciences, Saint-Petersburg, Russian Federation (anna_al_ivanova@mail.ru)
Ekaterina Salnikova[2], Institute of Precambrian Geology and Geochronology, Russian Academy of Sciences, Saint-Petersburg, Russian Federation
Julia Plotkina[3], Institute of Precambrian Geology and Geochronology, Russian Academy of Sciences, Saint-Petersburg, Russian Federation
Aleksander Kotov[4], Institute of Precambrian Geology and Geochronology, Russian Academy of Sciences, Saint-Petersburg, Russian Federation

Abstract

The problem of timing of ore-forming processes is very important for rare metal objects. In many cases, it is necessary to use non-traditional minerals-geochronometers like Ca-Fe garnet, microlite, cassiterite and columbite-tantalite to solve this problem. U-bearing columbite-tantalite group minerals (CGM) are common in rare metal pegmatites. This research is devoted to U-Pb geochronological studies of CGM and zircon from pegmatites of the spodumene (Li, Ta-Sn-Li, Ta-Cs-Li) and petalite (P-Ta-Li, Ta-Cs-Li) subformations of rare-metal pegmatite formation in one of the largest in the world the East Sayan rare metal belt (ESB), located in the southwest of the Siberian craton. The age of nearby granitoids of the Sayan complex, which were considered the source material for the rare metal pegmatites of the region, ranges according to various data from 1858±20 to 1901±16 Ma. For ESB-pegmatites age estimates from 1475±30 to 1835±35 Ma are known.

The objects of our U-Pb ID-TIMS study are CGM and zircon from pegmatite veins of the Aleksandrovskoye, Vishnyakovskoye (northwestern part of ESB) and Belorechenskoye (southeastern part of ESB) ore fields. Columbite-(Fe), columbite-(Mn) and tantalite-(Mn) are typical for Aleksandrovskoye, tantalite-(Mn) – for Vishnyakovskoye, tantalite-(Fe) – for Belorechenskoye. Preliminary acid treatment of CGM was carried out according to a modified method of Legros et al. (2019) in HF, HCl and HNO3.

Zircon from Aleksandrovskoye is extremely metamictized (Dα=4-13×10^19 α-decay/g) and enriched by U-Th-REE-inclusions, HfO2 up to 16.6 wt%, UO2 up to 2.1 wt%. It was subjected to chemical abrasion (1.5-2 hours) with high-temperature annealing according to unique modified method (Ivanova et al., 2021). Zircon fragmented down to submicron size, retaining no more than 1% of the original volume of the substance, and with longer exposure it dissolved almost completely. The age of zircon is 1803±6 Ma (MSWD=2.9). A similar age was obtained for CGM from the same vein: 1825±3 Ma (MSWD=0.34) for the quartz core and 1817±5 Ma (MSWD=0.001) for the quartz-mica (with tourmaline) zone of intense alteration of the host amphibolites.

The results of U-Pb geochronological study demonstrate the age coincidence for both CGM and zircon evidencing a high potential of CGM for precise and accurate dating of ore forming processes.

For the Vishnyakovskoye deposit, the CGM age of 1838±3 Ma was previously obtained (Salnikova et al., 2011), which clearly indicated that the pegmatites and granites of the Sayan complex were of different ages. Close age (1823±5 Ma) is obtained for the Belorechenskoye deposit.

The obtained data indicate that the ages of rare metal pegmatite of the ESB is for 30-50 Ma younger than the nearby granites of the Sayan complex and are the result of an independent magmatic event 1.82 Ga.

This study demonstrates an advantage of development of high precision geochronological investigation of the non-traditional minerals-geochronometers to understand ore-forming processes of strategic metals deposits: Ca-Fe-garnets in skarns, CGM and microlite in rare-metal pegmatites.

The study was supported by grants No. 22-17-00211 and No. 24-77-00056 from the Russian Science Foundation and by FMUW-2022-0003.

Deep Learning Application in Predictive Mineral Targeting of Southwestern Uganda: Leveraging Airborne Magnetic and Radiometric Data

Christopher J ALEXIS[1]*, Midwestern State University (chrisjralexis@gmail.com)
Andrew Katumwehe[2], Midwestern State University
Jonathan D Price[3], Midwestern State University
Kashif Mahmud[4], Midwestern State University

Abstract

This research integrates machine learning with established geological methods to overcome the complexities of mineral exploration, particularly in ore and rare earth element exploration within the Mesoproterozoic complex of southwestern Uganda. While crucial, traditional geological mapping faces limitations due to site accessibility, basement exposure, financial constraints, weather conditions, and private sector limitations. The study employs advanced deep-learning techniques alongside traditional geophysical data analysis from airborne magnetic, radiometric, and electromagnetic surveys to address these challenges. This integrated approach aims to enhance mineral mapping predictions' accuracy and precision. The methodology includes the application of various magnetic filters and derivatives, including reducing to the magnetic pole (RTP), first vertical (1VD) and horizontal derivatives (HDR) in the x, y, and z axes, tilt derivatives (TDR), applying the analytical signal (AS) to the magnetic data, and depth to basement estimation techniques, which enhances its interpretability.

In addition to the magnetic methodologies, this research incorporated radiometric data to refine identifying and delineating potential mineralization zones. The study highlighted areas of pervasive potassic alteration by generating composite equivalent thorium-to-potassium ratio (eTh/K) maps and ternary potassium-thorium-uranium (K-eTh-eU) maps. Such alterations are indicative of hydrothermal processes, which are often associated with the formation of mineral deposits. Integrating magnetic and radiometric methodologies enables a multi-faceted approach to exploration, leveraging each method's strengths to overcome their limitations. While magnetic data can reveal structural and lithological information, radiometric data directly measures surface geochemistry. Together, these datasets allow for effectively identifying hydrothermally altered rocks and delineating potential mineralization zones crucial to employing a supervised deep neural network model for predictive targeting.

The supervised deep neural network predictive targeting (SDNN-PT) model combined with traditional geophysical mapping identified potential ore mineralization zones and elucidated the controls of ore localization within the complex geological framework of the region through conventional methods and then predictive machine learning methods. The findings indicated two areas of significant interest where the granitic pegmatites proximal to intrusive granite exhibit pronounced magnetic lineaments derived from the first vertical and tilt derivatives. These lineaments indicate potential ore mineralization in linear structures such as faults, fractures, shear zones, or lithological boundaries. These findings provided a solid foundation for training the deep-

learning model employed in this study. They enhanced the predictive mapping capabilities for identifying similar mineralization zones across broader areas of interest.
Integrating insights from traditional geological methods with the predictive capabilities of machine learning represents a significant advancement in the field of geoscience, particularly in the context of mineral exploration for beryl, columbite-tantalite, cassiterite, and lithium-bearing silicates in pegmatite granites. This innovative approach, as demonstrated in the study of Uganda's Ntungamo District, leverages the strengths of both disciplines to overcome the inherent limitations of each, thereby enhancing the precision and efficiency of identifying potential mineralization zones. The study offers potential economic benefits through this improved exploration strategy in Uganda's mineral-rich regions and supports its aspirations to become an upper-middle-income country by 2040.

The legacy of Petr Černý in the study of granitic pegmatites

Tania MARTINS[1]*, Manitoba Geological Survey (tania.martins@gov.mb.ca)

Abstract

Petr Černý was a mineralogist based at the University of Manitoba in Canada and is well known and recognized for his study of granitic pegmatites. From his initial studies in his home country Czech Republic, he studied many other pegmatites in other parts of Europe (e.g., Finland), in Canada (e.g., Manitoba, Northwest Territories) and South America (e.g., Argentina). Most of Petr Černý's career was dedicated to the study of the world-class Tanco pegmatite. The Tanco pegmatite located at Bernic Lake, southern Manitoba, Canada is a well-known deposit for its large size, unique and diverse mineralogy, high degree of fractionation, and productivity.

The Tanco pegmatite was first discovered during a drilling program in the late 1920's exploring for tin. Production of tantalum did not start until late 1960's and continues to today with the focus of production shifting throughout the years between tantalum, cesium and lithium.

The Tanco pegmatite is one of the best studied pegmatites in the world due to Petr Černý's, his students and many other researchers' passion and dedication to the study of this deposit. From the definition of zonation, deep understanding of mineral chemistry systematics (e.g., micas, feldspars, tourmaline, columbite group minerals, phosphates, spodumene), fluid inclusions, metasomatism, structural emplacement controls, and mineralization, all these types of works resulted in a better understanding of the Tanco pegmatite. The results of the studies on Tanco have influenced the way we think about pegmatites, and pegmatite research across the globe.

Despite many studies and publication on the Tanco pegmatite, many questions remain unresolved there, such as: is there a parental granite, where is the feeder system (if existent), what is the relative timing of the different zones, how much has metasomatism affected the pegmatite, what kind of information can we read from fluid and melt inclusions, what more can isotopic systems tells us about the pegmatite (e.g., Pb, N, B, Li isotopes), to cite a few examples.

Multidisciplinary Approach to Exploring for Rare-Element Pegmatites in Western Australia

Paul DUURING[1]*, Geological Survey of Western Australia (paul.duuring@dmirs.wa.gov.au)
Sidy Morin-Ka[2], Geological Survey of Western Australia
Warren Ormsby[3], Geological Survey of Western Australia
Graciany Da Silva[4], Geological Survey of Western Australia
Vaclav Metelka[5], Consultant

Abstract

In Western Australia, rare-element pegmatites play a pivotal role as hosts for Li, Cs, and Ta mineralization, with the Greenbushes mine in the Yilgarn Craton and the Pilgangoora and Wodgina mines in the Pilbara Craton standing out as world-class examples. Western Australia is strategically positioning itself as a hub for battery minerals, leveraging its rich mineral endowment, skilled workforce, and proximity to major markets.

To expand its critical mineral resource sector, Western Australia faces three main challenges: (a) the ongoing need for refining genetic models related to the rare-element pegmatite mineral system, (b) the difficulties in integrating and enhancing the quality of geoscientific data, and (c) the substantial cost and effort required to obtain new data or improve existing datasets using advanced techniques.

To address these challenges, we use the Mineral Systems Approach – a holistic, multidisciplinary strategy – to build an in-depth understanding of geological processes that control the rare-element pegmatite mineral system. This approach benefits from integrating new findings from mineral deposit studies, thereby refining analysis and exploration strategies. It emphasizes the importance of coordinated data acquisition and the effective use of data at various scales to inform exploration priorities.

The Geological Survey of Western Australia (GSWA) implements three approaches to bolster mineral rare-element pegmatite exploration across the state:

Enhancing understanding of genetic models: By conducting thorough mineral systems analyses, GSWA aims to dissect the complex geological processes leading to the formation of critical mineral-rich pegmatites. A cornerstone of this effort is the online GIS-based Mineral Systems Atlas (www.dmirs.wa.gov.au/mineralsystemsatlas), which serves as a dynamic platform for explorers. This atlas, enriched with insights from collaborative research, offers a deep dive into the genesis of pegmatite deposits, focusing on aspects like fertile magma sources, structural pathways, trapping mechanisms, and preservation of mineralized pegmatites. It enables explorers and researchers to conduct targeted prospectivity analyses by integrating the provided GIS layers, prepared for immediate application, with their own datasets. This streamlined access facilitates the

identification of areas with higher potential for rare-element pegmatite discoveries.

Data quality and accessibility improvements: GSWA's data initiatives aim to revamp digital databases and integrate Artificial Intelligence and Machine Learning techniques to improve data reliability and usability. These efforts are expected to reveal hidden correlations within complex datasets, informing future data collection and exploration strategies.

Strategic data acquisition and enhancement: Some new datasets for pegmatite exploration include identifying deep structural pathways using passive seismic and magnetotelluric data, re-analyzing existing granite and lateritic samples for granitophile elements with enhanced detection levels, and creating isotopic maps for Nd, Hf, and O. Additionally, the chemistry of indicator minerals and the use of PRISMA satellite data for mapping pegmatite outcrops are key to refining exploration strategies.

Through these strategies, GSWA demonstrates a committed and innovative approach to overcoming the challenges inherent in the exploration of rare-element pegmatites. By improving genetic models, enhancing data quality, and strategically acquiring new data, we aim to further unlock the mineral potential of Western Australia, supporting its development as a leading hub for critical minerals.

[Keynote] Lithium pegmatites of Africa - a review

Kathryn Goodenough[1]*, British Geological Survey (kmgo@bgs.ac.uk)
Richard Shaw[2], British Geological Survey
Anouk Borst[3], K U Leuven
Paul Nex[4], University of the Witwatersrand
Judith Kinnaird[5], University of the Witwatersrand
Marieke van Lichtervelde[6], Geosciences Environnement Toulouse

Abstract

The continent of Africa records a long history of craton development and continental collision, which has allowed the formation of several swarms of lithium pegmatites of a variety of ages, including some of the largest known global examples. We have been working on many of these pegmatites, and in this talk will summarise what is known about the controls on their formation over time. The oldest lithium pegmatites in Africa are Neoarchaean in age, occurring in the West African and Kalahari cratons, and including the Bikita pegmatite in Zimbabwe that has been mined for many years. These pegmatites record complex parageneses with a variety of lithium minerals. Palaeoproterozoic pegmatites are widespread in the Birimian terranes of West Africa, where simple spodumene-bearing pegmatites are common. During the Meso- to Neoproterozoic, numerous orogenic belts developed across Central and Southern Africa; lithium pegmatites in these regions can be very large (for example, Manono-Kitotolo in the DRC) and have in many cases been mined for tin and tantalum in the past. The Neoproterozoic to Cambrian (Pan-African) orogenic belts are characterised by a wider mineralogical variety of pegmatites, with lepidolite and other lithium minerals being important. Finally, Palaeozoic pegmatites occur in the Variscan belts of Morocco, and are phosphate-rich. It is notable that each craton or orogenic belt appears to have a distinctive lithium pegmatite ‘fingerprint’ and we consider this to be linked to the particular sources, and partial melting conditions, for the different pegmatites. This talk will consider the likely source materials and processes by which this variety of lithium pegmatites formed.

Rare metal potential of North-Western Kalba (Eastern Kazakhstan)

Tatyana Oitseva[1]*, D. Serikbaev East Kazakhstan Technical University
(tatiana.oitseva@gmail.com)
Oxana Kuzmina[2], D. Serikbaev East Kazakhstan Technical University
Marina Mizernaya [3], D. Serikbaev East Kazakhstan Technical University
Ainel Bissatova[4], D. Serikbaev East Kazakhstan Technical University

Abstract

In the modern world, rare metals are a sought-after sector. They are used in the production of lithium-ion batteries, which are widely used in smartphones, laptops, electric vehicles such as hybrid cars, electric cars or e-bikes. Consumption of rare metals in the world will increase rapidly in the coming years. But, like all other resources, rich rare metal deposits can be depleted quite quickly. Calculations of statistical indicators and resource accounting databases have shown that the known rare metal ores in the world will run out in about 25 years, and the reserves of explored resources - in about 50 years. Thus, there is a tendency towards the discovery of new and detailed additional exploration of already known rare metal deposits. Since the main rare metal structure of East Kazakhstan is the Kalba-Narym belt, this justifies the relevance of its study. In metallogenic terms, the Kalba-Narym belt is divided into the following ore districts: Shulba, North-West Kalba, Central Kalba and Narym. The Central Kalba region has been well studied and developed thanks to well-known industrial deposits (Yubileinoe, Bakennye, Belogorskoe, etc.). The remaining areas are by no means unpromising for rare metal mineralization. North-Western Kalba, as well as the entire Kalba-Narym metallogenic zone, is characterized by a rare-metal profile of ore mineralization associated with the formation of granites of the Kalba complex. The North-Western Kalba ore district is located northwest of the Central Kalba region and combines pegmatite rare metal and hydrothermal (W-Sn) occurrences. The most promising seems to be the Ubinsko-Kaindinsky ore cluster, which includes the Kovalevskoye ore field of lithium-bearing pegmatites, the deposits Kvartsevoye, Kaindy, Novokaindy, Malo-Kaindinskoye, Ubinskoye, Alypkel, etc. The quartz deposit of rare metal pegmatites (microcline-albite-muscovite subformation) is characterized by greisen mineral zones with rich in tantalite. Another group of occurrences with albite-spodumene mineralization is of practical interest for lithium raw materials (Aktobe ore field). The Monastyrsky ore cluster represents placers of monazite of alluvial and alluvial-proluvial origin (Kanaika, Uzunbulak, Sartynbek, etc.), discovered by G.N. Shcherba (1939). As a result of a detailed study of the geological structure, formation conditions, mineralogical composition, collection of historical materials and field research last year, the North-Western Kalba area was considered as promising for the discovery of industrial rare metal mineralization.
This research has been funded by the Science Committee of the Ministry of Science and Higher Education of the Republic of Kazakhstan (Grant No. AP19676805).

Pressure relevance of pegmatite melt evolution: new insight about melt-melt-fluid immiscibility imprinted in pegmatite quartz

Woohyun CHOI[1]*, Kyungpook National University (choi313047@gmail.com)
Changyun PARK[2], Kyungpook National University
Jeongmin KIM[3], Korea Basic Science Institute

Abstract

This study investigates the microtextural and geochemical characteristics of pegmatitic quartz from the Boam mine area to elucidate the evolution of the Uljin Li-pegmatite melt.

Quartz, a ubiquitous mineral present from the initial stages of pegmatite formation, records significant evolution in texture and composition. Cathodoluminescence (CL) observations of quartz from the Main Orebody (MO) and Eastern Orebody (EO) of the Boam mine area reveal at least four distinct formation stages. Large pegmatitic quartz exhibits rhythmic layered textures, displaying interlayered banding with lepidolite and albitite. These quartz grains exhibit three distinct CL colors. The blue CL zone, characterized by a coarse-grained, massive appearance, diminishes in dominance from the border zone to the core zone. High Li and Al content, coupled with the lowest δ18O values, suggest a silicic melt origin. The green CL zone, displaying fine-grained textures and sharp boundaries with the blue CL zone, exhibits mosaic and fracture-healing textures, indicating pressure drops during crystallization. The yellow CL zone, predominantly fine-grained and characterized by fracture-filling and healing textures, displays diffusive characteristics indicative of a flux-enriched aqueous melt phase. Steady B composition in pegmatitic quartz suggests non-isobaric segregation of melts, maintaining pressure change intervention during melt immiscibility.

In addition to large pegmatitic quartz, secondary hydrothermal quartz is associated with fine-grained muscovites. These quartz grains exhibit similar CL intensities to the yellow CL zone of pegmatitic quartz, along with the highest δ18O values. Decreased Na composition suggests crystallization post-albitite formation, while the highest Ge composition indicates the lowest formation temperature, indicating a aqueous fluid origin. Consistent increases in δ18O throughout evolution suggest limited external fluid input during pegmatite formation.

These textural and geochemical findings of quartz from the Boam mine area highlight the significant role of pressure changes during pegmatite melt evolution, triggering melt-melt-fluid immiscibility. Furthermore, oxygen isotope analysis of quartz suggests minimal intervention of meteoric water throughout pegmatite formation.

Mineralogical and geochemical properties of the pegmatite zircons: Implications for the formation of immiscible melt and fluid during pegmatite evolution

Youseong Lee[1]*, Kyungpook National University (hatoz9@knu.ac.kr)
Changyun Park[2], Kyungpook National University

Abstract

In this study, we investigate zircons found in the Li-bearing pegmatite at the Boam Mine, Uljin. The microtextural and geochemical features of these zircons reflect the three-phase immiscibility (silicic melt – aqueous melt – aqueous fluid) that occurred during the evolution of the pegmatite system. These zircons are categorized into Type-A and Type-B based on their REE patterns, while displaying identical textural characteristics (T1, T2, T3 domain). The primary texture, T1 domain, is identified as relatively bright bands in oscillatory zoning and sector zoning. The T1 domain of the Type-A crystallized from the silicic melt, showing a positive Ce anomaly and a steep increase in concentration from LREE to HREE. In contrast, the T1 domain of the Type-B crystallized from the aqueous melt, exhibiting a negative Ce anomaly and a relatively LREE-enriched and flat REE pattern. Unlike the T1 domain, which crystallized from the immiscible melt, the T2 and T3 domains were formed through interaction with the aqueous fluid. The T2, a domain formed by a diffusion-reaction process, is characterized by the lowest crystallinity, porous and mottled texture. It shows the highest concentrations of U, Th, Ca, Al, Fe, and F among the three domains. Furthermore, both T2 domains of Type-A and Type-B exhibit a characteristic of total REE enrichment compared to the T1 domain. On the other hand, the T3 domain, formed by coupled dissolution-reprecipitation, displays embayment and inward-penetrating textures, exhibiting the highest crystallinity among all domains. This domain typically overprints T2 selectively, showing lower total REE and trace element concentrations, indicative of recrystallization. The formation of the T3 domain, which dissolved the pre-existing region, indicates an increasing abundance of F and alkali elements in the aqueous fluid. This is supported by the crystallization of mineral inclusions such as apatite, muscovite, and K-feldspar in this domain.

Metallogenesis of superlarge W-Cu ore systems in South China: Exampled by Zhuxi and Dahutang ore deposits

Xiaofei PAN[1]*, Institute of Geology, Chinese Academy of Geological Sciences
(pan_smile0551@sina.com)
Yanshen Yang[2], University of Science and Technology Beijing
Xianke Fan[3], Institute of Geology, Chinese Academy of Geological Sciences

Abstract

As one of the most important metal resources, the W-Cu deposits are rarely mentioned, especially on the regional tectono-dynamics, mechanism of magmatic mineralization and origin of the ore-forming material including W and Cu. The two super-large newly-discovered deposits Zhuxi and Dahutang W-Cu are located in the north Jiangxi province, which belongs to the superimposed part of foreland nappe thrust zone of the southeast coast of Eurasian continental Plate, and the Precambrian Suture between the Yangtze and Cathaysian Plates. The granites in the two deposits are complicated multiphase intrusions and their roles on the metallogenesis of tungsten a copper are unclear. And the pegmatite veins or shells, which represent the direct product of the transportation from magma to hydrothermal fluid, have been found out in the two deposits. Therefore, the Zhuxi and Dahutang W-Cu deposits have been studied in this project to clarify the metallogenic age and sequence, and magma-hydrothermal evolution. The Dahutang ore deposits consists of several sub-ore deposits and have already experienced multiple magma-hydrothermal events during 153-128 Ma. The granites in Dahutang area could be subdivided into early stage granites (151-138Ma) and late stage granites (138–128 M). Most of the ore bodies in the Dahutang W-Cu deposit were formed during 143-133 Ma, simultaneously to the early granites (151-138Ma). Extreme magmatic exsolutions have occurred in the Dahutang W-Cu area so that greisenization widely developed, and multiple pegmatite shells and thick-bedded UST quartz bands with several meter wide grew. Microthermometer of fluid inclusions indicate that the hydrothermal fluids are high temperature (>550 ~ 397℃) with two gups of salinity with 6.9 ~ 9.9 wt% NaCl eq. and 45.6~59.9 wt% NaCl eq., respectively. Strong water-rock reaction have occurred during the scheelite precipitation process, while fluid cooling and immiscible processes might happened to influence the precipitation of metal sulfide with minor scheelite during the hydrothermal quartz-sulfide±scheelite stage. The in-situ LA-ICP-MS analysis of fluid inclusions and UST quarts suggests that the magmatic fluid carried large amounts of copper enough to provide the copper source in Dahutang. The in-situ LA-ICP-MS analysis of sulfide have showed that the whole cryptoexplosive breccia type of sulfides, and most of the quartz-vein type of sulfides and disseminated sulfides are δ34S=−3 ~ +2‰, belonging to the magmatic origin. However, there are a few of extremely low negative sulfur isotope values (e.g. −36.34‰ to −8.25‰) in the quartz-vein type of sulfides and disseminated sulfides, showing that some sedimentary sulfur have been evolved into the two types of sulfide. The in-situ LA-ICP-MS U-Pb daing of wolframite and zircon, and mica Ar-Ar dating reveal that there are two ore-forming stages of 153-147 Ma and

143-141 Ma and a two-stage ore-forming model have been provided for Zhuxi deposit in this study.

The use of lithium as a Critical Mineral in Granitic Pegmatite

Alla DIAW[1]*, National Geological Survey in Senegal (alla.diaw@sgns.gouv.sn)
Rokhaya Samba DIENE[2], Organisation of Africa Geological Survey
Raymond SAGNA [3], National Geological Survey in Senegal

Abstract

Among critical mineral deposits found in granitic pegmatites, lithium is the most common due to its genesis. Granitic pegmatites exhibit the highest abundance of lithium.
Lithium is currently one of the most sought-after minerals globally due to its strategic position in sectors such as:
• Glass and ceramics (35%);
• Batteries and cells (31%);
• Greases and lubricants (8%).
Additionally, lithium plays a role in industrial chemistry processes.
The battery manufacturing, smartphone, and tablet sectors, along with the increased production of electric vehicles, have driven an 18% surge in lithium demand since 2010.
The mining sector is crucial in the transition toward a low-carbon economy. Solar panels, wind turbines, and electric vehicles heavily rely on minerals like cobalt, copper, lithium, nickel, and others. According to the International Energy Agency, limiting global warming to less than 2°C may require a fourfold increase in mineral supply for clean energy technologies over the next two decades.
In this context, these minerals play a vital role in Africa's energy transition. According to UBS AG, as reported by Bloomberg:
• Africa could enable China to control over 30% of the global lithium supply by 2025 (compared to 24% in 2022);
• By 2025, mines controlled by Chinese interests are expected to produce up to 705,000 tons of lithium, compared to 194,000 tons in 2022.
It is important to note that in the Ilymalo sector, south eastern part of Senegal, various studies conducted by BRGM in 1962 revealed a lithium-bearing silicate ore called spodumene within pegmatites associated with the Saraya Granitic Massif.
The lithium oxide (Li_2O) content is approximately 6%, and significant reserves are estimated to be over 5,000 tons.
For further lithium exploration, the focus should be on the borders of granitic pegmatite formations.

Genesis of the Koktokay pegmatitic rare-metal deposit (Altai, China): Constraints from the newly-recognized Triassic rare-metal leucogranite

Ping SHEN[1]*, Institute of Geology and Geophysics, Chinese Academy of Sciences (pshen@mail.iggcas.ac.cn)

Abstract

Rare-metal granitic pegmatites are commonly associated with granites. However, for the Koktokay No. 3 pegmatite in the Chinese Altai, hosting a giant Li–Be–Nb–Ta–Cs–Rb–Hf deposit, the parental granites have not yet been found. The genesis of the No. 3 pegmatite has been controversial for many years. We conducted geological, geochemical and chronological research on the intrusions and the Middle Ordovician metamorphic rocks of Habahe Group in the Koktokay district. We recognized the Be-Nb-Ta-bearing highly fractionated leucogranite in the open pit in the Koktokay deposit based on detailed field and petrographic observations. The leucogranites consist of fine- to medium-grained muscovite albite granite and fine-grained albite granite in which beryl (Be) and coltan (Nb–Ta) occur. The muscovite albite granite is the main body of the leucogranite, and the albite granite is restricted to the margin of the muscovite albite granite. Six coltan U–Pb ages of the leucogranites from the open pit fall at Koktokay in a narrow range of 224.2 ± 2.7–220.7 ± 4.0 Ma which are in good agreement with our one coltan U–Pb age of 219.8 ± 1.3 Ma of the No. 3 pegmatite and the previously published ages of the No. 3 pegmatite with zircon and coltan U-Pb ages of 220–218 Ma. The muscovite 40Ar/39Ar ages from the same leucogranite samples yield the age range of 181.1 ± 1.4 Ma ~ 177.2 ± 1.2 Ma, indicating a new early Jurassic hydrothermal event. Therefore, the emplacement of the leucogranites and associated mineralization occurred in late Triassic which was followed by a new mineralization at early Jurassic at Koktogay. These leucogranites are characterized by high Al2O3 and Na2O and show well-developed convex tetrad effect. They are volatile-rich, peraluminous S-type granites and are formed by highly fractional crystallization and underwent melt and fluid interaction. The leucogranite is enriched in lithophile (Li, Be, Nb, Ta, Cs, and Na) and volatile elements (e.g., B, F, P, H2O) with extremely low ratios of Zr/Hf (8.2–13.8) and Nb/Ta (0.8–5.9), indicating a fertile rock. In addition, the metamorphic rocks of the Habahe Group are mainly composed of mica schist. Their trace element contents are similar to that of the continental crust. Therefore, it is impossible to directly form mineralizing magma through partial melting of these metamorphic rocks. Both leucogranite and No. 3 pegmatite are similar in ages, mineral assemblage and geochemistry. It indicates that they are contemporaneous and cogenetic, implying a common magmatic source. A much larger, unexposed parental granite, from which the leucogranite and No.3 pegmatite have fractionated, must lie at inaccessible depths. A granite-pegmatite model is established that the parental granite at depth is connected with leucogranite and pegmatite at shallow which is likely responsible for the formation of the giant Koktokay No. 3 pegmatite.

[Keynote] Origin of Cu-Co mineralization in the Central African Copperbelt: Neoproterozoic syn-sedimentary-diagenetic processes overprinted by Pan-African orogenic mineralization events

Huimin SU[1]*, China University of Geosciences (Wuhan) (suhm@cug.edu.cn)
Shaoyong Jiang[2], China University of Geosciences (Wuhan)
Guoxiang Chi[3], University of Regina

Abstract

The Central African Copperbelt (CACB) hosts the majority of the Co resources in the world, however, whether these Cu-Co deposits were formed during the syn-sedimentary-diagenetic stage or by later hydrothermal processes at the orogenic stage is a matter of debate. The Luiswishi deposit, hosted in the least deformed and metamorphosed host rocks of the Katanga Supergroup within the CACB, was selected in this study to explore this issue. Petrographic observations indicate a certain correlation between the mineralogical compositions of the veins and their host rocks, with quartz-, dolomite-, and magnesite-(sulfide) veins occurring in silicic, dolomitic, and magnesitic host rocks, respectively. Four paragenetic stages were identified, i.e., the pre-ore stage with pyrite (Py0), syn-sedimentary-diagenetic Cu-Co stage with chalcopyrite (Ccp1), syn-orogenic Cu-Co stage with pyrite (Py2) and chalcopyrite (Ccp2), and post-ore stage with pyrite (Py3) as the dominant sulfides. U-Pb dating of hydrothermal monazites associated with the main vein-type mineralization and post-ore pyrite yielded ages of 523 Ma and 506 Ma, respectively, coinciding with the peak metamorphism of the Lufilian orogeny. Py0 exhibits elevated contents of Co and As but low Cu and Ni, with variable δ34SCDT values from -9.1‰ to +12.0‰. The δ34S values for Ccp1 vary with the lithology of the host rocks (avg. -1.3‰ for quartz siltstone; avg. 3.6‰ for dolomitic sandstone/dolostone; avg. 5.6‰ for magnesite rock). The coarse-grained Ccp2 from the discordant veins shows higher Sn and In contents than Ccp1, indicating that Ccp2 formed in a hydrothermal fluid with increased temperature. Py2 shows a gradual decrease in Co and As from the early phase (Py2a) to later phase (Py2c), reflecting the gradual depletion of these elements in the hydrothermal fluid. The sulfides in syn-orogenic vein-type ores show similar δ34S values as their corresponding syn-sedimentary-diagenetic sulfides disseminated in the stratiform ores, indicating that the sulfur for orogenic mineralization was mainly derived from the syn-sedimentary-diagenetic sulfides. Overall, the current study supports a model in which the sediment-hosted Cu-Co deposits in the CACB formed from Neoproterozoic syn-sedimentary-diagenetic processes overprinted by Pan-African orogenic mineralization events. The bulk of the metals and sulfur in the deposits were introduced in the syn-sedimentary-diagenetic stage, and the orogenic mineralization process mainly played the role of remobilization and upgrading of the syn-sedimentary-diagenetic mineralization.

Geochemical anomalies related to cobalt-nickel mineralization in the Eastern Kunlun Orogen, China

Yue LIU[1]*, CUG (liuyue7870@cug.edu.cn)

Abstract

The demand for Co and Ni metals is rapidly increasing worldwide, yet future metal supply remains uncertain due to the difficulty in discovering new deposits using traditional methods. The Eastern Kunlun Orogen (EKO) stands as a significant metallogenic domain located in the western segment of Chinese central orogenic belt. Since the discovery of the Xiarihamu super-large Ni-Cu-Co deposit in 2011, it has triggered a surge in intensified efforts to explore cobalt and nickel deposits in the EKO. Cobalt and nickel deposits can be roughly grouped into two genesis types: (i) magmatic Co-Ni sulfide deposit, and (ii) hydrothermal Co polymetallic deposit. In this study, advanced data processing methods including centred log-ratio (clr) transformation, compositional hierarchical clustering analysis (CHCA), compositional balance analysis (CoBA), local singularity analysis (LSA) and concentration-area (C-A) fractal analysis were applied to recognize Co-Ni mineralization-related geochemical anomalies from different perspectives based on stream sediment geochemical data. The clr-transformed method was used to eliminate the closure effect of compositional geochemical data. The CHCA and CoBA methods are employed to reveal Co-Ni mineralization-related multi-element combination pattern and constructed interesting compositional balances for anomaly mapping in space. The LSA is applied to recognize weak and concealed Co and Ni anomalies, and the C-A model was used to separate Co-Ni anomaly from geochemical background. Aided by the results of geochemical anomaly recognition, Co-Ni ore-forming characteristics of different genesis types were investigated, which allowed for delineating favorable prospecting zones with the purpose of exploring magmatic Co-Ni sulfide deposit and hydrothermal Co polymetallic deposit in the EKO.

Major types of Co-Ni deposits and their exploration in China

Shao-Yong JIANG[1]*, China University of Geosciences (Wuhan) (shyjiang@cug.edu.cn)

Abstract

Cobalt and nickel are very important strategic mineral resources worldwide. The world cobalt resource is mostly hosted by sedimentary and metasedimentary rocks, while nickel resource is mainly from laterite type deposits, and these deposits are generally large in scale, high in ore grade, and easy to explore. However, the current mining and utilization of cobalt and nickel in China are mainly from magmatic type deposits, such as the Jinchuan Cu-Ni-Co deposits (150000 tons @ 0.019% Co, 5.526 million tons @ 1.06% Ni), and the Xiarihamu Ni-Co deposits (42900 tons @ 0.025% Co, 1.18 million tons @ 0.68% Ni), occurring in small plutons with low ore grade, small deposit size, and Co mainly as by-product with complex occurrence. Recent studies have shown that metasedimentary rock hosted Co deposits and hydrothermal Co deposits are widely distributed in China, but their occurrence characteristics and enrichment mechanisms are unclear, and the resource potentials and economic values need to be comprehensively evaluated.

In China, the metasedimentary rock hosted Co deposits are mainly found in the Liaoji and Zhongtiaoshan metallogenic provinces in the Paleoproterozoic orogenic belts of the North China Craton, including the Dahenglu large Cu-Co deposit, the Zhoujia medium-sized Fe-Cu-Co deposit, the Tongkuyu, Bizigou, Tongmugou, and Hujiayu large Cu-Co deposits. All these deposits have been modified by multiple magmatic-metamorphic-tectonic events and superimposed hydrothermal events. The hydrothermal cobalt deposits are widely distributed in China. Many of these deposits are independent cobalt deposits or deposits with cobalt as the main metal resource, which have great prospecting significance and potential economic value, including the Tuolugou Co-Au deposit (20000 tons @ 0.066% Co) and De'erni Cu-Co deposit (28500 tons @ 0.089% Co) in the East Kunlun Mineralization Belt, and the Qibaoshan and Wubaoshan Cu-Pb-Zn-Co deposits (15000 tons @ 0.403% Co) in Jiangxi province and the Longhua small-scale and high-grade Ni-Co deposit (3226 tons of Ni and 285 tons of Co @ 17-27.9% Ni and 1.55-1.95% Co) in Guangxi province in the Qinhang Mineralization Belt.

Currently, we have a national key research and development project on going, aiming to reveal the ore-forming mechanism of cobalt and nickel and also the efficient exploration techniques for Co-Ni orebodies, in an attempt to find and evaluate more cobalt and nickel resources in China, to innovate the genetic theory of cobalt and nickel mineralization, establish ore genetic and prospecting models, strengthen the exploration technology and capabilities, and explore potential high-quality cobalt and nickel resources in China.

Unlocking critical metal resources from the Avebury metasomatic Ni sulfide deposit, Western Tasmania, Australia

JOSE LUIS LUIS BARILLAS DIAZ[1]*, University of Tasmania- CODES
(joseluis.barillasdiaz@utas.edu.au)
David Cooke[2], Centre for Ore Deposit and Earth Sciences (CODES), University of Tasmania
Lejun Zhang[3], Centre for Ore Deposit and Earth Sciences (CODES), University of Tasmania
Wei Hong[4], Centre for Ore Deposit and Earth Sciences (CODES), University of Tasmania
Yamila Cajal[5], Centre for Ore Deposit and Earth Sciences (CODES), University of Tasmania
Josh Denholm[6], Avebury Nickel Mine
Tony Chisnall[7], Avebury Nickel Mine

Abstract

Hydrothermal Ni systems are relatively rare and poorly studied. However, besides being a significant source of Ni, they may contain critical mineral resources (e.g., Co, PGEs, Bi, Sb). The Avebury Ni deposit is one of the best-known examples of non-magmatic nickel sulfide and cobalt arsenide deposits. It is located in the Zeehan mining district in the Dundas Region of Western Tasmania, Australia, characterized by complex geological evolution and diverse mineralization styles. The Avebury nickel sulfide orebodies formed within Cambrian serpentinized allochthonous mafic-ultramafic complexes and lie in the aureole of the strongly fractionated, reduced Devonian Sn-mineralized ~360 Ma Heemskirk granite.

The correlation of Bi, Sb and Au with Ni is evidence of hydrothermal-remobilized metasomatism at Avebury. The host rocks have been altered to skarn mineral assemblages, including diopside + hedenbergite + augite and tremolite-actinolite, and there has been intense borosilicate metasomatism, primarily axinite-(Mg) with accessory tourmaline. The mineralization occurs in the serpentine and serpentine skarn that replaced the ultramafics and, to a minor extent, in skarn developed in the Crimson Creek formation. The mineralized serpentine shows a positive correlation of Ni/Cr and Ni/Ti ratios from assay data. Prograde metasomatic reactions in mineralized magnesium-silicate skarn of Avebury are characterized by wollastonite + apophyllite, which hosted sphalerite and lesser galena and olivine + augite + diopside associated with nickel sulfides. The silicates in retrograde zones are clinozoisite + prehnite associated with arsenide Ni-Co mineralization.

The mineral textural relations from core logging and SEM/AMICS revealed a complex evolution of Ni and Co mineralization. The dominant nickel sulfide mineral at Avebury is pentlandite, which is associated with pyrrhotite, magnetite, and minor chalcopyrite. Pentlandite is hosted in olivine + clinopyroxene cumulates, which have been serpentinized in most cases where pentlandite occurs mainly as relatively coarse-grained sulfide blebs with pyrrhotite. Pentlandite also occurs in relatively fine-grained shattered disseminations within actinolite. The coarse pentlandite is fractured and encapsulated by magnetite, and Ni-arsenides have partly replaced pentlandite grains.

Pentlandite has altered slightly along grain edges to violarite and pyrite. Chalcopyrite may occur as exsolution intergrowths in millerite and pentlandite. In contrast to typical magmatic Ni deposits, the ratio of pentlandite is exceptionally high compared to pyrrhotite and chalcopyrite. Ni sulfides occur as coarse disseminations in metasomatized clinopyroxene-olivine cumulates in high-grade mineralized zones. Magnetite is associated with the sulfides in metasomatized serpentine. Ni-arsenides, including maucherite, nickeline, and gersdorffite have replaced pentlandite. Bismuth minerals, including parkerite and bismuthinite, and Sb minerals (ullmannite, hauchecornite, and breithauptite) are associated with Ni arsenides inferred to be hydrothermal. Cobaltite and alloclasite are the two main cobalt arsenide minerals, occurring in a mineralized halo within the Neoproterozoic volcanogenic sedimentary rocks of the Crimson Creek Formation proximal to the contact with the Cambrian serpentinite. Textural features demonstrate that the replacement of pentlandite by Ni-arsenides occurred late in the paragenetic evolution of Avebury. Apatite U-Pb ages from 374 ± 14 Ma to 347 ± 15 Ma from mineralized serpentine and skarn imply that hydrothermal remobilization of Ni-Co occurred at Avebury due to hydrothermal fluids derived from Devonian Heemskirk.

Resource Potential Evaluation of Magmatic Cobalt and Nickel in the East Kunlun Metallogenic Belt, Northwest of China

Feng ZHANG[1]*, China University of Geosciences,Wuhan (1956606774@qq.com)
Qinglin Xia[2], China University of Geosciences,Wuhan

Abstract

In the Kunlun orogenic belt of the East Kunlun region, multiple magmatic sulfide deposits of cobalt-nickel type, such as Xiarihamu and Shitoukengde, have been discovered along the Kunlun fault. The area still holds significant mineral exploration potential. This study focuses on the East Kunlun orogenic belt, and based on the metallogenic geological background and metallogenic model research, combined with multi-source geological geochemical and geophysical exploration data, it conducts a metallogenic potential analysis of magmatic cobalt-nickel deposits in the study area using a geology-constrained convolutional neural network (CNN) model. In the construction of the CNN model, a hard constraint layer for mafic-ultramafic rocks is added in the convolutional layer based on the characteristic of the magnesium-iron ratio content of basic-ultrabasic rocks in cobalt-nickel deposits, which screens the mafic-ultramafic rocks in the evidence layer and establishes a geology-constrained CNN model, endowing the data-driven CNN model with theoretical interpretability. To ensure sample balance in the prediction data and prevent overfitting during the model prediction process, a sliding window method is adopted to expand the positive samples. Predictive models are established before and after sample expansion, and ROC is used to evaluate the predictive models. The research results show that the accuracy of the geology-constrained CNN model is 92.1%, indicating excellent predictive performance. The results, highly consistent with known deposits, suggest that the model's predictions can be used for resource potential assessment of magmatic cobalt-nickel deposits in the East Kunlun metallogenic belt in northwest China.

Occurrence patterns and controlling factors of Co in the world-class Panzhihua Fe-Ti oxide deposit, SW China: implications for Co mineralization

Banxiao RUAN[1]*, China University of Geosciences (Wuhan) (bxruan@foxmail.com)
Ruiqin Liu[2], China University of Geosciences (Wuhan)
Xinlu Hu[3], China University of Geosciences (Wuhan)
Xinbiao Lv[4], China University of Geosciences (Wuhan)

Abstract

Cobalt is an important strategic critical metal mineral. The Panzhihua deposit is the world's largest iron and titanium oxide deposit, reported to contain 10,000-20,000 tons of cobalt with grades ranging from 0.01% to 0.02%, and the cobalt and nickel resources in the deposit have been able to be effectively recovered and comprehensively utilized. However, the occurrence of cobalt in this deposit, especially the characteristics of cobalt-containing minerals, is still unclear. We carries out Major and trace element geochemical analyses, SEM-EDS, LA-ICM-MS and mineral mapping for different types of rocks and minerals, and explores the variation of cobalt-nickel content and the state of cobalt-nickel accumulation at the petrographic, lithological and mineral levels. The Panzhihua deposit can be divided into 6 phase zones from shallow to deep, such as Upper zone, Middle zone(a), Middle zone(b), Lower zone, Bottom zone and Marginal zone, etc. Cobalt and nickel are mainly enriched in the Lower zone, with an average cobalt content of 174.95 ppm and an average nickel content of 131.65 ppm. Among the different lithologies in the Panzhihua deposit, cobalt and nickel are mainly enriched in the massive magnetite (massive-dense dipping ore). with average cobalt content of 277.06ppm and average nickel content of 281.09ppm. cobalt may occur independently as minerals such as cobalt pentlandite, linnaeite, and siegenite, or exist in isomorphous forms, substituting for iron (Fe) and nickel (Ni) in pentlandite, pyrrhotite, and pyrite. In chalcopyrite, cobalt exists mainly as microscopic inclusions.

Conclusion based on the previous analysis:

(1)Occurrence and mineralogical characteristics of cobalt. Cobalt predominantly occurs in sulfide minerals, indicating a strong affinity with sulfur. These sulfide minerals are mainly found in magnetite ores and ultramafic rocks.

(2)Differences in mineralization between nickel and cobalt. The mineralization of nickel primarily takes place during the magmatic stage, suggesting that nickel enrichment is mainly associated with magmatic activities, such as sulfur saturation and sulfide segregation. In contrast, cobalt undergoes enrichment both during the magmatic and hydrothermal stages, such as the flow and metasomatism. indicating a more complex mineralization process.

(3)In summary, while cobalt and nickel share some similarities in terms of their occurrence in sulfide minerals, there are significant differences in their mineralization processes. These differences reflect their distinct behaviors and enrichment mechanisms, providing valuable guidance for Co-Ni exploration and development.

Mineralization of Ni-Co and other critical metals in Early Cambrian black shales in the Yangtze Block of South China

Jing-Hong YANG[1]*, Nanjing University (yangjh@nju.edu.cn)

Abstract

Black-shale hosted deposits of Ni-Co and other critical metals occur widely in South China, which are either hosted in a thin stratigraphic horizon of the Early Cambrian Niutitang Formation along a 1,600 km-long NE-SW trending belt in the Yangtze Block (e.g., the Huangjiawan and Zhijin deposits in Guizhou province, Sancha and Cili deposits in Hunan province), or as cross-cutting veins locally (e.g., the Longhua Ni-Co deposit in Guangxi Province).

The first and major type of Ni-Co mineralization is the stratiform sulfide ore layers of Ni-Co (up to 7.0% Ni and 0.02% Co) and other critical metals, that were formed during syn-sedimentary seafloor hydrothermal venting and subsequent diagenesis at Early Cambrian in rift basins with Re-Os ages between 532 Ma and 521 Ma reported by various researchers. The black shale sequences are rich in organic matter (up to 10% TOC), sulfur and phosphorus, indicating an anoxic to euxinic ocean environment along the passive margin of the Yangtze Block. The major Ni-Co minerals in these sulfide ore layers consist of MoSC phase ([Mo,Fe,Ni][S,As]2C7), vaesite (NiS2), bravoite([Fe,Ni]S2), millerite (NiS) and jordisite([Mo,Ni]S2).

The second type of Ni-Co mineralization is the hydrothermal veins crosscutting the Cambrain fine clastic sedimentary rocks, representing by the Longhua Ni–Co deposit in Guangxi Province, Southwest China. This type of Ni-Co deposit is small in scale and comprises quartz-Ni(-Co) arsenide and sulfide veins in Cambrian strata with high concentrations of Ni (~ 17.55%) and Co (~1.55%) and a proven reserve of 3226 t of Ni and 285 t of Co. No occurrences of ultramafic, mafic or felsic intrusive rocks are found in the region, and the veins were formed at low temperatures (220-118 oC). The main ore minerals of Ni and Co include niccolite (NiAs), gersdorffite (NiAsS), maucherite (Ni11As8), cobaltite (CoAsS), pentlandite ([Ni, Fe]9S8), skutterudite ([Co, Ni]As2), chloanthite ([Ni, Co]As2), and parkerite (Ni3Bi2S2). Previously, a Re-Os isotope dating of niccolite samples from the quartz veins revealed a formation age of 463±9 Ma, in consistent with the Caledonian orogeny in South China (Huang et al., 2020).

Overall, the mineralization mechanism of Ni-Co and other critical metals in the Early Cambrian black shale sequence in the Yangtze Block of South China possibly includes multiple stages of metal enrichments, with the initial enrichment and/or first stage ore formation of Ni-Co polymetallic sulfides during early Cambrian syn-sedimentary sea-floor hydrothermal event, and the formation of high-grade Ni-Co ore veins during later Caledonian orogenic-driven hydrothermal event. The superimposed hydrothermal activity is of great important for super-enrichment of Ni-Co metals and more attention should be paid in future exploration of such kind

of hydrothermal type Ni-Co deposits in South China.

Platinum Group Elements and associated magmatic sulfide mineralization in the Tantalite Valley Complex, Southern Namibia

Daniel Reuben Ferreira[1]*, Stellenbosch University (21656118@sun.ac.za)
Bjorn Philip von der Heyden[2], Stellenbosch University
Martin Klausen[3], Stellenbosch University

Abstract

Orthomagmatic sulphide deposits are a primary source of Platinum Group Elements (PGEs), Nickel, Copper, and Cobalt. These elements are crucial for sustainability in a world that is increasingly moving towards a greener future and as such, exploration for these metals is of critical importance to facilitate the green energy transition.

The Tantalite Valley Complex (TVC) is a mafic-ultramafic complex located in southern Namibia. It forms one of four ultramafic bodies in the region belonging to the Kum Kum Suite that emplaced circa 1,2 Ga. Its crystallization history suggests that an immiscible sulfide melt formed and concentrated within an orthopyroxenitic host cumulate in the complex's southeastern sector. These sulphide aggregates manifest as disseminated sulphides (< 2wt. %) found at the interstices of cumulus minerals and are dominated by pentlandite (40 - 85 modal %) followed by pyrrhotite (20 - 60 %) and minor chalcopyrite (10 - 40 %). To date, only the ultramafic cumulates in the southeastern sector have been targeted by previous drilling campaigns. These ultramafic cumulates have a surface expression of less than 10 % compared to their gabbroic counterparts and leave the vast majority of the TVC unexplored.

The present study aimed to investigate the textures of the sulphide aggregates, their paragenesis, the origin of the sulphur within the magmatic system, and the fractionation of precious and semi-precious metals between different sulphide phases, including two known overprinting events. The investigation also aimed to explore the complex's mineralization potential in hosting a disseminated sulphur-poor Platinum Group Element deposit(s) or a sulphur-rich Ni-Cu (+-Co) deposit(s) and whether or not the TVC, and by extension the greater Kum Kum Suite, may be prospective in hosting at least one style of these deposit classes.

The results from in-situ multiple sulphur isotope analysis and whole rock sulphur/selenium ratios suggest that sulphur within the magmatic system is purely mantle-derived and negligible degrees of interaction occurred with sulphur-rich crustal sources. LA-ICP-MS studies indicate that deuteric pyrite is an important host of Ru, Rh, Os, and Ir and that magmatic pentlandite plays host to significant concentrations of Pd in solid solution. The R-factor for the complex is approximately 3,000 indicating an average value for mineral prospectivity. Based on these results the TVC might be considered most prospective for the sulphur-poor PGE-dominated deposit class.

Linking Selective Alteration, Mineral Compositional Zonation and Sulfide Melt Emplacement in Magmatic Ni-Cu Sulfide Deposits

Mengmeng Cui[1]*, Institute of Geology and Geophysics,Chinese Academy of Sciences (cuimm@mail.iggcas.ac.cn)

Abstract

The magmatic Ni-Cu sulfide deposits in orogenic settings are characterized by extensive alteration, presence of hydrous minerals, and the nature of hydrous parental magmas. The role of water in the formation of the magmatic Ni-Cu sulfide deposit remains unclear. Here, we present petrological and mineralogical investigations of the Hongqiling Ni-Cu sulfide deposit, a typical representative of such numerous deposits in the Central Asian Orogenic Belt. Observations at various scales of field outcrops, hand specimens, thin sections and microscopes reveal that alterations are selectively exposed in silicate minerals, particularly olivine and pyroxenes that are close to ore bodies and sulfides. It is worth noting that alteration of olivine and pyroxenes becomes weak when hydrous minerals (hornblende and phlogopite) are present. Profile analyses demonstrate that the olivine grains enclosed in or in contact with sulfides have compositional zonation with Fe, Mn, Sc and Zn concentrations higher in closer to the contacts with sulfides relative to the cores and contacts with other silicates, while those grains in sulfide-barren rocks show relatively homogeneous compositions. Sulfides in rocks and ores are all free of alteration and have mantle-like sulfur isotopic compositions. These features suggest that the selective alterations occurring in early crystallized phases were induced by sulfide melt intrusion and crystallization, instead of late-stage processes as previously thought. The sulfide melts segregated at the early stage of the magma evolution were presumably hydrous and buoyant in the silicate magma and therefore were transported upward and penetrated into silicate grains. The hydrous fluids released from the sulfide crystallization to hydrate surrounding mineral phases and rocks, because the crystallized sulfides cannot structurally accommodate hydrous components. The fluids also enhanced compositional exchanges between sulfides and silicates and accounted for the crystallization of hydrous minerals. The characteristics of selective alteration and regular variations in mineral composition have also been found in magmatic Ni-Cu sulfide deposits of craton settings (e.g., the third largest Jinchuan deposit), suggesting the common of selection alteration in magmatic sulfide deposits. It can be considered as a significant indicator of mineralization and exploration in mafic-ultramafic intrusions.

Ni-PGE enrichment in the Jaguar and Jatobá IOCG deposits, Carajás district, Brazil

Yuri Tatiana CAMPO RODRIGUEZ[1]*, University of Adelaide (ytcampor@unal.edu.co)
Nigel J. Cook[2], University of Adelaide
Cristiana L. Ciobanu[3], University of Adelaide
Kathy Ehrig[4], BHP
Maria Emilia Schutesky[5], University of Brasilia
Sam A. King[6], University of Adelaide

Abstract

Iron-oxide copper-gold (IOCG) deposits encompass a broad range of alteration styles and ore assemblages unified by a dominance of iron oxides (magnetite and/or hematite), and often with elevated concentrations of valuable critical elements such as cobalt (Co) and rare earths. In the Carajás Mineral Province, Brazil, several deposits display relatively high concentrations of nickel (Ni) and/or platinum group elements (PGE). These metals are not typically recognized in IOCG-systems. The uniqueness of the Ni-PGE enrichment in the Carajás deposits lies in their spatial association with crustal-scale altered mafic-ultramafic lithologies.

We undertook petrographic, compositional (LA-ICP-MS) and nanoscale (STEM) study of samples from two Ni-enriched IOCG deposits, Jaguar and Jatobá. Results show similar hybrid-style mineralization expressed by multiple stages of overprinting and substantial reworking of early assemblages. The geochemical and mineralogical signatures of the two deposits do, however, differ significantly. In the Jaguar deposit, hydrothermal evolution is documented by sulphide assemblages/textures indicative of an early magmatic Ni-(Cu) mineralization event superimposed by IOCG-style Cu-mineralization. The main Ni-host in Jaguar is pentlandite with additional Ni occurring within compositionally-zoned pyrite and minor millerite. Less common Ni-Bi-Te minerals, including parkerite and bismutohauchecornite, associated with other Bi-Te-minerals are commonly observed within microfractures in pyrite. Despite the less intense alteration, the Jatobá deposit is more enigmatic. Multi-stage evolution is recorded by sulphide textures and inclusions within magnetite, namely amphiboles and non-classical pyriboles (NCPs). Early magnetite-pyrrhotite assemblages records Mg-Fe amphiboles and NCPs formed within a mafic/ultramafic lithology. Pyrrhotite is extensively replaced by pyrite, the major Ni-bearing sulphide, during the onset of IOCG-mineralization, an event associated with formation of Ca-(Al) amphiboles and Ce-bearing Mg-hornblende. Later (ferro)tschermakite formation is associated with shearing during main ore deposition. Nickel also occurs as bravoite and siegenite in Jatobá. Conspicuously, Ni-Bi-Te minerals are absent. Instead, several platinum group minerals are identified, filling fractures in pyrite and associated with rare earth- and uranium-minerals. All Pd-minerals identified (kotulskite, merenskyite, naldrettite, sudburyite, and borovskite) contain mobile elements such as Te-Bi-Sb. The novel occurrence of Pd and Pt (sperrylite) within sulphide mineralization in deposits considered to be of IOCG-type highlights the potential for additional discoveries in analogous examples of hybrid mineralization outside the Carajás district. The convergence of two

distinct geochemical signatures and superimposed fluid-assisted remobilization events contribute to the significant Ni-budget in both deposits. Moreover, the Ni-enrichment appears not to be restricted to sulphides, with significant Ni also contained within magnetite and amphiboles, a finding that carries implications for ore processing.

Nanoscale study reveals multi-stage generations of amphibole-NCP assemblages occurring as inclusions within magnetite. Their presence emphasizes the interpretive value of magnetite, a refractory mineral, for identification of overprinting events in terranes with protracted geological histories. Likewise, the discovery of Ce-rich hornblende in Jatobá provides new avenues to understand the early, alkali-calcic alteration of IOCG-systems.

Geology and cobalt occurrence of the Cihai iron-cobalt deposit, eastern Tianshan, Xinjiang, China

Wei MEI[1]*, China University of Geosciences, Wuhan (meiwei09@qq.com)
Banxiao Ruan[2], China University of Geosciences, Wuhan

Abstract

The Cihai iron-cobalt deposit is located in the southern part of the eastern Tianshan, Xinjiang, northwestern China. The major iron orebodies are banded and nearly parallel to each other. The iron ores are hosted in an early mafic dike (i.e., diabase and pyroxenite) and in skarn. Magmatic-hydrothermal activity can be divided into four stages based on geological and petrographic observations:(1)K-Na alteration (stage I) is characterized by pyroxene being replaced by biotite and sodium metasomatism of Ca-rich plagioclase. (2) prograde skarn (stage II) is characterized by formation of abundant garnet and pyroxene, with minor magnetite. (3) retrograde skarn (stage III)is marked by formation of magnetite main ore and amphibole assemblage with minor epidote and zoisite. (4) stage IV is characterized by deposition of a pyrite-pyrrhotite-chalcopyrite-calcite-quartz assemblage, typically as sulfide-rich veins that cut the magnetite ores with lesser cobalt.
Whole rock analysis of the previous research results show that Co-enrichments were also recognized in massive sulfide ore (mean=928.67 ppm Co) and pyroxenite (mean=117.3 ppm Co). EPMA and LA-ICP-MS analyses showed that the main carrier of cobalt was Co-bearing pyrite (mean=6.09 wt% Co) in the form of Fe0.82~0.91Co0.09~0.18S2, and to a lesser extent, pyrrhotite (mean=567.89 ppm Co) and pyrite (mean=536.53 ppm Co), and minor chalcopyrite (mean=6.28 ppm Co). The Co-bearing pyrites occur as two forms: The first Co-bearing pyrites (CoI) occur as anhedral coexisting with pyrrhotite. The second Co-bearing pyrites (CoII) occur along the edges of subhedral pyrite, suggesting the Influence of late hydrothermal action. Formation of the Cihai iron deposit is closely related to post-collisional subvolcanic action and associated Cu-Ni-Co polymetallic mineralization in the eastern Tianshan.

The origin and mineralization processes of the Dulenggou copper-cobalt deposit in Eastern Kunlun metallogenic belt, western China

Wei WANG[1]*, China University of Geosciences, Wuhan (1768140159@qq.com)
Shao-Yong Jiang[2], China University of Geosciences, Wuhan
Hui-Min Su[3], China University of Geosciences, Wuhan

Abstract

The eastern Kunlun region in western China stands out as an important polymetallic metallogenic belt hosting gold, copper, iron, cobalt, and nickel resources. Within this belt lies the Dulenggou deposit, a notable copper-cobalt deposit. The ore bodies have lengths ranging from 106 to 335 m and widths ranging from 2.12 to 13.4 m. Copper grades within the deposit range from 0.45% to 28.41%, while cobalt grades range from 0.02% to 0.43%. The exposed formations include the Meso-Neoproterozoic Wanbaogou Group, Lower Triassic sandstone and conglomerate, the Ordovician-Silurian Nachitai Group, and Quaternary sediments. The Wanbaogou Group consists of intermediate basic volcanic rocks such as andesite, andesitic tuff, and tuffaceous limestone. The NaijTal Group consists mainly of andesite, chlorite sericite phyllite, and tuffaceous slate, which is the host strata of the Cu-Co-Ni orebodies.

We identified three cobalt minerals (cobaltine (CoAsS), siegenite ((Ni,Co)3S4), glaucodot ((Co,Fe)AsS)) and four nickel minerals (ullmannite (NiSbS), gerdorffite (NiAsS), violarite (FeNi2S4) and millerite (NiS)) coexisting with chalcopyrite in the Dulenggou deposit. Three stages of pyrites were identified: Py0, PyI and PyII, which are all depleted in cobalt, but PyI can contain Ni contents up to 8814 ppm (with an average of 2490 ppm). The sequence of mineral formation follows Py0 → PyI + Ccp + Co-Ni mineral (the major mineralization stage) → PyII.

The mineralization age of the Dulenggou deposit is determined by in-situ U–Pb dating of monazite occurring close to chalcopyrite and Co-Ni minerals with an age of 457±18 Ma, providing direct evidence confirming that the Cu-Co-Ni mineralization formed simultaneously with the host strata of the Nachitai Group (416 to 538 Ma). The δ34S values of sulfides range widely from 1.9‰ to 22.1‰. From Py0 to PyI to PyII, the δ34S values decrease from 17.6‰–22.1‰ to 9.1‰–14.6‰ to 1.9‰–7.7‰. These findings challenge previous views that this deposit is an epigenetic hydrothermal deposit formed during the Variscan-Indosinian period. This study indicates that the Dulenggou Cu-Co-Ni deposit is a syngenetic sea-floor sedimentary exhalative deposit (SEDEX).

Akira Imai[7], Kyusyu University

Abstract

Nickel laterite deposits, formed by chemical weathering of ultramafic rocks, are important Ni resources and potential targets for some critical metals, such as Co and Sc. Nickel laterite deposits are well developed in modern and ancient tropical and subtropical regions, such as New Caledonia, Caribbean countries (e.g., Cuba, Dominica), Western Australia, and Southeast Asia, including the Philippines and Indonesia. Among them, few systematic studies have been carried out for those in Philippines and Indonesia. In this study, we investigated the mineralogy and geochemistry of the Ni laterite deposit developed on the ultramafic rocks in the Acoje block of the Zambales ophiolite, Luzon Island, Philippines, to understand the chemical weathering processes of ultramafic rocks involving Ni enrichment. The Zambales ophiolite is the largest ophiolite complex in the Philippines, exposed in western Luzon Island. Weathered samples and bedrock samples were collected from one weathering profile and three drill cores developed on peridotites with different degrees of serpentinization. Major and some minor element concentrations were measured by XRF, and the mineralogical compositions were analyzed by XRD. Magnetic susceptivity and LOI of the bedrock samples were measured to estimate the degree of serpentinization.

The XRD results show that the bedrock samples are mainly composed of serpentine, olivine, orthopyroxene with minor amount of clinopyroxene, chromite and magnetite, suggesting that the bedrock is serpentinized harzburgite. In addition, the magnetic susceptibility and LOI values of the bedrock indicate varying degrees of serpentinization. To quantify the chemical changes that have occurred during the weathering process, an ultramafic alteration index (UMIA=100×[(Al_2O_3+Fe_2O_3)/(SiO_2+MgO+Al_2O_3+Fe_2O_3)]) was calculated. The calculated UMIA values and the molar ternary diagram (Al_2O_3+Fe_2O_3–SiO_2–MgO) plots follow the typical weathering trend reported for ultramafic rock weathering in tropical regions, indicating weathering from an initially Mg- and Si-rich bedrock to an Al- and Fe-rich surface. Furthermore, the higher UMIA values were observed in the weathering profiles developed on bedrock with a lower degree of serpentinization. Nickel enrichment was observed in the saprolite horizon in all weathering profiles. The weathering profiles with higher weathering intensities and higher bedrock Ni concentrations were associated with higher saprolite Ni concentrations. The saprolite horizon consists of an assemblage of serpentine + smectite + goethite. These minerals are considered to be

Ni host minerals as described in the previous study (Aquino et al., 2018). The elemental transfer calculation of major and minor elements using TiO_2 contents as an immobile element shows that Si and Mg were absolutely lost, with up to ~99 % losses in all weathering profiles during the weathering. Nickel showed high losses to moderate gains in the saprolite horizon, contrasting with the significant gains reported by Aquino et al. (2018). These results suggest that the Ni enrichment is mainly due to residual accumulation and the Ni content in the bedrock is a key factor to form the high Ni weathering profiles in the study area.

AfricaMaVal – Building Africa-EU partnerships on sustainable raw materials value chains: focusing on business network with upstream and downstream companies

Marko KOMAC[1]*, INTRAW (m.komac@telemach.net)
Vitor Correia[2], INTRAW
Eberhard W. Falck[3], INTRAW
Jean-Claude Gillineau[4], BRGM

Abstract

Securing the access to raw materials represents a critical issue for the EU ambition to deliver the Green Deal and perform the energy and digital twin transition. AfricaMaVal, a 3.5-year EU funded project aims to build an Africa-EU business network on whole CRM value chains (CRMVC). The consortium brings together African and European experienced organisations, associations, and networks deeply anchored and involved in the raw material domain with specific expertise, and knowledge.

The project is developing a responsible and sustainable EU-Africa partnership for sourcing minerals for the European industry. It focuses on creating a mutually beneficial environment that prioritises environmental, social and governance standards and results in long-term business opportunities for both, African and European companies. To achieve this, the project studies the mineral resources, financial, environmental, social, institutional, and economic aspects of the CRMVC, with particular emphasis also on artisanal and small-scale mining (ASM). The operational targets are the building of an Africa-EU business network on covering the whole CRMVCs, the development of a strategy for the integration of identified and emerging African-EU CRMVCs relevant for the energy and digital transition, and an identification and assessment of responsible investment opportunities (based on ten African country case studies with the target to evaluate 100 investment opportunities).
A specific work package is dedicated to building an Africa-EU business network with upstream and downstream companies. It aims to steer the development of strategic partnerships and workable business models for Africa-EU industrial value chains integration. The established networks will allow stakeholders in CRMVCs to connect, such as end-users. Strengthening local governance and responsible business environments, together with other institutions and development partners with a focus on the informal sector, is a particular objective. New business models are being developed aiming to integrate Africa-EU CRMVCs, considering both, horizontal and vertical integration. For this purpose, upstream and downstream business ecosystem are being mapped to capture relationships at local and regional levels (i.e., clusters of equipment providers, support services, transport, education, etc.), intra- and inter-cluster network relationships, and the interdependences of industrial and ASM clusters in the ten case study countries. This will help to further promote local content and to enable mining cluster actors to co-create added value, and

new businesses, products, and services by transforming the ways they interact. These measures will increase the entrepreneurial capacity of individuals and organisations within all sectors – research, academia, industry, and government at several dimensions – technological, environmental, economic, and societal.

As a result, project will elaborate on avenues for business relations to be strengthened by proposing a) targeted measures such as possible policy/financial incentives to stimulate the development of international clusters across CRMVC, b) alternative financing models based on integration of various international actors, c) organising targeted face-to-face or virtual B2B networking events vertically and transversally across CRMVC. The overarching aim is to foster win-win partnerships between clusters and value-chain actors in Africa and the EU based on the Raw Materials Networking Platform under development.

Resource potential of Russian Federation for critical raw materials. Lithium factor

Oleg Vladimirovich KAZANOV[1]*, Russian Mineral Resource Institute – VIMS (kazanov@vims-geo.ru)
Anna Mikhailovna Lapteva[2], Russian Mineral Resource Institute – VIMS
Ekaterina Sergeevna Malysheva[3], Russian Mineral Resource Institute – VIMS
Aleksandr Alekseevich Rogozhin[4], Russian Mineral Resource Institute – VIMS

Abstract

Russian Federation is one of the leading historical suppliers of battery quality nickel and cobalt. But the times have changed. Analysis of public data on the resource potential, exploration activity and public plans of the mining companies reveals that by 2030 Russia will join the group of lithium market leaders due to offensive exploration of the pegmatite deposits in Russian Arctic and Siberia. Further potential deals with non-pegmatite types of lithium deposits including lithium granites and hectorites and historical mine wastes. Hydromineral lithium source is under exploration in Angara-Lena basin's oil fields and North Caucasus where high lithium water composition seems to be DLE (direct lithium extraction) friendly. All potential sources of lithium are being studied by Russian Geological survey focusing on metallurgy and modern extraction techniques. In 2026 Russian Federation will start lithium mining to provide mineral concentrates for the national LCE producers. Based on lithium deposits that have been explored so far by 2030 Russia will be able to produce up to 100,000 tons LCE (lithium carbonate equivalent) affecting global lithium market. Significant part of the Russian lithium is to be consumed within the country as offensive national programs for electric vehicles and battery giga fabrics have started.

CRM-geothermal: Raw materials from geothermal fluids

David Govoni[1]*, European Federation of Geologists (efg.president@eurogeologists.eu)
Pavlos Tyrologou[2], European Federation of Geologists
Maureen Gallagher[3], European Federation of Geologists

Abstract

The energy and digital transitions require a large amount of mineral raw materials, some of which are considered 'critical' by the European Union. These Critical Raw Materials (CRM) are predominantly imported from non-European countries where environmental and ethical standards may be less strict than in the EU. However, the EU has largely untapped resources at its disposal in geothermal fluids, some of which contain significant amounts of CRMs.

The EU-funded CRM-geothermal project therefore proposes to combine the extraction of mineral raw materials and geothermal heat, a renewable energy resource from the ground that is available 24 hours per day. The technology solution developed by CRM-geothermal will thus help Europe fulfil the strategic objectives of the EU Green Deal and the Agenda for Sustainable Development while reducing dependency on imported CRM.

Although Critical Raw Materials are known to occur in geothermal fluids, there are still many uncertainties concerning their occurrence in different geological settings and the sustainability of their extraction. The actual extraction process is also a major challenge, requiring technology development. The Horizon Europe-funded CRM-geothermal project therefore aims to:

• establish an overview of the potential for raw materials in geothermal fluids for a large range of elements across the EU and third countries;

• determine the source of selected CRM, their mobility and potential for sustained extraction from geothermal brines;

• develop and optimise innovative extraction technologies for selected CRM from geothermal brines that can form a business case for European SMEs;

• assess the environmental-social-economic viability, create transparent and traceable value chains, and foster ethical sourcing of CRM;

• demonstrate at a pilot site the extraction technology for at least one CRM at the scale of a mini-plant and evaluate the system's sustainability.

The combined extraction technology will support the European Union and wider economic area in developing a more resilient and ethical CRM supply-chain from domestic sources, reducing its dependency on imports, which are exposed to market and political risks. The proposed solution will also help to bridge the gap between societal resistance to domestic raw materials extraction and increasing demand for raw materials that are critical for the Twin Transition. Finally, the combined extraction of minerals and heat will also increase the number of viable geothermal projects, fostering the green transition and diversifying Europe's energy portfolio.

CRM-geothermal is coordinated by the Helmholtz Zentrum Potsdam Deutsches Geoforschungszentrum (GFZ) based in Potsdam, Germany. The research consortium consists of

20 partners, involving 14 EU-based and 6 associated partners from UK, Switzerland and Kenya, covering academic and industry backgrounds.
CRM-geothermal is funded by the European Union. Views and opinions expressed are however those of the author(s) only and do not necessarily reflect those of the European Union or CINEA. Neither the European Union nor the granting authority can be held responsible for them.

Abstract

Certification of Competencies in Geosciences in Africa: Facts, Fictions, Geopolitical Considerations and African Union Perspectives
Tunde M. ARISEKOLA FNMGS
Africa Mineral Development Centre
African Union Commission Headquarters
Addis Ababa, Ethiopia
Email: ArisekolaT@africa-union.org
ABSTRACT
Africa is known for its diverse geology and abundant oil, gas, and mineral reserves. It ranks among the top in resources such as bauxite, chromite, cobalt, industrial diamonds, lithium, copper, manganese, phosphate rock, platinum-group metals, rutile, soda ash, and zirconium. Despite these vast resources, Africa has struggled to translate mineral and petroleum wealth into socio-economic benefits for its people. The “resource curse” phenomenon has plagued the continent, with poverty persisting alongside pockets of wealth. A significant portion of recent investments in mineral and energy exploration has focused on Africa, emphasizing the need for these investments to contribute to the overall prosperity of the continent directly.

Several critical areas have been identified as essential for sustainable resource development in Africa. These include the lack of quality resource information, the need for homegrown competent geoscientists, the capacity to negotiate fair deals, good governance, infrastructure development, and artisanal and small-scale mining support. African countries lack a comprehensive understanding of the true value of their mineral resources due to external assessments and certification processes that leave them vulnerable to the interests of multinational companies. This situation necessitates adopting measures that promote transparency, equitable exploitation, and optimal utilization of Africa's mineral resources.

The Africa Mining Vision (AMV), adopted by African Heads of State and Government in 2009, aims to achieve transparent, equitable, and optimal exploitation of mineral resources to foster sustainable growth and socio-economic development. The AMV emphasizes harmonising strategies, policies, instruments, and practices to enhance the participation of Africans and African countries in regional and global value chains. AMV Action Plan aims to improve Geological and Mineral information systems to underpin investment in exploration and mine development. However, the lack of a comprehensive resource classification and management system across the

continent, except for South Africa, poses a challenge. The Africa Mineral and Energy Resource Classification and Management System (AMREC) seeks to bridge this gap and become the first system to encompass oil, gas, minerals, and renewable energy resources in a single package. It also includes the implementation of the Pan-African Resource Reporting Code (PARC) for transparent financial reporting.

Therefore, there is a need to focus on the importance of certifying geoscientists as qualified or competent professionals, the requirements and assessment processes for certification, geopolitical considerations, and the perspectives of the African Union. It explores the paradox of Africa's mineral wealth existing alongside pervasive poverty and the exploitation of Africa's minerals by commodity business models. The discussion also delves into how Africa can overcome these challenges, adapt to the changing role of minerals in the world, and prepare for the new geopolitical landscape. The visionary agenda for minerals development in Africa, as outlined by the African Union, is presented, highlighting the role of the AMV and the African Minerals Development Centre (AMDC).
This presentation examines the importance of geosciences competencies for African

Major global producers of critical minerals in extraction and processing stages

JI WON MOON[1]*, U.S. Geological Survey (jmoon@usgs.gov)
Sean Y. Xun[2], U.S. Geological Survey
Jaewon Chung[3], U.S. Geological Survey
Steven D. Textoris[4], U.S. Geological Survey

Abstract

Under the global condition of continued conflicts in Europe and the Middle East region, high global price inflation, mixed recovery post COVID-19 and variant-wave, energy and mineral resources protectionism, minerals' criticality has resurged in studies to address the need to sustain advanced technologies, develop the economy, and ensure national security. Major global producers of critical minerals at the extraction and processing stages were investigated among 50 commodities of U.S. critical mineral list in 2022, which was determined by locality of concentrated production, significant consumption of the U.S., and high-cost raw material supply over low profit for manufacturing. Combined production dominance and net import reliance with major import partners would help determine which commodities may require more import diversification to lessen potential supply disruption. Commodities, of which China was leading producer in either of extraction and processing stages and leading import partners of the U.S., were found to be gallium, rare earths, bismuth, antimony, tungsten, magnesium, germanium, graphite, and barite. Vanadium and mica were commodities that China was the leading producer and the second-ranked import partner. Over the past few years there have been announcements of China's new and expanded export control policies. In 2020, these included the rare earth elements which are key to permanents magnets used in motors and generators and tungsten which is key to armaments and superalloys. In 2023, these were for gallium and germanium which are key for the semiconductor industry and for graphite, key for rechargeable batteries. While future supply disruptions cannot be predicted, based on this investigation, some mineral commodities face ongoing high production concentration and these include bismuth, antimony, magnesium, and barite.

(fj.gonzalez@igme.es)

Abstract

Rare earth elements and yttrium (REY) were analysed along the Tinto river, affected by acid mine drainage (AMD) originated from several leach inputs from waste-rock piles. While the Tinto river and AMD showed acid pH (0.73–2.46), AMD presented higher electric conductivities than the Tinto river (20.17–56.14 mS/cm and 9.34–3.42 mS/cm, respectively). Total ΣREY measured concentrations were up to 2600 ug/L in the Tinto river and 17056 ug/L in AMD. The AMD presented higher Ce, Nd, La, Y and Sm concentrations, with values up to 6196, 3485, 2604, 1465 and 845 ug/L, respectively.

Iron precipitates sampled on the Tinto river bed were characterized as schwertmannite (Fe8O8(OH)8-2x(SO4)xO16•nH2O), goethite (α–Fe3+O(OH)) and jarosite (KFe3(SO4)2(OH)6). These minerals showed an enrichment of critical raw materials (CRMs) such as Mn (up to 3%), Cu, Zn, As and Co (up to 3630, 3400, 2004, 106 ug/g, respectively). In addition, these iron precipitates also presented low REY contents such as Y, Ce, La, and Nd, despite these elements do not have a predisposition to be removed from solution through Fe precipitates. Schwertmannite is a mineral with a high specific surface area, which is positively charged at low pH. Hence, this precipitate can be capable of eliminating dissolved REY, as sulphated anionic complexes (e.g. REY(SO4)2-) by adsorption.

Waters and precipitates show an enrichment in MREE signature, followed by HREE with respect to NASC (North American Shales Composite) normalized REE patterns. The REE NASC-normalized patterns of the Tinto river water samples resemble those of the AMD samples, although the latter present an enrichment of LREE.

The characterization of acid waters and mineral precipitates is crucial to understand their potential as sources of strategic and CRMs. Furthermore, assessing the feasibility of recovering these materials would contribute to the promotion of a circular economy.

Serpentinization in the Malawi Rift- a potential to power the energy transition.

Chikumbutso Cyril KAMBILONJE[1]*, Malawi Geological Survey Department
(chiku.kambilonje.gsd@gmail.com)
chifundo Njala[2], Malawi Geological Survey Department

Abstract

Serpentinization, a geological process involving the hydration and metamorphism of ultramafic rocks, presents a promising avenue for sustainable energy production. The Malawi Rift, characterized by its tectonic activity and abundance of ultramafic rocks, emerges as a potential hotspot for leveraging serpentinization to drive the transition towards clean energy. This abstract explores the transformative potential of serpentinization in the Malawi Rift region and its implications for the global energy landscape.

The primary focus of this study is to investigate how serpentinization can serve as a cornerstone for transitioning towards a low-carbon economy. By harnessing the inherent properties of ultramafic rocks and the presence of water in the rift, hydrogen gas—a clean and versatile energy carrier—is produced through serpentinization. This hydrogen can be utilized in various applications, including electricity generation, transportation, and energy storage, thereby reducing dependence on fossil fuels and mitigating greenhouse gas emissions.

Through a comprehensive analysis of geological, technological, and socio-economic factors, this abstract delineates the feasibility and potential of serpentinization-based hydrogen production in the Malawi Rift. It elucidates the geological characteristics of the rift conducive to serpentinization, highlighting the abundance of ultramafic rocks and hydrothermal systems essential for the process. Furthermore, it examines the technological advancements required for efficient hydrogen extraction and utilization, emphasizing the need for scalable and cost-effective solutions to realize the full potential of serpentinization.

In addition to its technical aspects, this study explores the socio-economic implications of serpentinization in the Malawi Rift. It discusses the opportunities for local economic development, job creation, and infrastructure investment associated with establishing hydrogen production facilities in the region. Moreover, it underscores the importance of international cooperation and investment in supporting the development of serpentinization-based energy projects, fostering technology transfer, and capacity building.

Furthermore, this study addresses the environmental benefits of serpentinization-based hydrogen production, emphasizing its role in reducing greenhouse gas emissions and mitigating climate change. By displacing fossil fuels in various sectors, hydrogen derived from serpentinization contributes to cleaner air, improved public health, and enhanced environmental sustainability.

However, the study also acknowledges the challenges and uncertainties inherent in leveraging serpentinization for clean energy transition. Technical hurdles, such as optimizing hydrogen extraction methods and scaling up production processes, must be overcome. Additionally, socio-economic considerations, including regulatory frameworks, market dynamics, and community engagement, play a crucial role in shaping the success of serpentinization-based energy projects.

In conclusion, this study underscores the transformative potential of serpentinization in the Malawi Rift as a catalyst for advancing the global energy transition towards sustainability. By capitalizing on the natural geological processes of the rift, coupled with technological innovation and strategic collaboration, serpentinization offers a pathway towards a cleaner, more resilient energy future.

Differential hydrocarbon accumulation and enrichment in the northern Kuqa foreland basin, western China

Xinzhuo Wei[1]*, China University of Petroleum (East China) (18562066560@163.com)
Xianzhang Yang[2], Tarim Oilfield Company, PetroChina
Jianliang Liu[3], China University of Petroleum (East China)
Haijun Yang[4], Tarim Oilfield Company, PetroChina

Keyu Liu[6], China University of Petroleum (East China)

Abstract

The Kuqa foreland basin in western China is located in the northmost margin of the Tethys Geodynamic belt, the evolution of the basin and its petroleum system development were closely related to the closure of the Neo-Tethys Ocean. The Jurassic terrestrial reservoirs in the northern Kuqa foreland basin contains widespread hydrocarbon accumulations. However, the distribution and enrichment of oil and gas varies significantly among different tectono-structural domains in the foreland basin, including the central anticline belt, southern slope belt and deep sag belt. To understand the differential hydrocarbon enrichment mechanisms among the tectono-structural domains in the area, it is crucial to clarify the hydrocarbon accumulation process and evolution of individual domain. In this study, the hydrocarbon accumulation process of each tectono-structural belt was investigated using integrated quantitative grain fluorescence analysis, fluid inclusion petrography and micro-thermometry, in combination with structural evolution and burial history analysis. Five types of oil inclusion, with orange, yellow, yellow-whitish, blue-whitish and blue fluorescing colors, are widely developed in the central anticline belt. Combined with structural evolution and trap development history, it is believed that the trap was formed early, which determined the direction of continuous oil and gas charge and migration. Owing to differential destruction of oil and gas reservoirs by subsequent tectono-structural deformation, there exists huge differences between hydrocarbon accumulations in the east and west of the central anticline belt. The southern slope belt can be further sub-divided into a slope zone and a low uplift zone. The slope zone contains migration conduits for oil and gas passing through updip with no paleo-oil and gas accumulations. However, in the low uplift zone, small-scale structural traps were formed concurrently with oil and gas charge, thus entrapping oil and gas in this zone. Favorable reservoir and trap development are the key factors controlling hydrocarbon accumulation in this area. In the deep sag area, oil and gas inclusions are not well developed. Given a weak diagenesis and tectonic activity during the early stage, the initially charged low-mature oil was not recorded in the reservoir, but the late oil charge event was recorded by the blue-whitish oil inclusions. The lack of large-scale effective trap development throughout the structural evolution has been identified as the main cause for the absence of any major oil and gas accumulations in the Jurassic reservoirs in the study area.

[Keynote] Hydrocarbon enrichment in basins influenced by Tethyan evolution: A comparative analysis of the Persian Gulf Basin and the Sichuan Basin

Zhiliang HE[1]*, China University of Geosciences (hezhiliang@cug.edu.cn)
Zhijun JIN[2], School of Earth and Space Sciences, Peking University; SINOPEC Petroleum Exploration and Production Research Institute
Shuangjian LI[3], SINOPEC Petroleum Exploration and Production Research Institute, SINOPEC Key Laboratory of Geology and Resources in Deep stratum
Guoping BAI[4], School of Earth and Space Sciences, Peking University

Abstract

The hydrocarbon accumulation mechanisms and differences in the Tethyan realm serve as a hot research topic in the petroleum geology community in domestic and abroad. Both the Persian Gulf Basin in the Middle East and the Sichuan Basin in China that exhibiting anomalous hydrocarbon enrichment were situated on the southern and northern sides of the Tethyan realm, respectively. These two basins have recorded the whole geological processes from the opening to the closure of Prototethys, Paleotethys, and Neotethys sequentially. Based on the analysis of the plate tectonic evolution in the Tethyan realm, this study dissects the structures and hydrocarbon accumulation modes of both basins. Followed by a comparative analysis of the factors controlling hydrocarbon enrichment in the processes of plate breakup and convergence in the Tethyan realm, this study proposes petroleum exploration targets hereby. The results are as follows: (1) From the Mesoproterozoic-Neoproterozoic, the Persian Gulf Basin and the Sichuan Basin have undergone similar tectonic evolution in the early stage but diverse in the late stage. Evolution along the formation of the Prototethys, Paleotethys, and Neotethys oceans, both basins experienced multi-stage development and modification, forming two major extension-convergence cycles. Consequently, both basins are characterized by the vertical orderly superimposition of various basin prototypes in the order of rift - intracratonic basin, e.g., passive continental margin - foreland; (2) The fact that the Tethyan realm was located at medium-low latitudes for a long term, and the local anoxic environment formed in the processes of plate breakup and convergence did play a vital role in the formation of extensive source rocks. The source rocks are predominantly distributed in underfilled rifts and deep depressions that were connected to the ocean in the unidirectional continental breakup process, in the basin-slope structures and intra-shelf basins on passive continental margins, in the basinal lows within intracratonic basins, and in underfilled foredeeps of foreland basins. The favorable areas for the formation of carbonate reservoirs include platform margins, submarine highs and paleo-uplifts within platforms, and fault zones. The evaporite cap rocks, intimately associated with the basin evolutionary stages and global dry-hot events, are critical for large-scale hydrocarbon preservation; (3) Under the influence of Tethyan evolution, the Persian Gulf Basin and the Sichuan Basin share similar primary factors controlling hydrocarbon enrichment. The moderate tectono-sedimentary differentiation and structural modification in the process of prototype basin superimposition, as well as the spatio-temporal matching of critical elements for hydrocarbon accumulation, benefit the development of large oil

and gas fields. The macroscopic hydrocarbon distribution is dictated by source rock - cap rock assemblages, while the local hydrocarbon distribution is governed by trap-reservoir assemblages. The critical factors determining the differential hydrocarbon enrichment in the Persian Gulf Basin and the Sichuan Basin include plate size and position, basement stability, eustatic movement, paleoclimate, and tectonic transformation. Besides, variations in tectonic modification are closely related to the type, enrichment degree, and distribution of hydrocarbon reservoirs.

Post-rifting uplift and inversion of intra-plate basin: implication from the Doseo basin, Central Africa

Yifan SONG[1]*, China National Petroleum Company (songyifan@petrochina.com.cn)
Lirong Dou[2], Research Institute of Petroleum Exploration and Development, PetroChina,
Dingsheng Cheng[3], Research Institute of Petroleum Exploration and Development, PetroChina,

Abstract

There is a growing recognition that the post-rifting phase of basin evolution is far from being tectonically quiescent, as it can involve episodic uplift. However, the dynamic mechanisms responsible for this phenomenon remain a subject of controversy, particularly for intra-plate basins situated distant from active plate boundaries. Accurately determining the timing and magnitude of uplift is essential for elucidating the driving model behind these processes. In this study, we document the thermal history of the Doseo basin within the West and Central Africa Rift System (WCARS) using a combination of apatite fission track analysis and vitrinite reflectance data. Our findings reveal a period of accelerated exhumation during the late Eocene to Miocene epoch (~45-20 Ma), characterized by kilometer-scale uplift, which corresponds to the formation of angular unconformities, folds, and fault-related anticlines. This specific time interval appears to be critical for the Cenozoic petroleum system, coinciding with the peak maturation of source rocks and the simultaneous formation of compressional traps. When integrated with the seismic data and previously published thermochronological data, our research reveals two significant cooling and uplift events in WCARS: a Santonian extrusion event and a late Eocene exhumation event. Both of these events have the potential to impact the entire tectonic plate, and Tethys realm. Furthermore, this two-stage exhumation event aligns closely with the timing of the Africa-Europe convergence collision. Consequently, we come to conclude that far-field lateral compression emerges as the dominant driving mechanism for intra-plate uplift, outweighing the influence of the mantle model.

Abstract

Neoproterozoic-Early Cambrian petroleum systems are generally poorly known, although there have been several studies outlining proven ancient petroleum systems across the world, in particular along the Peri-Gondwana margin in present-day Australia, Pakistan, Oman, North Africa, and South China. The Sichuan Basin contains abundant evidence in the Lower Cambrian Qiongzhusi and Ediacaran Dengying formations for the existence of the oldest petroleum system in China. Using laser ablation-inductively coupled plasma-mass spectrometry (LA-ICP-MS) in situ U-Pb dating, we obtained high-precision age of four-stage dolomites, i.e., 551±20 Ma for the fibrous dolomite (FD), 509±38 Ma for the isopachous crust dolomite (ID), 453±52 Ma and 240±34 Ma for the coarse-crystalline dolomite (DD) and saddle dolomite (SD), respectively, in the Dengying Formation of the Pengtan gasfield at Central Sichuan Basin. Furthermore, the Re–Os isotopes of pyrobitumen yield two isochron ages of 333 ± 21 Ma and 140.5 ± 2.3 Ma, which represents the first stages of oil-destroyed event related to the Caledonian movement, and a followed thermal cracking event with the final timing of dry gas generation in the Central Sichuan Basin. Combined with fluid inclusion data and thermal-burial models, it constrains the time of second stage of oil-filling event during Early Permian-Triassic times. Thus, the development of the Leshan-Longnvsi paleo-uplift focused hydrocarbon migration to charge the paleo-oil and then cracked to gas fields, with two-stage of oil-fill process during the Paleozoic time across the basin center. This work highlights that the U-Pb and Re-Os geochronology has great potential to constrain the absolute timing of evolution of the oldest petroleum system. This work documented the whole U-Pb and Re-Os geochronology constraining the complex evolution history of the oldest petroleum system in the world.

Xiaowei FU[5], State Key Laboratory of Marine Geology, Tongji University
Zengyuan ZHOU[6], State Key Laboratory of Marine Geology, Tongji University

Abstract

Due to the combined influence of the Eurasian Plate, Indo-Australian Plate, and Pacific Plate, a series of multi-type and strongly reformed basins have developed in eastern Tethys (Southeast Asia). The East Indonesian Basin Group (EIBG) is situated at the convergence center of these three major plates and has undergone complex tectonic interactions from the Paleozoic to the Cenozoic, making it one of the basin groups with the longest period and most varied types in the eastern Tethys. This study indicates that the EIBG can be classified into two genetic types: the Australian North West shelf-related Basin Group (NAR) and the Collision-Transformed Basin Group between the North West Shelf of Australia and the Shelf of Sunda (CNS). The Paleozoic-Mesozoic basin types in the NAR are relatively simple, mainly composed of a series of passive continental margin basins such as Bintuni Basin, Timor Basin, North Seram Basin, and Buton Basin. The main source rock in the NAR is the Mesozoic Jurassic shale, followed by the Paleozoic Permian shale, both deposited in the rifted basin under the breakup unconformity before the opening of the Neo-Tethys Ocean. Among them, the Bintuni Basin has the latest breakup unconformity timing, the longest rift period, and the closest sedimentary conditions to the source rocks of the Bonaparte Basin in the North West Shelf of Australia, providing the best conditions for source rocks. The basin types of the CNS are more complex, including Cenozoic rift basins such as Kutai Basin and Banggai Basin, as well as Cenozoic backarc basins such as Sula Basin and Bone Basin, and Cenozoic foreland basins such as Salawati Basin. The main source rock in the CNS is middle-late Miocene Marine shale, which developed during the collision and thrusting phase, undergoing a series of strong tectonic modifications during the Cenozoic. The high heat flow (60-80 MW/m2) caused by late Miocene magmatic activity combined with the tectonic loading from plate collision promoted the maturation of source rocks in the CNS. Compared with other basin groups in Southeast Asia, the degree of hydrocarbon exploration in the EIBG is relatively low. In recent years, significant breakthroughs have only been made in the ultra-deepwater area of Kutai Basin in the CNS, while few discoveries have been made in the NAR. This is in stark contrast to the abundant hydrocarbon resources on the southern margin of the Neo-Tethys Ocean on the North West Shelf of Australia. Therefore, it will be an important direction for hydrocarbon exploration in the EIBG to accurately characterize the opening process of the eastern Neo-Tethys and clarify the evolution of Paleozoic-Mesozoic passive continental margin basins.

Abstract

The Tethys tectonic domain is one of the world's most hydrocarbon-rich regions. However, Yet, its eastern segment exhibits a scarcity in hydrocarbon reserves, characterized by significantly varied petroleum geological conditions in different basins, and a cohesive understanding has been elusive. This study bases on the tectonic evolution of the eastern Tethys, including the collision, rifting, drift, and agglomeration of the main terrains associated with the Gondwana continent, to systematically analyze the development and evolution characteristics of major basins and their petroleum geological conditions on each terrain. The study identified that the morphology and scale of these terrains critically influenced the genesis and conservation of hydrocarbon-rich basins. Large terrains, such as India, South China, North China, and the Tarim block, have the capacity to preserve multi-period superimposed basins related to pre-Gondwana basins, foreland basins during the collision with Gondwana, passive continental margin basins in the drift phase, and even foreland basins associated with the Eurasian continent agglomeration. The basins in these large terrains have significant oil and gas resource potential. In contrast, long and narrow terrains, such as Lhasa, Himalaya, and the Sibumasu block, had been extensively modified by subsequent tectonic activities including collisions and subductions, which severely limits their hydrocarbon potential. In these terrains, only basins formed during the latest tectonic phases related to subduction and other tectonic events can effectively preserved, potentially possessing favorable petroleum geological conditions in localized areas. This research provides a new perspective on the differential enrichment of oil and gas in the eastern Tethys tectonic domain.

The Impact of Tethys Evolution on Petroleum Accumulation in Kuqa, Papua, and Zagros Foreland Basins

shunqi CHAI[1]*, China University of Petroleum (East China) (chaisqi@163.com)
Keyu LIU[2], China University of Petroleum (East China)
Jianliang LIU[3], China University of Petroleum (East China)

Abstract

Understanding the formation and evolution of different types of foreland basins in the Tethys tectonic domain and associated petroleum resource enrichment is of great significance for unravelling the unidirectional splitting and convergence processes of multiple landmasses in the Tethys tectonic domain and uncovering the resource potential. Petroleum accumulation factors of three-type of Meso-Cenozoic foreland basins in the Tethys tectonic domain will be studied comparatively in this project, including the Kuqa regenerated type, the Papua back-arc type and the Zagros peripheral type, based on the geodynamic background of the Tethys tectonic domain. Research suggests that the different stages of tectonic evolution in the Tethys have a significant impact on the sedimentation, structure, and thermal history of the three-type of foreland basins, thereby affecting their petroleum accumulation conditions and enrichment characteristics. The petroleum accumulation in the Kuqa basin is influenced by the structural deformation of the foreland basin. The reservoir formation characteristics of the Papua basin dual influence of structure and sedimentation. The petroleum accumulation in the Zagros basin is mainly controlled by structural traps. (1)The evolution of the Kuqa Basin was indirectly influenced by the collision between the Indian and Eurasian plates. The closure of the Tethys Ocean resulted in strong compressive tectonic activity, forming a typical structure of foreland basins. This structural setting not only controls the distribution of source rocks and reservoirs, but affects the migration path and reservoir efficiency of petroleum. The marine invasion and regression in the Tethys Ocean control the formation and distribution of source rocks. Plate subduction and uplift in the closing process of the New Tethys Ocean resulted in increased basin subsidence and heat flow, and accelerated source rock maturation. The tectonic activity caused by the regional tectonic stress changes is conducive to the formation of sandstone reservoirs and creates a channel for the migration and accumulation of petroleum. (2)Under the influence of the Tethys evolution, the Papua Basin experienced a transition stage between sea and land, accompanied by multi-stage sedimentary filling events, which affected the source rocks and reservoir types. From the end of Mesozoic to the beginning of Cenozoic, the subduction of the remnant Tethys ocean basin to the south and the invasion of the Asian plate led to the intense tectonic compression in Papua, forming the unique conditions for hydrocarbon accumulation. The crustal heat flow changes caused by subduction indirectly controlled the maturation and accumulation of petroleum resources by influencing the thermal evolution history. (3)The north subduction of the Tethys Ocean and the late collisional orogeny caused the change of the deep geothermal gradient in the Zagros basin, and the maturity of source rocks increased rapidly in the Late Cretace-Neogene. Tectonic subduction improves the

reservoir properties of carbonate rock and sandstone in the basin. The sealing capacity of Marine shales and overlying evaporites was enhanced by plate collision and extrusion during the closing of the Tethys Ocean, and the temporal and spatial changes of fold and fault development directly led to the formation and evolution of tectonic traps in the basin.

Charging and leakage of natural gas in the YL13-1 structure, Qiongdongnan Basin

Yongbin QUAN[1]*, China University of Geosciences (Wuhan) (quanyongbin@cug.edu.cn)
Xinong Xie[2], China University of Geosciences (Wuhan)
Jinhai Yang[3], CNOOC China Limited, Hainan Branch, China

Abstract

Qiongdongnan Basin is an important natural gas-producing area in the north of the South China Sea. In recent years, many gas fields have been found, including the YL8-1 and YL8-3 gas fields in the Songnan Uplift. YL13-1 structure, which is the largest structure and farthest from hydrocarbon generation depressions, is the ultimate direction of natural gas migration in Songnan Uplift. Unfortunately, no gas was found here. Nevertheless, many natural gas inclusions were found with GGI greater than 5%, which indicates that natural gas accumulation had occurred. The source, accumulation, and leakage process of natural gas in the YL13-1 structure is still unclear, which restricts the further exploration of natural gas in this area.

In this study, the origin of natural gas in the Songnan Uplift is investigated using molecular and isotopic composition of natural gas. The charging time was inferred from the combination of burial history, the homogenization temperatures of coeval aqueous fluid inclusions, and the isotope-specific reaction kinetics of methane. Gas migration direction and pathway were investigated using the geochemical heterogeneity among different gas fields and were predicted by numerical simulation. The sealing capacity of the cap was evaluated by using logging and formation pressure testing data, which was compared with the height of the paleo and present gas column.

Results indicate that natural gas within the YL8-1 structure was generated from the Sonnan Sag in the north. The natural gas in the YL8-3 trap, however, was not only contributed by the Baodao Sag in the north but also by the Songnan Sag in the northwest and Lingshui Sag in the southwest. The main charging time is 5.5Ma. However, the YL13-1 structure cannot receive hydrocarbon supply from the western YL8-1/YL8-3 gas reservoir, because the gas water contact (GWC) analysis shows that the traps themselves are not filled. Both geological and numerical simulation analyses show that the structural ridge is conducive to the transport of natural gas generated in the Lingshui Sag to the YL13-1 structure. Natural gas originating from Lingshui Sag was indeed found in the shallow layer along the migration pathway, i.e. LS18-1 gas reservoir. According to the gas inclusion analysis, the height of the paleo gas column is at least 270 m. The formation pressure analysis, quite interesting, indicated that the maximum height of the gas column that can be sealed by the cap is 270 m. This indicates that the YL13-1 structure has been hydraulically ruptured and natural gas has been rapidly leaked. A gas chimney developed above the YL13-1 structure in the seismic section, indicating the existence of natural gas escape channels. More importantly, the discovery of gas hydrates in thermal genetics within the shallow layer of the YL13-1 structure further confirms the destruction of the ancient gas reservoir.

This study indicates that there are risks in sealing natural gas in the Sonnan Uplift due to the thin thickness and shallow burial depth (<500m). Therefore, further exploration should focus on deeper buried traps closer to hydrocarbon-generating depressions.

A machine learning method reveal the variations of organic matter enrichment mechanisms of freshwater vs. saline lacustrine oil shales driven by paleoclimate

Man LU[1]*, China University of Petroleum (Beijing) (luman1021@cup.edu.cn)
Qingyong Luo[2], China University of Petroleum (Beijing)
Guoqiang Duan[3], China University of Petroleum (Beijing)
Xinguang Wang[4], China University of Petroleum (East China)

Abstract

With the consumption of conventional petroleum resources, the exploration and development of unconventional hydrocarbons in recent years have supplemented the shortage of petroleum resources to some extent. In China, lacustrine oil shales have become an important target for the exploration of unconventional oil and gas beyond marine. The majority of Chinese lacustrine oil shales were deposited in saline lacustrine basins. Breakthroughs obtained in the exploration of lacustrine shale hydrocarbons of Upper Triassic Yanchang Formation and Upper Cretaceous Qingshankou Formation demonstrate a good prospect of freshwater lacustrine hydrocarbon exploration. So far, a growing number of research have conducted on organic matter enrichment mechanisms of oil shales mainly based on individual formations distributed within a single basin/region. A comprehensive study investigating differences of organic matter enrichment mechanisms between freshwater and saline lacustrine oil shales is still lacking. Here, we synthesized the geochemical data of seven major oil shales in China from all available publications with 147 proxies of 10985 samples. A Random Forest Classification Method was applied to investigate the differences between freshwater and saline lacustrine oil shales in terms of primary productivity, terrigenous nutrients inputs, redox conditions. Our results show that freshwater lacustrine oil shales were deposited in more oxic water with higher primary productivity and less detrital material inputs under more humid and warmer climatic conditions, that caused higher organic matter enrichment than saline lacustrine oil shales. By combining the major worldwide lacustrine oil shales, we compare the depositional time interval and paleogeographic localities of lacustrine oil shales with long-term climate evolutions during the Phanerozoic era. We found the major worldwide freshwater lacustrine oil shales were deposited during hothouse climate with higher temperature and precipitation than saline lacustrine oil shales, suggesting long-term climate as main factor controlling the different organic matter enrichment mechanisms of freshwater versus saline lacustrine oil shales.

The trace metal content in oils: a global approach

Svetoslav Velichkov GEORGIEV[1]*, Geological Institute, Bulgarian Academy of Science (s_georgiev@geology.bas.bg)
Emiliya Raeva[2], Geological Institute, Bulgarian Academy of Science
Gatien L.F Morin[3], Geological Institute, Bulgarian Academy of Science
Lora Bidzhova[4], Geological Institute, Bulgarian Academy of Science

Abstract

Like carbon, hydrogen, nitrogen, and oxygen, many trace metals are also transferred from the source rock into kerogen, bitumen, and oil during the successive stages of thermal maturation and chemical transformation of the original organic matter in the rock. Therefore, the amount of trace metals and certain trace metal ratios in natural petroleum products (crude oil, crude oil fractions, bitumen, tars, etc.) can be used, and have been used to constrain the origin of petroleum. In particular, vanadium and nickel concentrations and their weight ratios are the most widely used inorganic tools for oil-source correlations. Both Ni and V seem to be concentrated in the more polar, more aromatic and chemically complex fractions of crude oil, which also are often the most resistant to biodegradation and water washing. Therefore, V-Ni ratios, unlike the most commonly used organic biomarkers, are quantitatively preserved during secondary alteration of petroleum and are particularly useful for oil-oil and oil-source rock correlations involving biodegraded oils or heavy tar mats, for example.

Despite providing a promising tool for genetic correlations, the knowledge of trace metal contents of crude oils, their precursor and host molecules and their origin and genetic significance is highly fragmented. Apart from V and Ni, and to some extent Re and Os due to their value for geochronology of oil and oil fractions, little to no systematic research has been conducted on other inorganic constituents of petroleum for the purpose of genetic correlations. With few rare exceptions, published data are generally scattered and treated case by case, sometimes with insufficient geologic context or discussion.

Here, we present an extensive dataset of published trace metal data in crude oils and similar products, discussing the origin of trace metal enrichment and outlining new trace metal tools for oil-oil and oil-source rock genetic correlations. In particular, we focus on the distribution of trace metals within the main oil fractions and the host phases of metals in the oil, the mechanisms of metal transfer from source rock to oil and the susceptibility of various trace element ratios to secondary oil alteration. We also outline the main trends in trace metal enrichment depending on the tectonic setting of the petroleum field and the type, age and maturity of the source rock. Our data provide a solid foundation for the interpretation of trace metal content of oils and for the development of novel inorganic proxies for oil-oil and oil-source rock correlations.

Meng ZHAO[5], CNOOC China Limited, Tianjin Branch, Tianjin

Abstract

In recent years, a large amount of oil and gas has been discovered in the deeply-buried conglomerate reservoirs of the Paleocene Kongdian Formation (depth>3500 m) in the Bozhong Depression. However, the physical properties of the conglomerate reservoirs are highly heterogeneous. Therefore, this study discusses the formation mechanisms of the high-quality conglomerate reservoir.

Information, including helium porosity and permeability, thin sections, XRD, SEM, particle size analysis, fluid inclusion, stable carbon and oxygen isotope analysis, was used to discuss the porosity evolution of conglomerate reservoirs.

The sedimentary facies in the Paleocene Kongdian Formation in the study area are mainly composed of fan delta. The deeply-duried conglomerate reservoir is characterized by low porosity and low permeability Abundant potassium-rich feldspars, meteoric water leaching, grain dissolution by organic acids, overpressure and fracture are the main factors controlling the development of high-quality conglomerate reservoirs in the study area. The conglomerate reservoirs experienced the following diagenetic processes: (1) porosity enhancement through meteoric water leaching, (2) porosity loss during rapid mechanical compaction, (3) porosity enhancement through grain dissolution by organic acids and hydrothermal fluids, (4) early hydrocarbon emplacement, (5) late cementation, (6) fracture formation and (7) extensive hydrocarbon emplacement. However, the diagenetic evolution and porosity evolution at different areas show significant differences. The conglomerate porosity at the BZ19-A structure decreased from 32.6% to 10.6%. The net porosity loss caused by compaction and cementation is 22%. In comparison, the conglomerate porosity at the BZ25-B structure decreased from 32.8% to 13.2%. The net porosity loss caused by compaction and cementation is 19.6%. Compared with the conglomerates in the BZ19-A structure, conglomerates in the BZ25-B structure experienced relatively weak compaction, stronger overpressure and grain dissolution. Therefore, the conglomerate porosity in BZ25-B structure is better than that of BZ19-A structure. Moreover, the extensive presence of fracture in BZ19-A conglomerates is the main factor resulting in the higher permeability than BZ25-B structure.

A large amount of condensate gas has been found in the deeply-buried conglomerate reservoirs of Kongdian Formation. The gas production in this area indicate the great exploration potential. The

research results can provide theoretical support for reservoir quality prediction in deeply-buried conglomerates.

Integration of Rock physics and Geological processes in reservoir Properties Characterization. A case study applied on Plutonio Field of the West African Congo Basin

Mukhtar HABIB[1]*, Department of Petroleum and Gas Processing Engineering, Kaduna Polytechnic, Nigeria (mukhtarhabib102@gmail.com)
Xie Congjiao[2], Faculty of Earth Resources, China University of Geosciences, Wuhan.
Tianqi Zhou[3], China National Petroleum Corporation Limited, Beijing.

Abstract

This research aims at improving the prediction of reservoir properties from seismic amplitude by integrating geo-statistical modeling principle, extended elastic impedance and rock physics models. This general objective contains four specific goals: 1) To identify the predictable spatial trends of reservoir properties using geo-statistical modeling frame work: 2) To link properties with seismic velocities using extended elastic impedance inversion: 3) To link reservoir properties with seismic velocities through rock physics models and 4) To improve the understanding of seismically derived signatures of reservoir properties, depositional processes as well as digenetic process in the west African deep water environment. In order to achieve these aims, this study attempted to resolve one primary problems, that is how possible can reservoir properties be derived away from well control using the concept of extended elastic impedance inversion? And what do we see when compared with geo-statistically derived reservoir properties?

In order to resolve the problem, Geo-statistics was applied on plutonio field so as to predict the trend of reservoir properties, this was carried out for the purpose of having a bases for comparison with a subsequent model to be developed using extended elastic impedance. The geostatistical modeling process began with petrophysical analysis thereby generating a cut off criteria for reservoir properties, then followed by a Structural model that integrates the stratigraphic framework and fault system of the reservoirs, sedimentary microfacies (or sand bodies) modelling on the basis of drilling and logging data, isochronous stratigraphic correlation unit (as the framework), dynamic integration of parameters and characteristics of channel sand bodies as well as analysis of variation function. It went ahead to apply facies models as basis for reservoir property distribution by determining a rational model on the basis of stochastic simulation.

Again, deterministic seismic inversion and extended elastic impedance (EEI) were applied on the same area so as to obtain quantitative estimates of reservoir properties. To achieve this, the optimum EEI angles corresponding to reservoir properties were analyzed using well logs data, together with a lithology indicator. Pre-stack seismic data were simultaneously inverted into density, acoustic and gradient impedances cubes, through model based inversion algorithm. The last two broadband inverted volumes were projected to the Chi angles corresponding to petrophysical indicators, resulting to two broadband EEI volumes. At Well location, the EEI versus petrophysical parameters linear trends were then used to transform EEI volumes into quantitative porosity and shale volumes based on a specific lithology. A comparison was made

between the properties generated through EEI method with the initial geo-statistical method based properties, which shows that EEI is reliable and can be applied for the purpose of mapping favorable zones that may suggest possible future drilling locations.

Structural characteristics and evolution processes of intracratonic strike-slip faults: A case from the Gaoshiti-Moxi area, central Sichuan Basin, SW China

Qingqi ZHAO[1]*, China University of Petroleum (East China) (zqq_zgsydx@163.com)
Yangwen Pei[2], China University of Petroleum (East China)
Zhengshuo Miao[3], China University of Petroleum (East China)

Abstract

Geologists have realized that the development of intracratonic strike-slip faults plays important control on the hydrocarbon migration and accumulation in the past decades. In this research, a case from the Gaoshiti-Moxi area in the central Sichuan Basin was analyzed to understand the structural evolution of intracratonic strike-slip faults. Firstly, the faults' geometry was characterized based on 3D seismic sections and coherent attribute slices of key horizons. The displacements of the primary faults at different depths were also quantified to understand the spatial variation of fault throws. The shearing sense of strike-slip faults was then decided according to both the faults' alignment and horizontal offsets' distribution in plan view. Subsequently, multi-phased structural superposition models and evolution models were proposed. In section view, sub-vertical normal faults and negative flower structures were interpreted beneath the Triassic strata, whereas high-angle reverse faults and positive flower structures were interpreted within the Triassic strata. In plan view, the faults developed in the Lower Cambrian and Upper Permian are characterized with nearly W-E trending faults comprised of a series of soft-linked faults with small offsets. In contrast, the faults developed in the Upper Triassic present en-echelon patterns trending NWW. Three stages of faulting deformation in the Gaoshiti-Moxi area were identified by considering both the statistics of fault offsets and pre-existing regional structural belts in basements. (1) The initial stage from Late Sinian to Early Cambrian was dominated by the NEE trending tensional stress, resulting in the development of dextral transtensional faults. (2) The later stage of Late Permian was dominated by the NW trending tensional stress, and some pre-existing faults were reactivated and reversed into sinistral transtensional faults in the Permian strata. However, the faulting intensity in Late Permian is obviously was decreased compared to the initial faulting stage. (3) In the Late Triassic stage, being controlled by the NW trending contraction due to the uplift of the Longmenshan Mountain, en-echelon transpressional faults with small offsets were developed in the Triassic strata. The structural models proposed in this research may improve understanding in the multi-staged structural evolution of the intracratonic strike-slip fault systems and provide a geological theoretical reference for related hydrocarbon exploration.

Structure and Stratigraphic Architecture of Lake Edward Basin, Uganda: Implications for Petroleum System Analysis

Lauben TWINOMUJUNI[1]*, China University of Petroleum, East China
(lauben.twinomujuni@mak.ac.ug)
Keyu Liu[2], China University of Petroleum, East China

Abstract

This study delves into the geological complexities of the Lake Edward Basin in Uganda, situated within the Albertine Graben of the East African Rift System (EARS). Despite its potential as a hydrocarbon province, the basin's intricate geology poses challenges for exploration and development. Previous drilling attempt, including a significant wildcat, has yielded crucial data that, when combined with seismic and surface information, can offer vital insights for petroleum geological analysis. The interpretation of two seismic profiles in the strike and dip direction, along with well data, reveals various structural features such as normal and reverse faults, rotated blocks, flower structures, and pop-ups. Stratigraphic analysis delineates seven distinct depositional packages that have formed under varied environmental conditions including alluvial fan, fluvial channel, flood plain, alluvial plain, delta and open lacustrine. This architecture suggests sediment deposition was controlled by paleolake level/base level fluctuations probably forced by rift neotectonics and climatic changes as reported in other segments of EARS. In the context of sequence stratigraphy, the entirety of the depositional package appears to embody a single depositional cycle, characterized by transitions from proximal to distal sedimentary environments, followed by a return to proximal deposition. Analogous to other rift basins within the western branch of the rift valley, the Lake Edward Basin exhibits pronounced asymmetry, characterized as a highly asymmetrical half-graben with a progressive increase in depth towards the west, and the thickness of stratigraphic layers follows this trend. Multiple potential structural traps have been identified within the basin, presenting prospective opportunities for the retention of hydrocarbon reserves. Overall, the study contributes to a better understanding of the Lake Edward Basin's geological evolution and provides valuable information for hydrocarbon exploration and resource assessment in the region.

Organic petrological and geochemical characteristics of lower Paleozoic marine shale

Sherry (Xiaowei) Xiaowei Zheng[1]*, China University of Petroleum, Beijing
(zhengxiaowei1103@outlook.com)

Abstract

The lower Paleozoic shales are important source rocks and unconventional hydrocarbon plays both in China and Northern Europe. The lower Paleozoic shales in Tarim basin and Sichuan basin (China) are deeply buried and overmature, and hence the lacking of immature to early mature samples is a challenge for evaluating the initial source rock potential. However, the Alum shale (Northern Europe) owns various thermal maturities ranging from immature to overmature, which provide the Alum Shale a unique opportunity for detailed organic geochemistry and organic petrology research study. Interdisciplinary geochemical techniques, e.g., Rock-Eval pyrolysis, confined hydrous pyrolysis (gold tube), organic petrological methods, and Inductively Coupled Plasma Mass Spectrometry (ICP-MS) have been employed to unravelling the bulk geochemical parameters, microscopic organic matter properties, and organic-inorganic interactions.

The trace element results of the Th/U and V/(V+Ni) indicate reducing marine environment both in Alum Shale in the Baltic Basin areas and the deeply buried overmature shales in China. The dominant macerals change between the Cambrian and Ordovician Alum Shale, with alginite, amorphous organic matter, bituminite and solid bitumen as the major constituents in Cambrian, while zooclasts become dominant in Ordovician. The development of solid bitumen become dispersed with increasing thermal maturity. An original hydrogen index (HIo) restoration was established with the Alum shale as constraints. The HIo calculation model used is: HI=HI_o [1-exp{-(T_max/β)^θ }]+c, where HIo is 420 mg HC/g TOC (391.2 mg HC/g TOC to 448.8 mg HC/g TOC as 95% confidence bounds) as the most fitting for mature shales from northwestern Tarim basin.

The role of zooclasts in the bulk organic matter composition, kerogen type, and hydrocarbon generation potential are studied. Both non-granular and granular parts are observed in the graptolite periderm. The former is none-fluorescing, while the latter one has a brownish fluorescence and suggests remaining hydrocarbon generation potential. By connecting bulk geochemistry parameters from programmed pyrolysis and semi-quantitative maceral statistics, the abundance of dense zooclastic particles, including non-granular graptolite, chitinozoans and vitrinite-like particles, is seen to correlate with the non-generative organic carbon content. This refractory carbon-rich maceral enrichment represents autochthonous ‘refractory organic carbon dilution’ and leads to Hydrocarbon Index (HI) underestimation. Confined hydrous pyrolysis of a zooclastic cuticle-lean sample and a zooclastic cuticle-rich sample indicate that the former one has higher hydrocarbon generation potential and is oil-prone, while the latter one is gas-prone and

generates more CO2.

Through documenting a continuous graptolite reflectance (GR) of artificially matured graptolite-rich Alum shale after hydrous pyrolysis, a reflectance anomaly in gas window were observed in three different graptolite fractions (non-granular, nodular and granular graptolite). These three graptolite fractions have different trends of reflectance evolution and anomaly degrees, which indicates distinct chemical composition and differing pores generation capability. The GR anomaly indicates a potential underestimation when applying a linear formula between random GR and VR directly, hence a maturity correction should be applied on GR-based maturity measurement in gas and post-gas window.

GASEOUS ANOMOLIES FOUND IN AGRICULTURE FIELD AROUND SAGAR Distt., SOUTHERN FRINGES OF BUNDELKHAND REGION, MADHYA PRADESH. INDIA

AKANKSHA SAHU[1]*, MOIL LIMITED (sahu.akanksha3010@gmail.com)
S.K. Sarkar[2], MOIL Limited
Arun Kumar Shandilya[3], Dr. H.S. Gaur University Sagar

Abstract

ABSTRACT
The gaseous anomalies has been recorded in the Agriculture field in Sagar Distt. of M.P..
The discovery of the rare gas helium in hydrocarbon rich zone in the tube wells in agricultural field of Pipariya - Bhutoli Garhakota Tahsil and Meerkheri and Rahatgarh town in Rahatgarh tahsil of Sagar District in M.P., is a unique finding in the history of Earth Science in India. It is remarkable to note that values of helium contents varies from 0.34 % to 0.732 % along with the 72% to 99 % of methane and ethane, and minor amount of oxygen, nitrogen and CO2 gases in the hydrocarbon rich zone are recorded during the geochemical and stable isotope analysis. It has been found in the stable isotope δ C13 value the values for the methane is -43.6 per mil w.r.t. to 54.9 per mil w.r.t. PDB and for the Ethane gas is --24.9 to -- 26.4 per mil w.r.t. PDB in the gas samples collected in the saturated sodium chloride solution in the glass bottles at Rahatgarh, Meerkheri, Piparia, Bhutoli villages in Sagar District. The occurrence of rare helium gas in the Hydrocarbon rich zone is reported first time in Jan, 2007 from the tubewells of Sagar Distt, which were geochemically and stable isotopically analyzed at KDMIPE Dehradun & NGRI Hydrabad. The gaseous hydrocarbon analysis show the presence of moderate to low concentration of methane (C1) 1 to 104 ppb, Ethane(C2)-1 to 14 ppb, Propane(C3) 1 to 10 ppb, i- Butane (i C4) 1 to 9 ppb and nButane (n C4) 1 to 8 ppb in the soil samples collected from different locations.
The Result of the adsorbed soil gas and stable isotopic analysis of Ethane gas in these samples δ C13 value are ranging from -24.9 per mill w.r.t. PDB and -26.9 per mill w.r.t. PDB are indicative that this gas is of thermogenic origin, which must have been formed at very high temperature & pressure condition in the deeper horizon of the Great Vindhyan sedimentary basin of early Proterozoic (>500m.y.) period.

Characteristics of effective fracture development in deep-ultra-deep reservoirs and its impact on gas reservoir productivity

Xixue ZHANG[1]*, China University of Petroleum (East China) (934522670@qq.com)
Chengyan LIN[2], China University of Petroleum (East China)
Lihua Ren[3], China University of Petroleum (East China)
Chunmei Dong[4], China University of Petroleum (East China)

Abstract

In recent years, deep-ultra-deep oil and gas reservoirs in foreland basin thrust belt zones have received attention. Bozi area is located in the first row of thrust belt zones in front of the South Tienshan Mountains in the Kucha depression of the Tarim Basin, with low porosity characteristics of deep-ultra-deep reservoirs of the Lower Cretaceous Bashijiqike Formation and Baxigai Formation. Fracture is a key geological factor to improve the reservoir performance and influence the productivity.In this paper, taking Bozi 1 block as an example, geological data such as core analysis, thin section, imaging logging, well test and leakage are used. On the basis of regional tectonic background and stress field evolution, we carried out a study on fracture characteristics affecting the variability of gas wells' productivity, clarified the types of effective fracture genesis, characteristics and distribution laws, and discussed the influence of effective fracture in deep-ultra-deep reservoirs on the productivity of gas reservoirs.

The study gained insights: (1)Effective fractures in the study area were formed in the mid and late Himalayan period, mostly NW-SE orientated high angle tensional, reticulated and high angle conjugate shearing fractures. (2)Tectonic nature and tectonic type control the planar distribution of effective fractures. Under the effect of piggy-back propagation thrusting, the paleotectonic stress is weakened from north to south, and the fracture combination style shows the transition from conjugate broom type to parallel type, in which the conjugate broom type has the highest effectiveness. Under the effect of lateral extrusion, influenced by the ancient uplift, the strike-slip effect is weakened from west to east, and the small-sized abrupt anticline and large-scale thrust nappe anticline are developed sequentially. The core of the anticline develops high-angle tensional fractures and medium-high angle conjugate shearing fractures, with the best effectiveness. (3)Stress vertical zoning controls the vertical distribution of effective fractures, and tensile stress sections and stress transition sections are developed vertically in Bozi 1 block. The effective fractures in the tensile stress section are mainly tensional high-angle-near-erect fractures, which have the best effectiveness; the transition section is dominated by reticulated fractures and high-angle conjugate shearing fractures. (4)The influence of fractures on the productivity of deep-ultra-deep gas reservoirs in the thrust fault zone of the foreland basin should consider the geological genesis of effective fractures and the mechanical activity of fractures under the control of the present-day geostress. From the geological genesis of effective fractures, the fracture effectiveness of the core part of the abrupt anticline and thrust nappe anticline on the plane is good, and the productivity is high; the fracture opening degree of the vertical formation tensile stress section is

higher than that of the transition section, and the productivity is high. From the present-day stress, the smaller the angle between the fracture direction and the direction of the present-day maximum principal stress, the better the fracture opening degree and the higher the productivity during reservoir reconstruction. This study has guiding significance for the efficient development of oil and gas in the thrust-belt zone of the foreland basin.

Petroleum system development in the Iranian Zagros Basin in response to the Neo-Tethys evolution

Tianhou LI[1]*, China University of Petroleum, Qingdao 266580, China (17863969592@163.com)
Keyu LIU[2], China University of Petroleum, Qingdao 266580, China
Jianliang LIU[3], China University of Petroleum, Qingdao 266580, China
Beiwei LUO[4], Research Institute of Petroleum Exploration and Development, PetroChina, Beijing 100083, China

Abstract

The distribution of oil and gas in foreland basins along the Tethys tectonic domain is closely related to the evolution of the Tethys geodynamic system. Based on the analysis of the Neo-Tethys evolution, we investigated the hydrocarbon accumulation process of the Dezful Depression in the Iranian Zagros Basin. On the basis of 2D structure restoration, fluid inclusion analysis, and basin and petroleum system modeling, the tectonic evolution stages of the Zagros Basin were reconstructed, and the hydrocarbon accumulation process in the basin was deciphered. The results show that: (1) The passive continental margin basin-slope environment connected to the ocean during the evolution of the Tethys tectonic domain was a favorable location for the development of source rocks in the Zagros Basin during the Jurassic-early Cretaceous when ocean currents at the equator brought nutrient-rich water to the continental shelf. The extensive shelfal carbonate platform reduced the overall ocean wave and current energy and formed a relatively closed low-energy environment, forming multiple sets of high-quality source rocks in the sags. (2) Shallow shelf and slope carbonate platform were favorable areas for carbonate reservoir development. During the passive continental margin stage, the petrophysical properties of carbonate reservoirs were enhanced by dissolution. During the foreland basin stage, extensive tectonic fractures were developed in the carbonate reservoir due to folding and faulting. Deep hydrothermal fluids entered the tight limestone reservoir through these faults and fractures, resulting in dolomitization in the vicinity of the fractures and an improvement of the petrophysical properties of the carbonate reservoirs. (3) Thick gypsum/salt caprocks were well developed in the Zagros basin during marine regression, forming a number of regional caprock layers. The prolonged period of strong evaporation conditions in the middle and low latitude as the Arabian plate drifting northward and the dissolution of the exposed basement Hormuz salt were responsible for the formation of the evaporative caprock layers. (4) The Zagros Basin is characterized by an oil-rich foredeep and a gas-rich uplift. The types of traps are mainly structural (anticlinal) traps. The distribution of oil and gas is primarily controlled by source-caprock combination and local trap configurations. Hydrocarbon charge and accumulation processes during the tectonic evolution can be divided into two categories: Prior to the commencement of the foreland basin orogenic movement, oil and gas migrated locally via unconformity or lithological surfaces; afterwards, folding and thrusting occurred at the top of the anticlines. These faults enhanced the petrophysical properties of the carbonate reservoirs and became the primary conduits for secondary oil and gas migration. Oil and gas migrated underneath the Neogene caprock via major faults, forming numerous reservoir

accumulations.

Hydrocarbon charging process and phase evolution in the lower to middle Jurassic in Qiudong Sag, Turpan-Hami Basin, NW China: A response under the closure of the Paleo-Tethys Ocean

Shuxin QIN[1]*, China University of Petroleum (East China) (919600248@qq.com)
Jianliang Liu[2], China University of Petroleum (East China)

Abstract

The Turpan-Hami block, located in southeastern part of the Kazakh plate, developed a foreland basin during the Triassic to Jurassic period due to the dual effects of closure of the Paleo-Tethys Ocean on south side (Songpan-Ganzi orogenic movement) and South Tianshan movement on the north side. As a result, the Turpan-Hami basin developed multiple sets of lacustrine source rocks in the early to middle Jurassic, and entered piedmont depression stage with thick lacustrine clastic rock deposition in the middle to late Jurassic. Multiple sets of source rocks and reservoirs developed intermutually in the early to middle Jurassic, forming favorable source-reservoir-cap assemblage. Located in northern margin of the basin, the Qiudong Sag in the Taibei Depression was proven to have numerous gas resources in tight sandstone in the lower to middle Jurassic. Previous research on hydrocarbon accumulation period and process in that area is weak and diverging, restricting gas exploration in deep strata. In this research, hydrocarbon charging time, paleo-temperature and pressure were determined through systematic study of fluid inclusion petrography, spectroscopy, microthermometry, PVT phase simulation and calcite in-situ U-Pb dating and as well as combining with 1D and 2D basin modeling. The relationship between tectonic-sedimentary response in the early to middle Jurassic in Qiudong Sag and hydrocarbon generation and trap formation under the influence of Paleo-Tethys tectonic movement was first clarified. Oil and gas accumulation model was then established for the Jurassic tight sandstone in the Qiudong Sag. Results show that two types of fluorescent petroleum inclusions, yellow and blue, were developed in this area. From central to north and south sides of the Qiudong Sag, (1) the abundance of petroleum inclusions was gradually decrease; (2) the fluorescence color of oil inclusions was changed from single blue to blue and yellow coexisting; (3) the phase of oil inclusions was changed from condensate gas and liquid oil inclusions coexisting to single oil inclusion phase. One period of oil and gas accumulation occurred in the deep sag belt, mainly being the mixture of oil and gas charging. While for the southern slope zone and northern uplift zone, oil and gas, sourced from both in-suit and deep sag source rocks, was charged into these area in late Jurassic and late Cretaceous stages.

Hydrocarbon in the deep sag zone was in a gas condensate phase in both charging period and the present. While hydrocarbons in southern slope and northern uplift zones were in a liquid phase and normal pressure in the two periods of hydrocarbon charging and the present.

It is considered that high condensate oil-bearing tight gas in deep sag belt was formed by the simultaneous large-scale charging of oil and gas.

The research will promote geological understanding of evolution of the Paleo-Tethys Ocean on

the formation and accumulation of hydrocarbons in lower to middle Jurassic in the Turpan-Hami Basin, and also provide some theoretical support for further exploration in Qiudong Sag in Turpan-Hami Basin.

Characteristics and control factors of high poroperm carbonate reservoir of Mishrif Formation in the United Arab Emirates

Beiwei LUO[1]*, RIPEDCNPC (luobeiwei@petrochina.com.cn)
Jiquan YIN[2], RIPEDCNPC
Guangcheng HU[3], CNODC, CNPC
Haigang DUAN[4], RIPEDCNPC

Abstract

Mishrif Formation of Cenomanian Stage is the main oil-rich strata in the Middle East, especially around the Zagros fold and thrust belt. The kinetics of hydrocarbon generation the Cretaceous source rocks in UAE of the Rub al-Khali Basin is relatively weak, and the high poroperm reservoir is act as the key factor for hydrocarbon accumulation. However, previous research focus on the sequence stratigraphy, sedimentary facies and reservoir configuration, while the main geological factors that control high poroperm reservoir should be systematic analyzed. Based on core sections, lab-testing data from the drilled wells in UAE (The United Arab Emirates), the petrology and reservoir characteristics of typical sedimentary carbonate reservoir which have high porosity and high permeability in Mishrif Formation were summarized. In an addition, the evolution process of the high-frequency sequence in the Cenomanian Stage was identified using the new 3D seismic data. It is concluded that, the carbonate in Mishrif formation are mainly composed by sparry bioclastic limestone which associated with the rudist limestone and the pelitic or pelitic marl which contained a large amount of bioclastic. Several typical subfacies, including rudist build-up, high energy shoal, backshoal, foreshoal and inner-shoal can be identified. The rock types are mud microcrystalline limestone, wackstone and packstone, grain limestone and reef limestone. The sparry bioclastic limestone which deposited at rudist build-up and high energy shoal as the high poroperm limestone and their pore-spaces mainly composed by biological cavity, moldic and intergranular dissolution hole. It is infer that the high poroperm reservoirs are mainly controlled by multiple geological factors such as sequence framework, paleogeomorphology and diagenetic effects. There are three third-order sequences and seven system tracts in the Mishrif formation of the study area. Sequence cycles control the evolution and distribution of sedimentary facies, migration characteristics and stacking styles of favorable facies belts such as rudist build-up and high energy shoal around the innner ramp. The paleogeomorphology which restored by the high frequency sequence and residual thickness method shows that, the high energy shoal in SQ3 is inherited deposited and has a good positive correlation between the high energy shoal s inherited from the SQ3 stage and the paleohigh position. Under the influence of seawater, atmospheric fresh water and hydrocarbon fluids, the improvement and maintenance of high quality reservoirs in Mishrif formation are enhanced by both the constructive and reconstructive diagenesis effects. The fine description of the sedimentary features and control factors for high poroperm reservoir in Mishrif Formation provide a reasonable geological idea for the interpretation and modeling of favorable reservoir, and provides important inspiration for the

exploration and development issues in Middle East in future.

Abstract

The northward subduction of the Neo-Tethys oceanic crust triggered multiple magmatic activities in the West Myanmar Arc, which in turn influenced the deposition of sedimentary pyroclastic rocks from the Cretaceous to Eocene strata in the Central Myanmar Basin (CMB). The pore structure of these lithologic reservoirs is complex and rich in tuffaceous sandstone, which plays an adverse role in reservoir development in this region. To understand the development characteristics and genetic mechanism of the pyroclastic rocks within three sets of reservoirs in this area, a comprehensive analysis was conducted through borehole core observations, thin section identification, scanning electron microscope analysis, and mercury injection tests. The tuffaceous sandstone from the upper Cretaceous to the Eocene is dominated by intermediate-acid volcanic rock debris. The pyroclastic rocks exhibit evident chloritization and ironization, with residual intergranular pores being the principal type accompanied by a smaller amount of intergranular dissolved pores and intragranular dissolved pores. The highest porosity is observed in the Eocene tuffaceous sandstone, ranging from 8% to 12%. The Late Cretaceous to Paleocene sandstones exhibit lower porosity levels of only 4%–6%. These reservoirs are characterized by their low porosity and low-permeability. Despite the presence of a good source rock in this area, the volcanic debris particles filling the pores, as well as their subsequent devitrification, chloritization, and limonite mineralization, result in pore throat blockage and narrowing. The reservoirs in this area are small in size, exhibit poor reservoir connectivity and lateral continuity, and fail to meet the necessary conditions for commercial-scale hydrocarbon accumulation and migration.

Segmented activity of the Shuntuoguole Low Uplift strike-slip fault zone and its impact on oil and gas charge events: Constraints from calcite veins containing hydrocarbon inclusions

Mengting HANG[1]*, School of Geosciences, China University of Petroleum (East China), Qingdao, China (S22010059@s.upc.edu.cn)
Jinqiang TIAN[2], School of Geosciences, China University of Petroleum (East China), Qingdao, China

Abstract

The strike-slip faults within the craton exhibit distinct segmented kinematic characteristics and oil and gas enrichment tendencies. Although research has been conducted on the overlapping segments of strike-slip faults and the distribution characteristics of reservoirs, there is still a dearth of detailed investigation into the spatiotemporal coupling relationship between fault segmentation characteristics and oil and gas charge events. The strike-slip fault zone serves as the primary oil and gas-bearing structure in the Tarim Basin, holding significant importance in controlling deep oil and gas accumulation. This study integrates calcite U-Pb dating with quantitative fluorescence spectroscopy to identify the fault activity and periods of oil and gas charging in structural segments of two strike-slip faults (SHB No. 4 and SHB No. 8). Research findings indicate that the SHB No. 4 and SHB No. 8 faults exhibited varying degrees of activity during the mid to late Caledonian and late Hercynian periods. Both SHB 805X well and SHB 45X well, situated in the extensional segment of the strike-slip fault, underwent four stages of oil and gas charge events. Among these stages, yellow fluorescence color oil inclusions (λmax [wavelength at maximal light absorbance] ranging from 540 nm to 490 nm) formed during the mid-Caledonian period, blue-green fluorescence color oil inclusions (λmax ranging from 490 nm to 460 nm) formed during the late Caledonian period, blue fluorescence color oil inclusions (λmax ranging from 460 nm to 440 nm) formed during the late Hercynian period, and methane inclusions formed during the Himalayan period. SHB 804X well, located in the contractional segment of the strike-slip fault, experienced only one phase of gas charging during the Himalayan period. This suggests that the extensional segment of the strike-slip fault is more conducive to oil and gas charging compared to the contractional segment.

Multiple hydrocarbon accumulation model around Sangtamu fault zone in Lunnan area, Tarim Basin

GANG PENG[1]*, School of Geosciences, China University of Petroleum (East China), Qingdao,China (pg2714756005@gmail.com)
Jinqiang TIAN[2], School of Geosciences, China University of Petroleum (East China),Qingdao,China

Abstract

The Tarim Basin is located between the two orogenic belts of Tethys and Altay and the tectonic events in the orogenic belts around the basin have caused different tectonic deformations in the stratigraphic system within the basin from Cambrian to Quaternary. The Sangtamu fault zone is located in Lunnan area in east of Tabei uplift and the north of Tarim Basin. Through the petrological observation of core samples, fluid inclusion system analysis and testing, and crude oil fluorescence determination in the Sangtamu area, combined with the homogeneous temperature-burial history projection method, and the simulation of hydrocarbon production history of hydrocarbon source rocks, crude oil geochemical characteristics, and the history of fracture activities, the hydrocarbon complex formation model was established.The results show that the Ordovician in the Sangtamu area develops three phases of oil inclusions, which fluoresce in blue, yellowish green and yellowish brown. Carboniferous system develops two phases of oil inclusions, yellow-green and blue-white fluorescence. The Triassic system develops two phases of inclusions, respectively, blue-white and yellow. The filling time of Ordovician crude oil is the Late Caledonian-Early Hercynian, Late Hercynian, and Yanshanian. The Carboniferous System exists two phases of crude oil charging, which are the Late Yanshanian-Early Himalayan and Late Himalayan, and the oil and gas charging is mainly related to the Sangtamu Fault Basement Belt and the north-east-east oriented fracture. The Triassic system shows two phases of crude oil charging in the Himalayan period; the T3 layer has two phases of charging in the early Himalayan and late Himalayan periods, while the T1 layer only has the characteristic of charging in the late Himalayan period. The density of Ordovician average crude oil density is 0.84g/cm3; the density of Carboniferous average crude oil density is 0.87g/cm3; the density of Triassic average crude oil density is 0.88g/cm3.The Sangtamu fault zone and the NEE faults jointly control the crude oil properties and the hydrocarbon formation process. Inside the Sangtamu fault zone, the T1-T3 layer fracture is not completely through, and most of the crude oil along the injection point in the early Himalayan period only entered the T3 layer and produced lateral transportation; when reinjected in the late period, the crude oil in the T3 layer entered the T1 layer upward along the overflow point, resulting in the differential aggregation between the two layers. The low-mature oil charged into the Ordovician in the late Caledonian was adjusted upward into the Carboniferous along the NNE-directed fractures in the Yanshanian, leading to the high crude oil density in the present-day reservoir; the Triassic and Ordovician were charged with more late oil along the fractures. the temporal and spatial matching relationship between the fracture activity time and oil

and gas charging results in the existence of multiple periods of crude oil charging.

Hydrocarbon complex formation model around the periphery of the Lunnan fault zone in the Lunnan area of the Tarim Basin

Maogeng TIAN[1]*, School of Geosciences, China University of Petroleum (East China), Qingdao, China (tmg413529@163.com)
Jinqiang TIAN[2], School of Geosciences, China University of Petroleum (East China), Qingdao, China

Abstract

The Tarim Basin, as a typical superposition basin, is sandwiched between the tectonic domains of the Paleo-Asian Ocean in the north and the Tethys Ocean in the south. Lunnan area is located in the northwestern part of the Tarim Basin Tabei Rise, and the Lunnan Fault Zone is in the northern part of the Lunnan area, which is an important oil and gas exploration area. Under the effect of multi-phase tectonic evolution, many deep and large fractures have been developed, and the distribution of hydrocarbons is exceptionally complicated by the influence of fracture activities. Through petrological observation of core samples, fluid inclusion analysis, quantitative fluorescence spectral analysis of crude oil, simulation of hydrocarbon history of hydrocarbon source rocks, and the use of homogeneous temperature-burial history projection method as well as the geochemical characteristics of crude oil in the area of Lunnan Fault Belt, the accumulation period is determined, and the process of hydrocarbon formation is recovered by combining with the activity of fractures in different periods.

The results show that the Ordovician crude oil develops yellow and green colored oil inclusions, and the fluorescence wavelengths of the crude oil are 560-600 nm and 440-560 nm, respectively. Measurement of the homogenization temperature of the accompanying brine inclusions reveals that the homogenization temperature of the Ordovician is 90-110℃, and no accompanying brine inclusions were found in the yellow fluorescent oil inclusions; and the homogenization temperature of the Triassic System is in two phases: 70-85 ℃ and 100-110 ℃. Combined with the history of hydrocarbon generation and charging, Two phases of Ordovician crude oil charging existed, namely, the Late Caledonian and the Late Hercynian; the Triassic crude oil also has two phases of charging, namely, the Early Xishan and the Late Xishan phases. The geochemical characteristics indicates, Ordovician crude oil density 0.79-0.83 g/cm3, an average of 0.81 g/cm3, the wax content of 1.9-6.8%, an average of 3.69%; Triassic 0.83-0.88 g/cm3, an average of 0.85 g/cm 3, the wax content of 3.72-9.9%, an average of 6.06%.

Due to the fracture activity between different layers, it provides transportation channels for hydrocarbon migration and causes large differences in the nature of crude oil. After the generation of crude oil in the Late Caledonian, it was transported vertically to the Triassic along the Lunnan Fault Zone in the early Xishan, and mixed with the highly matured oil generated in the Late Hercynian, which had a high density and wax content; while the Ordovician mainly consisted of the highly matured oil generated in the Late Hercynian Period, which had a low density and wax

content. The fault activities in different periods provide transport channels for oil and gas, which eventually leads to the multi-stage charging of oil and gas in the Lunnan fault horst zone.

Anjiang Shen[6], Research Institute of Petroleum Exploration and Development, PetroChina

Abstract

Paleo-fluid circulation plays a critical role in the geochemical and geodynamic evolution of sedimentary basins. Improved understanding of subsurface paleo-fluid evolution aids in reconstructing the associated diagenetic and petroleum evolution of carbonate reservoirs. Multi-stage calcite cements generated by basinal fluids over time were investigated using a combination of petrography, geochemistry, fluid-inclusion studies, and in situ U-Pb geochronology interpretation. This study aims to gain clues about diagenetic and paleo-oil filling events within the Mishrif Formation, Mesopotamian Basin, Iraq. Three main phases of calcite cementation were petrographically, geochemically, and geochronologically distinguished, which can be attributed to varied diagenetic phases and environments. The earliest calcites occurred as rim granular cement featured high Sr, Na content, and low Fe, Mn content, and adjacent drusy/blocky cement featured high Mn content and low Sr, Na content growing along the moldic pores, interpreted as pene-contemporaneous cements formed in a subsurface environment featured by a mixture of meteoric and marine waters with an in situ U-Pb age of 96.8–85.5 Ma. The second calcites presented as blocky cements filled in the center of the moldic pores, with high Fe, Mn, and low Sr content indicating brine fluid during the shallow burial stage with an in situ U-Pb age of 69.44–67.62 Ma. The last blocky calcite cement in the vugs or fractures is characterized by a high Fe, Mn, and low Sr content derived from brine fluid in the deep burial environment, with an in situ U-Pb age of 24.7–12.7 Ma. In addition, we constrained two oil migration processes under an absolute time frame by integrating oil-inclusion fluorescence and in situ calcite U-Pb dating in different calcite generations hosting primary oil inclusions. The U-Pb age of 67.62–69.44 Ma for the second blocky calcite related to yellow fluorescence oil inclusion constrained the early timing of the oil-filling event, coinciding with the closure of the Southern Neo-Tethys. This early-stage hydrocarbon accumulation was sourced from the Sulaiy Formation and its equivalent Chia Gara Formation of the Upper Jurassic, whose Ro reached 0.6~0.75%. The younger U-Pb age of 24.7–12.7 Ma for the last blocky calcite containing green fluorescence oil inclusion defined the time of the late oil-filling event, agreeing well with the timing of the closure of the Neo-Tethys and Zagros orogenies. This late-stage hydrocarbon accumulation was derived from the same source formation as the early-stage, with a Ro of 0.85~0.97%. This study contributes to (1)

comprehending the differential diagenetic process in the impact of various diagenetic stages and hydrocarbon emplacement and (2) linking diagenetic sequence to tectonic evolution and hydrocarbon accumulation in foreland basins evolved from Neo-Tethys tectonics.

Main Controlling Factors on Cambrian Dolomite from the Tarim basin, northwest China: implications for Ultra deep Reservoir

Xuelian YOU[1]*, China University of Geosciences, Beijing (youxuelian@cugb.edu.cn)
Kehui zhang[2], China University of Geosciences, Beijing

Abstract

The deep reservoirs in the Tarim Basin are characterised by their large burial depths and ancient stratigraphy, making it one of the largest deep-lying oil and gas rich areas in China. The genesis of deep-ultra-deep dolomite reservoirs is crucial for exploration and development. In the Tarim Basin, the Cambrian sub-salt dolomite reservoirs are widely distributed, with the discovery of numerous carbonate hydrocarbon fields indicating vast reserves, offering significant prospects for ultra-deep reservoir exploration. This study employs big data methodologies to focus on the exploration and development of deep hydrocarbon reservoirs in the Cambrian of the Tarim Basin. It conducts data collection and analysis of porosity and permeability within Cambrian carbonate reservoirs in the western Tarim Basin. Based on the sedimentary evolution and distribution of carbonate-evaporite sequences, factors such as sedimentary facies, sedimentary thickness, distribution of fault zones, and source-reservoir combinations are considered as primary reference parameters. The study delineates the macroscopic distribution patterns of porosity and permeability and establishes three categories of favorable oil and gas zones. Predictive modeling is utilized to forecast oil and gas favorable zones within the Series 2, Miaolingian, and Furongian systems. Furthermore, the study analyzes the controlling factors influencing the development of Cambrian carbonate reservoirs on the northwestern margin of the Tarim Basin from both sedimentary and diagenetic periods. Factors such as tectonism, sedimentary environment, microbiology, compaction and dissolution are analyzed to understand the main causes of differences in porosity and permeability distribution. Firstly, the arid climate of the ancient era favored the development of carbonate reservoirs, with concentrated seawater being the primary source of carbonate fluid. Secondly, the geological genesis model of different types of carbonate reservoirs is associated with the content and crystal characteristics of carbonate minerals, which are crucial for the formation of storage space. Lastly, specific marine environments, such as the gypsum-bearing dolomite flat intertidal-subtidal zone under the arid climate background of the Middle-Lower Cambrian in the Tarim Basin, serve as favorable reservoir development areas. The main controlling factors of reservoirs in the Tarim Basin include periodic sea-level changes, diagenesis, multiple periods of dissolution, and moderate dolomitization. These factors collectively influence the formation and development of reservoirs. In conclusion, the Series 2 of the Cambrian carbonate reservoirs exhibits higher porosity and permeability, with a large distribution area, indicating favorable exploration prospects in areas such as Bachu-Tazhong and Kalping. The Miaolingian is mainly affected by diagenesis, with high permeability but smaller porosity and distribution range. The Furongian primarily in Kalping and Bachu areas, exhibits higher porosity, permeability, and greater sedimentary thickness, possibly indicating higher

reserves.

The hydrocarbon charging history and accumulation model of deep buried carbonate reservoirs in Yuqi area, Tarim Basin, Northwestern China

Zhiyi TIAN[1]*, School of Geosciences, China University of Petroleum (East China), Qingdao, China (z22010062@s.upc.edu.cn)
Jinqiang TIAN[2], School of Geosciences, China University of Petroleum (East China), Qingdao, China

Abstract

The Tarim Basin is located in the middle zone of the eastern section of the Tethys tectonic domain. It has experienced multi-cycle tectonic action and multi-stage oil and gas charging and adjustment transformation, and has the characteristics of large-area oil and gas. The crude oil properties of the Ordovician in the Yuqi area of the Tarim Basin exhibit a distinctive ring-like pattern of crude oil viscosity, becoming progressively denser from southeast to northwest. In certain localized areas, there are light oil reservoirs with abrupt changes in crude oil properties. The progress of hydrocarbon accumulation is complex and controversial, with limited previous research. In this study, we reconstruct the hydrocarbon charging history and establish the accumulation model by crude oil property analysis, fluid inclusion analysis, basin modelling, molecular geochemistry, in-situ calcite U-Pb dating and crude oil Re-Os dating. Molecular parameters indicate that the Ordovician crude oils have generally undergone biodegradation and the mixing of heavy oil and light oil is common. Quantitative fluorescence spectroscopy of hydrocarbon inclusions and fluid inclusion homogenization temperature (Th) combined burial history modelling, Re-Os dating and U-Pb dating indicate that there are three periods of oil charging in the Ordovician reservoir, which are the late Caledonian (463.2-420.5Ma), the late Hercynian (255-295Ma) and the Himalayan (10-20Ma). Since most of the oil and gas in the late Caledonian were destroyed, the current spatial distribution pattern of oil and gas properties and phases is mainly affected by the biodegradation intensity in the late Hercynian and the charging intensity of light hydrocarbon in the Himalayan. During the late Caledonian to Early Hercynian period, the source rocks of the Yuertusi Formation entered the oil generation window, and both the Luntai fault and the main strike-slip fault were active, creating dominant vertical migration pathways that facilitated the vertical migration of oil and gas. However, the reservoirs in this area are relatively shallow and lack effective cap layers, resulting the crude oil was destroyed. During the Late Hercynian period, the source rocks were in the high mature stage and experienced significant hydrocarbon generation. The shallowest burial depth of the Ordovician reservoirs was less than 2000m. The oil charged during this period commonly underwent biodegradation, resulting in the formation of present-day heavy to ultra-heavy oil reservoirs. During the Himalayan period, the source rocks in the study area still retained the hydrocarbon generation potential, and light oil and condensate hydrocarbon were continuously generated in the process of rapid subsidence and burial warming. Under the vertical transport of the late activated Luntai fault, they were charged into the reservoir and mixed with the early oil and gas. The local NNE-

and NEE-trending strike-slip faults around the Luntai fault are opened, resulting in high local light oil charging strength and forming the current YQX1 light oil reservoir.

The basic model and controlling factors of hydrocarbon enrichment in deep buried carbonate reservoirs: A case study of Tuoputai area in the Tarim Basin, Northwest China

Honglei XIE[1]*, China University of Petroleum (East China) (b20010021@s.upc.edu.cn)
Jinqiang Tian[2], China University of Petroleum (East China)

Abstract

With the increasing global levels of oil and gas consumption and the growing challenges in exploration, the target layers for hydrocarbon exploration are rapidly extending from shallow to deep and ultra-deep layers. Investigating the basic model and controlling factors of hydrocarbon enrichment in deep reservoirs is of great significance in improving exploration and development efficiency. The Tarim Basin is located in the central part of the eastern segment of the Tethys tectonic domain with complex tectonic evolution history. The Ordovician carbonate intervals are hot spots for exploration and are characterized by complex hydrocarbon properties and multistage accumulation. The crude oil properties exhibit a distinctive ring-like pattern, becoming progressively light from north to south. In this paper, we established the hydrocarbon enrichment model and analyzed its controlling factors in Tuoputai area by integrating the physical properties and molecular geochemical parameters of crude oils, fluid inclusion analysis, basin modeling and in-situ calcite U-Pb dating. The primary accumulation of Ordovician crude oils in the study area is mainly found in the strike-slip fault zones and their adjacent areas. Molecular parameters indicate that the crude oils have undergone biodegradation in the north of study area. Additionally, the maturity of the crude oils increases gradually from north to south. All the oils were derived from the same source rock, deposited in a reduced marine environment. The results of fluid inclusion analysis and basin modeling suggested the presence of three oil generation and charging events during the late Caledonian, late Hercynian and Himalayan. Calcite U-Pb ages provide constraints on the timing of the first and second charging episodes in the study area, at approximately 474–463 Ma, 450-426 Ma and ca. 278–267 Ma, respectively. Comparing the fluorescence spectra of reservoir oils and oil inclusions revealed that the late Hercynian is the major period of crude oils charging. The X-type conjugate strike-slip fractures developed in the study area have experienced multiple activity periods, which were conductive to hydrocarbon migration and accumulation. In the early Hercynian, tectonic uplift led to the destruction of late Caledonian-charged crude oils, and present-day crude oil properties are mainly controlled by biodegradation in the late Hercynian and light crude oils charging in the Himalayan. The deep Ordovician reservoirs exhibited a hydrocarbon enrichment model characterized by multiple charging events, vertical hydrocarbon supply, early uplift and erosion, followed by later recharging and deep burial preservation in Tuoputai area. The differential thermal evolution of source rocks and the multiple activations of strike-slip faults caused by tectonic movements are the main controlling factors for hydrocarbon enrichment. This study reveals the hydrocarbon enrichment mechanism in deep buried carbonate reservoirs, which is of great significance for oil and gas exploration and efficient

development.

Geochemical characteristics, genetic types and sources of gas accumulations in the northern Jizhong Subbasin, Bohai Bay Basin, eastern China

NIAN LIU[1]*, Beijing Research Institute of Uranium Geology (liuniancup@163.com)
Nansheng QIU[2], China University of Petroleum, Beijing
Man Lu[3], China University of Petroleum, Beijing

Abstract

Gas source and genetic type identification are important for gas system analysis and successful exploration. However, such crucial information is generally lacking or highly controversial in the northern Jizhong Subbasin, Bohai Bay Basin, hindering further gas exploration. The geochemical characteristics, genetic types and sources of gas accumulations are investigated based on a series of organic and inorganic geochemical analyses, including elemental and stable isotopic compositions, noble gases isotopic composition, and mercury content in gas in combination with molecular compositions of associated oils. Multiple genetic types of gases are identified in the northern Jizhong Subbasin, including biogenic gas, coal-derived gas and oil-associated gas. In particular, gases in the shallow Paleogene reservoirs are composed mainly of oil-associated gases derived from sapropelic organic matter in the Paleogene third member of the Shahejie Formation (Es3) and dark shales in the fourth member of the Shahejie and Kongdian formations (Es4+Ek). Gases in the deeply-buried Ordovician and Carboniferous–Permian reservoirs are mainly derived from coal with some contribution from oil-associated gases. The deep gases are mainly derived from the Carboniferous–Permian coal-bearing humic source rocks with contribution from mixed organic matter in the Es4+Ek source rocks.

Microbially generated gases, mainly distributed in the Paleogene Es3 and the first member of Shahejie Formation (Es1) reservoirs, are dominated by secondary microbially generated gas via carbon dioxide reduction. Microbially generated gases co-occur with biodegraded oils and are probably derived from sapropelic organic matter in the Es3 source rock. Based on the findings, it is concluded that shallow Paleogene rocks might be favorable reservoir zone for primary (kerogen) cracking gases generated from Type II1 kerogen. Dry gases derived from Type III kerogen and secondary cracking gases from Type II1 kerogen in the deep and ultra-deep Ordovician and Precambrian–Cambrian reservoirs can be other potential exploration targets in the northern Jizhong Subbasin.

Amirqulov Jalil[4], National University of Uzbekistan
Majidova Shirinbonu[5], National University of Uzbekistan

Abstract

The Ferghana Basin is located in the Central Asia and is a part pf paleotethis. The Ferghana Basin is located in the Central Asia. The basin lies within three countries: Kyrgyzstan, Uzbekistan and Tajikistan. The basin is a topographical depression within the southern Tian Shan Fold Belt, corresponding to the valley of the Syr-Darya (Naryn) river, and is surrounded by mountain ridges. The northwestern boundary of the basin is formed by the Severo-Fergana (North Ferghana) fault, which is a thrust fault dipping to the northwest and separating the basin from the Kurama and Chatkal ridges. In the northernmost part of the basin, the Chatkalo-Atoynak thrust fault bifurcates from the Severo-Fergana fault. The deformed zone that lies along this margin of the basin is known as the Northern Underthrust Zone. A major continental strike-slip fault, the Talass Fergana fault, lies to the east of the basin and trends northwest-southeast. The southern margin of the basin is formed by the Yuzhno-Fergana (South Fergana) fault, a south-dipping thrust that separates the basin from the east-west trending Turkestan and Alay ridges. A series of troughs lie along the northern margin of this fault, including the Buzhum-Khaydarkan and Lyaylyak troughs. The Yuzhno-Fergana fault bifurcates south of Fergana, and the northern arm of the northeast trending thrust fault delineates the prospective part of the basin. To the southeast of this thrust, the hanging-wall comprises the Kurshabo-Uzgem trough, the Karavan-Kokdzhar trough and the Kara-Chatyr massif. A major northwest-southeast strike-slip fault, the Vostochno-Fergana (East Ferghana) fault, is thought to cut through the center-east of the basin, paralleling the Talas Fergana fault, separating the eastern structural highs (Mayli-Say and Achi-Su) from the deeper part of the basin. The Central Graben lies along the axis of the basin and is bounded on either side by reverse faults or thrust faults, beyond which lie the surrounding terraces: the Southern Terrace in the south and the Chust-Pap-Namangan and Khodzhent terraces to the northwest.

The Ferghana basin is a roughly east-west trending very deep graben which was formed as a reaction to the various continental movements which took place in particular since the late Paleogene–Neogene.

The study of the geological and tectonic evolution of the Fergana region is an important component in the study of the history of geological development, sedimentation, prospecting and exploration of mineral deposits, including oil and gas. Based on the analysis of the results of interpretation of geological and geophysical materials, including including seismic and borehole data a paleotectonic reconstruction of the sedimentary cover of the Fergana region along the line

extending from south to north was made, which characterizes the geological and tectonic evolution at a certain stage of sedimentation.

Reunderstanding Of Hydrocarbon Generation Evolution And Hydrocarbon Generation Potential Of Lower Cambrian Source Rocks In Tarim Basin

Shiyang ZHOU[1]*, 1173295078@qq.com (1173295078@qq.com)
Qi Wang[2], 376460511@qq.com

Abstract

The evaluation of hydrocarbon generation potential of deep ancient marine source rocks is one of the key objectives ultra-deep oil and gas exploration.As the main source rock of the Lower Cambrian, Yuertusi Formation in Tarim Basin is a typical representative of deep and mature ancient marine source rock with the characteristics of old age, deep burial and high thermal evolution.In this paper,TOC analysis was carried out on core and outcrop samples to clarify the differences in the abundance of spatial organic matter.Comprehensive seismic,logging,sedimentary facies and geochemical data were integrated to improve and compile the isocontour maps of source rock thickness,TOC and vitrinite reflectance in different zones.At the same time,low-maturity Inca shale samples with similar tectonic latitude,sedimentary environment and source composition to the Tarim Basin were selected for thermal simulation experiments,and the hydrocarbon generation evolution chart under the closed system was established.By simulating the evolution process of hydrocarbon generation in geological history, and calculating the maturity degree(Ro) corresponding to each experimental temperature based on the EasyRo model, the hydrocarbon production component plates under different maturity levels were established to calculate the hydrocarbon production rate of source rocks in the critical period.Finally,based on the basic map of macroscopic distribution of source rocks and hydrocarbon production rate, the area calculation function of Petrel software is used to quantitatively characterize the amount of oil generation and gas generation in geological history.The result show that the source rocks of the Yuertusi Formation have produced a large amount of oil in the Hercynian period,and the crude oil in the reservoir is mainly preserved in deep burial.The source rocks of Yuertusi Formation still have great gas potential in the hilltop period and belong to the effective gas source rocks.The evolution of hydrocarbon generating focus reveals that the ultra-deep Aman transition zone still has a good oil and gas exploration prospect.

Cretaceous prototype basins, lithofacies paleogeography of Tethys region and their controlling on oil and gas accumulation

Tongfei HUANG[1]*, Beijing, China (huangtfei@126.com)
Guangya ZHANG[2], Beijing, China
Beiwei LUO[3], Beijing,China
Zhiliang HE[4], BeijingChina
Guoping BAI[5], Beijing,China

Abstract

Studying the paleotectonic situation, prototype basins, and lithofacies paleogeographic characteristics of the Tethys domain during the Cretaceous plays an important role in deepening the understanding of the oil and gas enrichment laws in the Tethys domain. On the basis of global prototype basins and lithofacies paleogeography research in the Early Cretaceous (125 Ma) and Late Cretaceous (90 Ma), this article focuses on the prototype basins and lithofacies paleogeography development characteristics of the Tethys domain in the above two periods, and then focuses on the control of Cretaceous tectonics and sedimentary evolution on the oil and gas accumulation conditions and enrichment laws of the Tethys domain. Research has shown that the Early Cretaceous period was in the first stage of the breakup of the Pangaea Supercontinent (fromT to K1), with the Cimmerian Continent drifting in a northeast direction, the Neo-Tethys Ocean rapidly opening and reaching its maximum width in the early Cretaceous. In the North Africa-Europe segment, and Middle East-Central Asia segments of the Tethys domain, rift basins and backarc basins are mainly developed on the Laurasia side, while passive margin basins are widely developed on the Gondwana side of the Tethys domain. Late Cretaceous was in the second stage of the breakup of the Pangaea Supercontinent (from K2 to present), with the African plate, Indian plate, and Australian plate drifting in a nearly northeast direction. The passive continental margin basins on the northern margin of the Gondwana and the rift basins and backarc basins on the southern edge of the Laurasia were in successively developed. The northern margin of the Gondwana and the southern margin of the Laurasia extensively developed a thick combination of sandstone, mudstone, and carbonate rocks in the early and late Cretaceous. The relatively stable coastal shallow sea -semi deep sea environment is conducive to the formation and preservation of Cretaceous mudstone source rocks and multiple sets of sandstone and carbonate reservoirs. These multiple combinations in vertical are conducive to the accumulation of oil and gas, especially in the northern margin of the Gondwana in Africa, Arabia, India, and the northern part of the Australian plate, where the geological conditions for oil and gas generation, reservoir, and cap are more favorable. The Persian Gulf region benefited from the superior petroleum geology conditions of the Cretaceous Tethys domain. The Arabian Plate continued to be located in a low latitude environment, with a relatively stable passive continental margin background for coastal shallow sea and semi-deep-sea sediments, which were conducive to the formation and preservation of organic rich source rocks in the Cretaceous and multiple combinations, which were prerequisite for those huge oilfields.

Geochemical characteristics and accumulation model of natural gas in the Cenozoic Bohaibay basin

Bo Yang[1]*, China University of Petroleum(Beijing), CNOOC Hainan Branch Company
(2022315002@student.cup.edu.cn)
Fujie Jiang[2], China University of Petroleum(Beijing)
Di Chen[3], China University of Petroleum(Beijing)

Abstract

Natural gas, acknowledged as one of the most environmentally friendly energy sources worldwide, is poised to play an increasingly prominent role in the global energy landscape. The Nanpu Sag, situated within the Bohai Bay Basin of China, stands out as a significant reservoir of natural gas resources. Nevertheless, a comprehensive understanding of the overarching natural gas accumulation model in this region has been lacking. Leveraging the natural gas composition and carbon isotope composition data derived from 30 gas samples obtained from 30 wells within the Nanpu Sag, this study undertakes an examination of the causes and classifications of natural gas, delves into the sources of natural gas, explores the vertical migration patterns of natural gas, identifies the controlling factors governing its accumulation, and establishes the principal accumulation models specific to the study area. Our findings reveal that the dominant alkane component in natural gas within the Nanpu Sag is methane, with concentrations ranging from 52.98% to 90.94%. Ethane and propane exhibit average concentrations of 10.30% and 5.66%, respectively, signifying a low level of natural gas maturity. Methane carbon isotope values predominantly fall below -35‰, while ethane carbon isotope values primarily reside within the -25‰ to -30‰ range, averaging at -26.37‰. Propane and butane carbon isotope values span from -20‰ to -28‰. The genesis of this natural gas is primarily characterized as mature to highly mature thermal degradation gas, with transitional and humic gas components. By evaluating the relationship between the natural gas's Ro and the source rock Ro and comparing the natural gas type to the parent material type, we ascertain that the primary source of natural gas stems from the third member of the Shahejie Formation source rock. Variations in CO2 and N2 content indicate a vertical migration of natural gas from the Es3 layer to the western Ordovician zone, featuring notable transitions in Es3 to Es1, Ng, and Nm. Methane content and methane carbon isotope variations highlight the primary migration traits from Es3 and Es1 to adjacent strata. Ultimately, consolidating prior research outcomes and summarizing the overall structural geological evolution characteristics of the study area, we establish two accumulation models: source-proximate accumulation and far-source fault-induced accumulation.

Abstract

The Marine shale in the Middle and Upper Yangtze region of China has experienced complex tectonic movement, and is one of the best areas to study the enrichment effect of oil and gas resources in the complex structural zone. The exploration and development of shale gas in the Sichuan Basin has gradually shifted from the stable zone to the complex structural zone outside the basin, which has made great progress, revealing the complex multi-scale geological process of shale gas formation and preservation conditions. Clarifying the shale deformation caused by tectonic processes and its influence on the development of shale reservoirs and the enrichment of shale gas is also helpful for the study of Petroleum enrichment and Tethys geodynamic system. The study shows that, as a key parameter affecting shale gas accumulation, the physical characteristics of shale reservoir are greatly affected by tectonic stress transformation and deformation, which not only affects the occurrence state of shale gas, but also determines the evaluation and exploration prospect of shale gas resource potential by changing the migration and enrichment of shale gas. On the basis of field structural geological investigation and deformation analysis, combined with laboratory test and simulation experiment, a systematic study was carried out on the evolution characteristics of Marine shale reservoirs in complex structural areas in southern China, such as pore structure, permeability and adsorption properties. The study reveals the intrinsic connection and mechanism of shale pore-fracture and organic matter, inorganic mineral particle structure evolution and tectonic stress, and identifies the remodeling mechanism of the shale reservoir physical property change. The findings contribute to the theory of shale deformation and gas accumulation, as well as offer a scientific foundation for the exploration of marine shale gas in the complex tectonic zones.

Ancient alkaline lacustrine formation mechanism and distribution characteristic of Fengcheng Formation in Junggar Basin, Northwestern China

Yunxian FENG[1]*, PetroChina Xinjiang Oilfield Company and School of Geosciences, China University of Petroleum (fengyunxian_198205@163.com)
Yong TANG[2], PetroChina Xinjiang Oilfield Company

Abstract

Alkaline lacustrine is considered as one of the most promising aquatic environments for source rock forming due to its high initial productivity and excellent organic matter preservation condition. Fengcheng Formation of Mahu Sag, the main oil-producing shale series in the northwest region of Junggar Basin, belongs to the Tethys structural domain surrounding Tianshan Mountain. It is the oldest alkaline lacustrine deposit in China. The mineral composition of Fengcheng Formation exhibits a wide diversity. Besides sedimentary pyroclastic rocks, it also includes dolomite, calcite and various types of alkaline minerals (such as trona, shortite, eitelite etc.).

According to the paleogeomorphy, Mahu Sag can be divided into three units: the edge fault zone, the slope transitional zone and the depression center. In the slope area, the formation consists mainly of calcareous siltstone, dolomitic mudstone and mixed rocks. In the depression center, mudstone deposits are accompanied by the alkaline minerals which are especially abundant in the second member of Fengcheng Formation.

In the slope area, the stratigraphic units of Fengcheng Formation contain a complete third-order sequences. From bottom to top, it develops andesite, fan delta conglomerate in the lowstand system tract, silty mudstone in the semi-deep lacustrine during transgression period, maximum flooding shale, and muddy siltstone of shallow water in highstand system tract. The geochemical data (such as trace element, isotopic geochemistry) indicate that the maximum flooding shale in the second member of Fengcheng Formation was formed in the reducing environment with the highest salinity in the deepest water body. And almost at the same time, the bulk alkaline minerals began to accumulate in the depression center.

Mahu sag is considered as a closed to semi-closed hydrological system due to the low leakeage rate of andesite subbottom of Fengcheng Formation. During the transgression stage, a large number of Na+, K+Ca2+ and Mg2+ formed by the weathering of pyroclastic rocks were injected into the lake with overland runoff. Meanwhile, the climbing CO2 concentration and strong evaporation caused by frequent volcanic activities also accelerated ion enrichment in the lacustrine water. Those solutes sank by gravity, which contributed to the vertical stratification of the water column. At the maximum flooding stage, low-solubility calcite was more easily formed in the shallow slope zone because of the lower salinity caused by the nearshore fresh water injection. On the other hand, as ion concentration continuously increased in the depression center, alkaline minerals were formed vastly at the bottom of lake center when the precipitation saturation was finally reached. After that, during the highstand tract development stage, the salinity in the sag

was diluted resulted from the frequent flood events, and the alkaline deposits were no longer formed in Mahu Sag. Such a complex suit of minerals within a formation are not only affected by volcanical activities and paleoclimate, but also influenced by paleogeomorphy and hydrological conditions.

Abstract

As universally acknowledged, large igneous province (LIP) events are, in general, associated with tectonic activity, paleoclimatic change, paleoenvironmental disruption, and the generation of sedimentary mineral resources; therefore, LIPs have attracted considerable research attention in the field of Earth science.

The Emeishan large igneous province(ELIP) was a major geological event that took place around the Middle–Late Permian boundary. The major episode of the ELIP is generally considered to have occurred at 260–259 Ma, although an increasing number of geological data have suggested that multiple episodes of magmatic activity might have occurred. Here we report astudy of a Lower Permian dolomite whose formation was influenced by the ELIP in the Sichuan Basin of southwestern China.

Results show two new pulsed activities at 273.2 ± 9.7 Ma to 269.1 ± 12.0 Ma (ELIP-I) and 263.2 ± 10.3 Ma to 258.7 ± 8.1 Ma (ELIP-II). The two stages of the ELIP magmatism and thermal activity controlled theregional tectonic, sedimentary, and diagenetic evolution and exerted a profound influence on the oil and gas reservoirs, source rocks, and lithofacies paleogeography. This study is the first to interpret the timing of the ELIP from analysis of hydrothermal dolomite and provides new clues and data for improving our understanding of the dynamic formation mechanism and Earth system of the ELIP.

Discovery, formation, and significance of the basement ancient uplift in the South Yellow Sea Basin

Dingyou LV[1], CNOOC China Limited, Tianjin Branch
Qingxun WU[2]*, CNOOC China Limited, Tianjin Branch, (wuqx@cnooc.com.cn)
Ying Guo[3], CNOOC China Limited, Tianjin Branch
Zhen Huang[4], CNOOC China Limited, Tianjin Branch
Zhiqiang Li[5], CNOOC China Limited, Tianjin Branch

Abstract

The ancient uplift plays an important role in marine oil and gas exploration, controlling large-scale marine oil and gas fields. No conventional model of ancient uplift has been found in the Lower Yangtze region. The latest research results indicate that there is a basement ancient uplift in the South Yellow Sea Basin, with Ordovician limestone directly covering granite and missing the Sinian and Cambrian systems.The zircon U-Pb dating results indicate that the cooling age of the granite is around 731-820 Ma. The overlying limestone of granite contains a large amount of biological fragments and a large amount of terrigenous debris, locally appearing red, and without thermal contact metamorphism. Comprehensive analysis suggests that the Ordovician limestone is in sedimentary cold contact with the underlying granite, confirming the existence of Pre-Ordovician ancient uplift in the South Yellow Sea Basin. The ancient uplift was characterized using seismic data, and the results showed that it is located in the middle of the central uplift, with an overall northwest distribution and an area of approximately 2100 square kilometers. Based on unconformity analysis and stratigraphic paleontological analysis, the formation and evolution process of ancient uplifts were clarified: after the intrusion of the Jinning period granite, the ancient uplifts dominated by granite were formed under the influence of the Tongwan movement, and the water bodies gradually deepened during the Ordovician period, and the ancient uplifts were gradually submerged.

The discovery of ancient uplifts has changed the traditional understanding of the "iron plate" within the Lower Yangtze Craton Basin during the Cambrian Ordovician, and requires a reconsideration of plate tectonics, tectonic evolution, and paleogeographic patterns. In addition, the existence of ancient uplifts indirectly confirms the existence of ancient depressions, and the edge high-energy facies zones of ancient uplifts have developed high-quality reservoirs, which are favorable oil and gas exploration zones.

Discovery and Geological Significance of Ancient Crystalline Basement in the South Yellow Sea Basin, Eastern China

Jian REN[1]*, Bohai Oilfield Institute,CNOOC (renjian5@cnooc.com.cn)
Zijun Han[2], Bohai Oilfield Institute,CNOOC
Yongqiang Yao[3], Bohai Oilfield Institute,CNOOC
Shaowei Chen[4], Bohai Oilfield Institute,CNOOC
Xilong Gao[5], Bohai Oilfield Institute,CNOOC

Abstract

Late Archean to Early Proterozoic crystalline basement is widely present in the Upper and Middle Yangtze craton. However, the fundamental issues regarding the formation and evolution of the early Precambrian basement of the Yangtze craton remain unresolved. On one hand, the existence of ancient crystalline basement in the Lower Yangtze region has been controversial, and on the other hand, oil and gas exploration practices in the Upper Yangtze region have indicated that the presence of ancient crystalline basement is essential for ensuring weak deformation of shallow cover layers and favorable conditions for hydrocarbon preservation. The existence of ancient crystalline basement in the South Yellow Sea area is crucial for the prospects of oil and gas exploration in the region. Based on the latest drilling data from the South Yellow Sea area, Lu-Hf isotope and Sr-Nd isotope tracing analysis of the Neoproterozoic granite samples were conducted. The results indicate the presence of Late Archean to Early Proterozoic crystalline basement aged between 2.5 Ga and 2.9 Ga in the South Yellow Sea area, and the age of this basement can be directly compared with that of the Upper and Middle Yangtze basement. In addition, based on the calibration of this well and the combined inversion methods of gravity, magnetism and seismic, the range of ancient crystalline basement was delineated, suggesting that the main body of the Lower Yangtze crystalline basement should be located in the South Yellow Sea Basin. This study demonstrates that some areas of the South Yellow Sea Basin are structurally stable zones protected by the crystalline basement, providing direction for future oil and gas exploration in the region. In addition, further exploration is needed regarding the relationship between the crystalline basement of the South Yellow Sea and the basement of the Gyeonggi block, as well as the response of the crystalline basement during late compression movement.

Discovery of Early Paleozoic “Rifting Troughs” in the South Yellow Sea and Its Significance for Oil and Gas Exploration

Haifeng Yang[1], Bohai Oilfield InstituteCNOOC
Jian REN[2]*, Bohai Oilfield Institute,CNOOC (renjian5@cnooc.com.cn)
Bo Yang[3], Bohai Oilfield Institute,CNOOC
Xiaogang Pei[4], Bohai Oilfield Institute,CNOOC

Abstract

The ancient “rifting trough” is a low terrain area formed by extensional subsidence in marine facies basins, where sedimentation primarily consists of mudstone as source rocks, with high-quality reservoirs developed along the margins of carbonate platforms, thus possessing excellent source-reservoir configuration conditions. In the marine sedimentary strata of the Upper Yangtze Sichuan Basin in western China, both upper and lower ancient rifting troughs have been successively discovered, and Continuous exploration around these two ancient rifting troughs has led to the discovery of two trillion cubic meters gas field clusters. The South Yellow Sea Basin in eastern China, located in the Lower Yangtze region, shares very similar lithofacies and paleogeographic conditions with the Upper Yangtze. Whether ancient rifting troughs are developed in this area is crucial for its exploration prospects. Based on the latest drilling stratigraphic analysis, the lithogeochemistry of samples, as well as new obtained gravity-magnetic and seismic data in the South Yellow Sea Basin, it has been confirmed that ancient rifting trough developed during the Early Paleozoic: 1)The late Ordovician thick mudstone thrust nappe encountered directly during drilling is an ancient rifting trough sedimentary system, which underwent thrust napping in the late stage2) The ancient uplift revealed by drilling is a granite intrusion formed in conjunction with ancient rifts, and the geochemical analysis of granite shows that it is a rifting type granite associated with the extensional movement of ancient rifting troughs during the same period3) The aeromagnetic data of the South Yellow Sea Basin shows obvious low magnetic anomalies, while seismic data shows local abnormal subsidence. The discovery of the ancient rifting trough in the South Yellow Sea laid the foundation for the formation of oil and gas reservoirs in the area and provides direction for the follow-up exploration.

New evidence of post Indosinian tectonic evolution in the South Yellow Sea Basin in eastern China

Rucai Zhang[1], Bohai Oilfield Institute,CNOOC
Jun Ming[2], Bohai Oilfield Institute,CNOOC
Zhen Huang[3], Bohai Oilfield Institute,CNOOC
Xilong Gao[4], Bohai Oilfield Institute,CNOOC
Jian REN[5]*, Bohai Oilfield Institute,CNOOC (renjian5@cnooc.com.cn)

Abstract

The South Yellow Sea Basin in eastern China is a superimposed basin of the Paleozoic marine facies and Cenozoic continental facies that developed on the basement of the pre-Cambrian. Due to limited drilling and seismic data in this area, the unclear understanding of the tectonic evolution processes and mechanisms since the Mesozoic has hindered further oil and gas exploration. Based on the analysis of apatite fission track and carbonate U-Pb dating of the latest drilling sample, and newly obtained seismic and gravity-magnetic data, the tectonic evolution in this area is analyzed. The study identifies four key tectonic events since the Mesozoic Indosinian period: 1) During the Indosinian period, the collision between the North China and South China plates caused significant north-south compression and thrusting in the area, with prominent thrust nappe structure on the northern side of the South Yellow Sea Basin . 2) The latest data indicates that during the late Yanshanian period, the area experienced a significant east-west compression, forming large-scale north-south thrusting structures, orthogonal to the thrust structures of the Indosinian period. 3) From the end of the Yanshanian period to the beginning of the Eocene, influenced by the subduction of the Pacific Plate, the South Yellow Sea Basin experienced a transition from depression to rifting, with the deposition of source rocks in local depressions. 4) During the Oligocene, the South Yellow Sea Basin underwent the last phase of significant tectonic compression known as the "Sanduo Movement," developing numerous north-south thrust faults in the rift zone. The clear evolution process indicates that the exploration of oil and gas in the Paleozoic strata of the South Yellow Sea should focus on the tectonic disturbances effects during the Indosinian-Yanshanian period and search for favorable preservation areas for oil and gas, while exploration in the Mesozoic-Cenozoic strata should focus on the scale of rifting and the adjustment and distribution of hydrocarbons by the Sanduo Movement.

Abstract

During drilling in the South Yellow Sea Basin, China, a thick layer of granite intrusion was encountered beneath the Ordovician limestone strata. The presence of this granite intrusion directly led to the absence of the Sinian-Cambrian strata in the study area, affecting oil and gas accumulation and posing a huge challenge for oil and gas exploration work in the area. In this study, lithological characteristics, age, and genesis of this granite intrusion were investigated using logging, logging, seismic, and analytical data, and its geological significance for oil and gas exploration was discussed. The study reveals: 1) The lithology of the granite intrusion in the study area mainly consists of light gray and gray granite, granodiorite, and quartz diorite, belonging to the high-potassium calc-alkaline series A-type granite. 2) Through U-Pb zircon dating and tectonic evolution analysis, it was determined that the granite intrusion formed during the late stage of the Neoproterozoic Jinning Movement when the Yangtze Plate transitioned from compression to extension, similar to the genesis background of Neoproterozoic granite in Sichuan Basin of the Upper Yangtze. The development of numerous asphalt-filled fractures confirms the presence of a structural environment conducive to the formation of large ancient rift basins in the study area. 3) The granite body exhibits characteristics of multi-stage pulsating intrusion, mainly divided into five stages, with different intrusive stages forming structural weak zones near the interface, promoting the concentrated development of intra-fracture reservoirs. 4) Based on fracture cutting and filling characteristics, the granite fractures are divided into four stages, formed during the Caledonian, Hercynian, Indosinian, and Yanshan-Xishan periods. The first and second stages of fractures are filled with asphalt, indicating the presence of ancient oil reservoirs, while the fourth stage represents effective open fractures critical for reservoir alteration and hydrocarbon accumulation. 5) Intense late-stage hydrothermal fluid activity in the granite development area promoted thermal evolution of Permian source rocks and the development of hydrothermal dolomite reservoirs in the Upper Paleozoic, suggesting the potential for the formation of large gas fields in the Upper Paleozoic. In summary, this suite of granite not only has the potential to form high-quality reservoirs, but also promotes thermal evolution of source rocks and the development of dolomite reservoirs in the Upper Paleozoic. The results of this study greatly deepen our understanding of the fundamental geological conditions of the South Yellow Sea Basin and are of great significance for the next step of oil and gas exploration.

The relationship between Structural Fracture Development and Hydrocarbon Accumulation in the Foreland Basin under the Tethys Evolution: Examples from the Kuqa Foreland Basin

LI SHANMING[1]*, China University of Petroleum East China (409703155@qq.com)

Abstract

The Kuqa foreland basin, situated in the eastern segment of the Tethys orogenic belt, is rich in oil and gas owing to its distinctive plate interactions and intricate tectonic history. This research employs balanced profile technique to partition the study area into distinct tectonic evolution stages. It integrates core observations, imaging logging, and stress field numerical simulation to delineate the spatial and temporal distribution characteristics of fractures within the area. Consequently, the study investigates the interplay between key tectonic evolution stages, fracture development patterns, and the accumulation of oil and gas resources in the region.

The results indicate that the Kuqa Foreland Basin has undergone five different stages of tectonic evolution.By aligning faulting periods with hydrocarbon accumulation period, three key periods emerge: the Late Cretaceous-Paleocene, the Kangcun period of the Neogene, and the Kuqa period of the Neogene. Stress field simulation results, coupled with assessments of fracture filling degree, effective fracture parameters, and fracture distribution across various strata, suggest an overall trend of structural fracture development first increase and then decrease from south to north,. Particularly, the Bozi-Dabei area within the Kelasu structural belt exhibits the most pronounced fracture development.Moreover, fractures within the Lower Jurassic Ahe Formation and the Lower Cretaceous Bashkizeke Formation vertically display higher degrees of development. For individual faulted folds, substantial fractures with lower abundance predominantly occur in core of the fold, indicative of heightened overall fracture development. Conversely, medium to small fractures with greater occurrence are prevalent in the fold's wings, signaling a lesser degree of overall fracture development. The presence of a network of fractures in fault zones and adjacent strata underscores favorable conditions for fracture development.

The Kangcun and Kuqa periods of the Neogene emerge as critical phases for structural fracture formation in the Kelasu and Bozi-Dabei areas, correlating with the second and third periods of hydrocarbon charging in the Kuqa Foreland Basin. Concurrently, disparities in the distribution of dominant fracture development zones contribute to the overarching oil and gas distribution pattern in the Kuqa Foreland Basin, characterized by "north-south zoning, vertical layering, and fold-related accumulation".

Research on the genesis and characterization methods of non-horizontal fluid surface in oil and gas reservoirs in the Middle East

XIAO DU[1]*, Sinopec Research Institute of Science and Technology (duxiao.syky@sinopec.com)

Abstract

The Arabian Basin is the basin richest in petroleum resources in the world, with large-scale and diverse types of oil and gas reservoirs. Affected by reservoir characteristics and accumulation conditions, non-horizontal fluid surface exist in a large number of reservoirs, which have an important impact on the reserve evaluation and development technology strategies optimization. Based on core analysis data, test data, monitoring data and production dynamic data, this paper applies fluid potential analysis and numerical simulation methods to study the controlling factors, types and characterization methods of non-horizontal fluid interfaces in oil and gas reservoirs in the Middle East.

Studies have shown that reservoir properties, hydrodynamic conditions, fluid density, and tectonic movement are the main controlling factors of non-horizontal fluid surface in oil and gas reservoirs. According to the genesis, it can be divided into property genetic type, hydrodynamic genetic type, fluid density genetic type and trap adjustment genetic type. Among them, if it is only affected by the properties of the reservoir, it is classified as property genetic type. If there are other controls factors are classified into corresponding genetic types, which are manifested as the joint influence of corresponding control factors and reservoir physical properties. Affected by reservoir heterogeneity, non-horizontal fluid surfaces are difficult to accurately predict through a small number of evaluation wells. This paper proposes a method and process to characterize such fluid interfaces: 1) determine the free water level at the wells through pressure gradient data; 2) determine the free water surface trend based on the genetic type; 3) correct the trend surface through well data and conduct uncertainty evaluation.

Bedding-parallel stylolites as a proxy for the sealing capacity of deep-burial carbonate cap rocks in the Tarim Basin, NW China

Jun WU[1]*, China University of Geosciences (Beijing) (junwu@cugb.edu.cn)
Tailiang FAN[2], China University of Geosciences (Beijing)

Abstract

The sealing capacity of carbonate cap rocks bearing different stylolite types is analyzed using a combination of petrographic, petrophysical, pore structure and sealing capacity characterization techniques. This study is based on examples of carbonate cap rocks that seal ultradeep hydrocarbon reservoirs of the Tarim Basin (China). Samples from both drill cores and their outcrop analogues are investigated to quantify how morphology does influence the sealing capacity of different types of stylolite-bearing rocks. The study cap rocks consist of mudstone, wackestone to packstone, grainstone and dolomitic limestone. Four stylolite types are identified: rectangular layer, seismogram pinning, suture & sharp peak and simple wave-like types. The difference in the sealing capacity of carbonate cap rocks is attributed to their pore structure connection and stylolite types. Samples bearing simple wave-like stylolites have the best sealing capacity, followed those with rectangular layer and suture & sharp peak types, whereas carbonates hosting seismogram pinning type have the lowest sealing capacity. The impact of stylolite segments on the rock sealing properties, however, differ from one segment to another. Rectangular layer type stylolites can be divided into three distinct segments (with good, moderate and poor sealing, respectively). Both the seismogram pining and suture & sharp peak stylolite types are divided in two parts, with the former one having moderate and poor sealing and the latter exhibiting good and moderate sealing. The simple wave-like type has a good sealing capacity all along the pressure-solution seam. The most effective sealing barriers for vertical fluid flow form when (1) calcite and siliceous cements are pervasively distributed in the vicinity of stylolites, forming highly cemented zones with lower porosity and permeability than their surrounding host rocks; (2) stylolites are enriched in insoluble residues; (3) rare microfractures and dissolution vugs are found along the stylolites. This work provides useful examples for the prediction of the sealing potential of stylolite-bearing carbonate rocks according to stylolite morphology in other geological settings.

The orogenic Mo deposit overprinted by gold mineralization

Nuo LI[1]*, Xinjiang Institute of Ecology and Geography, Chinese Academy of Sciences (linuo@ms.xjb.ac.cn)

Abstract

The Qinling Orogen in Central China underwent complex tectonic evolution and was finally formed through the continental collision between North China Craton and Yangtze Craton during Mesozoic. Here we report a case in the northern Qinling Orogen that was overprinted by metamorphic fluids. The Dahu deposit was initially explored as a gold deposit with salient features of orogenic-type mineralization. Recent underground exploiting has revealed the economic significance of Mo mineralization in the deeper part of auriferous quartz lodes. Such Au-Mo metal association made the Dahu deposit extremely unique, not only in the Qinling Orogen, but also worldwide, because no economically viable Mo has been reported for orogenic-type gold deposit. Gold and molybdenum mineralization are associated with a series of quartz lodes controlled by EW-trending and north-dipping faults. Geological, structural analysis and geochronological (including molybdenite Re-Os geochronology and hydrothermal monazite U-Pb dating) studies identify two mineralization episodes. The first episode is represented by Triassic (~216 Ma) Mo mineralization, with mineral association of quartz, K-feldspar, pyrite, minor sphalerite and monazite. A younger episode occurred in Cretaceous (~125 Ma), and resulted in gold mineralization and overprinted previous molybdenum mineralization. After that, quartz-calcite veins were formed, with limited contribution to mineralization. Detailed fluid inclusion studies indicate that the ore-forming fluids are featured by meso-to hypothermal, low-salinity and CO2-rich, which is identical to those responsible for orogenic-type deposits worldwide. Molybdenite was deposited at higher temperature and pressure (400−500 C, 138−331 MPa) in comparison to gold (215–464 C, 78−237). H-O isotope further revealed a metamorphic origin for the fluids and later mixing with meteoric water. Thus, the Dahu deposit represents a case that has overprinted orogenic Au mineralization on precursor Mo mineralization. The study also demonstrates the fate of ore deposits depending on subsequent tectonic evolution in complex orogenic belt.

Andrew Tomkins[6], Monash University, Clayton, Victoria, Australia
Hao Cui[7], University of Science and Technology Beijing, Beijing, China

Abstract

The source(s) for ore-forming components of orogenic gold deposits has long been debated. The metamorphic devolatilization model (Phillips and Powell 2010), or supracrustal metamorphic model (Goldfarb et al. 2001) is widely accepted to explain the genesis of orogenic gold deposits. It emphasizes that gold and auriferous fluid are originated from metamorphic devolatilization of pelites or altered basaltic rocks when crossing the greenschist-amphibolite facies boundary (Tomkins 2010; Zhong et al. 2015). However, this model is challenged by models that infer non-metamorphic fluids, such as magmatic or mantle-derived fluids, because it can not explain the presence of hypozonal orogenic gold deposits hosted in high-grade (amphibolite facies) terranes in greenstone belts (Groves et al. 2020; Kolb et al. 2015).

To evaluate the feasibility of metamorphic rocks as the source for gold-forming fluids, thermodynamic modelings were conducted to simulated the devolatilization processes of gold- and sulfur-bearing metapelite and metabasite, which are broadly suggested sources for gold-forming components, as well as altered komatiite, which also contributes large propotions of metmorphic rocks in Precambrian greenstone belts.

The simulation results of metabasites show that auriferous metamorphic fluids are mainly liberated by decomposition of chlorite and epidote during the transition from greenschist to amphibolite facies (450−550 °C). Up to ~2 wt.% of free water and ~1 to 1.5 ppb of Au (relative to rock mass) can be released from the source rock across this transition. It implies that the majority of Au (50%−70%) in a basalt will have been striped when entering amphibolite facies, taken that Archean basaltic rocks contain ~2 ppb of Au in average. At temperatures higher than the wet solidus of basalts, the gold releasing process ceases because breakdown of hydrous minerals would result in partial melting. The gold liberation pattern of pelite is similar for metabasite. After the breakdown of chlorite during the greenschist-amphibolite transition, the majority of gold in average pelite will be liberated from the source rock by metamorphic fluids.

The situation is different for devolatilization of altered komatiite, which is characterized by two pulses of fluid and gold liberation. First, ~4 wt.% of water and ~1−1.4 ppb of Au (relative to rock mass) can be released when crossing the greenschist-amphibolite boundary at ~550 °C due to breakdown of antigorite. After entering amphibolite facies, a sharp rise in gold liberation occurs at ~700 °C as responses to dehydration of talc and chlorite, which liberates ~0.5 wt.% of water and ~2 to 5.5 ppb of Au. Although the second step of devolatilization releases less amount of water

than the first, more gold can be scavenged because of the higher solubility of gold at high-temperature metamorphic fluids. As ultramafic rocks, komatiites have higher temperatures of wet solidus (~1000 °C) than basalts and thus maintain in solid states during the second step of fluid and gold liberation at ~700 °C. The simulation resutls prove that metamorphic fluids can effectively mobilize gold from source rocks, and the metamorphic devolatilization model can account for gold mineralization in both greenschist terranes and higher grade rocks.

The lithium behavior of during prograde metamorphism: implications for optimal crustal sources for mineralization

Ming XIAO[1]*, The University of Hong Kong (xiao.ming.cn@hotmail.com)
Guochun Zhao[2], The University of Hong Kong
Yingde Jiang[3], Guangzhou Institute of Geochemistry, Chinese Academy of Sciences
Chao Yuan[4], Guangzhou Institute of Geochemistry, Chinese Academy of Sciences

Abstract

A pre-enriched metasedimentary source is crucial for the generation of lithium (Li)-rich magma. However, the compositions and physical-chemical attributes of the source are poorly known due to its deep level in the crust. To reveal the key crustal source conditions such as the mineral assemblages, subsolidus metamorphic grades, and reworking degrees for the generation of Li-rich magma, whole-rock and in-situ mineral elemental analyses were conducted on a collection of Barrovian-type metamorphic rocks from the Chinese Altai, central Asia to investigate the host minerals and content variations of Li during the prograde metamorphism. These metamorphic rocks have similar greywacke-arkose sedimentary protoliths and encompass continuous biotite, garnet, staurolite, kyanite, and sillimanite metamorphic zones, corresponding to greenschist to upper amphibolite facies metamorphism. The in-situ LA-ICP-MS elemental results show that the staurolite mineral exhibits the highest Li-carrying capacity (Li contents up to 972 ppm) among other metamorphic minerals. It is noteworthy that staurolite, even in low volumetric proportions (e.g., around 10%), can dominate the whole-rock Li contents, which gives rise to the highest Li contents (94-105 ppm) in the staurolite zone and staurolite-bearing sillimanite zone in the studied metamorphic belt. A positive correlation was also observed between the Li contents in the studied and collected staurolites and their host metamorphic rocks, regardless of the lithologies of the host rocks and the metamorphic domains they are from. These observations suggest that staurolite-rich middle-high grade metamorphic rocks can emerge as a more fertile source for Li-rich magma, in comparison to rocks of other lithologies.

On the other hand, in-situ elemental results show that staurolites with the lowest MgO/(MgO+FeO) and/or Zn+Co values display the highest Li contents (619-972 ppm). This suggests that apart from inheritance from metamorphic reactions (e.g., muscovite + chlorite = staurolite + biotite + quartz + H2O), metamorphic fluids generated from local and regional metamorphic dehydration, especially, those that are rich in Li and poor in Mg-Fe-Zn-Co, can also elevate the Li contents in the staurolite. Based on these findings, a theoretical model that outlines the evolution of ordinary crustal sources into optimal sources for Li-rich magma can be proposed. The model shows that prograde metamorphism across the staurolite-in isograd accompanied by infiltration of Li-rich fluids/melts has the potential to generate Li-rich staurolites. Metamorphic rocks that contain high concentrations of Li-rich staurolites are likely to be the most suitable source for generating Li-rich magma.

In summary, this study has important implications for the budget and behavior of Li during crustal

reworking and evolution, which shed new light on the process of how a Li-enriched crustal source is formed.

Metal origin and redistribution of cobalt in the ore-forming fluid of sediment-hosted stratiform Cu-Co deposits: Evidence from geochemistry of sulfides from the Shizishan deposit, SW China

Wenbo LI[1]*, Peking University (liwenbo@pku.edu.cn)
Tianyao Fu[2], Peking University

Abstract

Differentiation of Co and Cu is very common in sediment-hosted stratiform Cu-Co (SSC) deposits and its mechanism remains controversial. In this study, we discussed the metal origin and the process of metal redistribution during through a systematic petrographic and geochemical analysis at the Shizishan Cu-Co deposit, SW China. The ore body at Shizishan can be divided into three layers from the bottom upward. L1 mainly includes disseminated chalcopyrite and minor cobaltite and pyrite. L2 includes chalcopyrite, bornite and a large amount of cobaltite in both disseminated and vein structure. L3 mainly includes vein chalcopyrite and minor pyrite. A two-stage metallogenic process can be recognized at the Shizishan deposit. The first stage was a diagenetic stage forming disseminated chalcopyrite and cobaltite. The second stage was controlled by tectonic activities and formed vein and nodule bornite, cobaltite and chalcopyrite. Additionally, underlaying the ore-bearing dolostone is a “red bed” stratum enriched in strongly altered pyrite.

Pyrite from the red bed strata has high Co and As content, which shows its potential as the Co origin of the ore body. However, Cu content of the red bed pyrite is extremely low. Chalcopyrite and cobaltite show distinct groupings of different styles. Chalcopyrite in low-Co layers is enriched in Co, Ni, As, Se, Ag, Sb and Pb compared with those in high-Co layers. Ni, Se, Sb and Pb are enriched in disseminated and vein cobaltite coordinated with Co and As. Different Ga, Ge and In contents in different types of chalcopyrite suggest that the post-diagenetic fluid had higher initial temperature than the diagenetic fluid and experienced a cooling process during upward migration. Ni-Se-Cd ternary graph demonstrates that chalcopyrite of all types generally has a magmatic source, suggesting unknown deeper igneous rocks enriched in Cu. Ag and Bi are obviously enriched in bornite, which also indicates the alteration of chalcopyrite by the post-diagenetic fluid.

In the diagenetic stage, Co was preliminarily enriched and formed disseminated sulfide. In the post-diagenetic stage, elements in red bed and diagenetic sulfides were redistributed due to metamorphic fluid activities. The mobilization of fluid in the post-diagenetic stage was probably derived by tectonic activities and constrained by fault zones and porosity of the strata. More abundant space for fluid migration and stronger temperature changes may contribute to the higher grade of cobaltite in the post-diagenetic stage. Although Co and Cu have different sources, they were both extracted into the ore-forming fluid during fluid migration and precipitated in the same stratum. Differentiation of Co and Co is related to such element redistribution in the post-diagenetic ore-forming fluid. Furthermore, according to these geochemical results and considering distribution characteristics of ore bodies from some other typical large-scale sediment-hosted Co deposits, we state that secondary enrichment of Co in the post-diagenetic fluid may be the key

factor of high-grade Co mineralization.

Saline fluids drive Cu mineralization in the Precambrian metasediments in the Trans-North China Orogen

Hong-Rui Fan[1]*, Professor (fanhr@mail.igcas.ac.cn)
Zheng-Jie Qiu[2], Dr.
Kui-Feng Yang[3], Dr.
Xiao-Chun Li[4], Dr.

Abstract

Epigenetic hydrothermal Cu-(Co) deposits are widely distributed in the Zhongtiao Mountains within the Paleoproterozoic Trans-North China Orogen in the North China Craton. The Henglingguan Cu-(Co) deposit in Zhongtiao is an epigenetic hydrothermal Cu deposit hosted within the meta-sedimentary rocks, consisting of the early disseminated mineralization and the late quartz vein mineralization. The parent ore fluids were likely subjected to the fluid immiscibility based as inferred from fluid inclusion petrography observations, microthermometry results, and fluid phase analysis of the H2O–NaCl-CO2 system. Pressure and temperature conditions of the fluid immiscibility were constrained at 320 to 340 °C and 3.5 to 4.0 kbar, respectively, according to the homogenization temperature-pressure conditions for the endmember of carbonic fluid inclusion. The combination of high salinity and high CO2 contents makes the ore fluids in the Henglingguan Cu deposits distinct from almost of the other major hydrothermal deposits. The parent ore fluids before fluid immiscibility had high salinity (XNaCl = 0.1 to 0.2) and significant CO2 contents (XCO2 = 0.1 to 0.15) based on the fluid phase analysis. In-situ composition analysis of individual fluid inclusions by LA-ICP-MS show that the ore fluids are rich in Na, Ca, Fe and Mn, and evolved towards Sr-Ba enrichment in the Ba-Rb-Sr ternary plot. This indicates that the ore fluids are metamorphic brine derived from the evaporitic sedimentary rocks. The negative sulfur isotope data (-10 to -11 ‰) further suggests a sedimentary rock source of sulfur for the hydrothermal Cu mineralization. The high salinity and high CO2 fluids are likely derived from the evaporative carbonate rocks developed on the basin margins or passive continental margins. This metamorphic brine served as effective medium in the transportation of Cu along its flow paths. The fluid cooling and decompression during the retrograde stage/post-collision exhumation were the key triggers for fluid immiscibility. The fluid unmixing is likely responsible for Cu mineralization in the quartz veins. Combining with the metamorphic P-T-t-m evolution path of the Henglingguan deposit proposed and a comprehensive understanding of the ore fluids evolution in this area, a saline metamorphic hydrothermal ore formation is proposed to explain the epigenetic hydrothermal Cu deposits hosted in the metasedimentary rocks. The source-transportation-precipitation of metallic elements was likely linked to the formation and closure of the Zhongtiao rift during ~2.2 to 1.85 Ga.

Orogenic gold mineralization in the Huangling region and its intimate tectonic linkage to the Neoproterozoic orogeny of South China

Huimin WANG[1]*, China University of Geosciences(Wuhan) (1516561213@qq.com)
Qinlin Xia[2], China University of Geoscience(Wuhan)
Zhou Zhou[3], Seventh Geological Brigade, Hubei Geological Bureau

Abstract

Gold mineralization types were rarely exposed in the Neoproterozoic accretionary-to-collisional orogen, particularly in China, throughout Earth's history. The Huangling region in South China contains more than 70 gold deposits/occurrences hosted in Archean-Paleoproterozoic metamorphic rocks and Neoproterozoic granitic complexes. However, the absolute age of hydrothermal mineralization, genesis, and their relationship with regional-scale processes, such as tectonism, magmatism, and metamorphism, remains unclear. Therefore, in this study, we investigated three gold deposits (Shuiyuesi, Hongwucun, and Guaizigou) hosted in different lithological units from the northern, central, and southern regions of Huangling, respectively. We conducted detailed fieldwork and analyzed the hydrothermal apatite and monazite geochronology and Sr-Nd isotopic composition of these deposits. The gold mineralization is mainly hosted within sulfide-quartz veinlets, and it is structurally controlled by second-order NW- or NNW-striking faults of the first-order NW trending main fault zone. Gold is present in various forms, such as native gold, electrum, and petzite or in fine-grained pyrite as invisible gold co-precipitated with alteration mineral assemblages that include sericite, quartz, and hydrothermal apatite, and monazite. LA-ICP-MS U-Pb dating of the hydrothermal monazite and apatite for the Shuiyuesi deposit yielded two ages: 831±2 Ma and 830±23 Ma. These ages are consistent with the weighted mean 206Pb/238U age of 834±3 Ma for apatite, obtained from the southern Guaizigou deposit within margin of error. Monazite and apatite dating of the Hongwucun gold deposit yielded younger ages of 810±3 Ma and 800±10 Ma, respectively. The new dates suggest that the gold deposits in the Huangling region underwent two distinct metallogenic episodes of gold mineralization during the Neoproterozoic, coeval with the temporal post-collisional mafic dykes, which postdated the regional metamorphism by ~100 m.y, as indicated in the Huangling region after the peak period of collisional orogeny and in response to an extensional setting, possibly due to asthenosphere wedging. The Sr-Nd isotope of apatite and monazite ($^{87}Sr/^{86}Sr$: 0.69555–0.76244, $\varepsilon Nd(t)$: −22.1– −2.9) and collective geochemical data indicate that ore-forming fluids are mainly consistent with magmatic sources with significant contribution from mantle materials. The results of the study suggest that the Huangling gold mineralization province is genetically related to Neoproterozoic post-collisional magmatism. Additionally, the region shares many characteristics of large orogenic gold provinces around the world, including alteration types, element associations, occurrence states of gold, and the evolution of orogenic belts, offering valuable new insights into the gold metallogeny of the early Neoproterozoic period, which is generally not known for its abundance of Au deposits.

Protracted gold mineralization in the southern part of the Mozambique Belt: Evidence from the Nanlia and Makorongo prospects, northeastern Mozambique

Manuel Augusto Manuel NOPEIA[1]*, Center for Regional Revitalization in Research and Education, Akita University, Japan (manuelnopeia@yahoo.com)
Akira Imai[2], Department of Earth Resources Engineering, Kyushu University, Japan

Daud Jamal[6], Department of Geology, Eduardo Mondlane University, Mozambique

Abstract

The Mozambique Belt (MB) strikes nearly N-S and extends southward from the Arabian-Nubian Shield to Mozambique. It resulted from a continent-continent collision between eastern Africa (Kenya-Tanzania) and a collage of continental blocks including Madagascar, Sri Lanka, Seychelles, India and East Antarctica during the Neoproterozoic Pan-African orogeny characterized by both metamorphism and magmatism which continued until ca. 500 Ma. The southern part of the MB underlies a vast area of Mozambique and Tanzania and hosts several types of mineralization, particularly orogenic gold deposits. The metallogeny of orogenic gold deposits in the region is still debated, which precludes sustainable gold exploration. The Nanlia and Makorongo gold prospects are hosted by the Xixano Complex and are about 15 km apart. The gold mineralization in the Nanlia and Makorongo prospects occurred as approximately E-W trending gold-bearing quartz veins hosted parallel to the foliation of orthogneiss. New Re-Os age data of sulfides associated with gold mineralization in these prospects suggest a prolonged gold mineralization time in the region, spanning from ca. 580 to 560 Ma. This mineralization age interval postdated the timing of peak metamorphism of the host-rocks established at ca. 631–607 Ma and was contemporaneous with the metamorphism of basement rocks between ca. 607 and ca. 564 Ma as well as the timing of magmatism in the area constrained at 573±17 Ma. The timing of the Nanlia and Makorongo prospects is similar to that of the Amani Gold Field associated with N-S quartz-carbonate veins hosted in the Ubendian Belt, along the southwestern margin of the Tanzania Craton in Tanzania, which was dated at 600–550 Ma. The gold mineralization in the Xixano Complex and the Amani Gold Field is interpreted to be related with the Pan-African orogeny. These gold occurrences were formed by H2O-CO2±CH4 fluids with low to moderate salinity, which have been interpreted to be derived by metamorphism of basement rocks. Although a metamorphic-devolatilization model for gold mineralization has been proposed for the individual gold occurrences, the protracted gold mineralization in the MB and Ubenduan Belt during the Pan-African orogeny is unlikely to be explained solely by crustal metamorphism. Therefore, a combination of crustal metamorphic and magmatic model should not be ruled out for the Pan-African orogeny-related gold mineralization.

Syn-metamorphic remobilization of stratabound Zn and Pb: a case study on the Jiashengpan deposit in northern China

Chang YU[1]*, University of science and technology Beijing (yuchangustb@126.com)
Richen Zhong[2], University of science and technology Beijing
Yuling Xie[3], University of science and technology Beijing
Wenbo Li[4], Peking University

Abstract

The Langshan-Zhaertai region in western Inner Mongolia is located along the Northern margin of the North China Craton (NCC). This area is a significant Cu-Zn-Pb polymetallic ore belt hosting several Zn-Pb-(Cu) deposits. The Jiashengpan deposit, developed in Mesoproterozoic rift sedimentary rocks, is the most important Zn-Pb polymetallic deposit in this area. The ore-forming genesis of Jiashengpan is under debate. It has traditionally been regarded as a syngenetic strata-bound or sedimentary exhalative deposit. However, some researchers noted that deformation, such as thrust faulting, of ore-hosting rift sequences had significant control on the formation of Zn-Pb orebodies.

To clarify the ore-forming process of Jiashengpan deposit, the systematic research of petrology, mineralogy, fluid inclusion, thermodynamic simulation and geochronology on Jiashengpan deposit have been carried out. The petrographic and mineralogical studies show that the early-stage sulfides are characterized by the widely developed massive pyrite with fine-grained textures or framboid structure, indicating a sedimentary genesis. Besides, syngenetic Zn-Pb-sulfides were observed as disseminated fine grains in dolomite, and in general of no economic interest. All the economically important Zn-Pb ores were formed during the late-stage remobilized mineralization, with hydrothermal pyrite and pyrrhotite and gangue minerals such as quartz, calcite and dolomite. The mineralization in remobilized stage shows characteristics of shear zone-controlled mineralization, such as mineral precipitation following mylonitic foliations of the host rocks.

The fluid inclusion studies reveal that the Zn-Pb remobilized fluid is mesothermal, low salinity and carbon-rich, which are consistent with the characteristics of metamorphic fluid. In addition, the remobilized fluid evolute from high-temperature oxidized fluid primarily composed of CO2 to low-temperature CH4-rich reduced fluid. Thermodynamic simulation results of remobilized fluid flowing through host rocks show that the syngenesis disseminated Zn and Pb in rocks can be dissolved and migrated by remobilized fluids, and Zn-Pb sulfides are efficiently precipitated from Zn-Pb bearing fluids during flowing into the carbonaceous strata, which is the roof rocks of the Zn-Pb ore bodies.

The 39Ar/40Ar dating study of syn-ore hydrothermal muscovite prove that the Zn–Pb mineralization took place in the Devonian (~380 Ma). This result agrees with zircon U–Pb ages of post-ore granite, which constrain the ore formation to be older than 277 ± 2 Ma. Ore formation was coeval with the emplacement of regional orogenic belts that formed as result of subduction associated with the closure of the eastern Paleo-Asian Ocean (~400 Ma).

Therefore, two-stage genesis of Jiashengpan deposit has been established: (i) syngenetic processes (during sedimentation or diagenesis of the host rocks) lead to pre-enrichment of Zn and Pb, forming Zn-Pb-bearing but sub-economic rift sedimentary rocks, and (ii) syngenetic sulfides were subsequently remobilized by metamorphic fluids, migrated, and concentrated along shear zones, resulting in high-grade Zn-Pb mineralization.

[Invited] A predictive exploration framework for primary and metamorphosed IOCG and affiliated critical and precious metal deposits in Metasomatic iron and alkali-calcic mineral systems

Jean-Francois MONTREUIL[1]*, Red Pine/MacDonald Mines Exploration
(montreuil.jean.francois@gmail.com)
Louise Corriveau[2], Natural Resources Canada, Geological Survey of Canada
Olivier Blein[3], Bureau de Recherches Géologiques et Minières

Abstract

Iron oxide-copper-gold (IOCG) deposits are one of a growing list of base (Fe), critical (Bi, Co, Cu, Mo, Ni, PGE, REE, W, U, Zn) and precious metal (Ag, Au) deposits that can form in Metasomatic iron alkali-calcic (MIAC) mineral systems. In each MIAC system, pervasive and intense infiltration metasomatism significantly changes the composition of host rocks through regional-scale fluid-rock reactions between a voluminous hypersaline fluid plume and the upper crust as its fluids evolve from high temperatures (HT; reaching ~900°C) to low temperatures (LT; cooling to ~150°C) conditions. In the process, zones of alkali-rich alteration (Na, K) form regionally while zones of Fe-rich alteration in which Fe is coupled with alkali (Na, K) and/or calcic (Ca, Mg, Ba) metals, and zones of alkali-calcic alteration with quartz or carbonates without important Fe addition form more locally. Iron-rich alteration occurs as oxides, silicates, sulfides and/or carbonates.

A sequence of mineralogical changes occurs in MIAC systems as metasomatism proceeds and can be described using a suite of alteration facies, each associated with distinct metal associations. LT to HT Na-(Ca) alteration routinely forms albitite, is associated with Fe-poor skarn alteration in carbonate rocks and represents the ground preparation and heating stage of a MIAC system. Albitite occurs preferentially along local to regional structural discontinuities and are frequently brecciated by superimposed deformation and alteration. As metasomatism proceeds, skarn alteration becomes increasingly Fe-rich and marks the onset of Fe-rich alteration and W mineralization. In silicate-rich rocks, HT Na-Ca-Fe alteration marks the onset of Fe-rich alteration. HT Ca-Fe alteration represents the thermal peak of MIAC systems and is associated with the formation of Fe skarn, iron oxide-apatite (IOA), and Fe-rich Ni deposits. Rare earths elements (REE) can be concentrated in the apatite of certain IOA deposits and constitute a by-product of IOA mining, alternatively REE are remobilized as ores and form primary REE resources in IOA deposits. HT Ca-K-Fe alteration is associated with the formation of Fe-rich Co deposits that can also contain significant Au, Bi and Cu. The formation of Cu-rich deposits like IOCG or iron sulfide-copper-gold (ISCG) deposits begins at the HT K-Fe alteration facies (magnetite) as the system has sufficiently cooled to decrease the solubility of Cu-chloride complexes and continues at the LT (K,Ba,Ca,Na)-(CO2,F,H+)-Fe alteration facies (hematite). These facies can also form primary U deposits typically hosted in albitite. The transition from aluminosilicate-rich LT (K,Ba,Ca,Na)-(CO2,F,H+)-Fe alteration to silica-rich LT (Ca,Mg)-

(K,Na)-Si-Fe alteration can generate primary Au or Ag deposits whereas Fe-poor alteration facies can form primary Au, Cu, U and Mo deposits.
Post-MIAC fluid circulation induced by orogeneses or renewed magmatism can remobilize any of the metals present in preexisting alteration zones and form zones of high-grade mineralization. Once formed, MIAC systems can become metamorphosed to amphibolite to granulite facies during orogenesis. In the process, each alteration facies develops new —metamorphic— assemblages but metamorphism leaves their atypical chemistry unchanged. This enables the use of geochemical indexes to identify metamorphosed alteration facies in support of field interpretation and facilitates mineral exploration of high-grade metamorphic terranes.

The polyphase development of gold mineralization in the Kibali gold district: Insights derived from the analysis of pyrite.

Yann Waku Mpaka[1]*, Stellenbosch University (yannwaku1@gmail.com)

Etienne Mwandale[7], Barrick Gold Corporation, Toronto, ON, Canada

Abstract

The Kibali gold district, situated on the Congo Craton, holds a substantial Neoarchean gold resource exceeding 28.7 Moz. Positioned within a fold-and-thrust belt shaped by compressional tectonics around 2.64 - 2.60 Ga, the gold deposits are primarily found in metamorphosed BIF and clastic sedimentary rocks within a major fault-thrust zone spanning 60 kilometers. The study encompasses eight gold deposits: KCD, Agbarabo, Rhino, Kombokolo, Gorumbwa, Pakaka, Tete Bakangwe, and Kalimva. Employing detailed pyrite textural analyses, in situ trace element analyses using Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICP-MS), and S isotopic composition analyses using Secondary Ion Mass Spectrometry (SIMS), the investigation unravels the gold metallogeny in the district. Eight distinct pyrite types (py-0a, py-0b, py-1, py-2, py-3, py-4a, py-4b, and py-5) are identified, each associated with distinct mineral-forming processes across a polyphase evolution. The syn-diagenetic py-0a serves as the primary gold repository (15.6 ppm median with a near-zero δ34S value) in older basin sediments deposited before 2.64 Ga. Py-0b corresponds to late diagenetic or early metamorphic pyrite in younger basin sediments, while solid-state metamorphic recrystallization leads to py-1. The early ore stage involves metal precipitation through sulfidation and carbonation (py-2) with high Au concentrations (3.1 ppm) and various trace element enrichments (As, Bi, Cr, Cu, Gd, La, Mn, Pb, Sb, W, and Zn). The second ore stage features deposition of py-4a (Au barren) and py-4b (avg. 5.5 ppm Au) formed by an over-pressured fluid. In the latter auriferous pyrite class, Au is concentrated in oscillatory zoned As-rich bands and is associated with high δ34S value (6.4 ‰ mean). Py-5, formed after the main ore stage, is generally Au-barren. Subsequent deformation events result in the remobilization and concentration of invisible gold to gold grains, contributing to the understanding of the origin and evolution of gold mineralization in the Kibali gold district.

Sulfur and iron isotope constraints on the source of ore-forming materials of the Xiajiadian sediment-hosted gold deposit, China

Xu-Yang LIU[1]*, China University of Geosciences (liuxuyang124@163.com)
Ya-Fei WU[2], China University of Geosciences

Abstract

Sediment-hosted gold deposits such as orogenic and Carlin-type gold deposits are one of the most important gold resources in the world. Although numerous investigations have been conducted to reveal the genesis of these deposits, the origin of metals and ore fluids remains debated. Here we present in-situ sulfur and iron isotopes analyzed by laser ablation–(multiple collector)–inductively coupled plasma–mass spectrometry [LA–(MC)–ICP–MS] for sulfides from the Xiajiadian sediment-hosted gold deposit (>50 t Au) in the South Qinling Orogen, China. The δ34S values of chalcopyrite in the adjacent Mesozoic dioritic porphyrite (−1.5‰ to 0.7‰, mean = 0.1‰) and underlying Proterozoic metavolcanic rocks (1.5‰ to 2.3‰, mean = 1.7‰) are lower than, but fall in the range of, those previously reported of pyrite in gold ores (−9.4‰ to 7.2‰, mean = 3.3‰). The variable δ34S values of pyrite in gold ores are comparable to those of pyrite from the host rocks of Cambrian black shales (−8.8‰ to 10.6‰, mean = 0.7‰). The δ56Fe values of pyrite in mineralized and hydrothermally altered host rocks (0.29‰ to 0.86‰, mean = 0.61‰) are similar to those of pyrite in the host black shales (0.10‰ to 0.72‰, mean = 0.49‰). However, the δ56Fe values of chalcopyrite in the metavolcanic rocks (−1.42‰ to −0.78‰, mean = −0.94‰) and pyrite in the dioritic porphyrite (−1.07‰ to 1.23‰, mean = 0.13‰) are lower than those of pyrite in the mineralized and unaltered host rocks. Additionally, rock geochemistry analysis shows that the contents of Au, As, Ni, Pb, Sb, Se, Tl, U, and Zn are positively correlated with that of carbonaceous matter in the host black shales. The Au content, however, shows a negative correlation with that of carbonaceous matter in altered rocks.

The comparable sulfur and iron isotopic compositions of pyrite in the ores and unaltered host black shales indicate the Cambrian black shales could have provided sulfur and iron for gold transport, sulfidation, and gold deposition. However, the contribution of magmatic sulfur from dioritic porphyrite and underlying Proterozoic metavolcanic rocks cannot be excluded. The iron isotopes show that the metavolcanic rocks are not likely to provide iron for gold mineralization. The high contents of gold and a series of trace elements in the host black shales and the positive correlation between these metals and carbonaceous matter indicate that gold can be partly derived from the host rocks. The negative correlation between the contents of gold and carbonaceous matter in hydrothermally altered rocks might indicate that fluid-rock interactions during gold mineralization could have remobilized the carbonaceous matter-related gold originally hosted in the black shales.

[Keynote] Metamorphic fluids and varieties of orogenic-type gold mineralisation

Andrew TOMKINS[1]*, Monash University (andy.tomkins@monash.edu)

Abstract

Regional metamorphism during orogenesis produced fluids that transported gold from source regions to the sites of orogenic gold deposit formation in the upper crust in numerous metamorphic belts around the world. Archean cratons have greenstone belts containing hydrated mafic-ultramafic rocks, felsic volcaniclastics and clastic metasedimentary rocks, whereas Phanerozoic metamorphic belts are dominated by turbidite sequences. Metamorphic dehydration of chlorite, and in some cases muscovite, produces large volumes of the low salinity, moderately reduced, H2S- and CO2-bearing fluid needed to form the gold deposits. Typical orogenic gold deposits contain minimal base metal enrichment, likely because gold can be transported in low salinity fluids as hydrosulfide complexes, whereas base metals tend to be transported as chloride complexes. Most Archean and Phanerozoic orogenic belts with greenschist to amphibolite facies metamorphic rocks contain orogenic gold deposits. However, there are some metamorphic belts that contain large numbers of mineral deposits, including gold-bearing deposits, but little or no typical orogenic gold mineralisation. Instead, there are numerous Cu-Au occurrences (some are iron-oxide Cu-Au mineralization style, others are iron-sulfide Cu-Au; IOCG and ISCG). Fluid inclusion studies have demonstrated that these Cu-Au deposits formed from highly saline fluids. A defining feature of these distinctly different metamorphic belts is that they contain thick sequences of scapolitic calc-silicate metasedimentary rocks, which evolved from modestly evaporitic muddy carbonate sediments. We have found that the presence of widespread Cl- and variably SO4-rich scapolite creates a system where metamorphic fluids are continuously buffered to oxidised and highly saline conditions. High salinity increases the solubility of base metals and gold, as well as other metal-complexing ligands such as sulfur, fluorine and phosphorus, and thus dramatically expands the range of metals that can be carried in the fluid. In this way, metamorphic belts with large volumes of evaporitic material are ideal for generating a broad spectrum of syn-orogenic hydrothermal ore deposit types - including IOCG, ISCG, Mo-Re and U-REE, but lacking Au-only. Unlike regions hosting traditional orogenic gold deposits, belts containing evaporitic sequences retain Cl-rich minerals to high metamorphic grades, allowing them to remain active as ore forming systems for prolonged periods. Supercontinent breakup, notably in the Mesoproterozoic, may have resulted in the formation of large, intracontinental basins well suited to the development of widespread evaporitic sequences. This, in combination with overprinting orogenesis and high temperature magmatism, may have provided the ingredients for widespread ore deposit formation at a global scale.

Base metal mineralisation at Agnigundala Sulphide Belt and deformation stages in Nallamalai Fold Belt, Cuddapah Basin, India

MOHD QAIM QAIM RAZA[1]*, Department of Earth Sciences, Indian Institute of Technology Bombay, Mumbai 400076 India (talk2qaimalig@gmail.com)
Anshul Sahu[2], Department of Earth Sciences, Indian Institute of Technology Bombay, Mumbai 400076 India
Md Inzmamul Haque[3], Department of Earth Sciences, Indian Institute of Technology Bombay, Mumbai 400076 India
Sakthi Saravanan Chinnasamy[4], Department of Earth Sciences, Indian Institute of Technology Bombay, Mumbai 400076 India

Abstract

In comparison to McArthur-Mt. Isa basin system of northern Australia, the Proterozoic Cuddapah basin of India also host several base metal mineralisations, however the grades of ore bodies are comparatively very low. The mineralisation (Cu-Pb±Zn) is dominantly hosted in strongly deformed and low-grade metamorphosed sediments of Nallamalai Fold Belt (NFB), Cuddapah Basin. The intensity of deformation and metamorphism decreases from the east towards west of the NFB. The stages of deformation (D1-D2) in NFB is linked with stages of deformation in Nellore Schist Belt occurring on the East and post to syn-kinematic granitic intrusion in the vicinity. The base metal mineralisations of the basin mainly exist in two sulphide belts known as Agnigundala at the northeastern part and Varikunta-Zangamrajupalle at the central part of NFB that represents basin level metallogeny. Therefore, studying the genesis of mineralisation will reveal the basin evolution in relation to regional tectonics.

In the present study, the detailed field work, extensive petrography of rock and mineralised samples, and fluid inclusion (FI) studies on mineralised vein samples are performed. The samples are collected from three base metal deposits of Agnigundala Sulphide Belt (Nallakonda, Dhukonda and Bandalamottu). The host rocks belong to Cumbum Formation of Nallamalai Group, Cuddapah Basin. The formation is comprised of dominantly shale (slate/phyllite) interbedded with dolomite and sandstone (quartzite). The base metal mineralisation is dominantly hosted in the interbedded rocks (copper dominantly in quartzite and lead dominantly in recrystallised dolomite). Mineralisation is stratabound dominated by copper at Nallakonda, both stratabound and vein-type copper-lead at Dhukonda while vein-type and interbreccia space filling dominated by lead at Bandalamottu. The mineralogy of the ore minerals is comprised of chalcopyrite, galena with minor amount of sphalerite. Gangue minerals are quartz and dolomite while pyrite is observed from pre- and syn-ore generations.

Development of pyrite porphyroblast, formation of pressure shadows around the pyrite and crenulation cleavages indicate multiple stages of deformation which is also inferred by earlier workers for the NFB. The post-mineralisation deformation of ore and gangue minerals are also evident from polycrystalline nature and sutured boundaries of quartz and folding of chalcopyrite-quartz vein along crenulation cleavage.

The FI in mineralised quartz-carbonate or quartz veins are primary and secondary, biphase liquid+vapour (L+V) and varying in shape (regular to irregular), size (<5−>40μm) and degree of fill (0.8−0.6). The FI microthermometry results from all three deposits showed a total solidification between −33°C to −49°C on freezing by bubble bursting. It indicates that FI are aqueous in nature. But on heating, inclusions either showed metastable condition by final ice melting at around +5°C or decrepitated while homogenisation. This also supports post mineralisation deformation-metamorphism. For some inclusions a broad range of homogenisation (L+V=L) temperature (125−235°C) was observed. To constrain the stages of deformation and basin evolution in relation to regional tectonics further geochemical and isotopic studies are required. Considering the ages of the mineralisation (~1600Ma), the granitic intrusions (~1590Ma) and Krishna orogeny (~1.68−1.6Ga), the study of the ore genesis at NFB may be a reliable window for understanding the Columbia supercontinent cycle.

The origin of the pyrite-pyrrhotite veins at Rampura Agucha, India.

Don CHATTERJEE[1]*, Indian Institute of Technology, Kharagpur (donchatterjee634@gmail.com)
Kamal Lochan Pruseth[2], Indian Institute of Technology, Kharagpur

Abstract

The world's largest open pit Zinc (Zn) mine and world-class base metal deposit-Rampura Agucha is exposed in Mesoproterozoic metasedimentary rocks of Bhilwara supracrustal belts of Aravalli-Delhi orogen at Rajasthan, India. The peak metamorphic conditions of 780°C and 6.2 kbar i.e., at granulite facies of metamorphism at the Rampura Agucha Zn-Pb deposit, has resulted in sulfide anatexis (Mishra and Bernhardt, 2009). The remobilized sulfide partial melt is expected to be lead(Pb) and copper(Cu) enriched containing considerable concentrations of low-melting chalcophile elements (Frost et al., 2002; Pruseth et al., 2014). Interestingly, in the Rampura Agucha deposit veins of exclusively pyrite and pyrrhotite, with minor sphalerite are encountered, in which subhedral to euhedral pitted pyrite grains occur with pyrrhotite permeating the vein. While sulfide melts are unlikely to be preserved, these veins can be ascribed directly to melting of pyrite and be considered an indicator to sulfide partial melting. In the Fe-S system (Ehlers, 1972), pyrite incongruently melts at 742±1oC to pyrrhotite + sulfur(S)-rich melt. This melt is easily remobilized into veins and on cooling, probably pyrrhotite is the first to crystallize, leaving the residual melt further enriched in sulfur(S). On further cooling pyrite crystals with numerous sulfur(S)-vapor inclusions may have formed, which now persist as pitted pyrite crystals.

Evolution of the metamorphic fluid in the ca. 1.89 Ga augen orthogneiss from the East European Craton

Laurynas ŠILIAUSKAS[1]*, Nature Research Centre (laurynas.siliauskas@gamtc.lt)
Gražina Skridlaite[2], Nature Research Centre

Abstract

Augen orthogneiss (ca. 1.89 Ga) is underlying ore bodies of the Varėna Iron Ore Deposit (VIOD) in the East European Craton (EEC). The applied phase modelling results indicate that assemblages of Cpx+Amf+Pl+Kf+Ilm+Qtz+melt±Bt (sample D8/845) and Amf+Pl+Kf+Mag+Ilm+Qtz+melt (sample D9/1124) are stable at a peak temperature of ~750° C, the pressure of 2-4 kbars and oxidizing conditions (logfO2 -13.5 to -13 and -13 to -12, respectively) which were achieved at 1.75-1.79 Ga (dark CL zircon rim ages). Similar T and P values were obtained from the Ti and Altotal in amphibole thermometry and barometry. Cl-enriched mineral assemblages have developed during the retrogression. Cl-rich scapolite forms a meshwork in the felsic domains. The most Cl-rich scapolite (Cl 0.74-0.96 apfu, EqAn 0.28-.037) grew in the presence of a Cl-rich fluid or melt and was in disequilibrium with calcite, whereas the late-stage scapolite (Cl 0.5-0.53 apfu, EqAn 0.50-0.54) was in equilibrium with calcite (XfluidNaCl 0.52-0.59; Ellis, 1978) at the very low water activity of 0.15-0.19 (Aranovich and Newton, 1996). The positive slope of the neighbouring Cl-rich scapolite-plagioclase tie-lines indicates their equilibrium with fluid, whereas negative slopes of the late-stage scapolite-plagioclase tie-lines show plagioclase and fluid disequilibrium (Kullerud and Erambert, 1999). The sporadic, Fe-rich, potassic-chloro-hastingsite (Cl 0.50-1.20 apfu, Mg# 0.00-0.32) is situated at the grain boundaries and defects of the peak-T amphibole.

As water is retained in the partial melt, and Cl partitions into coexisting aqueous fluid (Webster, 1997), small pockets of Cl-brine could develop after the peak and stabilise the Cl-rich scapolite. The amount of CO2 in the fluid was negligible at the peak temperature and gradually increased during the cooling when H2O and Cl were incorporated into retrograde titanite, biotite and amphibole, while the CO2 content was retained in the fluid until the formation of late-stage scapolite. The plagioclase-fluid disequilibrium indicates the dropping temperature at this stage. The cooling of the system and increase in CO2 would cause the evolved fluid composition to plot in an immiscible fluid field in the ternary H2O-CO2-NaCl system, resulting in low-Cl, low-density H2O-CO2 fluid and Cl brine (Heinrich, 2007), responsible for the formation of potassic-chloro-hastingsite.

This model suggests that only a small amount of fluid was present during the peak conditions, and all the free water was partitioned into the melt. Although the origin of Cl in the fluid is unclear (external fluid or fluid produced during the partial melting), the low-pressure and relatively high-temperature metamorphism of the augen gneiss may provide a mechanism for the development of a Cl-brine, that might be responsible for mobilizing Fe from the country rocks and forming of the rich magnetite ores overlying the studied augen gneisses (Skridlaite et al., 2019).

Haidong She[5], Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

The enrichment and mineralization of Rare Earth Elements (REE) and niobium (Nb) are hot issues in the economic geology field. The carbonatite related deposits have been the world's major sources of REE and Nb. It seems that carbonatites experienced multiple stages of hydrothermal activity tend to be more likely to form rich REE and Nb deposits. The most well known example is the largest REE deposit in the world, the Bayan Obo REE-Nb-Fe deposit in China. Isotopic dating indicate that the primary mineralization occurred at ~1300 Ma. After that, the deposit experienced two episodes of overprint at 450-400Ma and 280-260 Ma, respectively. The primary mineralization is characterized by accumulation of light REE, accompanied with enrichment of Nb. During the overprinting events, fluorine- and sulfate-rich fluids pervasively flow through the deposit. The post-ore overprinting events did not improve the ore tenor. However, it resulted in internal mobilization of elements within the deposit. For example, heavy REE is more mobile than light REE, leading to local enrichment of heavy REE. In addition, the post-ore hydrothermal overprint led to mobilization of Nb, during which small Nb minerals were transferred into larger minerals. In general, the element mobilization processes help to create beneficial resources and improve the exploitable level of the deposit.

In situ major, rare earth elements and U-Pb ages of apaite from orogenic Dongkeng gold deposit, Yunkai Massif, South China: implications for mineralization

Guozheng ZHANG[1]*, School of Earth Sciences and Engineering, Sun Yat-sen University (zhanggzh9@mail2.sysu.edu.cn)
Yi Zheng[2], School of Earth Sciences and Engineering, Sun Yat-sen University
Xi Chen[3], School of Earth Sciences and Engineering, Sun Yat-sen University
Mengxuan Chen[4], School of Earth Sciences and Engineering, Sun Yat-sen University

Abstract

The Dongkeng gold deposit is situated in the central part of the Yunkai Massif, west of the Wuchuan-Sihui falut, with a controlled reserve of 12t and prospective reserve of 20t, averaging approximately 5.68g/t. The orebodies are positioned along the NW-trending brittle-ductile shear fault, considered a secondary fault of the NE-trending Wuchuan-Sihui fault. The Yunkai Group of Proterozoic shallow-deep metamorphic rock series is exposed in the deposit, divided into three layers from top to bottom: eyeball-shaped migmatite, mica quartz schist, and banded migmatite. The mineralized zone occurs within the mica quartz schist zone, with a gold abundance value of 35.86×10-9. Amphibolite, diopside veins and small pegmatite veins are recognized within or near the deposit. High greenschist- to amphibolite- facies metamorphism with sillimanite- and cordierite-bearing mineral assemblages dominates in the shear zone. Metal minerals include natural gold, pyrite, auriferous bismuth, bismuth antimony, chalcopyrite, pyrrhotite, ilmenite, sphalerite and galena. The gangue minerals are primarily quartz, biotite, muscovite, apatite, zircon and chlorite.

Two phases of apatite were identified in the host rocks and ores. The early apatite (Ap1) was found in muscovite quartz schist, while the late apatite (Ap2) is associated with biotite, coexisting with ilmenite and Au. We conducted a study on the major, rare earth element (REE), and U-Pb age of these two phases of apatite. Two phases of apatite have high F/Cl ratios and exhibit an M-shaped REE chondrite normalized pattern. Ap1 contains approximately 8593.41~24198.49 ppm REE with an average of 13056.84 ppm, and marked negative Eu anomalies with δEu being 0.39~0.61 (averagely 0.47), REE is relatively concentrated; Ap2 contains about 2719.20~11182.49 ppm REE with an average of 6949.27 ppm, and marked negative Eu anomalies withδEu being 0.35~0.85 (averagely 0.65), REE is relatively dispersed. The Ap1 yielded Discordia U-Pb ages of 235.80±4.5Ma (MSWD=1.3, n=106); the Ap2 and ilmenite associated with Ap2 yielded Discordia U-Pb ages of 209.40±2.6Ma (MSWD=1.2, n=68) and 219±32Ma (MSWD =1.2, n=48), respectively. Collectively, the age data suggest that the Dongkeng gold deposit may have formed from two mineralization events during the Triassic, with second event being the dominant one.

Study on the Geochronology and Geochemistry of concealed granite in Tongmukeng Tin deposit in Yunshan, Jiangxi province

MENGQI JIN[1]*, University of Science and Technology of China (jmq9097@163.com)

Abstract

1. Introduction

The Tongmukeng deposit is located 30 km away in the northwest direction of Yongxiu county, near a small rock protrusion at the north-northeastern edge of the Yunshan granite. Based on detailed field geological investigations, combined with previous research results, this article explores the genesis and material source of the concealed granite of the Tongmukeng tin deposit through comprehensive research on the geochemical characteristics of the granite, zircon U-Pb dating, cassiterite U-Pb dating, and zircon Lu-Hf isotopes.

2. U-Pb Geochronology

Zircon U-Pb geochronology test results show that the weighted average age of zircon in the coarse-grained granite is 130.9 ± 1.3 Ma (MSWD = 0.48, 2σ, n=12), and the concordant age is 131.2 ± 1.6 Ma (MSWD = 0.47, 2σ, n = 12), which are consistent within the error range. The weighted average age of zircon in the fine-grained granite is 129.8 ± 3.1 Ma (MSWD = 2.7, 2σ, n = 9), and the concordant age is 128.6 ± 2.4 Ma (MSWD = 1.05, 2σ, n=9), which are also consistent within the error range. In both types of granite, zircon exhibits oscillatory zoning, and the Th/U ratio varies between 0.04 and 0.12, which is a typical igneous crystallization zircon. Therefore, combined with the results of other geochemical studies in the study area, it is believed that the concealed granite pluton was formed in the Late Yanshanian period, with the age of 128-131 Ma, which is consistent with the ore-forming age of the third stage of the Yanshanian metallogenic activity proposed by Hua et al. (2005) in the southern China, and it was formed in the tectonic environment of large-scale post-arc extension in the early Cretaceous.

Cassiterite U-Pb dating data show that the weighted average age of cassiterite is 131.4 ± 3.2 Ma (MSWD = 0.33, 2σ, n=12), and the concordant age is 132.7 ± 5.1 Ma (MSWD = 0.36, 2σ, n=12). It indicates that the tin mineralization age of the Tongmukeng mining area is 131-132 Ma, which is consistent with the concealed granite pluton-forming age in the area.

3. Whole rock geochemistry

The whole rock geochemistry of Tongmukeng granite shows a high SiO2 content and belongs to high-potassium calc-alkaline peraluminous granite. In the chondrite-normalized rare earth element diagram, Tongmukeng granite exhibits a right-dipping pattern, enriched in light rare earth elements and depleted in heavy rare earth elements. In this study, zircon samples that have undergone U-Pb isotope analysis were also analyzed for Lu-Hf isotopes in adjacent positions. The results show that the εHf (t) values of coarse-grained granite zircons range from -5.9 to -4.1, with an average of -4.95, and the two-stage Hf isotope model ages (TDM2) range from 1439 to 1554 Ma. The εHf(t) values of fine-grained granite zircons range from -8.0 to -4.0, with an average of -

5.03, and the TDM2 range from 1432 to 1687 Ma. It is considered that the source of the Tongmukeng granite is likely derived from the metamorphic sedimentary rocks of the Shuangqiaoshan Group.

Deposit-scale controls of disseminated-type orogenic gold mineralization in high-grade metamorphic turbidites from the Damara belt, Namibia.

Josia Tulongeni Shilunga[1]*, Stellenbosch University (josiashilunga@gmail.com)
Alexander Kisters[2], Stellenbosch University

Abstract

The recently discovered Twin Hills deposit is a new resource in the Neoproterozoic Pan-African Damara Belt of central Namibia described by a finely dispersed, low-grade and high tonnage disseminated and vein-style gold mineralization. The deposit comprises distinct clusters of economic-grade gold mineralization, measuring several hundred meters along strike, separated by several kilometer-long intervals of only sporadic and sub-economic gold grades. The underlying assumption of the 3D implicit modelling followed in this study is that the integration of gold grades and ore shells with structural and lithological data from oriented core logging reflects the underlying controls of hydrothermal fluid flow and mineralization at Twin Hills. Thus, this study aims to contextualize the controls of mineralization on a deposit-scale and discriminate factors that distinguish zones of economic-grade mineralization from intervening sub-economic domains that may guide exploration. Mineralization is developed on the subvertical southern limb of a regional-scale syncline hosted in highly-strained compositionally heterogeneous, amphibolite facies metaturbidites. Additionally, the stretch of the main mineralization in the central parts of the ~12 km long east-northeast-trending mineralized Twin Hills corridor coincides with the change of the fold vergence direction. Individual higher-grade clusters are controlled by the combination and interplay of two main factors, namely lithological contacts and subtle deflections of bedding of the highly-strained, subvertical metaturbidites. The ENE-trending mineralized corridor of the Twin Hills deposit is largely confined to imbricated and/or tightly folded packages of interbedded psammites-pelites within the otherwise pelite-dominated sequence. It is these units that promoted fracturing, fluid flow and the development of fine-scale vein networks as a result of pronounced strain partitioning between schist units (ductile) and interbedded psammites (brittle) during regional deformation (flexural-slip folding). High grade ore shoots (>1.5 g/t Au) follow these main lithological contacts, but are laterally confined to subtle (5-15°) clockwise deflections of bedding (dilational jogs) from its regional ENE trends. Outside these deflections, gold mineralization is sporadic and only sub-economic. The structural and lithological controls of the mineralization at Twin Hills closely resemble those of orogenic gold deposits, but the fine-grained and dispersed textures of gold and associated sulfide mineralization are more reminiscent of those found in disseminated gold deposits. We suggest that the Twin Hills deposit is an example of a hypozonal orogenic gold deposit formed under peak metamorphic amphibolite conditions.

Geochronological and sulfide geochemical evidence for gold mineralization related to post-collisional magmatism in the Wulonggou goldfield of the East Kunlun Orogen, northern Tibet

Qilin WANG[1]*, School of Earth Resources, China University of Geosciences
(1499361670@qq.com)
Jinyang ZHANG[2], School of Earth Resources, China University of Geosciences

Abstract

The relationships among magmatism, orogeny, and gold mineralization in lode gold deposits have been controversial for a long time. The East Kunlun Orogen in northern Tibet has experienced a complex Paleo-Tethyan tectono-magmatic evolution and hosts the largest Wulonggou lode gold deposits (>110 t). The Shuizhadonggou-Huanglonggou (SZDG-HLG) gold deposit is the largest in the Wulonggou goldfield and is an excellent candidate for solving the controversy through detailed field observations, magmatic and hydrothermal mineral in-situ U-Pb dating, and gold-bearing sulfide in-situ trace elements and sulfur-lead isotopes. Gold mineralization in the SZDG-HLG deposit includes sulfide disseminations and minor amounts of small quartz-sulfide veins in hydrothermal alteration assemblages along a ductile shear zone. Gold mineralization can be divided into four stages based on crosscutting relationships and associated alteration assemblages. U-Pb ages from magmatic zircon, hydrothermal rutile, and hydrothermal monazite support field relationships that gold mineralization was later than the ductile deformation but synchronous with the post-collisional porphyries. Gold mineralization evolved from high to low temperatures (560 ℃ to less than 300 ℃), accompanied by markedly decreased sulfur fugacities (-6.3 to -12.5) and oxygen fugacities (-20.7 to -40.5). The gradual increase of sulfur isotopes (δ34S) from stage 1 (-0.9 to 1.8‰ in Py1a) to stage 3 (up to 8‰) is ascribed to sulfide precipitation from a finite fluid reservoir, while the sharp decrease of δ34S ratios in stage 4 (down to -24‰) is caused by the fluid oxidation. The negative covariations of δ34S and Se/S ratios, positive correlations between Au and chalcophile elements (As, Sb, Te, and Bi) in most sulfides, and overlapping lead isotopes of sulfides and Late Triassic granodiorite-diorite confirm a post-collisional magmatic gold and sulfur source. This study demonstrates that lode gold deposits in Phanerozoic orogens having similar characteristics to their counterparts in Archean metamorphic terranes can be genetically related to post-collisional magmatism.

Fluid Inclusion Characterization of the Quartz Vein in Mineralized Banded Iron Formation of Hiriyur Formation, Dharwar Craton

MANJU SATI[1]*, DEPARTMENT OF EARTH SCIENCES, IIT ROORKEE (msati@es.iitr.ac.in)
RAJAGOPAL KRISHNAMURTHI[2], DEPARTMENT OF EARTH SCIENCES, IIT ROORKEE
SAKTHI SARVANAN CHINNASAMY[3], DEPARTMENT OF EARTH SCIENCES, IIT MUMBAI

Abstract

Altered metabasalt and quartz veins in BIF are the hosts for gold mineralization at Paramanahalli in the Chitradurga Greenstone Belt of Western Dharwar Craton, Peninsular India. In this work, the information on the composition, origin, and implications of the fluids responsible for mineralization in the area has been addressed with the help of fluid inclusion studies. Fluid inclusion petrography, micro thermometry, and Raman spectroscopy were performed on mineralized quartz veins in BIF. Three primary inclusions are significant: Type Ia-aqueous inclusions, Type Ib-carbonic monophase inclusions, and Type Ic-aqueous carbonic inclusions. Type- Ia and Ib are more abundant and are commonly found to coexist in veins. The micro-thermometric analyses of different inclusions indicate homogenization temperature (Th) ranges from 220˚C to 362˚C. The calculated salinity values (wt% NaCl eq.) vary from 1.07 to 18.10.This temperture has been confirmned by Chlorite thermometry (260-372˚C). The abundance of CO2 and CO2-H2O inclusions indicates the metamorphic derivation of mineralizing fluids. The fluid has low-moderate salinity, a medium-high temperature of Th, and low density similar to other orogenic lodes gold deposits reported elsewhere in the world. The Th-salinity plot of inclusions confirms this during our study. The results indicate a complex geological past, including metamorphism and syn-post hydrothermal alterations.

UNLOCKING HIDDEN RICHES: NEW METHODS FOR REPURPOSING MINING WASTE IN UZBEKISTAN

Shukhrat Rayimovich SHUKUROV[1]*, Institute of Geology and Geophysics named after Kh.M. Abdullaev (shuxrat2200@mail.ru)
Nosir SHUKUROV[2], Institute of Geology and Geophysics named after Kh.M. Abdullaev
Shohboz YOSHUZOKOV[3], Institute of Geology and Geophysics named after Kh.M. Abdullaev

Abstract

The Republic of Uzbekistan does have significant potential in the field of mining and production of non-ferrous, precious and rare elements, which are concentrated mainly in the Navoi and Almalyk mining regions. These resources extend beyond traditionally mined materials to "technogenic deposits" - waste materials from previous mining activities. This research focuses on repurposing these wastes, specifically from gold and gold-silver deposits managed by NMMC. A new methodology - "Landscape-Mineral-Geochemical System (LMGS)" was proposed. A large-scale geological and technological mapping of the watered area of dumps and off-balance ores of NMMC and AMMC were carried out according to this methodology. Were taken 272 samples, which were investigated by geochemical and mineralogical methods. The results uncover promising opportunities. The wastes contain abundant sulfide minerals (pyrite, arsenopyrite) undergoing active oxidation, generating various new minerals (goethite, hydrogetite, sulfites, etc.). Furthermore, the wastes harbor valuable chalcophilic elements (Cu, Zn, Pb, Sb, As, Bi, Se, Hg, Sn, W) in trace amounts within primary and secondary minerals like cuprite, zincite, scorodite, and lankarite. Additionally, elements like Ni, Co, Cu, Zn, and As are embedded within pyrite, arsenopyrite, and other sulfides. This research demonstrates the potential to extract valuable resources from mining waste, promoting sustainability and responsible resource management in Uzbekistan's mining sector.

Synthesis of Kudremukh Iron Ore Mine Tailings based on Geopolymer Aggregates using Fly ash as Precursor in Construction Industry

Ramaraju H K[1]*, Visveswaraya Technological University (hkramaraju@gmail.com)

Abstract

The increasing trend of solid waste generation has made its ecological disposal an important issue due to concerns about its hazardous social and environmental impact. One of the methods to minimize these issues is recycling of industry wastes. The construction industry has a great potential to absorb various industrial residues provided the recycled materials are properly characterized before its application as a construction material. Iron is the world's most commonly used metal—steel, in which iron ore is the raw material, represents almost 95% of all metals used annually. A huge resource of 25.24 billion tons of Iron ore is blessed to India. India produces colossal volumes of Iron ore mine waste of around 130 million tons every year and the same are dumped at adjacent mining destinations. In state of Karnataka, India, Kudremukh Iron Ore Company Limited (KIOCL) had operated the most sophisticated mechanized Magnetite iron ore mine to produce 22.5 million tons of Run of Mine (ROM) per annum with the state of the art beneficiation technology to produce 7.5 million tons of concentrate. Mine being low grade ore in nature and nearly 12 million tons of Iron Ore Tailing (IOT) were generated annually during the process of beneficiation and stopped its operations at the end of 2005. During the process of beneficiation, about 200 million tons of Iron ore mine tailings were deposited in Lakya dam which spreads about 2 square kilometers with a depth of 85-90 meters. The present research includes characterization of raw materials for physical, chemical and mineralogical properties. Trial and error method was used to fix fly ash to iron ore tailing ratio. Totally 4 different ratios were considered with fly ash to iron ore tailing ratios as 80:20, 70:30, 60:40 and 50:50. Binding materials such as Sodium hydroxide (NaoH) and Sodium silicate (Na2SiO3) were being considered in manufacture of coarse aggregates as an alternative to natural aggregates. Aggregate tests were conducted for the obtained Geopolymer aggregates and compared with the natural aggregates. Mechanical properties such as Compressive strength, flexural strength and split tensile strength of hardened concrete was determined. Finally, Non-Destructive testing (NDT) of hardened concrete was determined using Ultrasonic Pulse Velocity (UPV) test. Based on the experimental tests conducted on fresh and hardened concrete, the results recommend to use of mining tailing waste and Geopolymer as a raw material in the construction industry, as is the need of hour due to scarcity of raw materials.

[Keynote] Pyrophyllite as substitute raw material for future Industrial Development in India

ASIM AMITABH PRADHAN[1]*, FAKIR MOHAN UNIVERSITY (asimgeology@gmail.com)
MADHUMITA DAS[2], UTKAL UNIVERSITY, BHUBANESWAR
BISWANATH SAHOO[3], FAKIR MOHAN UNIVERSITY
ROSALIN DAS[4], FAKIR MOHAN UNIVERSITY

Abstract

Minerals are indispensable part of our life, and these natural resources are finite. Minerals are increasingly being extracted due to rapid growth of population and for our modern lifestyle. Minerals should be conserved by reducing wastage in the process of mining, recycling of metals using scrap metals, using alternative renewable substitutes and by adoption of improved technologies to use the low-grade ores at low costs. Pyrophyllite, an industrial mineral, can be used as a substitute for kaolinite mineral group in many industrial applications, such as in the ceramic, and pottery, and filler industries, because kaolinite mineral group are rapidly depleting.

Pyrophyllite ($Al_2Si_4O_{10}(OH)_2$) is characterized by various chemical, physical, and thermal properties that make it suitable for several industrial applications. It is a phyllosilicate often associated with quartz, mica, kaolinite, epidote, and rutile minerals. In its pure state, pyrophyllite exhibits unique properties such as low thermal and electrical conductivity, high refractive behaviour, low expansion coefficient, chemical inertness, and high resistance to corrosion by molten metals and gases. Pyrophyllite is a chemically inert hydrous aluminosilicate $Al_2O_3 \cdot 4SiO_2 \cdot H_2O$ [$Al_2Si_4O_{10}(OH)_2$], composed of 67% SiO_2, 28% Al_2O_3 and 5% H_2O. It is an early stage metamorphic mineral. Pyrophyllite is largely an overlooked raw material available in huge quantities in nature. This is mainly due to the fact that other comparable aluminosilicate raw materials like china clay are available in much purer form. Pyrophyllite occurrences are mainly in Chhatarpur, Tikamgarh and Shivpuri districts of Madhya Pradesh, Mahoba and Lalitpur districts of Uttar Pradesh and Keonjhar district of Odisha. The total reserve of pyrophyllite in India is 59.61 million tonnes.

The uses of pyrophyllite in industry include its application as a refractory material in the refractory industry and as a raw material in the ceramic, fiberglass, and cosmetic industries. Moreover, pyrophyllite is used as filler in the paper, plastic, paint, and pharmaceutical industries, as a soil conditioner in fertilizer applications and as a dusting agent in the rubber & asphalt industries.

To increase its market value, pyrophyllite must have high alumina (Al_2O_3) content, without impurities, and possess as much whiteness as possible. This paper deals with industrial applications of pyrophyllite and the specifications required for its use in industry as a substitute to minerals like kaolinite, talc, and feldspar. It also presents the most effective and economical techniques for enriching low-grade pyrophyllite ores to make them suitable for various industrial applications.

Keyword

pyrophyllite, specification, enrichment of low grade

Assessing the Impacts of Coal Mining on water quality in the Talcher Region, Angul District, Orissa, India

ARUN KUMAR NAIK[1]*, FAKIR MOHAN UNIVERSITY,BALASORE
(naik.arunkumar70@gmail.com)
ASIM AMITABH PRADHAN[2], FAKIR MOHAN UNIVERSITY,BALASORE
MADHUMITA DAS[3], UTKAL UNIVERSITY, BHUBANESWAR
SUSANTA KUMAR DAS[4], FAKIR MOHAN UNIVERSITY,BALASORE

Abstract

Coal is an essential energy source that plays a critical role in thermal power plant for electricity generation and supporting various industrial operations. Coal mining operations involve the release of pollutants into nearby water bodies through erosion, leaching, and runoff. These pollutants include heavy metals, such as mercury, lead, and arsenic, which can severely degrade water quality. Talcher is known for its thriving coal mining industry, has experienced remarkable growth and progress in recent years. This abstract provides a thorough examination of the effects of coal mining on water quality of the study area. The contamination of groundwater sources in Talcher not only jeopardizes drinking water supplies for local communities but also exacerbates the degradation of aquatic ecosystems and agricultural productivity. The water in the Talcher coalfield area is severely polluted, containing excessive amounts of harmful contaminants like Cd, As, Ni, Pb, and Hg that surpass the acceptable limits for drinking water. Mine effluent discharge has a significant impact on the water quality, resulting in increased pollution levels in downstream areas. 28 samples were collected from different locations of Talcher area and nine parameters viz. Cl-, F-, pH, Ca, Mg, SO4-, NO3-, Alkalinity and Hardness, have been considered to determine the water quality index (WQI). The American Public Health Association has established standards for the sampling of groundwater (APHA, 2005). The Bureau of Indian Standard (BIS, 2012) was used for assessing the potability of groundwater and establishing the Water Quality Index (WQI). The fluoride concentration in the water samples is >57% which exceeds the permissible limit. There is a prevalent issue in this region where individuals are experiencing skeletal fluorosis and dental fluorosis. The research indicates that the water requires appropriate treatment prior to its utilization for drinking, household purposes, or release into the environment. In order to achieve a harmonious and enduring water quality, it is imperative for the region to enhance its treatment facilities and embrace environmentally friendly mining practices. Additional investigation into groundwater quality and the surrounding regions is necessary to enhance water resource management.

Ultrasonic Leaching: A Green Leaching Technology of Clay-Type Lithium Resources in Salt Lakes

KAISHENG XIA[1]*, China University of Geosciences (xks_mail@126.com)
CHENGKAI LIU[2], China University of Geosciences
YI MENG[3], China University of Geosciences
ZHEN YANG[4], China University of Geosciences
CHENGLIN LIU[5], China University of Geosciences

Abstract

With the rapid development of the new energy car industry, lithium as an energy metal is increasingly important in recent years. Currently, the lithium carbonate used in industry mainly come from brine lithium and pegmatite lithium. Clay-type lithium as an new lithium resource widely distributed in unconsolidated mud sediments of modern salt lakes with level of 100*X ppm has not been developed and utilized on a large scaleTherefore, its development and utilization maybe alleviate the pressure on the supply shortage of current lithium resources. However, there are some problems in the current development and utilization for clay-type lithium resources in salt lakes, such as excessive acidity of the leaching solution and leaching residue, and environmental pollution etc. In order to overcome these problems, this study proposes a green leaching technology of clay-type lithium of some salt lakes in northwestern China. In this work, X-ray fluorescence spectroscopy, powder crystal X-ray diffraction, scanning electron microscopy and other analytical techniques were used to figure out main chemical composition, mineral composition, microscopic morphological of clay-type lithium resources. The results show that lithium mainly exist in kaolinite and montmorillonite as absorption occurrence. We have explored the optimal parameters of ultrasonic water immersion process, the experimental results showed that the leaching rate can reach to 64.34% when the leaching solvent temperature reaching 40℃, the leaching time is 2 hours, and the ratio of clay ore and pure water solid-liquid is 1:10. There is no significantly change of mineral composition after ultrasonic water immersion process. This green and economical leaching technology without roasting and acid leaching process shows great application prospects in the development and utilization for clay-type lithium resources.

The Role of Pyrophyllite in Advanced Materials: A Critical Review of Current Trends

BISWANATH SAHOO[1]*, FAKIR MOHAN UNIVERSITY (biswanathsahoo164@gmail.com)
ASIM AMITABH PRADHAN[2], FAKIR MOHAN UNIVERSITY

Abstract

Pyrophyllite, the naturally occurring aluminosilicate mineral has emerged as a noteworthy constituent in the realm of advanced materials, shaping current trends in the field of geology. This abstract provides a comprehensive overview of the role of pyrophyllite in advanced materials, encapsulating the current state of research, applications, and prospects. The lamellar structure of pyrophyllite, characterized by its aluminium-rich composition, used for various advanced materials. Its utilization spans diverse fields, from ceramics to polymers, composites, and environmental applications, and in the field of ceramics, pyrophyllite plays a pivotal role as an additive, influencing sintering behaviours, mechanicalstrength, and thermal conductivity. Pyrophyllite's incorporation into polymer composites has garnered attention for its ability to improve mechanical properties, thermal stability, and flame retardancy. The collaboration of pyrophyllite and polymers gives rise to materials endowed with improved properties, expanding their utility across diverse industries, including aerospace, automotive, and construction. The adsorption capabilities of pyrophyllite have been harnessed in future environmental remediation and water purification technologies and due to its high surface area and distinctive surface chemistry, pyrophyllite effectively adsorbs various pollutants, providing a sustainable solution for addressing environmental challenges. Integration of pyrophyllite into nanocomposites will offer opportunities for applications in electronics, energy storage devices, catalysis, and energy storage devices, such as batteries and capacitors, underscores its role in the pursuit of sustainable energy solutions. The current investigation is on the electrochemical properties of pyrophyllite-based materials to enhance energy storage capacity, cycling stability, and overall performance in next-generation energy storage systems. This work provides a panoramic view of the current trends in utilizing pyrophyllite in advanced materials. The ongoing research presented here emphasizes the dynamic role of pyrophyllite in shaping the landscape of advanced materials, providing insight into its potential impact on future technological advancements.

Exploration of geothermal resources by using geophysical method in the north of Changbaishan Mountain

Yan Wu GUAN[1]*, Jinlin University (guanyw@jlu.edu.cn)
Xu Jin[2], Jilin University

Abstract

There are rich geothermal resources near Tianchi Volcano on Changbaishan Mountain. In the traditional concept, the direct expression of geothermal resources is geothermal water. It often exists in the fracture zone. Therefore, our work adopts gravity, magnetic method, and CSAMT methods to explore the research area in Songjianghe Town, Jilin Province, China. Several apparent resistivity models have been built based on optimization inversion technology using 4 CSAMT profiles. We can focus on the low resistivity zones, which is may full of water. Main faults can been infered based on edge detection (such as vertical second derivative, Euler deconvolution, etc. which can be processed with Geosoft's Oasis Montaj) using of gravity and magnetic anomaly data. Based on all the information (low resistivity zones, fracture zones and geological structure characteristics), we can infer a more likely location for the existence of geothermal water and design two 2500m deep drilling holes. The actual drilling results confirmed the accuracy of the speculation and obtained a geothermal water resource of 75℃ at 2000m deep hole. A geothermal structure concept model can been built based on the electrical structure, main faults and regional geological structure. The heat source is deep magma chamber from Changbaishan Tianchi volcano. The geothermal aisles are high-angle Water-bearing fault zones. Water is the best medium for heat storage. Quaternary strata such as shallow volcanic ash are the best caps which Stop heat loss.

Hydrocarbon prospect in parts of the Nagapattinam sub-basin in the Cauvery Basin, deciphered from the biostratigraphy and source rock characterisation

Ashish SARKAR[1]*, Retired as Associate Professor from the Pandit Deendayal Petroleum University, Gandhinagar, India (ashish29s@yahoo.co.in)

Abstract

Among the category I petroliferous basins of India, Cauvery basin with nearly 25,000 sq. km on-shore and 30,000 sq km off-shore is a significant producing basin between 8°30' – 12°12' N; 78°30' – 80°30' E, where exploration began in 1964 by ONGC, and still witnesses the exploration activity in it. This basin involves a depression (Cauvery – Srilanka), consisting of horst and graben morphology with nine major tectonic elements having multiple sub-basins. Sedimentary fill in the basin is more than 6,000 m thick ranging between Permian – Recent, which overlies PreCambrian granites and Syenites. Cauvery basin developed during the break-up of Gondwana Land and underwent four phases of deformation, (i) Late Jurassic / Early Cretaceous syn-rift extension, (ii) Late Cretaceous late rift / early drift stage cooling contraction, (iii) Late Cretaceous – Paleogene drift stage strike slip reactivation, and (iv) Neogene passive margin subsidence.

The basin witnessed multiple transgressive and regressive events as is evident from the presence of five major unconformities. The oils, so far produced from the basin, are of paraffinic – naphthenic composition; light to very light (API gravity 41° – 49°) with 5.4% wax and 0.48% asphaltenes; more heavier (28° API) and lighter (56° API) oils are also present. Oil and gas have been generated from localized source rocks at different maturity (0.7 to 1.15% VRo). Isotopic signatures show, oils in various sub-basins are genetically different. In order to look for a new prospect in the basin, a hole was drilled in the Nagapattinum sub-basin. An account of the systematic study is presented in the present paper.

60 core samples, and 55 cutting samples have been studied between 6 and 3996.5 m drilled interval, which have yielded 28 species of benthic foraminifera, 20 species of planktonic foraminifera, and 12 species of ostracodes. Based on the fossil assemblages at different levels along with the FAD and LAD, biostratigraphy at the drilling location was established. While Andimadam Formation and Sattapadi Shale are the oldest in the studied sequence and belong to the pre Upper Cretaceous age, overlying Bhuvanagiri Formation to the youngest Tittacheri Formation range in age from Upper Cretaceous to Late Miocene, depicting the depositional environment from deltaic to outer neritic.

Source rock characterisation using rock-eval pyrolysis was attempted in the Sattapadi Shale and Andimadam Formation in the drilled hole to know the hydrocarbon prospect in the area. About 628 m thick Cretaceous sequence in the interval of 3231 – 3858 m, has fair to good amount of organic matter (TOC 0.62 – 1.33%, average being 0.9%), lower hydrogen index (HI 52 to 80 mg

HC/g TOC and oxygen index (OI) ranges between 46 and 133 mg HC/g TOC. The data suggests presence of type IV kerogen, and hence a poor hydrocarbon prospect in the area is interpreted based on source rock evaluation from Andimadam Formation and Sattapadi Shale.

Abstract

A fundamental aspect in successful development of civilization is the production of marketable product from minerals contained in the bowels of the Earth.

Obtaining minerals both today and in the foreseeable future is a necessity, which in terms of its volumes and nomenclature is growing at a much faster pace than population growth.

These two factors, despite their lack of alternatives, face problems as a result of their impact on natural systems, which must be eliminated.

First of all, we are talking about the rapid depletion of mineral resources, primarily metals in the bowels, expected within 30-150 years, as of 2050 according to proven statistics, in the continental part of earth's crust. Secondly, natural ecosystems that provide conditions for the existence of living matter are degraded and irreversibly destroyed as a result of the development of mining industry.

Paradoxically, good aspirations of human society to improve the quality of life are being fulfilled paired with destruction of natural balance of the environment in which comfortable conditions have been created by nature for man and the world around him.

From the emerging negative situation the goal of our work was determined: creation of an industry in which interaction of natural geological environment and technogenic systems for the extraction of metals, would make it possible to meet the needs of humanity on a historical time scale without irreversible anthropogenic destruction of natural environment.

The goal can be achieved by analysis based on a systems approach, exploring artificial systems (arising with the participation of man) for the extraction and processing of ore and designing these systems with a positive impact on the results of changes in the geological environment.

Simultaneously, an analysis was made of all possible sources of metal production, which could not only be natural primary georesources, but also secondary ones created by man.

The development of the subsoil and its preservation should be solved by creating a new objective reality in the combined application of the discovered specific essential and natural geological patterns of ore formation and previously unidentified properties of man-made systems used for ore extraction and processing.

As a result, all existing and operating sources of metal production from primary and secondary georesources were identified, technological solutions and schemes were created for their practical application both in geological environment in new mining frontiers and on the surface from artificially created dumps, all in the format of circular economy.

The output of our work lead to conclusion that the research performed is the basis for a full-scale supply of metals to humanity in the mode of resource production, resource conservation and the preservation of quality of natural environment in all its aspects.
The result of theoretical basis of the created socially organized system should be practical provision of metals to humanity for an immeasurably long time in the format of cost-effective, technologically feasible and safe production, for humans and the environment. In the presented report, we propose real technological solutions to fulfill this format.

Push and Pull factors as predictors of entrepreneurial dynamics in artisanal and small-scale mining: a case study on industrial mineral exploitation in South Africa

Ndivhudzannyi n Rembuluwani[1]*, university of venda
(Ndivhudzannyi.rembuluwani@univen.ac.za)
makia Lawrence Diko[2], university of venda

Abstract

Artisanal and Small-Scale Mining (ASM) entrepreneurship plays a pivotal role in the global mining sector, contributing significantly to employment and local economies. This study explores the push and pull factors influencing ASM entrepreneurship dynamics in the industrial minerals sector in South Africa. Push factors include poverty, limited employment opportunities, job security, economic instability, and mineral rush. Conversely, pull factors comprise the allure of potential financial gains, cultural ties to mining traditions, personal development, achievement, entrepreneurial drive, and the desire for autonomy. While there is a consensus on the benefits of pull, over push factors, the extent to which this assertion holds true for the South African case study, remains elusive. To contribute towards this on-going debate, the current study investigates (i) the extent to which Push-Pull factors influence the typology of ASM in the industrial mineral sector (seasonal, permanent, Rush-type and Shock-push ASM), and (ii) the challenges and opportunities. The study employed a mixed-method approach, combining qualitative and quantitative surveys with administration of closed and open-ended questionnaires (n=200), The initial findings suggest a predominance of Shock-push ASM (70%) over Rush-type ASM (20%). This observation is due in part to preference of commodity (industrial mineral versus metallic minerals) and the associated level of risks. The major constraint is associated with formalization of the ASM initiative and access to support systems (human and financial resources for capacity development and value creation). These preliminary findings offer valuable insights for policymakers, development practitioners, and community leaders seeking to formulate sustainable strategies that balance economic growth with environmental and social considerations in the ASM sector.

[Keynote] Geo-Resources in Sustainable Development

AFIA AKHTAR[1]*, AGID/GSB (afia@agni.com)

Abstract

Development and sustainable development are the most concerned terms widely discussed nowadays in the modern society and how to achieve these. But the problems like energy crisis, mineral & groundwater shortage; un-wise urbanization & industrialization, hazardous adverse impact, climate change, soil infertility, air-water-land pollution and consequently the imbalanced environmental ecosystem are major obstacles in achieving sustainability. To overcome these obstacles, proper application of geoscience knowledge along with the knowledge of multidisciplinary sciences is needed. The achievement of sustainable development largely depends on how much rich the country in her geo-resources, especially the hidden mineral resources and its capability to explore and exploit that resource for developing mineral based industries.

Geo-resources mineral-water-soil is the most vital commodities for developing industrialization, urbanization, and as a whole the civilization. These resources including fossil fuel which is a vehicle for rapid economic growth come from earth's components- atmosphere, lithosphere, hydrosphere and biosphere, the major four elements of earth system science. But any change or interaction in earth's components causes geo-hazards which have severe adverse impact on development and may even ruin the entire civilization.

Geoscience is an intuitive and day-to-day changing science. Therefore, in achieving sustainable development, regular updates and extensive research experiences are to be needed for understanding this science properly. So, for application of geoscience knowledge in development activities geoscientists must have to have good concept on earth, its components and to find out its hidden mineral resources, to utilize that resources in industrial development and to handle efficiently the negative impact of geo-hazards. Misuse of geo-resources, air-water-soil pollution, abuse of landscape, improper waste disposal, deforestation that enhance wildlife destruction and consequently the climatic change are the major causes for environmental deterioration and it is primarily due to lack of geoscience knowledge. By acquiring basic knowledge, even common people can contribute to nation-building development activities which will lead to sustainable development. But to get mass participation, people of a society must be aware about geo-resources and how it contributes in upgrading the living standard by achieving sustainable development. They also must be aware about how misuse & mismanagement of geo-resources and mishandling geo-hazardous adverse effect can deteriorate the environmental ecosystem which retards national economic growth with negative impact in achieving sustainable development.

My paper will illustrate the ways how to achieve sustainable development by proper utilization of geo-resources and also by avoiding misusing the resources as well as mishandling the adverse

impact of geo-hazards which causes huge destruction of properties and life. Good concept of geoscience knowledge and its right application in right time can help to deal with all of these in getting healthy development which will lead to reform the national economic infrastructure and then it will accelerate the high living standards of society, a sign of a sustainable development.

Abstract

In 2018, the Council for Geoscience embarked on an integrated and multidisciplinary geoscientific research in the Limpopo Province, South Africa, focusing on the Giyani Greenstone Belt (GGB) and surrounding areas. The objectives of the project were to support economic growth, address water security and promote environmental stewardship through an integrated approach that covers tasks across multi geoscience disciplines (i.e. detail geological mapping on a scale of 1:50 000, use of soil geochemistry datasets to assess the mineral potential, geophysical survey targeting deep crustal rocks to compensate for the poor outcrop in the area, geotechnical, groundwater and environmental studies to address socio challenges). Geologically, the GGB is situated along the boundary between the Kaapvaal Craton and the Southern Marginal Zone of the Limpopo Metamorphic Belt and comprises largely tonalite-trondhjemite-granodiorite rocks, metavolcanic and metasedimentary rocks, and various Archaean-Paleoproterozoic age granites. Integration of geological, soil geochemical and radiometric datasets delineated previously unmapped sequences in the region. These include delineation of mafic and ultramafic rocks of the GGB, as well as delineation of more evolved felsic rocks (i.e. Shamiriri Grantie body and syenite body in the surrounding area). Six 1:50 000 geological maps covering the entire GGB, and the surroundings were produced. A Magnetotelluric (MT) survey focusing on deep crustal features (>15km) was conducted in the central part of the GGB along a NW-SE oriented profile of about 30 km. This included the delineation of deep crustal shear zones and subsidiary structural zones. Integration of MT and geological datasets on deep geological structures confirmed that these subsurface

structures hold potential for structurally controlled gold mineralisation. This is corroborated by the results of the Induced Polarization geophysical surveys. Surface litho-samples in shear zone-hosted quartz lodes indicate that both the structural and lithological control are important. From a hydrological perspective the project area occurs in a semi-arid region with limited water sources. In order to address socio-economic challenges in the area, groundwater, environmental and geotechnical studies were conducted. These tasks were guided by stakeholder engagements which commenced in 2018. Hydrogeological results revealed that high-yielding groundwater occurrences are located along structural lineaments which control water flow. Groundwater analyses however, indicated high concentrations of arsenic close to historical mining areas, which present health risks to communities consuming groundwater in these areas. A geotechnical map of the region was produced and delineated areas suitable for urban and rural development. Environmental studies investigated the effects of historical and current mining activities in the region.

Effects of foreign direct investment and Belt and Road Initiative on the mining industries in the ASEAN countries

JI WON MOON[1]*, U.S. Geological Survey (jmoon@usgs.gov)
Sean Y. Xun[2], U.S. Geological Survey
Steven D. Textoris[3], U.S. Geological Survey

Abstract

The annual gross domestic products (GDP) growth rate of Association of Southeast Asian Nations (ASEAN) countries between 2010 and 2017 was 5.5%, which was higher than the world average of 3.0%. Since the launch of China's Belt and Road Initiative (BRI) in 2013, Chinese foreign direct investment (FDI) to ASEAN region totaled $43 billion. In this study, economic factors to mining and quarrying sectors in ASEAN countries were considered before and after launch of BRI and the combined effect of FDI and BRI on the development in mining sector were evaluated. When compared the data from 2013-2017 with 2010-2012 after the global recession in 2009, average GDP growth rate increased in Philippines, Cambodia and Vietnam. During the same periods, the increasing rate of FDI to mining and quarrying sector were higher in Malaysia, Laos, and Burma. Chinese-sourced FDI also increased in Malaysia, Laos, and Vietnam. The GDP in mining and quarrying sector expanded faster in Laos, Cambodia, and Burma. Higher increase of cement consumption in Cambodia and Laos were likely due to extensive infrastructure projects that China supported, in terms of both hydro- and coal-power plants ($5.3 billion), Kunming-Vientiane railway ($7 billion), respectively. Coal production of Laos also increased by 2,600% to support power plant which was developed in cooperation with Thailand. The mining industry in Laos was an exemplary beneficiary derived from the integration of direct multi-sourced FDI to mining sectors and indirect facilitation by infrastructure projects through BRI.

Abstract

With the widespread adoption of hydrogen fuel cells, the demand for platinum, a key raw material, is expected to increase. Platinum is thought to be mainly adsorbed by iron and manganese oxide, and concentrated in cobalt-rich crusts and hydrogenetic nodules, which makes it of potential byproduct value. The control of water depth on ferromanganese crust and nodules composition has been reported for a long time, while the Pt contents variation of them with water depth is not well known, which is also the key to the understanding of the Pt enrichment mechanism.

In this study, ferromanganese nodules and crusts from the summit (~1400m) to the piedmont (~5400m) of the Suda Guyot in the western Pacific Ocean were collected and analyzed for Pt contents by LA-ICPMS and isotope dilution. Since only the top surfaces of nodules and crusts would be in chemical equilibrium with seawater, and their interior sections are more affected by the paleoenvironment, the top ~1mm layers of specimens were scraped for Pt isotope dilution analysis. The Pt contents of surface layers range from 0.1 to 0.3 ppm, which is irrelevant to water depth but consistent with the Pt distribution characteristics of the Western Pacific seawater. According to the LA-ICPMS mapping results of nodules, Pt mainly occurs in the Fe-Mn oxide phase, and particles with high Pt are rare. The samples of different water depths showed comparable Pt chemical stratigraphic characteristics, with the highest content in the inner layer (up to 2 ppm).

All the results obtained in this study clearly indicate water depth appears to have a limited effect on the Pt contents of nodules and crusts from seamounts, while the formation age is likely to be the most significant factor affecting their Pt contents. The larger the proportion of the old/interior layer in the crusts and nodules, the higher the Pt content of the bulk sample. Compared to the insoluble Ce (IV) and Co (III) oxidized by δ-MnO2, Pt (IV) was considered soluble, which makes the oxidation of Pt (II) to Pt (IV) might have minor attributes to the Pt enrichment in ferromanganese crust and nodules.

Microstratigraphic characterization of mineral diversity of hydrogenetic ferromanganese crusts in the Northwestern Pacific seamounts.

Akira USUI[1]*, MaCRI, Kochi University (a-usui@kochi-u.ac.jp)
Hikari Hino[2], Kochi University and JOGMEC

Abstract

We carried out acoustic bathymetry, on-site observations, and bottom sampling with dredge, ROV, submersible, as well as surface ships, and in-laboratory analyses of the structural growth patterns, chemical and mineral variations on the basis of microscopical and XRD analyses, dating with microfossils, radiochemical chemistry, paleomagnetism and basement rock data. Microstratigraphic characterization on small to regional scales suggested similar patters in various scales and water-depth dependency broadly among hyrdrogenetic ferromanganese crusts in the NW Pacific areas. The comprehensive joint studies indicated also characteristic temporal patterns of common growth patterns over the Pacific areas such as increasing supply of detrital silicate minerals in the younger layers and clear phosphatization vents in the older layers. These correlations were supported by the fairly constant continuous growth without any large breaks within the hydrogenetic ferromanganese crusts from the Cretaceous to Neogene environments, throughout the seamount areas. The microscopic correlations well indicate common growth history and common temporal variation patterns as well as similar and continuous resource potential of useful metal resources. We need further future collaboration programs in geochemical and mineralogical characterization of the ferromanganese deposits in the NW Pacific jointly with domestic and international organizations and among various fields of sciences and technology. This paper is a short summary of the recent progress in mostly geological sciences mostly based on microstratigraphic analyses and on-site field study.

Seabed mining for a sustainable future

Thomas Kuhn[6], Federal Institute for Geosciences and Natural Resources, Hannover, Germany.

Abstract

A sustainable future requires a transition to a coherent, circular, and resource-efficient economy that combines technological, environmental, and social aspects and does not harm future generations. All available data indicate that we are on the verge of breaking the 1.5-degree Celsius threshold set out in the Paris Climate Agreement. Fossil fuels are by far the biggest cause of climate change, accounting for over 75% of global greenhouse gas emissions and almost 90% of carbon dioxide emissions. To reduce our dependence on fossil fuels, we need to invest in clean and sustainable alternative energy sources. Decarbonization will require large quantities of rare earth elements and other critical raw materials. Seabed resources are seen as a potential challenge for mineral exploration and extraction, as mineral deposits on land are becoming increasingly depleted. The major marine deposits include polymetallic sulfides, polymetallic nodules, cobalt-rich ferromanganese crusts, phosphorites, REY-rich muds, and placers [Sakellariadou et al., 2022].
In addition to climate change, the list of the most important environmental sustainability problems according to the UN 2030 Agenda includes the use of natural resources, waste production, water and air pollution, and declining biodiversity. Mining rare earth elements on land poses a significant threat to the environment, as large quantities of toxic chemicals are used during processing and refining, and uranium and thorium usually must be removed from the ores, even if not all ores are radioactive. It also causes significant impacts on non-living resources, i.e. the use and pollution of land, forests, water, and soil. The main obstacles to seabed mining are the impact on the entire seawater column, the habitats, and the communities. Given the high value of deep-sea communities and our limited knowledge, the scale of the potential impact is not easy to assess.

A major challenge will be to provide the large quantities of critical elements needed for the transition to green technology in a sustainable way. A key component of our mission will be the adoption of resource-efficient, ethical, and circular mineral value chains.
The DPSIR model framework can be used to support good natural resource management and policy as it combines socio-economic and environmental factors. The Driving forces (economic

growth, increase in world population) create Pressures (water pollution, habitat modification/removal, sediment disturbance, light and noise generation, air pollution) that change the State (exploitation of resources, including marine genetic resources, technological improvements, new job opportunities) and lead to Impacts (loss of biodiversity, metal prices on the world market, increase in wealth and well-being) that require Responses (regulations, ecological restoration, metal recycling, new technologies, knowledge accumulation, and transmission to future generations).

A first estimation of resource abundance in the Korea CFC contract area

Gyuha HWANG[1]*, Korea Institute of Ocean Science and Technology (ghhwang@kiost.ac.kr)
Wonnyon Kim[2], Korea Institute of Ocean Science and Technology
Youngtak Ko[3], Korea Institute of Ocean Science and Technology
Seung-Jin Yang[4], Korea Institute of Ocean Science and Technology

Abstract

Information on surface area and thickness is critical in estimating the resource abundance of cobalt-rich ferromanganese crusts (CFCs) covering the surface of seamounts. In this study, we obtained seafloor images and CFCs cores using ROV and a newly manufactured crust drill on the three Korean Contract seamounts (KC-7, KC-8, and KC-9) in the northwestern Pacific. Along the nine visual survey lines, a total of 66 CFCs drilling have been performed. The CFCs thickness was measured directly from the core sample, and seafloor conditions were manually classified into seven types from the seafloor image. Resultantly, we identify that 82.86% of the survey area (513,732 m^2 of 620,000 m^2) is covered by CFCs with a mean thickness of 11.49 cm across nine lines, indicating the abundance of 78,829 tons with a mean occurrence of 127.14 kg/m^2. As the visual survey could not cover the entire contract area, we consider that previously acquired backscatter intensities for the observed crust exposures were used to estimate the resource abundance for the CFCs exposure area. When the backscatter intensity for the CFCs exposure is applied in the three contract seamounts, the calculated resource abundance is highly variable ranging from 13,996,966 tons with 153.27 kg/m^2 to 22,684,912 tons with 155.38 kg/m^2, depending on selection criteria applied. Nevertheless, this study provides a reliable line-based resource estimation at this time.

Contribution of Multiple Metal Sources to the Formation of Hydrothermal Chimney and Mound in the Mirae-2 Vent Field, Central Indian Ridge

Sun Ki CHOI[1]*, Korea Institute of Ocean Science and Technology (chlsunki@kiost.ac.kr)
Jonguk Kim[2], Korea Institute of Ocean Science and Technology
Sang Joon Pak[3], Korea Institute of Geoscience and Mineral Resources
Wonnyon Kim[4], Korea Institute of Ocean Science and Technology
Ryoung Gyun Kim[5], Korea Institute of Ocean Science and Technology

Abstract

The recent discovery of the Mirae-2 vent field (MVF-2) in the Central Indian Ridge provides new insights into the seafloor hydrothermal mineralization influenced by multiple origins of ore-forming elements in mid-ocean ridge settings. Mineralogical and geochemical characteristics of the MVF-2 chimney and mound exhibit the prevalence of reduced sulfide assemblages (pyrrhotite + isocubanite + Fe-rich sphalerite) and Sn enrichments (up to 1000 ppm), indicating an affinity with ultramafic-hosted hydrothermal mineralization, but the significant occurrence of barite and galena, along with enrichments in Ba (>100,000 ppm), Pb (up to 8.91 wt.%), and Si (31.9 wt.%), reflects the involvement of distinct metal sources other than the interaction of fluids with ultramafic substrates. This multi-origin hydrothermal mineralization is more evident in in-situ S (for pyrite and pyrrhotite) and Pb (for sphalerite) isotope analyses. The extremely positive $\delta^{34}S$ values (+5.46‰ to +17.24‰) and unusually radiogenic Pb isotope ratios ($^{206}Pb/^{204}Pb$ = 18.531–18.559; $^{207}Pb/^{204}Pb$ = 15.540–15.564; $^{208}Pb/^{204}Pb$ = 38.632–38.693) of the MVF-2 sulfides indicate that metals and S forming chimney and mound were leached mainly from serpentinized ultramafic rocks and enriched mid-ocean ridge basalts (i.e., the MVF-2 basalts) near the ridge axis (~ 5 km away). We propose that the initial seawater underwent multi-stage reactions, involving the leaching of Ba, Pb, and Si from the MVF-2 basalts in the recharge zone, followed by interaction with ultramafic rocks (i.e., serpentinization) underlying the MVF-2. This process ultimately resulted in the generation of hydrothermal fluids derived from multiple sources. Consequently, the MVF-2 exhibit mineralogical and geochemical features that differ from those of other ultramafic-hosted sulfide deposits, despite its location on an oceanic core complex. Our results highlight that multiple origins of seafloor hydrothermal mineralization may be common on slow-spreading mid-ocean ridges, given the more complex sub-surface lithological structure beneath sulfide deposits compared to that of fast-spreading mid-ocean ridges.

Brothers volcano submarine hydrothermal system: upper parts of a porphyry Cu system

Cornel EJ DE RONDE[1]*, GNS Science (cornel.deronde@gns.cri.nz)

Abstract

High Cu-Au contents and strongly acidic vent fluids at Brothers volcano, Kermadec arc, are similar to those that formed the shallow parts of some porphyry copper and epithermal gold deposits. Two active, but distinct hydrothermal systems occur at Brothers volcano. One is magmatically-influenced and includes the Upper and Lower Cone vent sites that sit atop volcanic cones. The other is seawater-dominated and includes the Upper Caldera, NW Caldera and West Caldera vent sites, each perched on the caldera walls. The Upper Caldera vent field is host to numerous black smoker chimneys up to 20 m tall expelling fluids up to 320 °C. Hundreds of both active and inactive chimneys— reaching heights of ~15 m and discharging fluids up to 311 °C—are then perched on benches that cut across the caldera walls as part of the NW Caldera vent field.

Boundaries marking fluid flow can be defined by magnetic lows. For example, at the Upper Caldera site, an hour-glass shape (in plan view) denotes the magnetic low in the area, with a bulbous, open, top section ~1 km wide occurring near the Upper Caldera walls that extends ~800 m to the SE where it narrows to 400 m at the NW Caldera rim, occupying an area of ~0.68 km2 . This alteration zone then widens again to ~1 km and extends a further ~700 m towards the SE, encompassing an area of ~ 0.76 km2 that includes all of the NW Caldera site, and which extends onto the caldera floor.

The NW Caldera walls are characterized by normal faults that extend for up to 210 m (typically ~150 m) with throws up to 30 m. Extensive stockwork veining is exposed beneath the chimneys in the exposed faces of several of these faults, indicative of mobilization of metals that occurred prior to caldera collapse. Pyrite is the most dominant sulfide. These veins contain up to 10.1 wt.% Cu, 5320 ppm Zn, 3580 ppm As, 740 ppm Co, 467 ppm Mo, 296 ppm Pb, >90 ppm Se, >40 ppm Te, 40 ppm Bi, 37 ppm Sb, 16 ppm Ag, 12 ppm In, >11 ppm Tl and 1.9 ppm Au, consistent with a magmatic fluid contribution.

A series of boreholes were drilled into Brothers volcano by the International Ocean Discovery Program in 2018 and revealed hydrothermal alteration of the host dacitic volcaniclastics and lavas reflects primary lithological porosity and contrasting spatial and temporal contributions of magmatic fluid, hydrothermal fluid, and seawater. Initial hydrothermal activity, prior to caldera formation, is dominated by magmatic gases and hypersaline brines. The former mix with seawater as they ascend towards the seafloor, while the latter remain sequestered in the subsurface. Following caldera collapse, seawater ingress occurs by way of fault-controlled permeability, interacting with wall rock and the segregated brines, transporting associated metals towards the seafloor and forming present-day Cu-Au-rich chimneys.

Abstract

Ferromanganese concretions, found both in deep ocean environments and shallow-water coastal regions globally, have gained renewed scientific attention due to their multifaceted significance as underwater habitats, critical raw material sources, and invaluable repositories of paleoceanographic information. The magnetic properties of ferrimagnetic minerals within these concretions, along with the origins of their natural remanent magnetization, are areas of exploration still in their early stages. Recent discoveries have revealed the involvement of biogenic magnetite in the development of biogeochemical remanent magnetization within deep ocean crusts and nodules, emphasizing the influence of microbial catalysis in their precipitation. While extensive research on the magnetic properties of deep ocean Fe-Mn deposits has been conducted, investigations into fast-growing shallow-water concretions have been notably absent. Additionally, the specific mechanisms governing the formation and (bio)mineralization of diverse concretion morphotypes (crust-like, discoidal, and spheroidal) in shallow-water settings remain enigmatic.

Our study focuses on ferromanganese concretions in shelf areas and seas, utilizing samples from the Baltic Sea. We present magnetic characteristics, microstructure, and the origin of Baltic Sea concretions, shedding light on their formation processes and environmental implications. Employing a comprehensive approach, we combined nano- and micro-computed tomography imaging, electron microscopy, micro-X-ray fluorescence spectroscopy, and detailed magnetic

property investigations. Spheroidal concretions, prevalent in various coastal Baltic Sea regions, contain a higher proportion of fine-grained magnetite, accompanied by evidence of bullet-shaped magnetofossils produced by magnetotactic bacteria. These magnetofossils are typically associated with eutrophic and less oxic environments, supported by the possible presence of rhodochrosite, indicating diagenetic Mn release from surrounding sediments, particularly in deeper water settings. In contrast, crust and discoidal concretions in shallower waters display pedogenic-like magnetic characteristics, reflecting an increased continental influence. Microstructural analysis reveals multiple growth stages in the concretions, with laminated, columnar, and dendritic structures indicating varying hydrodynamic and depositional conditions. Generally, spheroidal concretions appear to form in more tranquil settings compared to discoidal and crust concretions.

Our results provide insights into the intricate interplay of environmental conditions, biogenic processes, and mineralogical composition influencing ferromanganese concretion growth and magnetic properties in the Baltic Sea. We argue that biogenic magnetite globally contributes to the remanent magnetization of both shallow and deep-sea ferromanganese concretions.

Abstract

Ferromanganese concretions, ubiquitously present in both deep ocean environments and shallow-water coastal regions worldwide, have rekindled scientific interest due to their significance as underwater habitats, repositories of paleoceanographic information, and resources of raw materials. In shallow-water settings, these concretions exhibit diverse morphotypes, such as crust-like, discoidal, and spheroidal. However, the processes driving the formation of these morphotypes and how the morphology influences their geochemical properties remain poorly understood.

We systematically examine element enrichment characteristics and conduct a comparative analysis of the geochemical and magnetic properties of shallow-water concretions from the Baltic Sea, focusing on the various morphotypes observed. The concretions generally exhibit similar or slightly enriched element contents when normalized to the composition of Earth's crust. Critical metal enrichments are somewhat lower compared to deep ocean diagenetic nodules and significantly lower compared to deep ocean hydrogenetic Fe-Mn crusts.

Although direct comparisons to deep ocean Fe-Mn precipitates are not straightforward due to the exceptionally rapid growth rates observed in the Baltic Sea compared to deep ocean settings, the trace element geochemical signature in these shallow-water concretions suggests a diagenetic origin. Additionally, the concretions exhibit morphotype and geochemistry-dependent magnetic properties.
A comprehensive understanding of the growth mechanisms and element enrichment processes of these concretions will contribute new insights into the spatial metal enrichment patterns and into paleoceanographic and environmental changes in the Baltic Sea and other shelf areas.

This research was funded by the Research Council of Finland (Fermaid project, grant 332249).

Abstract

Since 2018 EuroGeoSurveys (EGS) has developed GeoERA and GSEU programs drawing together the baseline data and knowledge needed to manage Europe's natural resources, including offshore mineral resources. Seabed minerals and their associated strategic and critical raw materials, in the Atlantic and Arctic oceans and the Baltic, Mediterranean and Black seas, are being analyzed based on extensive studies carried out previously. A complete database compilation includes 692 occurrences of volcanogenic massive sulfides and hydrothermal mineralizations, polymetallic nodules, cobalt-rich ferromanganese crusts, phosphorites and marine placers in pan-European seas. This standardized and harmonized database and the derived cartographic products contain the principal geological, metallogenic, environment and mining features of each occurrence. For the first time EGS is producing mineral occurrences, metallogeny, potential exploration areas, and predictive maps without limitations of national borders. More than 1190 individual samples collection provides information on the mineralogy and chemistry of the seabed resources, from shallow waters to deep-sea. The map on the CRM offshore occurrence of Europe is based on the 2023 CRM list of the European Commission, and enables the visualization and inspection of vast regions of the European seas. This study will contribute to increase the knowledge on the seabed environment and the associated geological resources, providing tools to policy makers for regulations and recommendations. Case studies and maps in progress will contribute to identify potential areas for environmental protection and responsible resource exploration and future extraction. Particular innovations of the studies in progress will include: first mapping of metallogenic provinces for offshore minerals pan-European setting; definition and mapping of strategic and critical raw materials associated with each deposit; identification of gaps defining underexplored marine areas; proposals for pilot zones with a high mineral potential for future research/ exploration with preservation or exploitation purposes; and the reinforcement of the European network of experts in seabed minerals.

Kristoffer Solvi[6], Norwegian Offshore Directorate
Andreas Bjørenstad[7], Norwegian Offshore Directorate

Abstract

The deep-sea mineral resources of the Norwegian continental shelf consist of deposits of polymetallic sulphides and polymetallic crusts; the area is not favourable for polymetallic nodules. For many years, the Norwegian Offshore Directorate (previously the Norwegian Petroleum Directorate) has collaborated on a scientific basis with academia in marine research on seabed minerals minerals in the deep-water areas of the Norwegian continental shelf in the Norwegian and Greenland seas. In particular, geological, geophysical and environmental data have been acquired during annual joint marine research cruises with the University of Bergen and the University of Tromsø since 2011 and 2019, respectively. Since 2018, the Directorate have carried out its own data acquisition cruises based on commercial tenders. During these activities, the Directorate has acquired high-resolution multibeam data, geophysical and electromagnetic data, together with drill cores, and samples by ROV. The data that had been acquired until 2022 have been released to the public and were the basis for the resource assessment report published by the Directorate last year.

For sulphide deposits, the stochastic estimates of total in place contained metal in sulphides are considerable, with copper at 38,100,000 tonnes, zinc at 45,000,000 tonnes, gold at 2,317 tonnes, silver at 85,200 tonnes, and cobalt at 1,000,000 tonnes. In addition, the prospective area for manganese crusts is estimated to cover more than 8,500 km^2, presenting a significant potential for various metals that may be of interest including manganese, cobalt, scandium, vanadium and possibly some of the REE elements. More details of the metal grades will be presented. Further marine data acquisition cruises have been carried out, two in 2023 and three in 2024. These cruises have been concentrating on the Knipovich Ridge and in the areas to the northwest of the Mohn Ridge outside of the axial valley. These recent data have confirmed hydrothermal vent deposits along the Knipovich Ridge, and also supports the potential for considerable sulphide and crust resources in northwest of the Mohn Ridge. This year's exploration have confirmed the major sulphide mound named Deep Insight that was discovered by the EMINENT Project under the lead of the University of Bergen in 2022. The Deep Insight deposit seems to be about 250 meters vide and 150 meters high, is in-active and located in the uplifted area adjacent to, but outside the spreading rift valley of the Mohn Ridge. It is the largest hydrothermal sulphide structure know today on the Norwegian Continental shelf. Furthermore, the recent data show the systematic

thickening of the crust deposits as one moves northwestwards away from the Mohn Ridge spreading valley. There is a gradual thickening from about 5 cm along the valley to more than 30-35 cm in the north west at about 150 km from the spreading axis. The saw blade was about 40 cm wide, but did not reach the substrate in the thickest parts. So far, it sems that the metal concentration does not change with thickness but stays more or less constant. More details in this will be presented.

Abstract

In January 2024, the Norwegian Parliament reached the agreement to open an area for mineral activities on the seabed on the Norwegian continental shelf as proposed in the Government's white paper no. 25 (2022-2023). This decision followed from an opening process that was initiated by the Ministry of Petroleum and Energy (now the Ministry of Energy) in 2020. According to the decision, Norway will adopt a precautionary, knowledge-based approach in proceeding with a stepwise and responsible development of seabed mineral activities on the Norwegian continental shelf, in which environmental considerations will be upheld in all phases of the activity. The Government has now decided that it this year will start the process for announcing areas for the application and award of licenses for exclusive mineral activities.

The opening process consisted of two main parts: an impact assessment process and a minerals resource evaluation. As part of the impact assessment, government agencies and leading expert institutions prepared background reports and impact studies summarized in the document "Impact Assessment for Mineral Activities on the Norwegian Continental Shelf," included in the Government's white paper. The Norwegian Offshore Directorate (formerly the Norwegian Petroleum Directorate), the ministry's specialist directorate for seabed minerals, prepared a resource assessment study for the area under investigation. The assessment indicates significant potential mineral resources on the Norwegian continental shelf. Some of these resources may be extractable. The impact study, the resource assessment study and the results from the marine exploration and research available, including the data acquired during the three cruises this year (January to June) will be the basis for selecting areas to be announced in the first licensing round. These aspects will be dealt with in more detail in the presentation.

Applicants for licenses must present the details of their initial geological knowledge of the area in question, their technical competence, financial capability, and a work program designed to clarify whether the area holds resources that are feasible to develop for extraction, which is expected to include exploration activities in that respect. However, before extracting mineral resources, license holders must submit an extraction plan, including an environmental impact assessment for the

project, to the Ministry of Energy for its and the Parliament’s approval.

In-situ monitoring reveals the vertical stratification characteristics of sediment plume in deep-sea mining

zhihan Fan[1]*, Ocean University of China (fanzhihan@ouc.edu.cn)
yonggang JIA[2], Ocean University of China

Abstract

The spatial and temporal distribution of sediment plumes determines the environmental impact of deep-sea mining, and accurate modeling of the three-dimensional distribution of plumes depends on in-situ monitoring of plume concentration changes. However, existing studies lack in situ monitoring devices for continuous vertical changes in deep-sea sediment plumes. In this study, a plume in-situ monitoring device was developed, and a Self-Potential inversion model of suspended particle concentration was established through artificial neural network (ANN) training. In situ perturbation and monitoring have been carried out in the 5750m water depth of the polymetallic nodule area in the Western Pacific Ocean. The vertical concentration variation characteristics of the sediment plume within 0.74m from the bottom have been monitored in situ with a vertical resolution of 2 cm. The results show that the vertical plume concentration of sediments is stratified, with the upper plume concentration being low and the lower plume concentration being high in the 0.74m range. The mass of the lower plume accounted for more than 75% of the total particle mass, and the proportion of the lower plume gradually decreased with the increase of time. This study provides a new method for in-situ observation of vertical concentration of deep-sea mining plumes, increases the understanding of vertical concentration distribution characteristics of mining plumes, and provides data support for accurate simulation of temporal and spatial distribution of plumes.

Abstract

Polymetallic nodules contain enormous amounts of critical metals, making them the top priority for future deep-ocean marine mining. Recent deep-ocean mining tests (2021-2022) of polymetallic nodules in the Clarion-Clipperton Contract Area by Global Sea Mineral Resources (GSR) and the Metals Company (TMC) suggest that environmental impacts caused by nodule mining operations are inevitable but manageable. How to mitigate those impacts is of critical importance and has become a core issue of concern by the international community. The most straightforward way of mitigation that the contractors and mining companies are seeking is to improve the design of the mining vehicle, which however has high industrial costs. Others propose to use flocculant to enhance particle settling to reduce the impact to benthic biology from the creation of a sediment plume. But to our knowledge, no one has proposed a mechanism for mitigation by optimizing the path of the mining vehicle.

In this contribution, we propose a geological measure for optimizing the mining path based on in-situ tests of geotechnical properties of abyssal sediments in the Clarion-Clipperton nodule field. We carried out 35 in-situ tests at 11 stations on the abyssal plain of the A-5 Block in the China Minmetals Contract Area, which covers a variable range of water depths (5150-5350 m) with rugged topography. By establishing a quantitative relationship between sediment penetration strength (a proxy for substrate hardness) and the BPI topography parameter, as well as the sediment grain size, we found that platforms have coarser sediments and harder substrate compared to basins. This was explained by a lateral sediment redistribution model where suspended sediments previously eroded from nearby platform by bottom currents is redeposited in the basins, which was exerted by periodically changing bottom currents. It is expected that a harder substrate would result in lower subsidence depth of the mining vehicle, thus disturbing less sediment, resulting in a decreased sediment plume. The proposed mining plan can mitigate the

environmental impacts of the unexploited basin areas, which will also contribute to the recovery of the ecosystem.

Quantifying the rare earth element enrichment process of bioapatite in deep-sea REY-rich sediments

Hao Wang[1]*, Second Institute of Oceanography, Ministry of Natural Resources (wanghao@sio.org.cn)
Xiaohu Li[2], Second Institute of Oceanography, Ministry of Natural Resources
Bin Fu[3], Institute of Geochemistry, Chinese Academy of Sciences
Zhenggang Li[4], Second Institute of Oceanography, Ministry of Natural Resources
Yanhui Dong[5], Second Institute of Oceanography, Ministry of Natural Resources
Jie Li[6], Second Institute of Oceanography, Ministry of Natural Resources

Abstract

The rare earth element and yttrium (REY) compositions of bioapatite (e.g., fish tooth and bone) in marine sediments are often used as a potential proxy for paleoenvironmental conditions, and its Nd isotopic signature has been widely used to reconstruct ocean circulation. Furthermore, deep-sea REY-rich sediments (total REY (ΣREY) ≥ 400 ppm) have received increasing economic interest after Kato et al. (2011) reported that it can be a new REY resource. As the dominant REY-host phase in deep-sea REY-rich sediments, bioapatite has also been used to study the REY mineralization process. However, the REY enrichment of bioapatite and REY transfer from Fe–Mn micronodule to bioapatite remain unclear owing to a lack of quantitative studies on these processes under variable redox conditions (oxic vs. suboxic). To address these uncertainties, we conducted in situ geochemical analyses of fish teeth and Fe–Mn micronodules from two REY-rich sediment cores (GC01 and GC02) collected from the Clarion–Clipperton fracture zone in the central equatorial Pacific. We found that the Ce/Ce* ratios of fish teeth from GC01 (sediments ΣREY = 723 ± 274 ppm) and GC02 (sediments ΣREY = 506 ± 65 ppm) gradually increased with depth under oxic conditions, with calculated oxic pore water-derived REY increasing from ~3% (surface layer) to ~30% (200cm layer). In deep sediment columns (>200 cmbsf), the suboxic pore water contributed a small amount of REY (~3% to ~14%) to fish teeth, as evidenced by sharp increases in Ce/Ce* ratios of fish teeth and decreases in Ce/Ce* ratios and increases in YN/HoN ratios of micronodules. Therefore, the Nd isotopic compositions of fish teeth in core-top samples of deep-sea REY-rich sediments could be used to construct ocean circulation, but the fish teeth in core-deep samples may be unreliable archives of ancient bottom seawater. In addition, the majority of REY in bioapatite was sourced from bottom seawater, and a small amount (~4.3%) of REY was sourced from micronodules. Additionally, micronodules accounted for only ~2.1% of the REY in bulk sediments. Therefore, the micronodules had limited effect on the formation of REY-rich sediments. Meanwhile, the low sedimentation rate enables the sediments to accumulate more bioapatite and allows sufficient time for the bioapatite to acquire REY from the bottom seawater at the sediment–water interface; thus, it is the key factor controlling the formation of deep-sea REY-rich sediments.

Hydrothermal activity within seafloor hydrothermal vent fields along the Southwest Indian Ridge

Weifang YANG[1]*, Second Institute of Oceanography, MNR (yangweifang@sio.org.cn)

Abstract

The modern seafloor hydrothermal system on ultraslow-spreading Southwest Indian Ridge (SWIR) exhibit diverse characteristics. The SWIR is characterized by an ultraslow-spreading rate (14 mm/yr), thin crust, ridge segmentation, deep axial valleys, a heterogeneous magma supply along the ridge axis, which is composed alternately of magmatic-enriched and magmatic-barren segments. The magmatic-barren segments often develop detachment faults and oceanic core complexes. From west to east along the SWIR, there are numerous hydrothermal fields, such as Sudi, Baidi, Chunxi, Yuhuang, Longqi, Suye, Duanqiao, Changbai, Junhui, Qiaoyue, Baishen, Tianzuo, Tiancheng, Mt. Jourdanne and Old city. Hydrothermal sulfides were developed among part of these hydrothermal fields. Sulfide chronology research can reveal multi-stage formation and superposition processes of ore bodies, as well as the formation and evolution history of sulfides, their growth and hydrothermal fluid activities more accurately. The 230Th/238U dating method was widely applied to determine the age of seafloor hydrothermal sulfides. Here, we collected 74 sulfide ages from Yuhuang, Longqi, Duanqiao, Tianzuo and Mt. Jourdanne hydrothermal fields that have been reported. The 74 nonzero chronological data from hydrothermal sulfide samples provide the first quantitative characterization of the spatial and temporal history along the SWIR. The SWIR sulfide dates indicate that hydrothermal events have been distributed unevenly through the time interval from 100 kyrs to 0.2 kyrs. Hydrothermal events in the SWIR demonstrate that over the past 20 kyrs, hydrothermal activity in the SWIR has been relatively active. In contrast, between 40 kyrs and 100 kyrs, hydrothermal activity was relatively infrequent and short in duration. The maximum activity occurred at 15–11 kyrs, 9–7 kyrs and 6–0.2 kyrs. Compared with fast-, intermediate-, and slow- spreading ridges, sulfide ages from the ultraslow spreading center are widely distributed. There is no age correlation between the hydrothermal events at different sites along the MAR, CIR and SWIR. Hydrothermal fields, such as Yuhuang, Duanqiao and Tianzuo, are large and have good resource potential whereas the Mt. Jourdanne HF is small in scale and resource.

Potential Impact of Polymetallic Nodules Deep Sea Mining on the World Commodity Markets

Anna Mikhailovna LAPTEVA[1]*, Russian Mineral Resource Institute – VIMS
(annam.lapteva@gmail.com)
Alexandra Dmitrievna Chernova[2], Russian Mineral Resource Institute – VIMS

Abstract

Mining of deep-sea polymetallic nodules can bring significant amounts of Cu, Ni, Co and Mn to the market, whereas even relatively small additional supply at an unfavorable moment can unbalance the market or put pressure on prices. The consequences of falling price depends on actual reduction scale and economic condition of market participants.

If the market situation is unfavorable, the start of nodules mining can lead to global, regional or local consequences that are closely interconnected.

Global consequences are the disruption of the market supply/demand balance, which can cause an oversupply of one or more of the metals in question.

A decrease in prices of a metal or metals in question will provoke a cascade of diverse local and regional consequences, and all these cascades will develop simultaneously.

One of the cascade scenarios is:

Deteriorating shrinking revenues up to the point of companies losing profitability → reduction in production (limited capacity utilization) or suspension production → reduced wages or lay-offs → decrease in their purchasing power of families of employees of the affected companies → decrease in consumer demand from families of employees → decreased revenues in the service sector → closure of some service companies → lay-offs in the service sector → general decrease in the standard of living and employment in the communities of presence of the affected companies → reduced tax proceeds on regional and national levels → negative social consequences (social tension, population migration, etc).

Local and regional consequences will manifest itself on the global level. Reduced global production of the metals in question will shift the supply/demand balance towards shortages and cause respective change in price dynamics. The structure of the mining and metallurgical industries and the global value chain will also undergo changes.

The industry structure and the global value chain may be affected by the beneficiaries of nodules to be mined. Let's assume, that the “destination" of nodules are companies supplying metals to the countries-sponsors of the mining contractors. These countries are: China, Japan, France, Germany and Belgium. All these countries are major importers of mining and/or metallurgical products of the metals in question. A new source of these products will lead to a decrease in their imports from countries - traditional supplier. Thus, China imports manganese ore in large quantities (primarily from South Africa, Gabon, Ghana, Brazil), copper products (Chile, Peru, Mongolia, etc.), nickel (Philippines, Indonesia) and cobalt (DRC). These countries also main supply these metals to other countries. Nodules mining might lead to decreased import from traditional supplier

countries or cause such import to disappear altogether.

Abstract

Rias Baixas, a funnel-shaped estuarine inflow system into the coastal drainage area located in NW Spain, is mainly surrounded by Variscan metamorphic and intrusive coastal outcrops. Heavy mineral placer occurrences and deposits were formed in coastal areas by weathering of these rocks. Balarés beach (Ponteceso, Coruña) is an example, 3,600 tonnes of ilmenite (Ti) and other by-products (garnet, zircon, rutile, monazite and cassiterite) were extracted from this deposit between 1941 and 1952. This work is part of the European HORIZON project S34i (https://s34i.eu/) and summarizes the first results to evaluate the critical raw materials (CRM) associated with placers in the coastal areas of the Ría de Vigo. Baluarte and Fontaiña (Vao Beach), Límens, Santa Marta, Alemans, Ratas and Canabal beaches were explored in March and September 2023, while potential placer occurrences were recognized according to IGME internal reports (1976 and 1979). Ten sandy-sediment samples were collected in the heavy minerals-enriched surface layer in March 2023. At each site, three different sampling points were taken from 1 cm depth within an area of 1 m2. Organic matter and carbonate were eliminated, and then the samples were graded by granulometry. Fine to medium sands (<0.250 - >0.125 mm) were selected for heavy mineral separation by liquid density using bromohoform. Geochemical analysis was carried out using ICP-MS. In the field trips were identified two main placer occurrences: Santa Marta and Vao Beach. Both areas are dominated by reddish accumulations of heavy minerals in multilayers to a depth of about 50 cm. Surface patches of black minerals (about 1 to 10 m2) characterise the other beaches and the western part of Santa Marta Beach. Granulometry shows medium to fine sands, and heavy mineral contents have been quantified up to 46%, in multilayer enriched. In addition, Vao and Santa Marta samples show high accumulation of Zr, Nb, Hf, Ta, Th, U, La, Ce, Nd, Sm and others (bulk sample). Further analysis is underway to quantify the percentage weight of each heavy mineral. The placer occurrences in the Rias Baixas show great potential for CRM accumulation, especially close to the sand and crystalline rock substrate contact at the beaches, and in depositional centres in shallow waters areas.

Magnetite concentration in serpentinite from the Central Indian Ridge, a tracer of natural H2 formation

Wonnyon KIM[1]*, Korea Institute of Ocean Science & Technology (wkim@kiost.ac.kr)
Jihye OH[2], Korea Institute of Ocean Science & Technology
Jonguk KIM[3], Korea Institute of Ocean Science & Technology

Abstract

Natural hydrogen is attracting global interest as a potential future clean energy resource. While numerous studies have investigated its generation and potential terrestrial reservoirs, our understanding of hydrogen production in the ocean remains limited. Much of the existing research has focussed on the hydrogen ecosystem associated with the hydrothermal vents. It is well known that olivine and pyroxene in ultramafic rocks form serpentine minerals upon reaction with seawater or hydrothermal fluids, leading to the formation of magnetite and hydrogen as by-products. Consequently, the quantification of magnetite generated during this reaction can serve as an indicator of hydrogen production by employing relevant mineral chemical equations. In this study, we collected serpentinized rock samples using the ROV from the Cheoeum Vent Field and Onnuri Vent Field areas in the Central Indian Ridge. To identify the magnetic properties of serpentinite, we conducted various rock magnetic measurements on the prepared samples. The saturation magnetization (Ms) of stoichiometric magnetite is always 92.36 Am2kg-1. The magnetite concentration within a sample can be estimated by normalizing the sample's Ms with the Ms of magnetite. Notably, ferrous oxide (FeO) within olivine has no magnetic remanence, thereby allowing the Ms of serpentinite to reflect the concentration of newly formed magnetite. The calculated magnetite concentration ranges from 0.76 to 3.74 wt.%. Furthermore, there was a strong correlation (r2 = 0.87) observed between Ms values and easily measurable magnetic susceptibility. Analysis of magnetic hysteresis and first-order reverse curve revealed the presence of single-domain magnetite and its weathering trend towards coarsening grain-size and increasing coercivity. Under the microscope, the magnetite aggregates formed along micro-fractures of serpentinite, displaying distinct euhedral shapes. Comparison with serpentinization degree, as inferred from densities, indicated that significant magnetite formation occurred after reaching ~70% serpentinization.

The comparative analysis of rare earth oxide amount in terrestrial ore deposits and deep-sea sediments

Hyosang KWON[1]*, Korea institute of Geoscience and mineral resources (khs9419@kigam.re.kr)
Yuri Kim[2], Korea institute of Geoscience and mineral resources
Yoon Mi Kim[3], Korea institute of Geoscience and mineral resources

Abstract

Rare earth elements and Yttrium (REY) are crucial strategic resources for highly advanced technologies. However, given the heavy reliance on China for most REY resources, there is growing interest in deep-sea REY to overcome the potential risk to the global supply chain. In this study, we conduct a comparative analysis of REY concentrations and enrichment mechanisms of the REY in the terrestrial ore deposits and deep-sea mud in the Pacific Ocean to understand the differences in REY distribution patterns between terrestrial and ocean. Comparing the Bayan Obo mine, which is classified as a carbonatite-related REY deposit, and the Hongcheon deposit with the Southwestern Pacific, the total contents of REY oxides are higher in the terrestrial deposits. However, a detailed comparison of the REY component shows that the HREE/LREE ratio in the Southwestern Pacific is found to be 56 times higher than the Bayan Obo Mine in China and 18 times higher compared to Hongcheon. In addition, seafloor sediments in the Southeast Pacific host 15-27 times higher La/Dy ratios and about 78-140 times enriched in Y concentrations than terrestrial deposits. While the content of rare earth oxides is much enriched in terrestrial deposits, the ratio of economically valuable HREE in deep-sea sediment is higher, suggesting the need for further consideration of the REY resource development in the ocean.

Depth-dependent variations in paleoceanographic records of the ferromanganese nodules in the Arctic Ocean: High-resolution Raman spectroscopic study

Sangmi LEE[1]*, Department of Geology , Gyeongsang National University, Korea. (sangmi@gnu.ac.kr)
Hyo-Im Kim[2], Department of Geology and Research Institute of Molecular Alchemy, Gyeongsang National University
Hyen Goo Cho[3], Department of Geology, Gyeongsang National University
Hyo Jin Koo[4], Pusan National University

Abstract

Ferromanganese nodules, which are the aggregates of diverse metallic elements (e.g., Mn, Fe, Ni, and Co) formed by precipitation from the aqueous system, serve as critical archives for reconstructing paleoceanographic records. Determining the chemical compositions and the mineral species within concentrically growing structures in the ferromanganese nodules can provide invaluable insights into environmental factors such as the oxidation state of the aqueous system, temperature, and pH. Recently, it has been confirmed that the substantial amount of ferromanganese nodules in the shallow water regions of the Arctic Ocean, are notably sensitive to climate variations. These nodules have been observed in the East Siberian Sea at depths ranging from approximately 70 m to 250 m. Recent microscopic and XRD studies have reported that the external morphology, internal structure, and bulk mineral compositions vary with the water depths, suggesting that the geochemical conditions may differ depending on the water depths. We performed the high-resolution Raman spectroscopy, a powerful tool for examining the manganese oxide mineral species at several micrometer scales, on the natural manganese nodules collected from different depths from 73 to 240 m in the East Siberian Sea. To observe the internal textures and the distribution of chemical compositions, the scanning electron microscope (SEM) and electron microprobe (EPMA) were also performed. Note that the porous texture is more prevalent in the nodules from deeper depths. The Raman results show the distinct variations in the mineral species from central to the outer rim parts regardless of the water depths: notably, the todorokite (i.e., tunnel structure) is predominant in the central part, while the birnessite (i.e., layer structure) is prevalent in the outer rim part. However, the trend in the transition from todorokite to birnessite varies with the water depth. Combining the SEM and EPMA results, the detailed Raman profiles of mineralogical variation with varying samples are somewhat correlated with their internal structure. The observed variations in the mineralogical and textural characteristics in the ferromanganese nodules from the varying depths will be helpful for unraveling the paleoceanographic conditions in the Arctic Ocean.

Abstract

The transition to renewable energy and the acceleration of technology demand vast amounts of hi-tech metals that are critical in green energy technology. More than 10% of Finland's sea areas are covered by a layer of ferromanganese concretions, centimeter-scale accumulations of iron and manganese oxides. In addition to iron and manganese, concretions contain hi-tech metals, such as cobalt. Due to increasing demand for hi-tech metals near future, companies will likely start mining concretions from the Baltic Sea. The porous concretions host diverse microbial communities that regulate metal and nutrient cycling in the concretions. It is crucial that the seafloor ecosystem is not damaged while concretions are extracted. This study provides information on Baltic Sea Fe-Mn concretion growth rates and conditions in laboratory experiments. We collected the ferromanganese concretions from the Gulf of Finland in 2022 for a 12-week laboratory incubation and metal tracer experiments. Triplicate concretion and one abiotic control sample were collected into bottles containing artificial brackish seawater and incubated in the dark at +5 °C in an orbital shaker at 100 rpm to imitate seafloor conditions. Bottles were sampled at the beginning and the end of the 12-week incubation experiment. We measured the headspace methane concentrations and pH of the incubation solution. We analyzed the concretion growth with X-ray computed tomography and freshly formed concretion material with a scanning electron microscope. We measured total phosphorus and metal concentrations (Mn, Fe, Co, V, Ni, Zn, Mo) of the incubation solution with triple quadrupole ICP-MS. Our results showed that concretions grew in laboratory conditions, and new growth was close to 10 um within 12 weeks. Headspace methane concentrations decreased in all samples after an incubation but least in abiotic controls, where the microbial activity was eliminated. This indicates that microbes living on the surface of concretions utilized methane. Metal concentrations in the abiotic controls increased more than in the biotic triplicates after a 12-week incubation, indicating that metals dissolved from Fe-Mn concretions into the incubation solution faster without the activity of microbial communities. Here, we propose that microbes occupying the concretions have an important role in the concretions' growth and the factors affecting the accumulation and release processes of metals. This work was

supported by the Finnish Natural Resources Research Foundation and the Research Council of Finland (Fermaid project, grant 332249).

Abstract

The Canary Islands seamount province counts with hundreds of seamounts and submarine hills located in the area around the islands. The seamounts located in the south-west stand out for their Late Jurassic/Cretaceous age (146-72 Ma), great surface area and presence of mineralizations with potential economic importance.

For this research, forty-three cobalt rich Fe-Mn crusts have been selected as representative of the crust deposits on the slopes and summits of eight seamounts (Las Hijas, Bimbache, Amuley, Gaire, The Paps, Echo, Drago and Tropic) between 1600 and 5000 m water depth.

The analyses have shown that the crusts are dark brown to black, porous and fragile, formed by the accretion of thin laminae (<50 microns) that are packaged according to two main structures: sub-parallel and dendritic. Bulk mineralogy is dominated by Mn oxides (Fe-vernadite, birnessite, todorokite, buserite/asbolane), intergrown with Fe oxyhydroxides (goethite group). In addition, there is the presence of small amounts of accesory minerals represented essentially by silicates, carbonates and authigenic phosphates.

The geochemistry obtained reflects the main mineralogy, showing high average contents of Fe (25%) and Mn (17%) and lower amounts of the other major elements (in total <15%). Among the trace elements, crusts are rich in many critical and strategic elements with high average content of Co, Ni, Cu, V, Mo, Te, REYs and PGE (5000, 2300, 600, 1000, 450, 40, 3000 µg/g 240 ng/g respectively). Different discriminant diagrams given for almost all crust a hydrogenic origin. The calculation of growth rates and age using the "cobalt chronometer equation " in bulk samples supports this hydrogenetic origin for studied crusts, with very low growth rates (1-2 mm/Ma) and ages between 7 and 110 Ma, confirmed with EPMA transect analyses with ages reaching 90 Ma.

The high-resolution analyses allowed to know the Fe-Mn crusts in detail. Mineralogical analyses

have been obtained in solid samples micro mineralogical analyses (micro-XRD, Raman and FT-IR) resulted in the presence of intergrown vernadite, buserite, asbolane or todorokite. These minerals have been confirmed by transmission electron microscopy analysis, in which Mn oxides with interlaminar spacing between 9 and 10 Å have been recognized.
High-resolution geochemical analyses carried out directly on the Fe-Mn oxyhydroxide laminae using EPMA and LA-ICP-MS. In this way, laminae formed by buserite, asbolane or todorokite have a higher content of Mn, Ni and Cu (respectively more than 50, 6 and 2%) and lower content of Fe, Co, REYs and Te (respectively 2-3% and 1000, 160 and 1 μg/g on average). Vernadite laminae present similar contents of Fe and Mn (18 to 24 %) and high contents of Co, REYs and Te (up to 1, 0.5% and 200 μg/g).
The pilot hydrometallurgical experiments have shown high recovery rate of strategic elements Co, V and REY (between 60 and 80 %) resulting in a possible recover of 350, 60 and 200 T of these elements in one square kilometer of the summit the Tropic Seamount. compared to samples in which only ferric vernadite was found (81 and 70 %).

Bayesian linear regression with Gaussian mixture likelihood for outlier detection of metal grades

Yufu NIU[1]*, CSIRO Mineral Resources (yufu.niu@csiro.au)
Mark Lindsay[2], CSIRO Mineral Resources
Richard Scalzo[3], CSIRO Data61
Peter Coghill[4], CSIRO Mineral Resources
Lequn Zhang[5], CSIRO Mineral Resources
Kunning Tang[6], School of Minerals and Energy Resources Engineering, University of New South Wales

Abstract

High-grade porphyry Cu deposits are being exhausted. The falling head grade of ore aggravates the burden of mining industries because of the higher expenditure for dealing with waste. Ore sorting has the capacity to sort ores with high-grade Cu from barren rock, thus reduce the downstream operation cost, transport cost, and environmental footprint, thus improving the profitability and sustainability of mining operations.

Ore sorting can rapidly measure average key metal grade for pods of ores on a conveyor belt. However, the measurement of other metal grades are also critical for the optimisation of the subsequent mineral processing. Because of measurement error, latent geological features, and natural heterogeneity, data usually have outliers. When inferring related metal grades in mineral processing, outliers can produce significant bias and interfere related decisions such as chemical dosage and water/energy expense. Therefore, it is crucial to detect outliers for metal grade inference.

We present a Bayesian linear regression model with Gaussian mixture likelihood to identify outliers for the relationship of Cu and Fe grade in porphyry Cu deposit. Mine block model was used to split data for inferring local grade. Results show the proposed model can dramatically reduce mean square error, thus offer more accurate inferences than maximum likelihood estimation. Results also indicate that outliers may be crucial when planning mining operations. This method provides a reliable way to capture outliers in linear relationship of metal grades. This is particularly useful for mineral inference in ore sorting and decision-making in downstream mineral processing.

Multiscale variance prediction of metal grade for sortability assessment of bulk ore sorting in Cu deposit

Yufu NIU[1]*, CSIRO Mineral Resources (yufu.niu@csiro.au)
Lequn Zhang[2], CSIRO Mineral Resources
Peter Coghill[3], CSIRO Mineral Resources
Mark Lindsay[4], CSIRO Mineral Resources / Mineral Exploration Cooperative Research Centre, Centre for Exploration Targeting, School of Earth Science, The University of Western Australia / ARC centre for Data Analytics for Resources and Environments (DARE)
Kunning Tang[5], School of Minerals and Energy Resources Engineering, University of New South Wales

Abstract

Average Cu grades are decreasing as most Cu deposits have exhausted their high-grade ores leading to mining producing more waste. A solution is required to reduce waste levels while maintaining Cu production. Bulk ore sorting can rapidly estimate the grade of ore on a conveyor belt using a magnetic resonance technique that has been successfully used to detect chalcopyrite amongst the waste minerals at the scale of a few tonnes of ore. However, not all deposits are sortable due to the deposit type, heterogeneity of minerals, and spatial grade distribution. This raises a question: how do we determine the sortability of a deposit? Grade variability as a function of scale is the primary attribute to evaluate the sortability of a deposit. Bulk ore sorting falls between the intensively studied scales of variation at a block level of 1000s of tonnes and the sub-gram liberation scale. Where applicable all scales of variation can be used to improve ore processing efficiency.

In this study, we applied non-linear regression methods to estimate the relationship between tonnage scale and the variance of Cu grade by a sequence of geochemical data collected from bore core data characterising a sedimentary-hosted Cu deposit. The bore core data was used to calculate the variance of Cu grade at “small” (<1 Ton) and “large” scales (>10000 Ton). Then, the variance of Cu grade was predicted at a sortable scale (2 - 300 Ton) from model inference. The corresponding magnetic resonance data was utilised to validate model accuracy. Results show that our model can accurately predict grade variance at a sortable scale. The predicted grade variance at sortable scale can help stakeholders and engineers determine whether a deposit is sortable or not before installing bulk ore sorting sensors. Thus, the related decisions can be made from there. The methodology developed can be applied to other resources and may be used to estimate the potential returns of bulk sorting and hence whether it is likely to be economical. As more deposit and mining types have bulk ore sorting applications a comprehensive model can be developed for use in green field sites.

Enhancing named entity recognition in geoscience by using a domain-specific schema

Sandra Paula VIILLACORTA CHAMBI[1]*, CSIRO (sandra.villacortachambi@csiro.au)
Mark Lindsay[2], CSIRO
Helen McFarlane[3], CSIRO
Klaus Gessner[4], Geological Survey of Western Australia
Erin Gray[5], Geological Survey of Western Australia

Abstract

Sparse or non-unique data, subjective or hyper-localised observations, and linguistic ambiguities have historically hindered communication or interrogation of geoscience-related concepts and models. In the context of mineral systems analysis, it is both scientifically and economically valuable to establish a coherent framework and vocabulary that precisely describes the geological phenomena and their relationships involved in ore deposit potential.

Accurate classification of geological entities is not only beneficial for enhancing human understanding of scientific research publications, but is pivotal for machine learning applications, such as summarising research papers in ways that enable swift and impartial analysis. Natural Language Processing (NLP) plays a critical role in this context, with Named Entity Recognition (NER) as a crucial NLP component. The efficacy of NER, however, is significantly influenced by the specific context of its application. In the geoscience domain, the successful implementation of NER requires additional support from tailored specialised ontologies and schemas. Moreover, the integration of advanced NER techniques, customised for the complex geoscience literature, is essential to optimise automated NER processes. Such optimisation is crucial for expediting the development of geoscience knowledge graphs, tools explored for enhancing the capability for rapid and objective analysis through visual representation.

This paper describes the development of a specialised geoscience schema aimed at improving the accuracy of geological entity classification. In this CSIRO Pilot project, we tested Flair, a proven effective algorithm in complex fields like medicine. The Flair NER accuracy was evaluated by analysing geoscience corpora obtained from Portable Document Format publications on iron deposits in Western Australia; using GeoIELite, a schema deployed to create geoscience knowledge graphs. This exercise provides insights into improving the precision of NER in geoscience and underscores the broader significance of standardised vocabularies in enhancing data management and analysis within geosciences.

Identifying and Quantifying Indirect Trade Flows of Commodities

Jamie BRAINARD[1]*, US Geological Survey (jbrainard@usgs.gov)
Andrew Gulley[2], US Geological Survey
Nedal Nassar[3], US Geological Survey

Abstract

Tracking international mineral commodity trade is crucial for evaluating supply risk. Evaluations of mineral supply risk often consider import reliance on import partners as a measure of exposure to potential supply disruptions in those countries. However, inspection of United States (U.S.) import data reveals trade flows where reported import partners do not produce the relevant mineral commodity. These findings imply that these countries instead serve as intermediaries in an indirect trade network. The potential for trade to impact national policy necessitates identification of these discrepancies to more accurately capture the physical flow of goods. Here we develop a network analysis methodology to: 1) map indirect trade networks back to original producers, 2) quantify indirect trade, and 3) compare indirect trade with direct imports (as reported in the trade data). While this method could be applied to any mineral commodity (or other good), we apply it here to the supply chains for aluminum and antimony because of their inclusion on the 2022 U.S. Federal Critical Minerals list.

By using this method, in one instance we were able to increase the attribution of U.S. imports of antimony ores to mine producers by >77% over the reported direct imports in one study period. These results indicate that discrepancies between direct and indirect trade appear to correlate with the volume and value of commodities traded, with bulk commodities having less indirect trade. We also show how this methodology can be linked across multiple commodity forms moving downstream from mining. This approach enables us to better estimate the provenance of the initial mined material that has been later transformed via processing .

Leveraging Bayesian Hierarchical Models to Mitigate the Impact of Mineral Exploration Uncertainty on the Mineral Value Chain

Lequn ZHANG[1]*, CSIRO (lequn.zhang@csiro.au)
Mark Lindsay[2], CSIRO
Yufu Niu[3], CSIRO
Jingxu Jin[4], Macquarie University
Sandra Occhipinti[5], CSIRO

Abstract

The minerals value chain encompasses a broad spectrum of activities each contributing to the supply of metals sustaining global socioeconomic structures and supporting net-zero initiatives. These activities, such as mineral exploration, stockpiling, processing and selling in the end market, are subject to internal and external factors that affect the reliable and consistent supply of metals. The cumulative effect of these factors leads to significant uncertainty that impacts the final value of metal products.

Mineral exploration, the starting point of the minerals value chain, significantly influences subsequent stages by introducing uncertainty that affects decision-making and operational efficiency. This phase is crucial for developing resource models, which are essential for accurately capturing geological, mineralogical, and economic parameters of mineral deposits. These models are fundamental to mine planning and feasibility analysis, aiming to optimize extraction and enhance the economic value of mining projects. However, the complex nature of ore bodies, combined with the reliance on incomplete and often error-prone datasets, presents a substantial challenge, leading to increased uncertainty in resource estimation.

To address this challenges, this paper advocates the adoption of Bayesian Hierarchical Models (BHM) as a powerful tool for mitigating the uncertainties when model resource from mineral exploration data. Existing resource models often rely on grade and density estimates derived from a limited number of samples, which are seldom representative of the true geological heterogeneity of the mineral deposit. This lack of representativeness can lead to significant inaccuracies in tonnage estimates, potentially resulting in over- or underestimation of the available resources and directly impacting the economic evaluation and operational planning of the mining project. By using BHM model, the knowledge, such as lithology, alteration, block can be included in the models as the prior information, which provide a robust framework for the resource models.

A case study on a porphyry copper deposit illustrates the practical effectiveness of our proposed approach in a near-mine senarios. The results from this study demonstrate that the hierarchical model significantly reduces the resource model uncertainty, thereby enhancing the accuracy of resource estimation and improving the reliability of decision-making processes throughout the mineral value chain.

[Keynote] Fundamentals Enabling Integrated Mining Value Chains

Kerry TURNOCK[1]*, BHP (kerry.turnock@bhp.com)

Abstract

The mining value chain is a complex, multifaceted system that accounts for activities from resource identification through to closure. Whilst often represented simplistically, it spans a multitude of disciplines, behaves in a nonlinear fashion, and is required to support simultaneous decision making over different time horizons and spatial entities.

The integrity of the mining value chain is relative to its capability to predict, respond and react to a range of questions and requirements that support trade-off decisions between optimisation and execution. Maintenance of value chain integrity requires a high degree of integration which, in turn, is only successful when it is multidisciplinary and accounts for data, systems, processes, people, technology, and timescales.

Advancements in automation, simulation, artificial intelligence, robotics, and interoperable platforms in support of the mining value chain are continuing to define and redefine the way we do business. However, the aspiration to capture the benefits of these advancements can only be achieved when they are anchored to sound basics.

A common attribute of reliable, integrated mining value chains is that they are underpinned by robust fundamentals. These fundamentals include:
1. Timely, reliable and trusted data
2. Decision making capability that accounts for uncertainty and variability
3. Systems that are able to integrate and consume multidisciplinary inputs
4. Probabilistic planning and
5. Unbiased representation of the real world that has not been oversimplified.

Investing in the above fundamentals adds significant value for a mining operation. It enables design and planning optionality, improves our understanding of risk and supports rapid, confident and superior decision making across the entire value chain from exploration to closure.

Overview of key Mineral requirements in the era of Intelligent vehicles: taking Software-defined vehicles as an example

Zizhan CHEN[1]*, CAGS (cdesignf1@hotmail.com)

Abstract

The rise of intelligent automotive technologies, particularly Software Defined Vehicles (SDVs), has prompted increasing demand for a range of critical minerals. These minerals—such as lithium, cobalt, copper, gallium, germanium and rare earth elements—are indispensable for manufacturing advanced automotive batteries, electric motors, and various electronic components integral to SDVs.

In the context of this surge in demand, this paper examines the relationship between the evolution of smart cars, specifically SDVs, and the consequent impact on global mineral resources. We start by mapping out the demand trends for crucial minerals necessitated by SDVs, dissecting the primary drivers behind this escalated need, including the proliferation of electric vehicles (EVs) and autonomous driving technologies.

These trends lead us to consider the implications for the mineral supply chain. Notable concerns in this sphere include potential supply risks, geopolitical tensions arising from the scramble for resources, and the environmental repercussions of increased mining activities. Additionally, we delve into sustainable strategies like the circular economy and mineral recycling, which have the potential to mitigate reliance on freshly mined resources and minimize environmental degradation.

The examination provided here aims to supply a comprehensive understanding of the key mineral demand landscape in the age of intelligent vehicles and proffers considerations for addressing the associated challenges. As technical advancements continue and policy landscapes evolve, strategies that focus on material efficiency, bolster recycling practices, and enhance supply chain transparency and resilience will be pivotal in ensuring sustainable supplies of these critical minerals.

Through this synthesis, we aspire to shed light on the pathways available for managing the demands of an industry at the forefront of technological innovation while considering the finite nature of the resources it relies on. With the continuous advancement of technology and the adoption of responsible resource management policies, a balance is achieved between the development of the intelligent automotive industry and the optimal utilization of critical minerals.

Quantitative assessment of exploration criteria: A case study from the Yilgarn Craton in Western Australia

Mosayeb KHADEMI[1]*, Mineral Exploration Cooperative Research Centre (MinEx CRC) and University of South Australia (mosayeb.khademi_zahedi@mymail.unisa.edu.au)
David Giles[2], University of South Australia and Mineral Exploration Cooperative Research Centre (MinEx CRC)
Mark Lindsay[3], Mineral Exploration Cooperative Research Centre (MinEx CRC) and CSIRO - Mineral Resources
Caroline Tiddy[4], University of South Australia and Mineral Exploration Cooperative Research Centre (MinEx CRC)
Andrej Bona[5], Mineral Exploration Cooperative Research Centre (MinEx CRC)

Abstract

Mineral exploration requires a process to systematically reduce the exploration volume whilst maximizing the chance of success. Most exploration programs make volume reduction decisions in a qualitative way based on expert assessment of multiple, disparate datasets and geological concept. In this talk we present a quantitative method to assess the performance of key mineral exploration criteria using a case study from the Yilgarn Craton gold province in Western Australia.

We conducted Capture-efficiency and Receiver Operator Characteristic (ROC) analyses, seeking the exploration criteria which result in the maximum number of deposits per target volume. Capture-efficiency plots have axes of known deposits contained within the search criteria versus fractional volume (in this case simplified to area) of the search criteria. ROC plots have axes of "True Positive Rate" (known deposits contained within the search criteria) versus "False Positive Rate" (unsuccessful drill holes within the search criteria). We tested four regional-scale search criteria identified as the most useful by Witt et al. (2013), namely; i) within greenstone belts, ii) proximity to mafic granites, iii) increased fault density areas, and iv) proximity to fault bends. We also included proximity to maximum downhole Au grades >2 ppm for Witt et al. (2015), which is more appropriate to camp-scale exploration. The locations of known gold deposits were used as positive instances in the ROC analysis, while the locations of unsuccessful drill holes, outcropping and bedrock granites were set as negative instances.

In both the Capture-efficiency and ROC methods, the most effective search criteria (in scale order) were: inclusion within greenstone belts (30% area containing 94% known deposits), within 10 km of mafic granite (14% area, 58% deposits) and within 1 km of maximum downhole Au grades >2 ppm (15% area, 73% deposits).

Contrary to some popular exploration models, fault density and proximity to fault bends proved inefficient as search criteria. Maximum Capture-efficiency for these criteria occurred using buffer

distance of ~20 km, which is geologically unreasonable for faults. Given the well-established structural controls on gold mineralization in the Yilgarn, the poor performance of structural criteria in this study most likely reflects our inability to map faults and shear zones in an accurate and unbiased way.

The area under curve of the Capture-efficiency plots was consistently higher than for the ROC plots. This is a predictable outcome resulting from the assumption that any area outside the search criteria is a 'true negative' in the Capture-efficiency method, whereas only unsuccessful drill holes outside the search criteria are 'true negatives' in the ROC. Thus, the lack of drilling outside the known greenstone belts means that the large volume occupied by granite belts is 'untested' - as accurately illustrated in the ROC analyses. This highlights two challenges of 'data driven' mineral exploration techniques; 1) difficulties in areas of sparse or uneven data distribution and, 2) susceptibility to conceptual exploration models which result in sparse or uneven data acquisition, i.e., our conceptual models drive how we invest in surveys particularly in perceived lower exploration potential areas.

Phosphogypsum stacks from Năvodari (Romania) as secondary resource

Aurora Maruta IANCU[1]*, Geological Institute of Romania (iancu.maruta@yahoo.com)
Stefan MARINCEA[2], Geological Institute of Romania
Cristina SAVA GHINET[3], Geological Institute of Romania
Delia Georgeta DUMITRAS[4], Geological Institute of Romania

Abstract

The phosphogypsum (PG) stacks occupies significant areas in Romania: four important deposits, i.e., Turnu Măgurele, Bacău, Valea Călugărească and Năvodari (Romania), extends for more than 182 hectares. These deposits, in spite of their negative influence on the environment, constitute an important raw material resource, especially for road projects or plaster industry.

The phosphogypsum stacks from Năvodari are located westward from the homonymous town, on an area of 48 ha. They represent the by-product of a local phosphate fertilizer plant, now inactive.

The physical-chemical characteristics of the PG deposits depend on the composition and characteristics of the raw phosphate rock, and of the sulphuric acid used for attack. At Năvodari, the dihydrate process was used for PG production. The work temperature was of about 80oC, leading to the formation of H3PO4 acid with a P2O5 concentration between 28 - 32% and of phosphogypsum as by-product. The mineralogical composition of PG includes gypsum ($CaSO_4 \cdot 2H_2O$) and secondary brushite ($CaHPO_4 \cdot 2H_2O$) as main crystallized phases, with remnants of quartz and additional calcite issued by the lime added as acid compensator. The qualitative chemical composition of the main phase, resulted as average of 18 EDS point analyses, is (in wt.%): Ca = 45.33 – 66.20, (SO4)2- = 39.40 – 53.21, and (PO4)3- = 0.84 – 7.21. Chemical analyses by ICP-AES method mostly indicate siderophile elements such as V, Cr, Ni, Cu, Zn, Zr, Pb, Th. The presence of these elements can be correlated with the chemical composition of the raw phosphate rock, as well as with the presence of Fe and Al. These are derived at acid pH conditions from sesquioxides of initial phospathic mineral. Another series of elements such as Cd, Cr, Ba, Mg, Na and K can substitute Ca in gypsum structure.

ICP-AES chemical determinations of minor elements pointed out higher contents for Sr (800-1500 ppm), while the elements such as transitional metals have low contents: Cd: 1.0 – 2.2 ppm, Cr: 2.1 – 17 ppm, Ni: 1.8 – 7 ppm, Pb: 3.7 – 33 ppm, Zn: 12 -34 ppm. The REE+Y contents are relatively low: Er = 1.8 – 7.8 ppm, Y = 37 – 114 ppm and La = 15 – 140 ppm. Minor contents of Cu (43 – 142 ppm), Zr (46 – 160 ppm), Sc (0 – 12 ppm) and Co (3 – 32 ppm) were also detected. Taking into account that no harmful elements were detected and the radioactivity is low, we propose the use of the stack for road construction.

Abstract

Cobalt (Co) and nickel (Ni) are essential components in the cathode production of lithium-ion batteries. As the global electric vehicle market grows, the demand for Co and Ni in rechargeable batteries is rapidly rising. The Ni-Co supply chain is complex due to uneven geographic distribution of primary sources, the wide variability of deposit and ore types necessitating distinct refining processes and their manufacturing demands. The ability to identify the geographic origin of Ni and Co metals is critical to ensure a responsible value chain from ore to battery yet it is challenging due to complexity of the supply chain. Magmatic sulfide deposits are one of the primary sources for Ni and Co, and are mostly found in Canada, Australia, Russia as well as Finland. Finland also offers a close-loop value chain from mining and refining to recycling of batteries.

In this study, we analysed raw ores, mineral concentrates, as well as various metallurgical products sourced from a mine in northern Finland, which is a major Ni-Cu-PGE resource in the Central Lapland greenstone belt. We used a field emission scanning electron microscope (FESEM) to acquire high-resolution mineral feature maps and determine major to minor chemical compositions of the target minerals. Trace element contents and sulfur isotope ratios in sulfide grains, e.g., chalcopyrite, pyrite, pyrrhotite and pentlandite were then measured in-situ with laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS). Metallurgical processed samples such as solid residues and leachate solutions (evaporated to dry powders), iron-removed samples, and nickel sulphate powders, were prepared as pressed pellets and their trace elements and sulfur isotopic compositions were directly analysed in-situ by LA-ICP-MS. Finally, the trace element compositions and sulfur isotope ratios of these samples were compared by multivariate data analysis to extract robust fingerprints that possibly remained conservative along the value chain. The effect of extractive and refining metallurgy processes in altering geochemical signature of the original ore deposits are also evaluated. By a combined application of mineralogical and geochemical analytical techniques, we aim to develop a geochemical fingerprinting tool to trace Ni and Co from the original mining ores to the end products. The outcome of this research helps to improve transparency and sustainability of raw material supply along the battery value chain.

Soil organic matter loss due to anthropogonic activities in settlement area in Forest steppe and Gobi region of Mongolia

Telmen TURMUNKH[1]*, Department of Earth and Environmental Sciences, Korea University (telmen808@gmail.com)
Ganzorig Ulgiichimeg[2], Institute of Geography and Geoecology, MAS
Seong-Taek Yun[3], Department of Earth and Environmental Sciences, Korea University

Abstract

Physical, chemical and biological properties of soil are closely related to soil organic matter (SOM) that considered one of the main indicators for soil health. Recent human activities contribute significantly to land degradation and soil erosion, particularly in urban areas due to the concentration of population, industry, and construction. Therefore, monitoring of SOM is needed as a simple and cost-effective way to assess land degradation and erosion. This study aimed to investigate the status of the SOM loss in settlement areas located within the climatically and topographically distinct, Forest Steppe and Gobi regions of Mongolia and compare the impact of urbanization on SOM across the contrasting Mongolian natural zones. To quantify SOM loss, surface soil samples were collected from seven settlement areas, alongside reference sites from fenced weather stations and near undisturbed areas. Our investigation revealed significant difference in SOM loss between natural zones. In the Gobi region, SOM loss ranged from 10% to 60% compared to reference sites, with an average decrease of 39% due to urbanization. The Forest Steppe showed a sharper decline, experiencing an average loss of 63%. While both regions have significant loss in SOM, the Gobi showed greater variation between settlements, with a coefficient of variation reaching 56%. This observation highlights more complex interactions of factors influencing SOM content in the Gobi region compared to the Forest Steppe. The inherently lower SOM content in the Gobi region (1.7%) compared to the Forest Steppe (3%) suggests a fundamental difference in ecosystem functioning between these regions. Soil organic matter loss provides general overview of land degradation in the two regions; however, it may not assess the full complexity of land degradation and soil erosion processes. To enhance understanding and achieve a more accurate assessment, this study suggests the integration of multiple soil properties and methodologies.

Geometallurgy for the Energy Transition

Kathryn Goodenough[1]*, British Geological Survey (kmgo@bgs.ac.uk)
Richard Shaw[2], British Geological Survey
Eimear Deady[3], British Geological Survey

Abstract

In recent years, substantial focus has been placed on the critical raw materials, particularly those required for the transition to a decarbonised energy system. These include the battery raw materials, such as lithium, cobalt, graphite, nickel and manganese; the rare earth elements, used for high-strength magnets; and a variety of other metals required for electrification of energy systems. Although recycling approaches are developing rapidly, currently these raw materials are largely derived by mining of primary resources; and demand is expected to grow over the coming years, leading to investment in the opening of new mines. It is common for exploration companies to present ‘headline’ data on their resources in the form of grade and tonnage information, but for many of the critical raw materials, geometallurgical information is also essential. Energy transition technologies require high-purity mineral products, and processing routes to achieve this are variably developed for different ore minerals. Thus the details of ore mineralogy and texture are vital to the economics of critical raw material deposits, and description of mineral paragenesis is essential to the characterisation of any deposit. This talk will give an overview of some of the challenges in critical raw material supply chains, and will describe case studies that highlight the importance of geometallurgy.

The processing behaviour of the sphalerites from the Big Syncline deposit, South Africa

Gloria Boikanyo MOTLOBA[1]*, University of Johannesburg (beekay.motloba@gmail.com)
Albertus Johannes Smith[2], Department of Science and Innovation-National Research Foundation Centre of Excellence 5 in Mineral and Energy Resource Analysis, Department of Geology, University of Johannesburg
Karel Viljoen[3], Department of Geology, University of Johannesburg
Derek Rose[4], Mineralogy Division, MINTEK

Abstract

Big Syncline is the only one of the four Aggeneys-Gamsberg Ore District deposits of the Northern Cape Province of South Africa that remains unexploited. It comprises economic zinc > lead > copper mineralization. Future exploitation of this deposit requires a good understanding of the ore textures and mineralogy for beneficiation purposes. In accordance, two of the most commonly occurring mineralized units at Big Syncline, the mineralized pelitic schist and garnet-magnetite units, are investigated with regards to sphalerite petrography and mineralogy and its potential impact on zinc flotation recovery and grade.

Detailed optical petrographic analyses revealed three colour variations in the sphalerite: the opaque (i.e., black) and ruby-red varieties prevalent in the mineralized pelitic schist unit; and the honey-yellow variety more common in the garnet-magnetite unit. Scanning electron microscopy with energy-dispersive X-ray spectroscopy and electron microprobe analyses indicated increasing iron content from the honey-yellow to ruby-red to opaque sphalerite varieties. The latter two varieties were also observed to have elevated manganese contents. Overall, elevated manganese content was observed only in the mineralized pelitic schist unit, despite the minor occurrence of the ruby-red sphalerite variety in the garnet magnetite unit.

Laboratory-scale differential flotation was applied to the two mineralized units to determine their processing behaviour. Despite poor selectivity, the garnet-magnetite unit produced a bulk zinc concentrate of superior quality to the mineralized pelitic schist unit. However, the latter showed better selectivity with the bulk of the zinc reporting to the zinc concentrate. The reduced overall quality of the mineralized pelitic schist unit concentrate is attributed to the increased dilution associated with the high abundance of gangue sulphides in the flotation feeds as well as the higher contents of iron and manganese and lower zinc in the sphalerite. Furthermore, the higher manganese content in these sphalerites leads to higher manganese recovery in the zinc concentrates, which can lead to later processing problems during electrowinning. Compared to the mineralized pelitic schist, the garnet-magnetite unit has less gangue sulphides in the feed and higher zinc in sphalerite leading to better concentrate grade. Although the garnet-magnetite unit has higher manganese content in the feed, it is hosted in silicates, leading to substantial manganese rejection to the tailings.

Abstract

Geometallurgic block models play a crucial role in optimizing mining operations, including metal production scheduling and cash flow management throughout the mine's lifespan. However, constructing accurate models for tin (Sn) mining operations faces challenges due to data scarcity and sparsity, leading to increased model uncertainty. This study proposes a methodology that integrates rock quality designation (RQD), lithologic, and geochemical information to address these challenges in Sn mining projects. By incorporating stochastic simulation methods such as sequential Gaussian simulation and indicator geostatistical techniques, we aim to improve the reliability of geometallurgic block models. RQD, a quantitative measure of rock quality, serves as a valuable indicator for detecting fracture zones, which are typically host to veins containing higher grades of Sn. Understanding the correlation between RQD and underlying geology is crucial for identifying areas of higher economic value and optimizing mineral exploitation. The study area, located in the Southeast Asia belt, is recognized for its potential Sn deposits. Utilizing data from 25 inclined boreholes, our research emphasizes the importance of integrating geostatistical methods with diverse data types to support informed decision-making in mining projects. This approach aims to minimize costs, maximize profitability, and enhance the sustainability of mining operations. In conclusion, the combination of geostatistical techniques and comprehensive data analysis holds significant promise for improving the efficiency and effectiveness of tin mining projects, ultimately contributing to the success and sustainability of the mining industry.

Abstract

Historical tailings storage facilities (TSFs) are being revisited everywhere in the World for their potential in commodities of recent interest, such as Indium, Lithium or REEs, as well as to mitigate their environmental risks. This interest has sparked the development of methods to quantify their value. In this contribution we present one such method for estimating both the grade and recoverability of target commodities, i.e. not just how much of the component is present in the tailings and where, but also how much is expected to be recovered with a specified minerals processing route.

The method exploits (i) particulate data from automated mineralogy systems (such as e.g. mineral liberation analysis, MLA) covering the TSF of interest, plus (ii) MLA analyses of the results of beneficiation tests on a handful of samples. A machine learning method (lasso regularised multinomial logistic regression) is trained on this second data set (ii) for predicting the chances of any particle to be recovered into the concentrate product as a function of its properties as measured by the MLA. This allows to calculate the expected proportion of mass of each component (both commodities and waste components) reporting to each output stream, not only for each MLA sample of the training set (ii) but also of the samples (i) from the TSF. These can then be interpolated with a geostatistical analysis.

We applied this framework to a TSF in the Ore Mountains, near Freiberg (Saxony, Germany). We applied an n-fold validation strategy, showing significant agreement between predictions and actually observed behaviour. This supports our claim that the proposed method has a strong predictive power.

Machine learning assisted geostatistical modelling of geometallurgical domains

Will Patton[1], BHP
Ute Anja MUELLER[2]*, Edith Cowan University (u.mueller@ecu.edu.au)
Emet Arya[3], Riotinto
Ilnur Minniakhmetov[4], BHP

Abstract

The spatial modelling of geometallurgical domains is important for the characterisation of an ore deposit allowing quantification of various rock types, their properties and the overall value of a project. To quantify uncertainty in the layout of various geometallurgical domains and ensure a proper representation of the heterogeneities in chemical and physical properties of the orebody, integrating machine learning techniques into geostatistical modelling workflows is becoming more common. Spatial machine learning techniques can be used to derive geometallurgical categories from multiscale, multiresolution and high dimensional measured rock properties. Here we show an application of the spatial random forest algorithm to define geometallurgical domains from geometallurgical test work data (oxide grades, mineral concentrations, and associated recoveries). The layout of geometallurgical domains and variabilities of associated rock properties are mapped with hierarchical truncated gaussian simulation. Geometallurgical properties in the form of size fraction recoveries can then be predicted using machine learning regression. Finally, uncertainties are quantified to assess risk following a confidence interval based framework. This approach can be used to identify zones of high uncertainty where collection of additional data might help mitigate or minimise risks and in turn improve forecast production performances.
The approach will be illustrated with an iron ore case study.

Analyzing Refractory Gold and Deleterious Elements in Historical Witwatersrand Tailings: Implications for Gold Extraction Strategies

Steve Jason CHINGWARU[1]*, Stellenbosch University (stevejayce@gmail.com)
Bjorn von der Heyden[2], Stellenbosch University
Margreth Tadie[3], Stellenbosch University

Abstract

The Witwatersrand Basin, recognized as the world's largest gold province (containing 53,000 Au), has generated over 6 billion tons of mine tailings throughout its century-long mining history. As the basin has matured in gold production, these tailings are concurrently subjected to metallurgical processing alongside primary gold ores, utilizing traditional cyanidation techniques for gold extraction. Despite these efforts, the tailings persist as strongly refractory, with an estimated 1325-1855 tons of gold remaining in tertiary tailings. The complete mineralogical distribution of this remaining gold is not thoroughly understood. This research concentrates on extensively characterizing the refractory properties of gold-containing Witwatersrand tailings from various spatially diverse goldfields, employing physical separation coupled with mineralogical and chemical analyses. The findings indicate that the heavy mineral concentrate exhibits a higher gold concentration ranging from 0.71 to 10.12 ppm, whereas the light (< 2.95 g.cm-3) and slimes (< 10 μm) fractions show gold concentrations of 0.05-0.22 ppm and 0.17-0.76 ppm, respectively. Further in-depth in-situ analyses and leach tests of distinct mineral fractions suggest that the gold is enclosed within the tailings' mineralogy in the form of 'invisible' or 'solid-solution' gold, predominantly within pyrite and arsenian pyrites, with concentrations ranging from 0.01 to 2730 ppm, accounting for up to 420 tons of gold (approximately 31% of the total gold). Additionally, the tailings' sulphides harbor a significant concentration of detrimental and critical heavy metals (e.g., As, Ni, Co, etc.). The identification of invisible gold presents a potentially underutilized resource, constituting a substantial portion (50-70%) of the refractory nature of gold. The primary Witwatersrand ores are renowned for their native liberated gold, which elucidates the refractory nature of the residual re-dump gold during traditional extraction. The outcomes of this study carry implications for mining practices, economic considerations, environmental concerns, optimization of processing flowsheets, and insights into the origin of the Witwatersrand.

ROLE OF IN-SITU TECHNIQUES IN IRON ORE MINERAL BENEFICIATION

Basanth Rath[1], NMDC Chattisgarh
P V SUNDER RAJU[2]*, CSIR-NGRI (perumala.raju@gmail.com)

Abstract

Banded iron formation (BIF) represents one of the most distinctive rock types that occurred widespread in space and time in the earlier part of the Precambrian in most of the shield areas of the world. India ranks 4th in terms of iron ore production with 246 million tons (MT) which is around 8% of the total iron ore production worldwide. High-grade ore consists of more than 62% Fe which mainly comes from Hematite (Fe-69.9%), Magnetite (Fe-72.4%), Goethite (Fe-62.9%), Limonite (Fe-60%) etc. As the demand for high-grade ore increases day by day, it can be estimated that the existing reserves may be exhausted in another 60-70 years. In Table 1 different minerals in varied ore types are shown and in such cases, the low and medium-grade ores (Fe-45%-62%) need to be utilized. To enhance the grade of any ore, the comminution process plays the main role in terms of creating an economically viable mineral beneficiation process. To achieve so, in-situ mineral characterization techniques such as light microscopy (LM), Scanning Electron Microscopy (EM), X-ray diffraction techniques, and Automated mineralogical techniques(Fig 1) help in getting sufficient and reliable data with accuracy and precisionin a very short time, the combination of various analytical techniques has been used and based on these data, suitable mineral beneficiation methods have been developed and adopted to a lab scale and pilot scale level and achieved the planned results which will be discussed during the presentation

Forms of ore bodies in the Pirmirab mine

Anzor MAKHAMMATOV[1]*, Institut of Geology and Geophysics named after H.M.Abdullayev. (anzormb97@mail.ru)
Mirali Turapov[2], Institute of Mineral Resources
Gulnoza Karamatova[3], Institut of Geology and Geophysics named after H.M.Abdullayev
Mirkomil Kuyliev[4], Institute of Geology and Geophysics named after Kh. M. Abdullaev

Abstract

One of the main goals of Uzbekistan's geology is to expand its gold mineral base. Therefore, we have tried creating a multi-factor model of several gold mines, one of which is the Pirmirab mine. Scientists at the Central Research Geological Prospecting Institute of Non-ferrous and Noble Metals introduced the method of creation of a multi-factor model of deposits [1]. We used geological forecasting and prospecting methods combined with geophysical and geochemical databases. A new model based on the following materials was made: 1) Geological map of the Chadak mining area 1:25000; 2) Geological structure scheme of Chadak ore field. A geological structure model of the Pirmirab and a geological block diagram of southern Pirmirab were created. A geological scheme of the Pirmirab mine and a model of ore bodies (multifactorial)was designed [2]. The created model shows that ore bodies in the Pirmirab deposit are developed at about 2.5 km2 in the central part and 2 km2; in the south, they narrow to 1 km2 and less. Determining the ideal shape of ore bodies confirms their morphological models based on the ratio of length and thickness. They are divided into three classes: Class I - 0-150 m in length, 0-50 m in length and thickness ratio; Class II - 150-300 m in length, 50-100 m in length and thickness ratio; Class III - more than 300 m in length, more than 100 m in length and thickness ratio [1]. Ore bodies are morphologically different in Pirmirab. Plate-like, columnar, and apophysical bodies are standard. In terms of location, it is subparallel to the Chadakbashi fault. The analysis of the structural model of the ore bodies shows that the concentration of gold in closed bodies is higher than in others. In the Pirmirab deposit, the width of the formation of the ore bodies narrow from the top of the area to the depth. It can be concluded that - represents a connection of the ore body system with a standard root part. According to geochemical information, the strong correlation of gold and silver indicates the abundance of electrum minerals in the area.

Abstract

Gold mining plays a significant role in the Philippines minerals industry. One of the most productive gold deposits in recent years is the Bonanza-Sandy vein epithermal system in Maco Mine, Masara Gold District in Mindanao island. However, despite its long history of productive mineral extraction, more recent ores extracted in the area have been reported to become more complex, which presents metallurgical challenges. This study therefore focuses on examining the refractory gold ore characteristics of the Bonanza-Sandy vein by utilizing both conventional and automated mineralogical techniques.

The NW-trending Bonanza-Sandy Vein system has three main ore types: hydrothermal breccia, quartz sulfide and quartz-carbonate veins. The gangue minerals predominantly consist of quartz, calcite, rhodochrosite, white mica (muscovite-illite) and chlorite. Pyrite is the most dominant sulfide, and often occurs as fragmented grains or occasionally as pitted and elongated minerals. Associated with pyrite are sphalerite intergrowths, galena inclusions, and sparse chalcopyrite grains. The ore manifests either as gold-silver tellurides (typically hessite or petzite), as electrum minerals or more rarely as native gold grains. Mineral liberation analysis (MLA) data reveals that a significant proportion of gold ore (~90%) is binary-locked or ternary-locked within pyrite, sphalerite, and chalcopyrite. Only a small proportion of the gold grains are in a liberated state. The results also indicate that 80% of the gold grains are smaller than 12 microns in size. Further ore characterization from sequential extraction will provide additional insights into the nature of the refractory gold ores. These findings can hopefully provide significant input to enhance ore recovery and design more efficient extraction strategies.

Controls on the formation of porphyry Mo, Cu and Au deposits in the Qinling Orogenic Belt, central China

Li TANG[1]*, China University of Geosciences Beijing (ltang@cugb.edu.cn)

Abstract

The Qinling Orogenic Belt (QOB) hosts one of the world-class porphyry Mo belts (proven Mo resource of 8.43 Mt), several porphyry-skarn Cu and Au deposits, and abundant barren granitoids. The Late Jurassic to Early Cretaceous mineralized and barren porphyry systems are broadly coeval and distributed in the eastern part of the QOB. The key factors controlling the porphyry fertility and diversity are not well understood, with magma source, magmatic water content, magma oxidation state, sulfur and halogen values, and nature of magma chamber, among other aspects. The fertile porphyries of Mo and Au deposits are characterized by enriched Sr-Nd-Hf isotopes, relatively low δ18O values of 4.58 to 8.65‰, abundant Neoarchean to Paleozoic inherited zircons and high apatite MnO contents, indicating a mixed magma sources from partial melting of the Neoarchean to Paleoproterozoic lower crust, subducted continental crust of the Yangtze Block and the metasomatized lithospheric mantle. The ore-forming porphyries of Cu (-Mo) deposits have depleted isotopic features and distinct magma source from partial melting of the Triassic juvenile lower crust with significant contribution of mantle derived mafic magma. We suggest that the lithospheric architecture and magma source are the primary controlling factors for the diverse Cu (-Mo), Mo (-W) and Au mineralization in Qinling. Chlorine and fluorine contents also show contrast between Cu-related and Mo-related porphyries, with the former being Cl-rich which is favorable for extraction and transportation of Cu, and the latter is F-rich which is crucial for porphyry Mo mineralization through lowering viscosity, promoting crystal fractionation and partitioning of Mo into fluid. The fertile porphyries in the Cu (-Mo) deposits have adakite-like Sr/Y ratios and high magmatic water content involving early amphibole fractionation and suppression of plagioclase fractionation. The less evolved porphyry Mo (-W) magma share similar geochemical features with the porphyry Cu (-Mo) and Au magmas, whereas the highly evolved porphyry Mo (-W) magma shows moderately high water content that cannot suppress plagioclase fractionation. The diverse porphyry Mo (-W) and Au mineralization with comparable magma source are controlled by the higher magmatic water content and oxidation state of the porphyry Au magma. The barren suites show overlapped Sr-Nd-Hf-O isotopes, whole rock Fe2O3/FeO ratios, zircon ΔFMQ and Ce4+/Ce3+ values, and apatite SO3 contents with the different types of fertile porphyries. The flat roof of the barren batholiths resulting in lack of fluid flow and focusing into a small volume could account for the barren porphyries, whereas the highly evolved late phase with favorable geometry would have higher potential for porphyry mineralization.

GENETIC CLASSIFICATION OF SAUSAR GROUP, CENTRAL INDIA: A HOLISTIC APPROACH

SANJOY KUMAR SARKAR[1]*, MOIL Limited (sksarkar.moil@gmail.com)
M M Abdulla[2], MOIL LIMITED
A K Saxena[3], MOIL LIMITED

Abstract

Abstract: The manganese deposit located in Madhya Pradesh and Maharashtra, Central India is part of the Sausar Group and is well-known for its thick and bedded manganese deposit. Over the years, several attempts have been made to determine the origin of the Sausar Group. Different theories have been proposed to explain the genesis of the Sausar Group. Most researchers have suggested that the Sausar Group was formed through a metasedimentary process, while others believed that the manganese in the Sausar sequence originated from a volcanogenic source, followed by sedimentation and metamorphism. In this research paper, detailed studies were conducted on the manganese deposits of the Sausar Group, including Gumgaon, Kandri, Munsar, Tirodi, Chikla, Dongri Buzurg, Balaghat, and Ukwa, and various pieces of evidence were collected to shed light on the genesis of the Sausar Group.

To understand the genesis of the Sausar Group, several scientific studies were conducted, including field surveys, geological mapping, structural interpretation, sampling of ore mineral and associated rocks, and their petrological, mineralogical, and geochemical analysis. The study revealed that the manganese deposit of the Sausar Group is volcanogenic, involving both hydrothermal and volcano-sedimentary deposits in the formation of manganese ore, followed by sedimentation and metamorphism. The manganese ore of the Sausar Group is associated with jasper and is classified as a "Jasperiod Manganese Deposit" of volcano-sedimentary origin.

Origin of fluids in the Lancangjiang tin belt, southwestern Yunnan, China: evidence from trace elements and boron isotopic compositions of tourmaline

Yiting ZHU[1]*, Institute of Geology and Geophysics, Chinese Academy of Sciences
(yiting.z@foxmail.com)
Xiaofeng Li[2], Institute of Geology and Geophysics, Chinese Academy of Sciences
Yong Yu[3], Guilin University of Technology
David R Lentz[4], University of New Brunswick, Fredericton

Abstract

The Lancangjiang tin belt is located the eastern margin of the Tibetan Plateau, the northern segment of the Southeast Asia tin belt, which is known for its Sn, W, and base- metal deposits. Tourmaline alteration and high boron concentrations are typical features of the magmatic–hydrothermal systems of the Lancangjiang tin belt. Our new data for tourmaline intergrowth with cassiterite reveal complex geochemical features that provide valuable information on the origin of ore-forming fluids of this boron-rich tin belt. Most of tourmaline collected from the tin deposits and metamorphic rock all belong to the alkali-group dravite series, except some plot into X-vacant group. The composition of tourmaline differs among the ore districts, but all exhibit Fe-poor (0.61–1.08 apfu and Mg-rich (1.43–2.06 apfu) compositions, with Fe/(Mg+Fe) values in the range 0.18–0.46. Most trace elements in tourmalines exhibit lower concentrations <50 ppm, including large-ion lithophile elements (e.g., Cs and Ba), and high-field strength elements (e.g., Nb, Ta, Hf, Th). However, some trace elements [e.g., Zn (17–278 ppm), Sr (6–1240 ppm), V (7–1685 ppm), and Sn (2–1359 ppm)] exhibit high concentrationsof up to several hundreds or thousands of ppmin the tourmaline. The δ11B values of tourmaline from tin deposits range from −14.7 to −11.3‰, except for those tourmalines in the Man Makhsan tin deposit, which range from −12.0 to -8.1‰, but they are all largely overlap the δ11B values of the S-type granite and tourmalines from tin deposits worldwide (−18 to −7‰). The δ11B values (−14.7 to −8.1‰) and the positive correlation between Sn content and ratios of Nb/Ta, Al/Ga, and K/Cs in ore-related tourmaline indicate that the exsolved ore-forming fluids come from highly fractionated S-type granitic magma, which are mainly B-, Sn-, and Al-enriched fluids. We concluded that the lower ratio of Fe/(Mg+Fe), higher oxygen fugacity, and aluminum saturation of tourmaline are beneficial for cassiterite precipitation, as well as an indicator for the ore-forming potential of larger scale tin deposit systems.

Abstract

The principal purposes of this investigation are to determine sulfide and sulfosalt hosts for precious metals, and other valuable trace elements and to find the Ag partitioning trends among coexisting sulfosalts and between sulfosalts and sulfides at the Chodarchay deposit in the Alborz belt, NW Iran. The Chodarchay is the only porphyry-epithermal mineralization in the Alborz, so investigating the genetic model for the deposit using the chemistry of minor and trace elements is particularly important. Evaluating minor/trace element (not only Au and Ag but also other strategic and critical metals) distribution in sulfides and sulfosalts enables distinguishing among the elements present in a solid solution and the micro-scale inclusion of other minerals. Electron Probe Micro Analysis (EPMA) and fire-assay trace-element data are presented for base metal sulfides, accompanying sulfosalts, and other minerals at the Chodarchay. Discovered Bi–sulfosalts include cuprobismutite group minerals (cuprobismutite, hodrushite, and paderaite), aikinite–bismuthinite series (aikinite and friedrichite), emplectite, makovickyite, galenobismutite, gustavite, heyrovskyite, neyite, cupropavanite; and As-Sb-bearing Cu sulfosalts (watanabeite and colusite). The Au-Ag occurrence was reported from the neyite, emplectite, and gustavite. Sphalerite is the only Au host mineral among the sulfides as a nano-mineral phase. Silver hosted inside Cu-(Fe) sulfides as a solid solution, the significant part of them are chalcopyrite and Ag-rich Bi-sulfosalt micro-inclusions inside the chalcopyrite. The Ag-rich minerals crystallize from fractionated fluids that cooled during rising. The Ni concentrations in the pyrite imply that it was sourced from mantle mafic-ultramafic rocks. Bismuth assemblages precipitated at >350°C, and the cuprobismutite group at >300°C. The fluid temperature for the Ag and chalcopyrite precipitation is from 200 to 350°C and the sphalerite Fe/Zn ratios show that it was precipitated between 220 and 280°C. The supergene process and rare secondary enrichment of Ag and Au took place in the oxidation zone; this enrichment is dependent on the presence of manganese, so the concentration of gold is greater at shallower depths. The mentioned temperatures confirm porphyry-epithermal types and different stages of mineralization in the deposit, from the medium-high temperature hydrothermal (linked to mantle contribution) to an epithermal system with a surface supergene deposit.

Abstract

The Kuh-e Janja porphyry Cu-Au deposit is located 60 km southeast of Nehbandan in southern Iran, within the northern part of the Sistan Suture Zone. Several distinct stockwork vein types are recognized, differing in morphology, vein mineralogy, and associated alteration type. Early biotite (EB) veins containing biotite and minor amounts of quartz, magnetite, and anhydrite form the earliest veins. They are crosscut by A veins that are typically several millimeters in thickness and associated with potassic alteration envelopes. The abundant A veins at Kuh-e Janja consist of Q1 quartz that shows textural evidence for extensive recrystallization. Primary oscillatory growth zoning is rarely preserved in Q1 grains. Fluid inclusions in the quartz have been affected by post-entrapment modification. The A veins are interpreted to have formed at high (≳500°C) temperatures at lithostatic pressures. AB veins contain euhedral Q2 quartz crystals that have grown perpendicular to the vein walls within vugs. Molybdenite occurs as ribbons in recrystallized Q1 and Q2 quartz or as an infill in open spaces between the euhedral Q2 quartz crystals. The euhedral Q2 quartz crystals show well-developed sector and oscillatory growth zoning and are characterized by hypersaline liquid-rich and coexisting vapor-rich fluid inclusions that were entrapped at temperatures below ~500°C at the transition from lithostatic to hydrostatic pressure conditions. The AB veins formed at conditions of K-feldspar stability. Zones of high Cu grades at Kuh-e Janja are typified by the presence of abundant hairline fractures coated by chalcopyrite, pyrite, and minor molybdenite. These C veins are surrounded by minor chlorite alteration of the host rocks and crosscut all earlier vein types. The contacts between the early Q1 and Q2 quartz grains and chalcopyrite are irregular in shape. Chalcopyrite crosscuts the primary oscillatory zoning of the Q2 quartz grains suggesting that sulfide deposition occurred under conditions of retrograde quartz solubility. Wallrock or hydrothermal biotite in contact with chalcopyrite is frequently chloritized. Vapor-like single-phase fluid inclusions occur along healed microfractures hosted by euhedral Q2 crystals that are in contact with chalcopyrite in C vein. As many of the

fluid inclusions host small triangular opaque phases interpreted to be chalcopyrite, the vapor-like, near-critical density, single-phase fluid likely was the ore-forming fluid. Late D veins containing variable proportions of pyrite and quartz are surrounded by texturally destructive sericite alteration envelopes of the host rocks. Q3 quartz contains primary and secondary liquid-rich fluid inclusions entrapped at hydrostatic pressure conditions. Rare polymetallic E veins at Kuh-e Janja contain Q4 quartz, sphalerite, galena, and minor chalcopyrite. The study of the different vein types suggests that hypogene Cu mineralization at Kuh-e Janja occurred after potassic alteration of the host porphyry at temperatures close to the ductile-brittle transition. The mineralization formed from vapor-like, near-critical density, single-phase fluids along hairline fractures during their escape from lithostatic to hydrostatic conditions.

[Keynote] Rare metal deposits related to magmatic hydrothermal processes in China

Shao-Yong JIANG[1]*, China University of Geosciences (Wuhan) (shyjiang@cug.edu.cn)
Hui-Min Su[2], China University of Geosciences (Wuhan)
Zhenpeng Duan[3], China University of Geosciences (Wuhan)
Lu Zhang[4], China University of Geosciences (Wuhan)

Abstract

Rare metals including Lithium (Li), Beryllium (Be), Rubidium (Rb), Cesium (Cs), Zirconium (Zr), Hafnium (Hf), Niobium (Nb), Tantalum (Ta), Tungsten (W) and Tin (Sn) are important critical mineral resources. The distributions of rare metal deposits in China are mainly in several orogenic belts, namely, the Central Asian orogenic belt (the Altay and Southern Great Xingán Range regions); the Qilian–Qinling–Dabie orogenic belt (the Middle Qilian, South Qinling and East Qinling mountains regions); the Kunlun–Songpan–Garze orogenic belt (the Western Sichuan and Bailongshan–Dahongliutan regions), and also in the South China Block (the Northeastern Jiangxi, Northwestern Jiangxi, and Southern Hunan regions).

The major types of rare metal deposits in China include the highly fractionated granite type; pegmatite type; alkaline granite type; carbonatite and alkaline rock type; with minor amount of volcanic rock type and hydrothermal alteration or vein type. All of these types are genetically related to magmatic hydrothermal processes. The highly fractionated granite-related rare metal deposits (mostly Nb-Ta-Li-Be-Rb-Cs-W-Sn) are widespread in China, particularly in the South China, such as Jiangxi province (Yashan, Huangshan, Songshugang), Hunan province (Xianghualing, Jianfengling, Zhengchong, Renli) and Guangxi province (Shuiximiao, Jinzhuyuan), which were formed mostly during the Yanshanian 160–120 Ma, with a few in the Indosinian during 240–200 Ma. These deposits are mostly related to the high degree of fractional crystallization processes of the granitic magma and the formation of ore minerals are largely concentrated in the last magmatic stage (particularly the Nb-Ta-Li-Be-Rb-Cs) and transition to early hydrothermal stages (particularly the W-Sn). The important pegmatite-related rare metal deposits include the recently found Renli deposit in Hunan province, the Jiajika and Lijiagou deposits in Sichuan province, the Bailongshan and Dahongliutan deposits in Xinjiang. Most of these deposits have been considered as the highly evolved products of S-type granitic magmatic differentiation where the magma originate from marine sedimentary materials. However, direct anatexis origin for some of these rare metal pegmatites has also been proposed, such as the Keketuohai No 3 pegmatite in Xinjiang, western China. The most representative example of the alkaline granite type rare metal deposit in China is the super-large Baerzhe Zr–REE–Nb-Be deposit in the Southern Great Xingán Range region of Inner Mongolia, with the formation of ore minerals mostly during the magmatic stage but has a strong melt-fluid interaction during the ore-forming processes.

In addition, there are also new types of rare metal deposits recently found in China, including the Leptynite type and Breccia pipe type. The former is represented by the Yushishan Nb–Ta–(Zr–Hf–REE) deposit in Middle Qilian orogenic belt that was genetically related to magmatic and metamorphic hydrothermal activity, and the latter is represented by the Weilasituo Li–Rb–Sn–W–Zn–Pb deposit in the Southern Great Xingán Range region, which has a typical magmatic hydrothermal origin.

Iron-oxide apatite deposits formed by accumulation of magmatic hydrosaline liquids

Xin-Fu ZHAO[1]*, China University of Geosciences (Wuhan) (xfzhao@cug.edu.cn)
Li-Ping Zeng[2], China University of Geosciences (Wuhan)
Wang Liao[3], China University of Geosciences (Wuhan)
Yi-Zhe Fan[4], China University of Geosciences (Wuhan)

Abstract

Iron oxide-apatite (IOA or Kiruna-type) deposits typically consist of a magnetite-apatite-actinolite/diopside assemblage and are spatially associated with extensive Na-(Ca) alteration and breccia. The origin of these deposits is highly controversial and has been ascribed to the separation of iron-oxide/sulfate-(carbonate) melts, magnetite emulsions, or replacement of aqueous fluids from silicate magmas. Here, we propose a new model based on the findings from a cluster of IOA deposits located in the early Cretaceous Ningwu andesitic volcanic field, eastern China. The Ningwu volcanic field in the Middle-Lower Yangtze River Valley metallogenic belt, Eastern China, hosts tens of Mesozoic IOA deposits. These deposits have mineral assemblages typical of actinolite (diopside)-apatite-magnetite. They occur as coarse-grained veins, massive replacement, and fine-grained disseminations in the albitized, often brecciated, apical zones of diorite porphyry intrusions, the overlying andesites, and adjacent sedimentary rocks. The orebodies are mainly hosted within the apical zones of the shoshonitic dioritic intrusions and/or at the contacts between the intrusions and overlying country rocks. The intrusions commonly have porphyritic textures and are compositionally similar to the overlying andesitic volcanic rocks suggesting they were formed at a shallow subvolcanic setting.

Magnetite mineralization was closely associated with extensive hydrothermal alteration zone of several km in diameter. The inner alteration zone within the intrusion is characterized by extensive albitization of albite and scapolite. It was gradually transitioned to an intermediate zone dominated by diopside/actinolite, epidote, apatite, and chlorite. The outer zone has extensive carbonate veins with possible abundant pyrite. Precipitation of magnetite was slightly later than albitization and was likely coeval with apatite and actinolite suggesting they are formed by metasomatic replacement.

The primary magnetite grains from ores with various textures contain similar and variable trace element compositions with up to 5wt.% Ti + V, and show characteristics of high-temperature hydrothermal magnetite in magmatic-hydrothermal systems. Diopside and garnet as well as magnetite contain fluid inclusions with multiple daughter minerals (vapor+halite+sylvite±anhydrite± iron chloride±liquid±hematite), which show extremely high salinities up to ~90 wt.% NaClequiv and homogenization temperatures of ~800℃. In combination with oxygen isotopes of the magnetite-apatite assemblage and the association of shallow-seated ore-hosting porphyry, available evidence suggests that these deposits formed from hydrosaline liquid exsolved from subvolcanic diorite porphyry intrusions at magmatic temperatures. The

hydrosaline liquids were likely in equilibrium with silicate melts during the magmatic-hydrothermal transition. Fluid expansion and evolution of such unusual hydrosaline system is responsible for the extensive Na-Fe alteration and brecciation, which is characterized in IOA deposits.

Abstract

The Bayan Obo deposit hosted by the H8 dolomite is a world-class rare earth element (REE) deposit with considerable niobium (Nb) and iron (Fe). Permian granites are widely exposed in the mining area and have a close spatial association with Nb mineralization. Whether the granites contributed Nb, or only remobilized existing mineralization is important for understanding the controls of ore formation. Previous studies mostly focused on REE, whereas research on Nb has been limited. This is mainly due to the difficulty of accurately determining the age of the Nb mineralization, namely the fine-grained and texturally complex nature of Nb-bearing minerals with exceptionally low U. Although microbeam techniques show promise to tackle the aforementioned challenges, its application is hampered by matrix effects caused by the diverse composition of Nb-bearing minerals. Here we report the application of a high-precision secondary ion mass spectrometry (SIMS) Pb-Pb isochron approach that enables young samples (i.e., <500 Ma) to be dated without matrix-matched reference materials. A variety of Nb-bearing minerals from eastern Bayan Obo were analyzed, yielding Pb-Pb isochron ages of 276 ± 10 Ma (pyrochlore, 394–6864 ppm U in the rim and 6563–19858 ppm in the core), 277 ± 36 Ma (fersmite, 18–61 ppm U; fergusonite-Ce, 45–95 ppm U), and 257 ± 46 Ma (aeschynite, 342–1006 ppm U). In combination with the deposit geology and petrographic observations, these ages link the high-grade Nb mineralization to Permian granites (271 ± 1 Ma). Although these granites are not particularly rich in Nb, skarn formation during their emplacement could have remobilized the existing Nb mineralization, which would also have increased the grain size of the Nb-bearing minerals facilitating their extraction. Our study shows that high-precision SIMS Pb-Pb analysis holds promise for directly dating mineralization without matrix-matched reference materials, and the new results emphasize the need to consider the role of the metal re-enrichment for exploration and extraction at Bayan Obo and elsewhere.

Overlapping Alkalic Porphyry Cu-Au and Magnetite-Apatite mineralization in the Iron Mask Batholith, British Columbia, Canada

Andres Felipe GONZALEZ DURAN[1]*, University of Michigan (andresfg@umich.edu)
Adam Simon[2], University of Michigan
Robert Holder[3], University of Michigan

Abstract

The coexistence of porphyry-style mineralization and Iron Oxide Apatite (IOA) mineralization is a rare geological phenomenon documented sparingly worldwide. The Quesnel terrane, a mineral province in British Columbia, Canada, is recognized for hosting several late Triassic to early Jurassic alkalic intrusions genetically associated with porphyry deposits. These deposits exhibit significant Cu-Au-(PGE) mineralization, characterized by an elevated presence of magnetite. In particular, the Iron Mask Batholith hosts multiple Cu-Au deposits with abundant magnetite, particularly in massive lodes, as well as magnetite-rich orebodies, challenging conventional understanding of magnetite's role within the porphyry mineral system. This study explores the nature of magnetite mineralization in the Iron Mask Batholith, conducting a comparative analysis with similar deposits in British Columbia. Field observations and mineral chemistry reveal that magnetite lodes, containing apatite and actinolite, predate the Cu-Au mineralization stage, forming at higher temperatures. Notably, magnetite-apatite-actinolite lodes in several locations were not overprinted by Cu-Au-rich mineralization. This contrasts with areas such as New Afton, Ajax, and Copper King, where magnetite spatially coexists with Cu-Au mineralization. The massive magnetite lodes unaffected by Cu-Au mineralization exhibit distinctive features, including pegmatite-like zones, colloform magnetite, and symplectites with magnetite and Ti oxides, commonly associated with IOA deposits elsewhere. In contrast, the magnetite found in contact with porphyry Cu-Au mineralization exhibits extensive textural evidence of fluid-mediated re-equilibration. Additionally, the Cu-Au stage also formed coevally with some disseminated and veinlet-type magnetite, introducing complexity to the understanding of these systems. Unlike other alkalic porphyry deposits in British Columbia, with significant magnetite content, the Iron Mask Batholith's deposits are characterized by magnetite and apatite lodes partially superimposed by later Cu-Au-Fe-PGE-rich fluids. This unique feature, exclusively observed in the Iron Mask Batholith so far, prompts intriguing questions about the potential genetic link between the two mineralization styles during the magmatic-hydrothermal evolution of the Quesnel terrane.

Recycled fluids in magmas of continental-collisional porphyry Cu deposits: Insights from mercury isotopes

Bo XU[1]*, China University of Geosciences (Beijing) (bo.xu@cugb.edu.cn)

Abstract

The sources of fluids and metals in ore systems in continental-collision settings are not well known. Mercury isotopes displaying unique mass-independent fractionation (expressed as Δ199Hg), may provide important constraints, given that Hg is a highly volatile metal and an important component of hydrothermal fluids. Here we report new Hg-isotope data on ore-forming porphyries, barren magmatic rocks, and mantle-derived mafic magmas from southern Tibet. The fertile porphyries and coeval mafic magmas display mainly positive Δ199Hg values (up to 0.25‰), while Δ199Hg values in barren magmatic rocks and mafic magmas are largely negative (Δ199Hg: −0.54 to 0.00‰). The positive Δ199Hg values observed here are consistent with previous results on seawater and marine sediments, suggesting that the fluids involved in the genesis of post-subduction porphyry copper deposits (PCDs) were derived from mantle lithosphere metasomatized by previous oceanic subduction. Recycled marine materials contain abundant volatiles (e.g., Cl, S and H2O), and we infer that the initial enrichment of these volatiles in magma sources, a key step in the formation of giant PCDs in continental collision zones, reflects refertilization of the subcontinental lithospheric mantle by slab-derived fluids. The Hg-isotope data record this mantle enrichment, and provide an alternative view to current enrichment models that focus on melting of the lower crust.

FELSIC VOLCANIC HOSTED COPPER-GOLD MINERALIZATION AT MUNDIYAWAS-KHERA AREA, ALWAR BASIN, WESTERN INDIA: A PROSPECTIVE MODEL FOR EXPLORATION

ISRAIL KHAN[1]*, GEOLOGICAL SURVEY OF INDIA (israilkhan@rediffmail.com)
Prabodha Ranjan Sahoo[2], IIT (ISM), Dhanbad
Janmejaya Sahoo[3], Geological Survey of India
Shahina Siddiqui[4], Geological Survey of India
Manashree Mishra[5], Geological Survey of India
Pradeep Kumar Jena[6], Geological Survey of India

Abstract

The semi-concealed Mundiyawas-Khera copper-gold deposit in Alwar Basin, western India, is hosted by a sequence of volcanic and volcaniclastic rocks of the Proterozoic Delhi Supergroup. The litho types exposed in the study area are represented by felsic volcanic of rhyo-dacite composition interlayered with sedimentary sequences composed of quartzite, carbon phyllite and dolomitic marble intruded by numerous quartz and carbonate veins. Sporadic surface indications of copper mineralization have been identified in the form of malachite stains, Olivenite, Conichalcite and occasional fresh specks of chalcopyrite, arsenopyrite and pyrrhotite. The sulphide mineralization viz. chalcopyrite, arsenopyrite, pyrrhotite and minor pyrite mainly occurs in the form of disseminations, streaks, stringers, veinlets, fracture fillings and occasional as massive form. Both syngenetic mineralizations occur as fine disseminations within the felsic meta volcanic rocks and the epigenetic remobilized sulphide veins are preserved in the area. Petrographic studies of the host rocks show chalcopyrite as the principal copper ore mineral alongside pyrrhotite, arsenopyrite, pyrite and minor sphalerite. The rare mineral assemblages include cubanite, pentlandite, Bi, native gold (Au) to electrum, glaucodot, makovickyite and bravoite. EPMA studies of the ore sections reveal the presence of Au-Ag in the form of alloy (1:1 ratio), nugget gold, Ag-Au-Bi alloy and Ag-Au-Bi-Te alloy.

Sulfur isotopic studies of the core samples from the study area shows δ34SVCDT(‰) values for sulfide mineral samples from Mundiyawas-Khera show a range from -7.62 ‰ to + 7.10 ‰ with an average value of +3.42‰ with signatures of more or less similar to Precambrian VHMS (volcanic hosted massive sulfide) type deposits. The δ34SVCDT(‰) values closer to zero indicates magmatic/ igneous (volcanogenic) source / deep homogeneous source/ mantle source for the sulfide mineralization which is recorded in case of VHMS deposits. Hydrothermal alteration from the study area is well preserved in the form of the development of rich sulfides along with scapolite, tourmaline, tremolite, carbonate, sericite, epidote and chlorite. Hence, a strong hydrothermal activity is recorded at the Mundiyawas-Khera area supported by spaceborne mapping with well-defined hydrothermal alteration zones using SWIR bands of ASTER. Fluid inclusion micro thermometry results suggest a temperature range of 280°C to 320°C pointing towards an epithermal to mesothermal type deposit.

Exploration has established the presence of economically viable high tonnage low grade copper-gold-silver deposit at Mundiyawas-Khera deposit with a proven indicated ore resource of 40.49 Mt @ 0.37% Cu; 4.19 Mt@0.80 g/t Au and 2.71 Mt@ 7.07 g/t Ag respectively over a cumulative strike length of 1705 m. Host rock association, hydrothermal alteration, nature of mineralization augmented with mineralogical data predicts the mineralization to be VHMS type mineralization in the Mundiyawas-Khera area. Hence, the present understanding of the control of mineralization and metallogenesis of the copper-gold mineralization in the area will lead to new avenues for exploration strategies in a similar geological milieu.

Evolution of pyrite and Cu-Fe-sulphides in the Olympic Dam Cu-U-Au-Ag deposit, South Australia: Evidence from micron-scale EBSD study coupled with LA-ICP-MS analysis

Samuel Anthony King[1]*, University of Adelaide (samuel.king@adelaide.edu.au)
Nigel John Cook[2], University of Adelaide
Cristiana Liana Ciobanu[3], University of Adelaide
Kathy Ehrig[4], University of Adelaide, BHP Olympic Dam

Abstract

The world-class Olympic Dam iron-oxide copper gold (IOCG) deposit, South Australia, displays inwards and upwards zonation of Cu-Fe-sulphides from pyrite-chalcopyrite, bornite-chalcopyrite, to bornite-chalcocite assemblages, interpreted as a preserved primary feature. The deposit is hosted within the Olympic Dam Breccia Complex that formed dominantly in association to the ~1.6 Ga Roxby Downs Granite. Mineralisation is penecontemporaneous with the host intrusion and includes lower-grade disseminations throughout an area of brecciated and altered granite (outer shell) surrounding the resource.

This study aims at understanding the extent to which superimposed tectonothermal events have modified the mineralogy of the deposit since initial formation. Abundant evidence for fluid-assisted mobilization, recrystallization, and phase transformation, is identified in other mineral groups yet is generally believed to be obliterated in Cu-Fe-sulphides. To test this hypothesis, electron backscatter diffraction (EBSD) is employed to reveal microstructures alongside laser-ablation inductively-coupled-plasma mass spectrometry (LA-ICP-MS) element mapping on the same grains to relate microstructures to trace element (re)distribution. We compare pyrite, a refractory mineral that readily retains evidence of superimposed deformation, with chalcopyrite, a softer sulphide commonly associated with either pyrite or bornite.

Pyrite forming representative disseminated assemblages in the outer shell preserves evidence for two stages of ductile behaviour between intermittent fracturing. Pyrite displays compositional zoning with respect to As, Co, and Ni that has been disrupted by microstructures. Such microstructures correlate with domains enriched in Ag-Au-Pb-Bi-Te. Analysis was performed on chalcopyrite representative of the outer chalcopyrite-pyrite margin of the deposit, as well as the chalcopyrite-bornite zone. The first case shows chalcopyrite with inclusions of carrollite, whereas the second association is illustrated by progressive marginal replacement of chalcopyrite by bornite. EBSD shows chalcopyrite consists of fine aggregates, despite a single grain appearance, and displays {110} and {112} twinning. In contrast, bornite surrounding chalcopyrite has a mostly homogeneous single orientation. Silver, Bi, Pb and Sb can be traced along chalcopyrite grain boundaries and to a lesser extent along twin planes, even though bornite preferentially concentrates Ag-Bi-Sb-Pb relative to chalcopyrite.

In summary, the results show the first convincing evidence for ductile deformation in pyrite from a brecciated IOCG deposit. Furthermore, natural chalcopyrite is shown to be a rich source of

microstructural and -textural information, preserving (220) and (001) crystallographic preferred orientations, twinning, grain boundary migration recrystallization, and foam textures. Coupled EBSD-LA-ICP-MS analysis provides valuable new insights into ore genesis and superimposed events, with the novel use of chalcopyrite EBSD studies showing low- to medium-temperature evolution. This complements data from coexisting pyrite, a mineral that conventionally depicts higher-temperature deformation. Grain-scale elemental distributions also confirm the key role played by microstructures in Cu-Fe-sulphides as traps for value-add critical/precious metals (Ag, Bi, Sb, Au Te) and deleterious Pb.

This work will be complemented by nanoscale studies of bornite and chalcocite to assess micron-scale data in terms of Cu-Fe-sulphide speciation, intergrowths, and mineral inclusions; to better constrain their value for interpretation of ore genesis and especially in discriminating co-crystallisation from replacement.

Jurassic-Cretaceous W-Sn polymetallic ore formation and exhumation in South China: Tectonic-magmatic-metallogenic models

Huan LI[1]*, Central South University (lihuan@csu.edu.cn)

Abstract

South China contains the largest W-Sn province in the world, with the mineralization age dominantly at 160-150 Ma. Recently, A lots of mineralization-related A-type granites have been identified in the area. Was the tectonic setting a back-arc extension? Or a rifting?
For ore field structure: what tectonic stages, ancient stress fields, and ore-controlling structural systems controlled the formation of the world's largest W-Sn mineralization province? For ore deposit structure: what are the ore-controlling laws of various levels of structures? What are the combination types of structures at different depths? For regional exhumation and mineralization preservation: what are the differences in the degree of exhumation among different mineral deposits? How to evaluate the prospecting prospects and provide quantitative discrimination basis for deep ore exploration? This study conducts a systematic study on the tectonic-magmatic-metallogenic models of South China, aiming to reveal the Jurassic-Cretaceous W-Sn polymetallic ore formation and exhumation processes. This research found that the Mesozoic W-Sn mineralization in South China was controlled by normal faults in early rift graben system. South China experienced three important tectonic deformation events: Indosinian near EW compression, early and middle Yanshanian NW-SE compression, and late Yanshanian NW-SE extension. The Middle Jurassic to Early Cretaceous represented an important tectonic inversion period, and the transformation of tectonic stress from compression to extension led to large-scale W-Sn mineralization in South China. The degree of ore deposit exhumation gradually decreases from southeast epicontinental to northwest intracontinental in South China. Intracontinental South China possesses better prospects for ore exploration. Primary exhumation events of the South China resulted from changing subduction processes of the Paleo-Pacific Plate, which include slab break-off and foundering in the Late Jurassic, progressive slab retreat in the Early Cretaceous, and normal subduction in the Late Cretaceous, with minor exhumation events presumably triggered by the Paleogene opening of the South China Sea Basin. This research highlights the use of combined methods (including structural geology, low-temperature thermochronology and geochemistry) in studying the genesis of ore deposits and the exploration of critical metals.

Jyoti Priyam Sharma[4], Indian Institute of Technology (Indian School of Mines) Dhanbad, India
Venkatesh Satya Akella[5], Indian Institute of Technology (Indian School of Mines) Dhanbad, India

Abstract

Copper, lead and zinc deposits are located in the Proterozoic Aravalli Delhi Fold Belt of western India. As per the present understanding, these deposits have formed due to diversified origin and are classified as IOCG type for Khetri copper deposit, and SEDEX type mineralization for Pb-Zn mineralization in the Aravalli group of rocks. The mineralization in these deposits is hosted within the meta-sedimentary rocks of amphibolites to granulite facies condition. The ore minerals have also undergone different stages of deformation and metamorphism. Scapolite occurrences are observed in the metapelitic rocks hosting copper mineralization in the Nim ka Thana and Khetri copper deposit, whereas the scapolite is well developed in the copper-mineralized felsic volcanic rocks of the Alwar basin. Although these copper-bearing belts represent two different basins, the mineralization age is considered to be of similar age. Scapolite composition in both the copper mineralized areas is also marilaitic in nature despite their diverse host association. Since, scapolite is considered as a metasomatic product and often produced from halite-rich precursor sediments, the hydrothermal link of the scapolite is mainly ignored. However, the intricate relationship of the marialitic scapolite with the sulfide minerals suggests the interaction of the ore-bearing hydrothermal fluid with the country rocks for scapolite formation. Marialitic scapolite in felsic volcanic rock and sulfide inclusions in scapolite favours a strong criterion for chlorine rich hydrothermal fluid source for scapolite development and can be a guide for exploration targeting.

Andres Cardenas[7], UNINORTE

Abstract

The Plomosas deposit is the product of a sequence of overlapping events of Pb–Zn, Ag and Au epithermal low sulfidation mineralization that occurred in Mexico's southwestern Sierra Madre Occidental (SMO). Field observations, detailed petrography, and U–Pb age dating of the entire stratigraphic sequence were used to characterize the magmatic evolution of the district and to obtain new insights into the evolution of the SMO. The stratigraphy at Plomosas is distinct from other areas to the north as it lacks Jurassic marine units, Cretaceous continental volcanic successions as well as Cretaceous and Paleocene batholiths. The local basement is composed of undeformed Late Jurassic volcaniclastic units and coeval felsic intrusions. Early to late Oligocene silicic ignimbrites, intermediate lava flows and occasional basaltic flows unconformably overlie the Jurassic basement. Several Oligocene intermediate to felsic porphyry bodies and rhyolitic domes crosscut the stratigraphy. The upper volcanic sequence is separated into two packages by an angular unconformity. Mineralization produced an early Pb–Zn-mineralized hydrothermal fault hydrothermal breccia, followed by Cu–Ag veins and late Au veins. The Pb–Zn mineralized breccia is hosted by ~30 Ma Oligocene volcanic units that form the basal sequence. The Cu–Ag and Au-rich veins overlap and crosscut the early hydrothermal features and cut the Late Oligocene volcanic cover that unconformably overlie the basal sequence. Our results highlight the importance of episodes of Oligocene magmatism to the genesis of mineralization in the southwestern SMO specifically through a genetic link between Pb–Zn veins and intermediate Oligocene intrusive bodies, and of Ag and Au veins with Late Oligocene volcanism.

Abstract

The Chinese Bayan Obo deposit is a world-class rare earth element (REE) deposit with considerable niobium (Nb) and iron (Fe) resources. A complete genetic understanding on all metals is fundamental for establishing genetic models at Bayan Obo. With extensive research being focused on REE enrichment, the timing and controls of Nb enrichment remains unresolved at Bayan Obo, which is mainly due to the challenges in dating, i.e. multistage thermal events, fine-grained minerals with complex textures and the rare occurrence of uranium-enriched minerals with mature dating methods. Based on robust geological and petrographic frameworks, here we conducted ion probe uranium-lead (U-Pb) dating of ferrocolumbite to unravel the timing, hence the genesis of Nb mineralization. Three types of hydrothermal ferrocolumbites—key Nb-bearing minerals—are identified based on their textures and mineral assemblages. They yield U-Pb ages of 1312 ± 47 Ma (n = 99), 438 ± 7 Ma (n = 93), and 268 ± 5 Ma (n = 19), respectively. In line with deposit geology, we tentatively link the first, second and third stage Nb mineralization to Mesoproterozoic carbonatite magmatism, ubiquitous early Paleozoic hydrothermal activity, and Permian granitic magmatism, respectively. While quantifying the contribution of metal endowment from each stage requires further investigation, our new dates highlight that multi-stage mineralization is critical for Nb enrichment at Bayan Obo, which may also have implications for the enrichment mechanism of Nb in REE deposits in general.

Mineralization and remobilization of heavy rare earth elements in carbonatite rocks: insights from in situ elemental and Sr–S isotopic compositions of sulfate minerals

Si-Qi LIU[1]*, China University of Geosciences, Wuhan (1012850690@qq.com)
Shao-Yong Jiang[2], China University of Geosciences, Wuhan
Wei Chen[3], China University of Geosciences, Wuhan

Abstract

Currently, heavy rare earth elements (HREEs, Gd-Lu + Y) are critically important due to their high supply risk. Carbonatites and related rocks have long served as premier sources of light rare earth elements (LREEs, La-Eu), but there has been increasing concern regarding their potential for heavy rare earth element mineralization in recent years. The Huayangchuan deposit, located in the Qinling orogen of Central China, hosts supergiant uranium (> 20 kilotons) and 550 kilotons of rare earth element reserves, and most of the mineralization is hosted by carbonatite dykes. Heavy rare earth elements in the Huayangchuan deposit mostly occur as oxides (samarskite, euxenite, etc.) encased within rock-forming minerals (calcite and aegirine-augite) in carbonatites, suggesting early precipitation from the magma. Generally, these primary oxide minerals underwent later metasomatism along their rims and internal cracks.

Barite-celestine is widespread in the Huayangchuan deposit and can be divided into three types based on detailed textural observations. In this study, in situ elemental and Sr–S isotope analyses of three different types of sulfates are applied to decipher the mineralization sequence and constrain the nature of the fluids responsible for their formation. First, Brt-1 mainly occurs as veins cutting primary carbonatite minerals. It exhibits high total rare earth element contents (ΣREE = 1069 – 1809 ppm) and 87Sr/86Sr ratios matching those of fresh carbonatite (~0.70500), indicating its magmatic origin. Second, celestine in late zeolite-bearing veins (Brt-2) likely formed during the hydrothermal stage at lower temperatures. The much lower REE contents (ΣREE = 5.56 – 17.5 ppm) for Brt-2 reflect the substantial consumption of light rare earth elements before the transition from magmatic to hydrothermal stages, while the higher radiogenic 87Sr/86Sr ratios (~0.70600) suggest input from crustal materials. The third type of barite (Brt-3) is poorly crystallized and occurs as interstitials filling fractures and cavities in early-formed minerals (quartz, calcite, etc.). The high and variable 87Sr/86Sr ratios (0.70862 to 0.71077) of Brt-3 indicate contributions from the surrounding gneiss and can be elucidated through a binary mixing model between carbonatite-derived igneous species and an external fluid influx.

This study discusses the magmatic mineralization and hydrothermal reworking of HREEs in the Huayangchuan carbonatite rocks, providing a paradigm for the behavior of HREEs in carbonatite systems. The HREE mineralization potential of carbonatites is primarily controlled by their source budget. Then, the interactions between the carbonatitic magma and the wall rocks might have consumed the magma volume and ligands therein, potentially leading to the saturation of HREEs and triggering their early precipitation. Finally, HREEs are soluble in many geological fluids;

thus, late metasomatic fluids can assist in the formation of HREE minerals in hydrothermal veins and altered wall rocks but can also cause the destruction of primary ore minerals.

Investigation of mineralogy, geochemistry, and fluid inclusions of the Ghalozendan iron deposit, Azerbaijan province, NW Iran

Soqra RASTI[1]*, PhD (azam.rasti@yahoo.com)
Ali Rostami[2], Payame Noor University
David R. Lentz[3], Department of Earth Sciences, University of New Brunswick, Fredericton, NB E3B 5A3, Canada

Abstract

The Ghalozendan iron deposit is situated in the Sanandaj-Sirjan Zone (SSZ) in NW Iran. The SSZ comprises Paleozoic to Cretaceous sedimentary and metamorphic rocks as part of the Hinterland Fold-Thrust Belt and the Zagros Thrust System. The dominant mineral host rock in this deposit includes granite, rhyolite, meta granite, meta rhyolite, genesis, and schist units related to the Late Precambrian. Iron mineralization is often parallel to the host rock and controls litho-structurally in the contact of schist rocks. The major ore mineral is magnetite and occurs as massive, lenticular, and disseminated ore. Hematite, goethite, pyrite, and chalcopyrite are minor phases. Geochemical investigations show that the Ni, Cr, Co, ΣREEs content of the Ghalozendan deposit is consistent with a typical hydrothermal origin. The iron ores are characterized by a negative positive correlation of Fe and LREE. The rhyolite and granite rocks in this area are regarded as the source of iron and heat in the mineralizing system. The fluid inclusion data from quartz suggest that the ore-bearing hydrothermal fluids with an average salinity of 5-15 wt% NaCl equivalent at a temperature of 130-400 ℃ are the source of iron mineralization. Microthermometric investigations suggest that Ghalozendan is a mesothermal type that formed due to cooling + mixing of the hydrothermal fluid with meteoric water which changed the chemical composition of the fluid and its temperature and pH drastically. The decrease in temperature and pressure, supplemented fluid neutralization due to the mixing of the hydrothermal fluid with meteoric water, controlled Fe precipitation in this deposit.

[Keynote] Facts and myths about orthomagmatic ore deposits

Vadim Kamenetsky[1]*, Center of Deep Sea Research, Institute of Oceanology, Chinese Academy of Sciences (dima.kamenetsky@hotmail.com)

Abstract

The existence of metallogenic provinces is controlled by a number of interrelated factors that are responsible for a regional geochemical anomaly. The ultimate manifestation of such anomalies is one or several ore deposits reflecting energy-driven geological phenomena associated with paleogeography, structure, lithology, tectonic evolution, magmatism, sedimentation, fluid flow etc. The ore forming processes that are born out of the juxtaposition of five necessities, namely the source region, transport pathway, appropriate time, sufficient energy and depositional site, all have a definite control on the physical and chemical characteristics of any deposit.

Accumulations of metals (e.g., Cr, Ni, Cu, PGE) in mantle and crustal rocks are almost universally assigned to magmatic processes and lithologies. However, none of the above listed requirements for the formation of an ore deposit have been satisfactorily constrained for chromitites, Cu-Ni-PGE sulphide deposits, Cu-Au porphyries, and iron oxide – apatite +/- Cu-Au (IOA/IOCG) occurring in different geodynamic settings and allegedly related to different parental magmas.

Although discussions regarding formation of many types of deposits have been varied, current thinking still has an orthomagmatic “flavour”, where fertile (i.e. metal-rich) volatile-bearing magmas, liquid and fluid immiscibility, effects of mixing, mingling, contamination, prolonged fractionation, fluid boiling etc. are envisaged. In contrast to the mainstream research, my new approaches to understanding the origin of diverse metal deposits in high-temperature rocks are based on the laws of dialectics - the transformation of quantity into quality; the interpenetration of opposites; and the negation of the negation. When these laws are applied to grasping genetic aspects of the supergiant “orthomagmatic” deposits in my studies, such as Olympic Dam (U-Cu-Au-Ag, IOCG), Bushveld (Cr-Pt-Pd, chromitites in the layered complex), Noril’sk – Talnakh (Cu-Ni-Pd-Pt, sulphide ores in the layered complex) and a variety of Cu-porphyries, non-magmatic sources of metals and bona fide non-magmatic processes available and instrumental over significant time intervals become evident. These new data and non-orthodox thinking will be presented at the conference and, hopefully, stir further actions of separating facts from myths in the community of petrologists, geochemists and economic geologists.

Magmatic initial and saturated water thresholds determine copper endowments: insights from apatite F-Cl-OH compositions

Yingcai SUN[1]*, China university of geosciences (Beijing) (toknowsyc@163.com)
Qiushi Zhou[2], China university of geosciences (Beijing)
Rui Wang[3], China university of geosciences (Beijing)
Madeleine Humphreys[4], Durham University

Abstract

Magmatic volatiles (H2O, F, Cl), particularly water, are critical in the formation of porphyry copper deposit, for its significance as a carrier for metals. Magmatic water contents can be estimated using geochemical characteristics or directly measured using melt inclusions. However, accurately determining the water content, particularly the initial and saturation thresholds of deep ore-forming magma, remains challenging Further insights into these thresholds and the evolution path of volatiles are necessary to comprehend their impact on copper mineralization. To address this problem, we used apatite and forward modelling methods to reconstruct the evolution histories of magmatic water. Samples investigated include granitoid rocks and apatite from highly copper-mineralized and barren localities. Generally, our research suggested that both ore-related and ore-barren magma systems are hydrous, the modeled magmatic water contents vary significantly among systems whether mineralized or not, and the major difference lies in the threshold of water saturation (6.0 wt.% for barren systems, and up to 10.0 wt.% for highly mineralized systems). By integrating geochemistry data, phenocrysts assemblage and modeling, we infer that the ore-related magma are stored at deeper depth with higher water solubility. In conclusion, we propose that the degree of magmatic water saturation plays a crucial role in the formation of porphyry copper systems. Magmas with a high potential for mineralization not only exhibit increased water solubility but also experience significant water enrichment upon saturation. The deeper storage depth and injection of hydrous mafic magma are likely contributing factors to the elevated water solubility.

Paleoarchean volcanogenic massive sulfide (VMS) mineralization in the Nondweni Greenstone Belt, Kaapvaal craton: Direct links to submarine felsic eruptions, not to komatiites

Sebastian TAPPE[1]*, UiT The Arctic University of Norway (sebastian.tappe@uit.no)
Thendo Netshidzivhe[2], University of Johannesburg
Allan Wilson[3], University of the Witwatersrand
Harald Strauss[4], University of Münster
Fanus Viljoen[5], University of Johannesburg

Abstract

The Nondweni Greenstone Belt is located in the southeastern region of the Kaapvaal craton in South Africa and contains significant volumes of 3.53-3.45 Ga mafic-ultramafic lava flows (komatiitic and tholeiitic basalts). Minor felsic volcanic rock units, such as massive rhyolites and deformed quartz-feldspar-mica schists (felsic schists), also occur and are demonstrably linked to small base-metal sulfide ore bodies, interpreted here as VMS-type mineralization (e.g., sphalerite, pyrrhotite, chalcopyrite, pyrite, galena, acanthite). CA-ID-TIMS U-Pb zircon analysis yields a magma eruption age of 3531.91 ± 0.46 Ma for the felsic volcanic rock unit that hosts VMS-type mineralization at the abandoned St James mine, which renders this Zn-Cu-Pb-Ag mineralization among the oldest preserved of its kind, offering insights into ore-forming processes that took place on and below the Paleoarchean seafloor. Rare-earth element geochemical modeling suggests that the felsic volcanic rocks formed by moderate degrees of partial melting of hydrothermally altered basalts similar in composition to those from the Nondweni Greenstone Belt. Regarding ore formation, we envisage a scenario where basaltic ocean floor, near a back-arc spreading ridge, had been intensively altered and subjected to elevated temperatures, which facilitated localized melting at low pressures (<2 kbar) resulting in the production of rhyolitic magmas accompanied by hydrothermal sulfide deposition. This model is supported by evidence from multiple sulfur isotope data ($\delta^{34}S$ and $\Delta^{33}S$), which demonstrate that the basaltic rocks contain unfractionated magmatic sulfur and the rhyolitic rocks contain sulfur sourced from altered oceanic basalts. In contrast, the rhyolite-associated VMS-type mineralization records even more complex sulfur interactions, including contributions from surficial mass independent fractionated sulfur isotopic components; that is, these sulfide ores exhibit a negative S-MIF signature of -0.53‰ $\Delta^{33}S$.

Abstract

Copper (Cu) and gold (Au)-enriched seafloor massive sulfide deposits found in intra-oceanic subduction settings are typically associated with hydrated and oxidized magmas. However, the processes driving their formation remain subject to debate. While it is recognized that S-undersaturated differentiation plays a role in enriching these metals in magmas, the specific mechanism by which Cu and Au are partitioned, whether into exsolved sulfides or aqueous fluids, remains uncertain. Recent studies have underscored the potential role of dense sulfides liquefied from magmas during their evolution, particularly when they become attached to bubbles of aqueous fluids and subsequently transported towards the surface. However, the rarity of such bubble-sulfide associations in natural settings hinders our understanding of whether sulfide flotation play a significant role in the transport of Cu and Au.

We introduce a distinctive case study of the sulfide-bubble associations within the volcanic suite of Fatu Kapa (ranging from basalts to trachy-dacites), which is associated with Cu- and Au-rich seafloor massive sulfide deposits. We measured Cu, Pb, and Zn contents of glasses and whole rocks using LA-ICPMS and ICP-MS, respectively, and analyzed Pd contents of glasses and whole rocks using nickel-sulfide fire assay combined with isotope dilution method. Through textural observations of magmatic sulfides and chalcophile element modeling within the Fatu Kapa magmas, our study elucidates that simultaneous sulfide and aqueous fluid formation lead to the formation of floating sulfide-bubble compound drops within the magmas. This phenomenon plays a pivotal role in the genesis of Cu-Au-rich hydrothermal ore deposits.

Open System Boiling of Saline Fluids form Salt-rich Ionic Melts: implications for formation of some IOA-IOCG systems

David R LENTZ[1]*, University of New Brunswick (dlentz@unb.ca)

Abstract

Various hypotheses have been proposed for Iron Ore-Apatite & Iron Ore-Copper-Gold deposits (IOA-IOCG) that are still very controversial, with many end-member models proposed for their origin. One end-member of those IOA-IOCG systems that is often described is the occurrence of magnetite-apatite (vein-dykes) with either diopside or actinolite within intermediate to mafic intrusive and extrusive igneous systems. These are obviously quite different from the Fe-Ti cumulates that are common to tholeiitic to alkalic mafic systems. Fe-oxide-silicate melt immiscibility has been proposed as has high-T hydrothermal systems linked to magmatic hydrothermal systems and circulating brines, extending to subsurface seawater reactions within boiling open systems. Shallowly emplaced tholeiitic to calc-alkalic magmatic systems forming within a submarine setting have the ability to generate convective hydrothermal systems that have been widely linked to formation of massive sulfide deposits, which form on or near the seafloor, but generally at considerable ocean depth to inhibit boiling in the system. Many volcanic islands and shallow marine rifts, rise to within the boiling zone though, so residual salinities of the boiling fluids can be driven up the salt saturation curve to values >> 50% salt, so can be described as hydrous molten salts (salt melts). Hydrothermal exchange of Na chlorides with Fe in the basalt-gabbro to ferroan andesites-diorites causes reduction during widespread alteration, and formation of Fe- & Ca-bearing chlorides within NaCl-rich salt melts with minor dissolved silica and mobilization of phosphoric acid. At T's > 450ºC, these Na-Fe-Ca exchange reactions in an open degassing system with abundant heat produces skarnoid-style alteration within spilitic metabasic to metadioritic rocks. The coalescence of hydrous ionic Fe-Ca-bearing salt melts and emplacement along structures will differentially evolved H2 from water with decreasing geostatic pressure, resulting in auto-oxidation of FeCl2 within the salt melt to form magnetite. Fe and P are typically coupled in both igneous and hydrothermal systems, so saturation of magnetite would lead to apatite saturation in the salt melt to saline brine. Ti and many other high field strength elements (HFSE), including REE, dissolves in hydrous ionic melts, so can be easily mobilized relative to near neutral brines at lower Ts. These brine to salt melt reactions will be S limited, as there is considerable Fe in these specific igneous systems to lower sulfur activity, thus stabilizing magnetite. Silica activity is also reduced due to calc-silicate saturation. Saturation of magnetite from Ti-bearing ionic melts (like ferroan carbonatites) can be quite Ti-rich; it is possible that titaniferous magnetite can saturate from high-T salt melts as well. Saturation of calc-silicates and apatite with Ti-bearing magnetite in the altered igneous groundmass, as veins, and vein-dykes and even exhalates (?) result from brine to hydrous ferroan Na-Cl salt melt reaction; these salt melts can extend to T's > 650oC. Chalcophile metals, like Cu and Au, probably represent hydrothermal endmembers of these processes with aH2S controlling saturation with decreasing T, forming the

CG in IOA systems (IOCG). IOA-IOCG systems form within the boiling zone, so within subvolcanic oceanic islands, shallow rift sequences, and primitive arc settings.

Geological aspects of the Manto type copper deposits in the Sabzevar metallogenic zone, NE Iran

Susan EBRAHIMI[1]*, Department of Mineral Exploration, Faculty of Mining Engineering, Petroleum and Geophysics, Shahrood University of Technology, Shahrood, Iran (ebrahimisusan@gmail.com)

Abstract

The Manto type deposits are the second important copper deposits following porphyry reserves in Iran. These deposits occurred within Alborz magmatic assemblage (AMA), Urumieh-Dokhtar magmatic arc (UDMA), Sanandaj-Sirjan zone (SSZ), Lut block, and Sabzevar zone (SZ), which are hosted by Cretaceous to Eocene volcanic and volcano-sedimentary rocks. The UDMA and SZ are the most significant metallogenic provinces in Iran for Manto-type Cu-(Ag) exploration. The Sabzevar structural zone extends east-west for over 400km which is bounded to the south by the Doruneh fault and Atari and Mayamey faults in the north. The basement of the SZ consists of Precambrian metamorphic rocks covered by Paleozoic sedimentary rocks. The Sabzevar oceanic basin was created by rifting in the Late Triassic to the Mid-Cretaceous in the Central Iran microcontinent and began to close during the Late Cretaceous to the Early Paleocene due to the subduction of north-central Iran and eastern Alborz belt. The fragments of the oceanic Sabzevar crust remain as an Ophiolitic complex extending over 150 km length and 10-30 km wide. The post-ophiolitic sequences in the SZ covered by a thick sequence of Tertiary volcano-sedimentary rocks associated evaporate beds.

Based on the spatial distribution, different metal association, and geodynamic setting, ore deposits of the SZ can be separated into two groups. The Cretaceous mineralization consist VMS deposits are widespread of significant economic importance for Cu, Zn and Pb; and Mn ore deposits into the volcano-sedimentary sequences, and also chromite deposits associated with peridotites, gabbro and basalt. The Cenozoic mineralization includes Cu-Au porphyry, red-bed and Manto type Cu-(Ag) deposits.

Strataband copper deposits in the northeast of Iran are widely distributed along the Sabzevar to Semnan, forming an important cupriferous metallogenic zone in the SZ. Most of Manto-type deposits in NE Iran formed in the Eocene extension back-arc basin, which developed during the subduction of the NeoTethyan crust beneath the Iranian plate. These deposits are hosted within thick volcano-sedimentary sequences of Eocene age. Numerous geological and geophysical studies have been undertaken on these deposits over the years such as Dochileh, Abbasabad, Pirmardan, Asmanoo, Chah Moosa, Choghondar Sar, Kal Abri. Fluid inclusion data in these area indicate the primary copper mineralization are commonly generated in the range of 150 to 430 °C and less than 20% NaCl respectively. Sulfur isotope composition of the copper minerals (range between -25 to +24 ‰) imply the magmatic source/or leaching of the igneous rocks and marine sedimentary environments.

Practical assessment of ore-magmatic systems of Greater Altai

Oxana KUZMINA[1]*, D. Serikbaev East Kazakhstan Technical University (kik_kuzmins@mail.ru)
Tatyana Oitseva[2], D. Serikbaev East Kazakhstan Technical University
Marina Mizernaya[3], D. Serikbaev East Kazakhstan Technical University
Olga Ageyeva [4], D. Serikbaev East Kazakhstan Technical University

Abstract

Greater Altay was formed in the process of collision of the Kazakhstan and Siberian lithospheric plates. It combines four ore belts formed in different geodynamic conditions. In the Rudny Altai belt, large and unique pyrite deposits were formed in the rift-based ore-magmatic system, in the genetic connection of gold-copper-polymetallic mineralization with Devonian basalt-andesite-rhyolite volcanism. In the period of exploitation more than 500 ton of gold was mined at Ridder-Sokolnoye deposit. The collision ore-magmatic system (C1-C3) is productive for the formation of sulfide copper-nickel, copper-porphyritic and gold ore deposits. The ore-controlling systems include deep fault systems, thrust-melange structures, small intrusions and dikes of gabbro-diorite-granodiorite-plagiogranite series (C2-3-C3). Bakyrchik deposit is the largest gold-sulphide-carbon type deposits. Rare metal and rare earth deposits were formed in the post-collisional (orogenic) geodynamic setting in a genetic connection with the Permian granitic magmatism. In the Kalba-Narym belt, higher basicity granitoids are productive mainly for pegmatite mineralization (Ta, Nb, Be, Li, etc.), albitite-greisen metasomatites (Li, Ta, Sn) and quartz veins (Sn, W) are associated with normal granites, with leucogranite - hydrothermal (W) and crystal-bearing pegmatites, alkaline granites - Nb-Zr-TR. Ogonite dikes are indicators of hidden rare-metal mineralization. Large industrial rare metal objects are Yubileinoye, Bakenny, Belogorskoye, on the example of which a detailed study of potential rare metal ore occurrences is currently being carried out. The found metallogenic trend of geodynamic environments and different productivity of ore magmatic systems are the basis for starting prognostic-prospecting works.

Abstract

Regularities of formation, prognostic criteria of gold-sulphide formation deposits in East Kazakhstan

Mizernaya M. A., Kuzmina O.N., Oitseva T. A., Kudaibergeneva A., Tsymbal Polina

1 D. Serikbaev East Kazakhstan Technical University, Ust-Kamenogorsk, Republic of Kazakhstan, bdyachkov@mail.ru

The territory of East Kazakhstan is a part of Central Asian mobile belt. It is a unique polygon for its complex geological development and rich mineral deposits (Cu, Pb, Zn, Au etc.). Gold ore deposits are represented by different ore formation types. Proper gold ore deposits were formed in the process of Kazakhstani and Siberian lithosphere plates collision and localized in Zaisan suture zone of Great Altai. Basic gold ore zones (West Kalba, Zhanan-Boko-Zaisan) envelope Charsk-Gornostaevsk ophiolitic belt. Major deposits of gold-sulphide-carboniferous formation (Bakyrchik, Bolshevik and others) are compared with world deposits Suhoi Log and Muruntau in black-shale strata. Gold ore deposits of non-traditional apocarbonate type (Suzdalskoye) are controlled by the system of diagonal deep faults (West Kalba). Deposits of volcano-calciferous-terrigenous formation are ore-hosting (C1v2-3). Gold ore mineralization is associated with minor intrusions and dikes of collision type (C2-3-C3). Ore bodies are represented by zones of gold-sulphide mineralization with vein-impregnated ores. Gold is in free form and as an impurity in pyrite, arsenic pyrite. Basic typomorphic minerals are pyrite, goethite, magnetite, gold, as well as antimonite, galenite, cassiterite, scheelite and others. For the first time rare minerals were found in ores (ferrimagnetite, alamosite, gersdorffite, microlite). Ore-bearing zones are determined by magnetic anomalies of high intensity that is related to magnetite. Geochemical elements are indicators of ore formation: Fe, Mn, As, Sb, Ag, Cu, Pb, Zn. New perspective areas for discovering gold-sulphide deposits (including concealed and buried deposits) were defined on the basis of developed regional and local prognostic-prospecting criteria [1].

This research has been funded by the Science Committee of the Ministry of Science and Higher Education of the Republic of Kazakhstan (Grant No. AP19676805)

New evidence for the intrusion-related gold deposit origin of Luanjiahe deposit in Jiaodong Peninsula, China

Xiaofeng Yao[1]*, Development and Research Centre, China Geological Survey
(yaoming212@qq.com)
Zezhong Du[2], Development and Research Centre, China Geological Survey

Abstract

1. BACKGROUND

The Jiaodong Peninsula, one of the most important Au ore provinces in China, more than 5000 t of Au reserves have been found in the northwest of Jiaodong Peninsula, in which most gold deposits lie along (N)NE–(S)SW-trending major faults. Two kind of mineralization and alteration were developed: altered rock- and quartz vein-types. The altered rock orebodies commonly have interstitial and cataclastic ore textures, and display symmetrical zones of alteration, from an inner zone of silicification, a middle zone of pyritization and sericitization, to an outer zone of K-feldspathization. The quartz vein orebodies are controlled by secondary normal faults or steep tension joints related to the major faults. The debate on the correlation between ore formation and magmatism is ongoing in the Jiaodong Peninsula because few intrusive rocks exhibit a clear association with ore deposits.

2. GEOLOGY OF LUANJIAHE DEPOSIT

The Luanjiahe gold deposit is located in the northern section of the Zhaoping fault, northwestern Jiaodong Peninsula. Alteration and mineralization are mainly restricted to the faults. The alteration, along the fault, includes K-feldspathization, silicification, sericitization, and carbonatization. The silicification and sericitization occur close to the inner zones of the fault, while K-feldspathization occurs in the outer zone. The orebodies are commonly located in the zone with silicification, sericitization, and pyritization. The main sulfide mineral is pyrite, with minor galena, sphalerite, and chalcopyrite. Native gold is closely associated with pyrite, chalcopyrite, and keatite.

3. EVIDENCE FOR THE IRGD ORIGIN

A mineralized and weakly altered biotite monzodiorite stock was found in the footwall of the Zhaoping fault, in a borehole within the deposit. Some special structure, micro texture, and isotopic chemistry characteristics achieved in the biotite monzodiorite, associated with the intrusion-related gold deposit origin, are described as follows:

(1) Miarolitic cavities, occasionally connected, are typically infilled by medium- to fine-grained quartz, calcite, disseminated pyrite, and biotite in some parts of the stock.

(2) Aplite veins and drops, characterized by fine-grained quartz and alkali feldspar, change gradually in grain size within the transition zone between the biotite monzodiorite and aplite.

(3) Skeletal and dendritic quartz, are always associated with plagioclase and biotite in the biotite monzodiorite.

(4) Explosion breccias, comprises clasts of biotite monzodiorite and aplite dike, and hydrothermal

quartz cement.
(5) S isotopic compositions of pyrite within the ores in the biotite monzodiorite ($\delta^{34}S$ = −1.7‰ to +7.3‰; mean = +3.5‰), are roughly consistent with those of magmatic sulfur.
Skeletal and dendritic quartz, late-stage aplite dikes and drops, reflect sudden undercooling during magma ascent. Explosion breccias and miarolitic cavities that are infilled by hydrothermal and ore minerals, were probably induced by saturation in volatiles, the upward transport of aqueous fluid, and subsequent hydrothermal fracturing. The S isotopic characteristics are indicative of a magmatic source. These findings, combined with the reported age of 123 Ma, show that the intrusion has close spatial, temporal, and geochemical relationships with Au mineralization in the area. Luanjiahe gold deposit can be regarded as an intrusion-related gold deposit.

Abstract

The Longhua Ni-Co deposit is a newly discovered super-normal enrichment hydrothermal vein deposit in Dayaoshan, Guangxi, China. Exploration work preliminarily confirmed that it has a potential to be a medium to large Ni-Co deposit. In this study, new geochronology, petrogeochemistry and Sr-Nd-Hf isotope data for the granites related to mineralization were obtained, in order to discuss the granite genesis and tectonic setting. The LA-ICP-MS zircon U-Pb age of the Dajin granites is 448 Ma, which is within the time range of Caledonian magmatic activity in South China. Dajin granites are rich in Si, Al, Ca and Mg, as well as LILE (such as Rb, Th and U) In constrast significantly depletion is shown for Eu, Ba, Sr, P, Ti. All above features indicate that it is a typical high-differentiation A-type granite. The whole-rock εNd(t) values of Dajin granites are in the range of -1.99 to -4.26, zircon εHf(t) values are in the range of -9.4 to -4.2 and the peak age of TDM2 is between 1300 and 1400Ma. The granites are inferred to be formed by the partial melting of the lower crust mafic rocks during the Proterozoic period. Dajin granites were formed in the post-collision and extensional tectonic environment in an intracontinental orogen.

After the collision, Dayaoshan area was in a tension environment, and huge pressure was released along the fracture zone, which caused the upwelling of asthenosphere, baking and triggering the melting of Ni and Co-rich Neoproterozoic-Mesoproterozoic metamorphic mudstone and metamorphic greywacke to form Ni and Co-rich magma chamber. At the same time, a series of NE-NEE trending fracture zone were also formed during this period, along which Ni and Co-rich magma intruded upward into the upper Cambrian strata, forming ore source layer. During the process of magma upwelling, it mixes with magma produced by partial melting at different depths of the crust, undergoes a certain degree of crystallization differentiation, and finally emplaces, forming a highly differentiated magmatic rock with large progressions. At the same time, due to multiple stages of magma emplacement and post hydrothermal activity, the rich Ni and Co ore source layer is continuously activated and extracted. During the process, the fluid rich in volatile matter (F, Cl, etc.) participates in the enrichment of Ni and Co, and continues to migrate upwards along the near E-W structural fault, ultimately precipitating into quartz vein type Ni-Co deposits.

The critical mineral potential of the Kennedy Igneous Association: Petrogenesis, tectonic setting, and metallogeny

JONGHYUN LEE[1]*, James Cook University (jonghyun.lee@my.jcu.edu.au)
Ioan Sanislav[2], James Cook University

Abstract

Background
The Kennedy igneous association (KIA) is widespread intrusive and extrusive, which are dominantly felsic and silicic magmatism, throughout northeastern Queensland during the Carboniferous to the Permian. Geophysical data show that Permo-Carboniferous KIA belt forms a WNW-NNW trending.
Most of granites aged over 310 Ma are concentrated within the Kidston and Kangaroo Hills subprovinces. However, magmatism between 310-290 Ma occurred in the Herberton, Tate, and Burdekin Falls subprovinces closer to current coastline. After 290 Ma, the magmatism locations migrated north-eastwards into the Hodgkinson province, changing from mainly I-type to S- and A-type magmatism. These migration and transition have been interpreted as subduction zone retreat because of slab roll-back.

Mineralization
A variety of significant mineralization including Sn-W (±Mo, Bi), epithermal Au±Ag, and possibly porphyry/skarn Cu-Au mineralization associated with KIA are hosted in northeastern Queensland. For example, the Kidston, Red Dome, and Mount Leyshon are the representative of Au deposits, and there are Sn-W(±Mo) deposits such as the Bamford, Collingwood, and Wolfram camp deposits. However, Sn-W deposits related to KIA are dominantly located in the Herberton and Hodgkinson province, while Au deposits are concentrated in the Georgetown and Charters Towers provinces.

Geochemistry
Geochemical graphs are delineated to see transitions from the Kidston, Herberton and Tate to the Daintree subprovinces (from inland to coast). Igneous suites in the Herberton and Tate supbrovinces include the Almaden, Ootann, and O'Briens creek (OB) suites and S-type granitoids in the Daintree subprovince can be divided into Cooktown suite and other S-type suites.
OB is the most fractionated features among I-type granitoids, and Cooktown suite is more fractionated than other S-types. Some samples from the Kidston subprovince show higher Sr content trend from those from the Almaden and Ootann suites. Most of granitoids are basically sub-alkaline and high-K calc-alkaline series. I-type granitoids plot in I-type and boundary between meta- and peraluminous, but S-type granitoids are mostly peraluminous. The Yataga granodiorite and Almaden suite dominantly plot in VAG, while other I-type granitoids are boundary between VAG and WPG in tectonic setting discrimination graphs. S-type granitoids fall in VAG and syn-

COLG and especially Cooktown suite has more syn-COLG characteristics.
Samples from the Kidston subprovince and Yataga granodiorite has lower Rb/Sr ratio compared to other I-type suites, while OB and S-type granitoids associated with Sn and/or W mineralization show higher Rb/Sr ratio because they are more fractionated. Furthermore, some samples of the Kidston subprovince fall in adakite field associated with Au-Cu mineralization showing higher Sr/Y ratio. They are close to the affinities of Cu-Au mineralization plotting in TTG and Cu-Au ore-productive field unlike other samples.

Conclusions
As ages of granitoids become younger, the location of emplacement changed from inland toward current coastline. Young-aged S-type granitoids in the Daintree subprovince are more related to Sn-W(±Mo) mineralization. We will compare and analyse the geochemical and isotopic data after grouping by ages and subprovinces to understand changes of tectonic environment over time. Based on this research, we have a plan to interpret relationship between mineralization and magmatism derived from tectonic setting changes.

Sulfur and lead isotope geochemistry of granitoid rocks in the Taebaeksan Mineralized District, South Korea

Byeongyong YU[1]*, Kongju National University (yah0707@smail.kongju.ac.kr)
Dongbok SHIN[2], Kongju National University
Heonkyung IM[3], Korea Institute of Geoscience and Mineral Resource
Jaeguk JO[4], Kongju National University

Abstract

The role of granitoid and host rocks in the formation of metallic ore deposits is important, as their characterization is fundamental for understanding the genetic environment of ore deposits. The study area, the Taebaeksan mineralized district (TMD) in South Korea, encompasses the Precambrian metamorphic complex, the Paleozoic carbonate rocks, and granitoid intrusions of various ages. This study seeks to characterize the sulfur and lead isotopes of granitoid rocks prior to determining the relationship between the granitoid rocks, deposits, and host rocks. The Precambrian and Jurassic granitoid rocks exhibit average δ34S values of +5.8‰ (n=3), whereas the Cretaceous granitoid rocks show a lower value of average +3.5‰ (n=13). Regarding the lead isotope ratio, the Precambrian and Jurassic granitoids show a wide variation, ranging from 206Pb/204Pb=17.520 to 22.407 (avg. 20.314, n=3), while the Cretaceous granitoids exhibit a relatively narrow range of 206Pb/204Pb=18.329 to 19.259 (avg. 18.568, n=13). The sulfur and lead isotope results can be used to evaluate the influence of the country rocks. If the granitoid rocks had been influenced by carbonate rocks, they would exhibit relatively high δ34S values. However, they fall within the range typical of igneous rocks and display a positive correlation with SiO2 content, suggesting the effect of magma differentiation. Lead isotope analyses indicate that the influence of basement rock in the formation of granitoid rocks cannot be ignored. However, when compared with sulfur isotopes, no correlation was observed between them, suggesting that they did not mutually influence each other.

Sumit Mishra[5], Centro de Geociencias, Universidad Nacional Autónoma de México (UNAM), Boulevard Juriquilla 3001, CP 76230 Querétaro, Querétaro., México.

Abstract

The San Francisco Manganese deposit is located in Jalisco, Mexico, within a continental volcanic province of the southwestern Sierra Madre Occidental. The regional geology is defined by a mosaic of volcanic and subvolcanic rhyolites, andesites, and their pyroclastic counterparts, and diorite plutons. Over a 10 x 10 km expanse encompassing the deposit, a coherent rock sequence unfolds, though its regional continuity remains elusive due to the complex volcanic terrain. The deposit is hosted by red tuffs with interbeds of green tuffaceous sandstone. Mineralization exist within two distinct zones: an iron-oxide-rich zone with modest manganese contents to the northwest and a manganese-oxide-rich zone to the southeast—where the deposit attains maximum thickness while exhibiting its lowest iron content. The manganese mineralization occurs as stratabound irregular orebodies and lenses hinting at a syngenetic sedimentary genesis. Manganese ore comprise predominantly of braunite with minor pyrolusite and traces of neltnerite and rhodochrosite which display a variety of textures such as laminated, disseminated, massive, replacement and open space filling. Iron oxides exist in the form of fine grained hematite and magnetite. Accessory minerals include quartz, calcite, barite, hematite, cryptocrystalline silica, and calcite. Electron microprobe analysis of braunite, the predominant mineral, gives average values of MnO2, SiO2 and Fe2O3 as 84.2, 9.6, and 0.9 percent, respectively, which is close to the ideal composition. The geological and geochemical characteristics of the San Francisco Manganese deposit provides important clues about the deposit's genesis, environment of formation and origin of manganese. The presence of volcanic and subvolcanic rocks, tuffs, and their pyroclastic counterparts and absence of epigenetic hydrothermal replacement, advocates for a syngenetic exhalative origin. The deposit is characterized by low trace element (Co, Cu and Ni) abundance and high Mn/Fe ratios (>500), typical of hydrothermal deposits. The Mn-Fe-(Ni + Cu + Co), MnO2-MgO-Fe2O3, and Na/Mg diagrams display signatures of a terrestrial environment. Geological and geochemical characteristics of the deposit point to deposition within a shallow water basin by subaerial volcanic activity during hiatus between two major eruptive cycles.

Cathodoluminescence, trace element and fluid inclusion studies of the ginguro-bearing crustiform veins in the Hokuryu Ag-Au deposit, Hokkaido, Japan

Omar Baculna SOBERANO[1]*, Akita University (obsoberano@gmail.com)
Ryohei TAKAHASHI[2], Akita University
Pearlyn Cabarubias MANALO[3], Akita University
Andrea AGANGI[4], Akita University

Abstract

The Hokuryu deposit was one of the largest producers of silver (Ag) and gold (Au) in Omu, Hokkaido, Japan. A type of ore in the deposit is ginguro-bearing crustiform veins that contain hundreds of ppm of Ag. Here, we investigate the detailed characteristics of these ginguro-bearing veins through the application of cathodoluminescence (CL), mineral chemistry and fluid inclusion techniques.

Petrographic observations show that the ginguro is mainly composed of a skeletal intergrowth of hessite and sulfides, such as sphalerite, pyrite, chalcopyrite, and galena. These ore minerals are mostly confined within a colloform band composed of microcrystalline quartz and adularia. The microcrystalline quartz exhibits microspherical texture that is made up of individual sphere having an apparent diameter of ~1-5 μm. Adularia located within the interstices of these quartz microspheres displays anhedral to rhombic habit with sizes ranging from ~1 to 10 μm. The quartz microspheres exhibit blue CL, with a peak at ~400 nm in the CL spectrum. Mineral chemistry analysis of these blue CL-emitting quartz microspheres shows Al and K concentrations of ave. 2940 ppm (n = 40) and ave. 1117 ppm (n = 40), respectively.

In addition, the ginguro-bearing microcrystalline colloform band is typically followed in the mineral deposition sequence by macrocrystalline comb quartz and tabular adularia, in which trace amounts of hessite and sulfides were also found. The comb quartz also generally exhibits blue CL with ~400 nm peak, but has significantly lower Al (ave. 2560 ppm, n = 14) and K (ave. 187 ppm, n = 14) concentrations. Moreover, primary two-phase liquid-rich inclusions were recognized along the cleavage planes of tabular adularia. Homogenization temperature and apparent salinity from three fluid inclusion assemblages are ave. 272°C and ave. 6 wt. % NaCl equivalent, respectively.

Hyper-enrichment of gold via quartz fracturing and growth of polymetallic melt droplets: example from the Xiaoqinling lode gold district, central China

Wei Jian[1]*, China University of Geosciences (Beijing) (weijian851@gmail.com)

Abstract

The precipitation of gold in hydrothermal ore deposits is generally attributed to the supersaturation of gold in aqueous or aqueous-carbonic fluids. However, it appears doubtful whether ore fluids can ever reach bulk saturation with respect to gold, because of the relatively low concentration of dissolved gold species compared to gold solubilities. This suggests there may be precipitation mechanisms that are not controlled by bulk gold solubilities, especially for the formation of ultrahigh-grade gold veins. This is because gold supersaturation triggered by processes such as boiling and fluid mixing will be accompanied by the precipitation of quartz, calcite, and other common vein minerals, which strongly dilute gold grade. This contrasts with the observation that gold minerals, e.g., native gold or Au-(Ag)-tellurides, are frequently a major or dominant component in micro-fractures of ultrahigh-grade gold quartz veins that can contain kilograms of gold per tonne or more.

Using a combination of scanning electron microscope (SEM) imaging and energy-dispersive X-ray spectrometry (EDS), heating-freezing experiments, and hydrothermal diamond anvil cell experiments, we present evidence for entrapment of polymetallic melt droplets in gold-bearing quartz veins from the Xiaoqinling gold district, central China. We propose a model of ultrahigh-grade gold enrichment through polymetallic droplet growth induced by quartz fracturing and generation of hydrogen and silanol groups during earthquake faulting. We propose that polymetallic melt droplets of Au-Ag-Te-Bi–rich composition form through adsorption-reduction of metal complexes on fractured quartz surfaces, where surface silanol groups and hydrogen serve as reductants. The melt droplets subsequently grow by catalyzing reduction of metal complexes and absorbing metals from fluids percolating in the fractured quartz network. The mobile and reactive polymetallic melt droplets can repeatedly react with the fluid on protracted quartz fracturing, and efficiently continue to scavenge gold from multiple pulses of gold-undersaturated ore fluids. Gold particles themselves are also known to act as catalysts during the reduction of positive gold ions. Repeated fracturing of quartz could then possibly also trigger self-catalyzed growth of metallic gold without the mediation of polymetallic melt droplets.

Fluid Evolution of the Wunugutushan Porphyry Copper-Molybdenum Deposit in Inner Mongolia: Insights from Quartz Fluid Inclusions and Muscovite Compositional Studies

Xiangkai CHU[1]*, Institute of Geology and Geophysics, Chinese Academy of Sciences (chuxiangkai20@mails.ucas.ac.cn)
Ping SHEN[2], Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

The Wunugetushan porphyry copper-molybdenum deposit in Inner Mongolia, China, is a significant porphyry deposit with 2.5Mt copper and 0.2Mt molybdenum resources. However, complex fluid activity has resulted in the ore-forming fluid evolution process of the deposit remaining unclear. This study conducted microthermometry on quartz fluid inclusions at different stages, and investigated variations in muscovite compositions using electron probe microanalysis, laser ablation inductively coupled plasma mass spectrometry, and shortwave infrared spectroscopy. By integrating the analysis results, the process of mineralizing fluid evolution has been reconstructed.

Based on the cutting relationships of hydrothermal veins, mineral assemblages, and their sequence of formation, the fluid ore-forming process is divided into four stages: quartz-potassium feldspar stage, transitional stage, quartz-sericite stage, and carbonate-clay alteration stage. Fluid inclusions in quartz veins are abundant. It can mainly be divided into four types of inclusions: carbon dioxide inclusions, vapor-rich inclusions, liquid-rich inclusions, and daughter mineral-bearing inclusions. In the quartz-potassium feldspar stage, fluid inclusions mainly consist of vapor-rich inclusions and daughter mineral-bearing inclusions, with a minor presence of carbon dioxide inclusions, and homogeneous temperatures mostly exceeding 500°C. In the transitional stage, fluid inclusions are dominated by vapor-rich and liquid-rich inclusions, with homogeneous temperatures around 420°C. In the quartz-sericite stage, fluid inclusions are predominantly vapor-rich and liquid-rich inclusions, with homogeneous temperatures ranging from 480 to 280°C. In the carbonate-clay alteration stage, fluid inclusions are primarily liquid-rich inclusions, with homogeneous temperatures mostly below 300°C. Carbonate signals are detected in the liquid phase compositions of fluid inclusions in the quartz-potassium feldspar and transitional stage, while carbon dioxide signals are detected in the gas phase. In the later stage, both gas and liquid phases are dominated by H2O. Studies of fluid inclusions indicate that during the early stage, magmatic hydrothermal fluid predominate, with gradual input of meteoric water leading to a decrease in temperature, salinity, and metal content. This fluid formation resulted in a later stage alteration assemblage dominated by carbonate and clay minerals, overprinting the early alteration of the deposit, and precipitating small amounts of lead-zinc minerals. Boiling fluid inclusions assemblage developed in quartz surrounding sulfides suggest that, apart from cooling effects, fluid boiling also plays a significant role in mineralization.

The composition and spectral characteristics of different genetic muscovite in the Wunugutushan

porphyry deposit exhibit significant differences. Muscovite associated with molybdenite is richer in Al, K, Sr, and Ba, with an Al-OH characteristic wavelength ranging from 2197 to 2203 nm. Muscovite associated with chalcopyrite contains higher Si, Ti, Fe, Mn, Mg, Cu, Zn, Sn, and W, with an Al-OH characteristic wavelength ranging from 2200 to 2206 nm. The Al-OH wavelength of mica in Wunugetushan porphyry deposit is related to the distance from the mineralization center, while the wavelength < 2203nm indicates the molybdenum mineralization and closer the mineralization center.

In summary, the quartz fluid inclusions composition of muscovite are of significant scientific importance in understanding the evolution of fluid and exploration.

New geochronological constraints on the giant Nurkazgan porphyry Cu-Au deposit, Central Kazakhstan

Haoxuan FENG[1]*, Key Laboratory of Mineral Resources, Institute of Geology and Geophysics, Chinese Academy of Sciences (fenghaoxuan15@mails.ucas.ac.cn)
Reimar SELTMANN[2], Centre for Russian and Central EurAsian Mineral Studies, Department of Earth Sciences, Natural History Museum London
Ping SHEN[3], Key Laboratory of Mineral Resources, Institute of Geology and Geophysics, Chinese Academy of Sciences
Xiangkai CHU[4], Key Laboratory of Mineral Resources, Institute of Geology and Geophysics, Chinese Academy of Sciences
Seitmuratova ELEONORA[5], Satpaev Institute of Geological Sciences

Abstract

The Nurkazgan Cu-Au deposit in the Central Kazakhstan, containing 3.93 Mt Cu and 293 t Au, is one of the giant porphyry copper deposits in the Central Asian Orogenic Belt. It is spatially associated with the Karaganda dioritic to granitic intrusive complex. Although some studies have been done on characteristics, and petrogenesison this intrusive complex, its magmatism history and genetic link to the porphyry mineralization are still poorly constrained. In this study, new zircon U-Pb geochronology analyses of various intrusions of the Karaganda complex have been performed. Furthermore, the timing of mineralization has been directly dated by the hydrothermal rutile SIMS U-Pb, and molybdenite Re-Os dating.

Firstly, our fieldworks and SHRIMP and LA-ICP-MS zircon U-Pb dating confirms five ore-bearing porphyry phases in the Karaganda: (1) early granodiorite porphyry, the oldest intrusion consisting of the main body of the Karaganda complex, have a 206Pb/238U weighted mean age of 440.8 ± 2.4 Ma; (2) early quartz diorite porphyry with a 206Pb/238U weighted mean age of 440.7 ±2.5 Ma; (3) the second pulse of quartz diorite porphyry emplaced at 429.7 ± 2.1 Ma; (4) the late granodiorite porphyry having a 206Pb/238U weighted mean age of 402.8 ± 3.7 Ma, and (5) the late quartz diorite porphyry emplaced at 402.0 ± 3.9 Ma. The later three porphyry phases are newly recognized. Collectively, the Karaganda intrusive complex has a punctuated magmatic history distributed over 35 m.y., and marked by three rather than a single episodic porphyry events: early (~440 Ma) and late (~430 Ma) Silurian, and early Devonian (~402 Ma).

Secondly, in-situ SIMS U-Pb dating of hydrothermal, Cu-rich (up to 13.2 ppm) rutile co-precipitated with chalcopyrite from the breccia-type ores indicates that the main-stage mineralization has been formed at 428.9 ± 6.9 Ma, which is coincident with the LA-ICP-MS zircon U-Pb age of the second pulse of quartz diorite porphyry (~430 Ma). Additionally, the rutile shows light REE-enriched chondrite-normalized REE patterns with moderate negative Eu anomaly similar to the ~430 Ma quartz diorite porphyry but in contrast to other dioritic intrusions. The similarity of U-Pb ages and REE patterns support that this porphyry acts as the causative intrusion responsible for the main-stage ore formation.

Finally, a molybdenite sample obtained from the main-ore stage stockwork vein near the contact

between the early Silurian quartz diorite and the late quartz diorite porphyry (402.0 ± 3.9 Ma) has a Re-Os age of 418.6 ± 1.8 Ma, which is slightly younger than the U-Pb age determinations of the rutile. This indicates that the Re-Os isotope system was disturbed by the second thermal and mineralizing event related to ~402 Ma quartz diorite porphyry.

Geology, alteration and mineralization of the Pemberton Hills porphyry system, Canada: anatomy of a lithocap

Pete HOLLINGS[1]*, Lakehead University (Peter.Hollings@lakeheadu.ca)
Patrick Hamilton[2], Lakehead University
Andrew Jedemann[3], Lakehead University
Lejun Zhang[4], University of Tasmania
David R Cooke[5], University of Tasmania
Ramon Taningco [6], Freeport-McMoRan
Ingemar Arellano[7], Freeport-McMoRan

Abstract

The Pemberton Hills porphyry system is located in northern Vancouver Island, British Columbia, Canada and forms part of a northwest trending belt of Jurassic porphyry and epithermal deposits and prospects within the Wrangellia Terrane. The porphyry environment at Pemberton Hills has been the target of limited exploration, despite the presence of a well-developed lithocap, and proximity to the Island Copper Mine (345 Mt @ 0.41% Cu, 0.17% Mo, 0.19 g/t Au), and the Hushamu (304 Mt @ 0.21% Cu, 0.1% Mo, 0.29 g/t Au, 0.55 g/t Re) and Red Dog prospects (23.6 Mt @ 0.32% Cu, 0.46 g/t Au).

The host rocks at Pemberton Hills include a wide range of volcanic units (andesites, basalts, flows, volcaniclastics, tuff, volcanic and hydrothermal breccias) and plutonic rocks (granodiorite, tonalite dyke, quartz diorite) with the lithocap hosted mainly in volcanic breccias and pyroclastic units, and local porphyritic intermediate volcanic rocks. Potassic and propylitic alteration mainly occurs within and proximal to plutonic rocks across the study site. Locally intense phyllic alteration, characterized by fine-grained quartz, white-mica, and pyrite, is generally constrained to samples located in the center of the study site to the northeast of the lithocap, and overprints previously formed mineral assemblages. The lithocap is characterized by the presence of pyrite, kaolinite, chlorite, and illite at the periphery and in minor faults in the propylitic alteration halo; quartz, alunite, dickite, pyrite increasing in abundance towards the centre; and a core of quartz, dickite, pyrophyllite, zunyite, topaz, and alunite, which has been interpreted as the upflow zone of the lithocap. Silicic alteration occurs on the shoulders of the upflow zone in the NE of the lithocap, generally cropping out as large ridges of resistant material. Texturally, these domains were typically massive but locally showed vuggy textures.

Intrusive units peripheral to the lithocap have been dated at 172.34 ± 0.11 Ma, 172.01 ± 0.17 Ma, 171.77 ± 0.13 Ma and 171.44 ± 0.25 Ma using U-Pb zircon methods. These ages overlap with a Re-Os age of 172.3 ± 0.8 Ma from molybdenite from the lithocap and U-Pb ages of an epidote vein and andraditic garnet-epidote-calcite-pyrite vein, both 170.1 ± 1.8 Ma. Three Ar-Ar ages of 166.2 ± 0.3 Ma, 167.1 ± 0.7 Ma, and 166.7 ± 0.3 Ma were generated using alunite from different locations within the lithocap. These ages broadly overlap with intrusions at the Island Copper mine as well as other Island Plutonic Suite intrusions in the area and suggest the lithocap formed late in the evolution of the Pemberton Hills system.

Nature and Characteristics of Gold Deposit of Bhitar Dari Area of Gorumahisani-Badampahar Greenstone Belt of Iron Ore Group, East Singhbhum District, Jharkhand, India.

PANKAJ KUMAR[1]*, Geological Survey of India (pankaj.kumar1@gsi.gov.in)
Abhishek Das[2], Geological Survey of India
Nandu Khalkho[3], Geological Survey of India

Abstract

Worldwide, Archaean greenstone belts are mostly characterized by lode gold deposits with major deposits situated in cratonic areas of Australia, Brazil, Canada, India and South Africa (Foster,1984, Mcdonald, 1986, Ho and Groves, 1987). Archaean greenstone belts gold deposits/ occurrences are generally tectonically classified as orogenic gold deposits (Groves et.al 1998, Goldfarb et.al, 2001). The Palaeo-Meso Archaean volcano-sedimentary sequence of Gorumahisani-Badampahar greenstone belt occurs along the northeastern fringe of the Archaean Cratonic core region (ACCR). Volcano-sedimentary sequence along the fringes of ACCR in this eastern part of India are widely referred as Iron Ore Group of rocks.

The Bhitardari area belongs to Gorumahisani-Badampahar greenstone belt of Iron Ore Group and generally comprises inter-banded sequence of phyllite, tuffaceous phyllite, carbonaceous phyllite, quartzite, cherty quartzite, fuchsite, conglomerate, BIF, chlorite-schist and Ultramafics. Interfolial quartz and quartz-carbonate veins, which shows alteration in the form of silicification, ferruginisation & limonitisation at places, traverse along and across all the major lithunits of the area and acts as a host for gold mineralization in the area. Quartz/ quartz-carbonate veins of the area are mostly associated with syn-D2 shear zone. Predominance of the auriferous quartz veins, quartz-carbonate veins/ veinlets along S2 foliation in the area indicates major auriferous lode formation occurred during D2 event, which is otherwise most prominent deformation in the area. The main gold mineralizing event in the area is shear controlled and probably coeval with this regional deformation in the area.

Systematic sub-surface drilling has been carried out in the area to delineate the zone of gold mineralisation and to estimate the resource, first time in the northern limb of the fork shape structure in the IOG rocks in this part of the Singhbhum Craton. Sulphide minerals in the form of chalcopyrite, pyrite, pyrrhotite, sphalerite, galena, arsenopyrite and Millerite have been reported. Mineralization in the area occurs irrespective of lithology. Pyrite and arsenopyrite is the common sulphide mineral present in the area along with other sulphides, at low metamorphic grade. Gold occurs in the area in two distinct forms, as free milling (nugget) gold as well as invisible gold(refractory) within the pyrite. Gold values in the range of 60 ppb to 13.9 ppm occur in the area and resource has been established, on the basis of analytical result received by fire assay techniques. The auriferous lode of the area is defined as portion of the mineralized zone which was considered for resource estimation, have minimum Au value of 0.1 ppm over a minimum width of 1.5 m. The gold deposit established in the area is characterised as high sulphide,

epigenetic type Archaean lode gold deposit.

The formation of gold-rich goethite and hematite in an epithermal gold deposit

Feng-Xia HUANG[1]*, China University of Geosciences (6988350@cug.edu.cn)
Ya-Fei WU[2], China University of Geosciences

Abstract

Gold is closely associated with iron oxides such as hematite (α-Fe2O3) and magnetite (Fe3O4) in some hydrothermal gold deposits, indicating that gold and iron oxides are co-precipitated from oxidizing fluids. In addition, supergene hematite and goethite [α-FeO(OH)] are enriched in gold, which is released from hydrothermal auriferous sulfides under near-surface weathering conditions. Gold in these iron oxide-related deposits mainly occurs as visible gold grains as well as micron to nanoscale gold particles, forming easily extracted high-grade (tens to thousands of g/t) gold ores. However, processes that control the formation of iron oxide-related high-grade gold ores are largely unknown.

Here, we used scanning electron microscopy, laser ablation–(multiple collector)–inductively coupled plasma–mass spectrometry [LA–(MC)–ICP–MS], and transmission electron microscopy (TEM) to reveal the formation processes of gold-rich goethite and hematite in a high-grade ore (~36 g/t Au) from the Jinying epithermal gold deposit, China. Two types of iron oxide have been identified: (1) goethite that occurs within the fractures of pyrite or as overgrowths along the margins of pyrite; (2) aggregates of goethite and hematite within quartz of the mineralized sandstone. Type-1 goethite only contains rare gold particles, whereas a large number of fine-grained gold particles (<1 μm) occur within the type-2 aggregates of goethite and hematite. In-situ trace elemental and sulfur isotopic analyses show that the pyrite contains little gold (<0.68 ppm) and shows different sulfur isotopic compositions (mean = -2.1 ‰) with barite (mean = +16.4 ‰) that is intergrown with type-1 goethite. TEM analysis shows that type-2 goethite contains numerous spherical gold nanoparticles (5–300 nm), whereas gold nanoparticles in hematite are irregular and larger than those in goethite. Spherical gold nanoparticles tend to aggregate into irregular ones in hematite.

The different sulfur isotopic compositions between pyrite and barite indicate that type-1 goethite is not likely to form from the direct weathering of pre-existing pyrite. Instead, the two types of iron oxides might be precipitated from the oxidizing ore fluid that formed as a result of interactions between the original ore fluid with the wall rocks of Neoproterozoic hematite-bearing quartz sandstones. However, it is also possible that the addition of oxidizing meteoric water contributed to the formation of iron oxides at Jinying deposit. TEM results indicate that gold nanoparticles might be originally enriched into goethite and then aggregate into large ones in hematite. Our results provide new insights into the formation of high-grade iron oxide-related gold ores in hydrothermal gold deposits.

Ivan Belousov[6], CODES, University of Tasmania

Abstract

The Martabe lithocap, located in western Sunda magmatic arc, Indonesia, has multiple gold-silver mineralisation centres. The lithocap hosts at least six high sulfidation epithermal deposits, including Purnama, Ramba Joring, Barani, Tor Uluala, Horas, and Uluala Hulu, in an area that is 7 km long × 3 km wide. This district is estimated to contain > 8 million ounces (Moz) Au and 75 Moz Ag, with a 0.5 g/t gold cutoff. The Martabe lithocap and Au-Ag orebodies are hosted mainly in Miocene basaltic andesite and Pliocene hornblende-phyric andesite and porphyritic dacite dome complexes that were overlain by a Quaternary rhyodacitic complex related to eruption of the Toba Supervolcano. Silica ridges dominated by vuggy quartz and quartz – kaolinite/dickite – pyrite assemblages are prominent at Purnama and Barani (central-south zone), whereas quartz – alunite – dickite – pyrite alteration assemblages are laterally restricted to the northern zone, including Ramba Joring, Tor Uluala, and Uluala Hulu. Extensive illite – montmorillonite – pyrite ± quartz alteration is widely developed in an approximately N-trending graben, and is flanked by chlorite ± epidote – calcite – pyrite alteration to the west. High-resolution microscale textural mapping shows that euhedrally tabular alunite has overgrown large quartz crystals and/or replaced primary aluminosilicate minerals, whereas abundant pyrite and minor barite infilled interstices between alunite and quartz. LA-ICP-MS trace element maps of pyrite reveal different zoned textures and compositional variations at Martabe. Pyrite from the central zone at Purnama has simple zoned texture and chemical compositions, characterised by As-Tl-Ti-rich cores and Au-Ag-Bi-Cu-Co-Ni-rich rims. Pyrite from the northern part of the district (e.g., Uluala Hulu) shows complex, multiple core-rim compositional characters, implying multiple mineralisation stages and high gold enrichment on the pyrite rims of each growth stage. The Martabe alunite has a narrow range in 1480 nm absorption feature, from 1477 to 1484 nm, with an increasing wavelength towards Purnama and Ramba Joring. In situ micro-analytical results demonstrate that the alunite is mostly K-rich, with minor Ca-rich huangite, whereas Na-rich natroalunite is notably absent. Several trace elements (e.g., Ba, Pb, and Sr) have high concentrations in alunite from both the northern (Uluala Hulu) and southern (Horas) areas, but are comparatively depleted in the central region. Sulfide micro-inclusions have been detected in the alunite that are characterised by anomalously high Cu (≤ 0.2 wt.%) and Au (≤ 40 ppm) values. These micro-inclusions occur in alunite proximal to mineralisation centres in the Martabe lithocap. This study suggests that alunite and pyrite textural and compositional characteristics may provide robust vectoring tools towards high-grade Au ores

and heat centres in the lithocap environment.

South African coal and coal by-products as potential alternative sources for rare earth elements: A case study of the Ermelo, Soutpansberg, Tuli, Utrecht and Waterberg coalfields

Christopher Baiyegunhi[1]*, University of Linpopo (christopher.baiyegunhi@ul.ac.za)

Abstract

Rare earth elements (REE) demand is rapidly increasing as new energy and energy storage technologies are developed, and conventional REE deposits are unable to meet the world's high REE demand. As the gap between global REE demand and supply widens, the search for alternative REE resources has become a global concern. Recent studies have shown that coal is a potential untapped resource for REE. South Africa is known to host large reserves of coal, estimated between 15 and 55 billion tons, and more reserves of coal are expected to be recovered. As a result of the need to diversify the source of REE, South Africa has significant opportunities to join the world's supply. Thus, there is growing interest in researching the occurrence, distribution and concentration of REE in South African coal and ash. In this study, laboratory-derived coal ash, power station coal fly ash and corresponding feed coals collected from different coalfields in South Africa were investigated for their chemical and mineralogical characteristics. The collected samples were analysed using x-ray diffraction (XRD), mineral liberation analyser (MLA), proximate analysis, ultimate analysis, scanning electron microscopy coupled with energy dispersive spectrometry (SEM+EDX) and inductively coupled plasma (ICP-MS). The XRD, SEM and MLA results revealed typical REE-bearing minerals (i.e., monazite, xenotime, parisite and allanite) in the samples. The back-scattered electron (BSE) detector images show a mix of locked, intermediate, and freed REE-hosted minerals. The REEs concentrations in the coal and ash samples ranged from 101 to 143 ppm and 389 to 587 ppm, respectively. In addition, the H– and M-type REE enrichment types were recorded in the samples. As expected, the REE concentrations in the ash samples are higher than the average upper crustal values, and higher than the global average hard coal ash values, but lower than the REE-rich coal ashes recorded for various deposits globally. In general, the results show that the REE occurrence, distribution and concentration differ between the different coalfields, which could be related to the sediment source in the peat swamp and subsequent mineralogical precipitation and alteration.

The volcanic-hosted beryllium deposits in eastern China: Tectonic setting, Ages and Metallogenic potential

Xiaofeng LI[1]*, Institute of Geology and Geophysics, CAS (xiaofengli@mail.iggcas.ac.cn)
Zhu Yiting[2], Institute of Geology and Geophysics, CAS
Deng Xuanchi[3], Institute of Geology and Geophysics, CAS

Abstract

Volcanic-hosted Be deposits generally refer to epithermal low-temperature metasomatic and vein deposits occurring in volcanic-subvolcanic rocks, and related to high silica rhyolite and granite porphyry. Volcanic-hosted Be deposit is the major sources for beryllium production in the world. A large number of Mesozoic volcanic-subvolcanic rocks occurred in eastern China, but the metallogenic conditions, metallogenic potential and the prospecting prospect of volcanic-hosted Be is also unclear. This abstract clarifies the prospecting clues of volcanic-hosted Be deposits discovered recently in eastern Chin. The existing volcanic-hosted Be deposits (mineralization occurrences) in eastern China mainly hosted in the volcanic rocks of Zhangjiakou Formation, Nanyuan Formation and Jilongzhang Formation; The metallogenic chronology of volcanic-hosted Be deposits (mineralization occurrences) shows that they are mainly formed in the Late Jurassic, early Early-Cretaceous and early Late-Cretaceous. The early Early-Cretaceous is the main metallogenic period, which is basically consistent with the time of the extensional structure of Eurasia-Asia Continents in the Early Mesozoic, and the time limit of the tectonic regime transition in eastern China. It concludes that it preserves good metallogenic potential of volcanic-hosted Be deposits and a broad prospecting prospect in eastern China. The Great Xing'an Range and its adjacent areas, as well as the southeast coastal areas in China are the favorable for volcanic-hosted Be deposits (mineralization occurrences) prospecting in the future.

The chemical composition of helvine-group minerals and implications for the genesis of beryllium deposit: cases studies from Dawan, Qidushan and Taoxikeng deposits, southeast China

Yiting ZHU[1]*, Institute of Geology and Geophysics, Chinese Academy of Sciences (yiting.z@foxmail.com)
Xiaofeng Li[2], Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

Helvine-group minerals have characteristic chemical compositions and textures and occur in different environments within magmatic–hydrothermal deposits. However, their origin is still unclear. There are several quartz-vein beryllium deposits (Be-bearing minerals is mainly composed of helvine-group mineral) with different element assemblages existing in southeastern China, including the Dawan Be–Mo, Qidushan Be–Zn–Sn, and Taoxikeng Be–W deposits. We present the chemical composition of helvine-group minerals analyzed by electron probe micro-analysis EPMA and laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS). The EMPA data show that the helvine-group minerals from the three deposits is helvine and/or danalite. A wide variety of different trace elements display high concentrations in the different deposits (e.g., helvine-group minerals from the Dawan deposit are rich in Li, B, Sc, V, Ga, Y, Sn, Cs, Th, and U; those from the Qidushan deposit are rich in Sc, Cd, and Sn; whereas those from the Taoxikeng deposit are rich in Y, Cd, Sn, Ta, and total rare-earth elements ∑REE. The material analysed from the Dawan deposit have the highest concentrations of Li (28.03–134.96 ppm), Sn (126.01–709.24 ppm), Sc (108.10–287.64 ppm), Cs (0–37.24 ppm), Th (4.78–112.63 ppm), and U (0.79–4.13 ppm). The material analysed from the Taoxikeng deposit have the highest concentrations of Y (594.95–899.95 ppm), Cd (22.63–25.21 ppm), Ta (0.41–0.86 ppm), and ∑REE (281.69–451.79 ppm). However, those from the Qidushan deposit have the lowest concentrations of Y (10.21–37.70 ppm), Sn (0–26.88 ppm), U (0–19.06 ppm), Eu (0–0.14 ppm), and Cs being below the detection limit. All of them are rich in heavy REEs but poor in light REEs with distinctive REE patterns. Our results reveal that both crystallographic substitution and fluid composition control the enrichment of trace elements in helvine-group minerals. The textures and the trace element compositions of helvine-group minerals can represent various parageneses and ore-forming fluid compositions. We propose that the δ Eu values and La/YbN ratios can be used as markers to discriminate the genesis of helvine-group mineral precipitated from different environments, based on the chemical compositions and the origin of ore-forming fluids.

Abstract

In recent years, the research and prospecting of Himalayan rare metal mineralization have made significant breakthroughs, making Himalaya a potentially important rare metal mineralization belt. We recently discovered pollucite-lepidolite-albite granite and spodumene-bearing pegmatite in the Gyirong-Nyalam region. Among these, the pollucite in the Tsalung Valley is first discovered in the Himalayan belt in China. Additionally, the discovery of spodumene-bearing pegmatite at the Gangbu is another lithium ore occurrence after the discovery of spodumene-bearing pegmatite at the Qunggya Kang (Pusila), Gabo, Ra Chu, and Ku Chu regions in the Himalayas. The occurrence of pollucite indicates that the magma experienced an extremely high degree of fractionation, reflecting that the Gyirong-Nyalam region should have an excellent prospect for rare metal mineralization. The dating results of monazite, columbite-tantalite, and cassiterite from the tourmaline muscovite granite, spodumene-bearing pegmatites, and pollucite-lepidolite-albite granite showed that the age of the tourmaline muscovite granite and spodumene-bearing pegmatites are 25 Ma, and the pollucite-lepidolite-albite granite is formed at 19~18 Ma, confirming a two-stage of mineralization. In comparison to the spodumene pegmatite in the Himalayas, the pollucite-lepidolite-albite granite exhibits different whole-rock and mineral compositions, suggesting they may have different fractionation processes. Notably, the elevated fluorine (F) is proposed to greatly enhance the magmatic fractionation and the degree of rare-metal element enrichment. Importantly, most spodumene-bearing pegmatites from west to east in the Himalayas have a similar formation age and field occurrence, indicating that the lithium mineralization is temporally and spatially coherent along the strike of the Himalayan belt. Combined with the metamorphic and deformation characteristics of the strata, we propose that the Li-Rb-Cs mineralization is mainly controlled by the development of the South Tibetan Detachment System (STDS). It's also noteworthy that abundant Cs-bearing geyserite deposits are exposed along the Yarlung-Tsangpo River, indicating there is a potential link between the endogenic and exogenic rare-metal deposits, emphasizing how the Himalayan orogeny controls mineralization.

Abstract

Beryllium, with its unique chemical properties, is dispensable and irreplaceable in many industries related to high-tech applications and products vital to national security, which makes maintaining stable supply of this metal for the economy and defense very essential. Bertrandite ore from the volcanic rocks and beryl ore from the pegmatite or granites are the major Be sources of the world and have been the focus of future exploration in many countries. The southern Great Xing'an Range (GXR) of the northeastern China is well-known for its widespread and large abundances of Mesozoic granites and volcanics, which was thought to have great potential for the Be metallogenies. However, the actual spatial-temporal distribution and metallogenetic condition of the Be deposits and occurrences in the southern GRX were rarely reported in the past. Our work in recent years confirmed twenty-one reported Be deposits or occurrences in the southern GXR and newly identified five Be occurrences that mainly associated with granite-pegmatite, quartz vein, and greisen. Beryl is the most common ore minerals in these new Be occurrences with secondary bertrandite and phenacite found in certain occurrences. Two metallogenetic episodes, including the middle to late Triassic (240~213 Ma) and the Early Cretaceous (144~125 Ma) were observed, corresponding to the post-collision extension after the closure of the Paleo Asian Ocean and the lithospheric extension caused by the roll-back of the subducted Paleo-Pacific oceanic plate, respectively. Systematic mineralogical, petrological and geochemical studies revealed that the Be deposits and occurrences from the southern GXR are genetically related to the coexisted highly-fractionated granites of the region and experienced strong fluid-melt interaction during the enrichment and mineralization of Be. In addition to the hydrous fluids released from the shallow granitic reservoir, deep magma reservoir-derived fluids were also involved and facilitated the depositing of Be minerals. Our results suggest that the granite-pegmatite hosted Be deposits and occurrences are widespread in the southern GRX and might be an important resource of the Be minerals.

Rare Metals in Coals of Far East of Russian: Concentrations & Resources in Coal deposits

VLADIMIR ILICH VYALOV[1]*, Southern Federal University, Rostov-on-Don, Russia (vladimir_vyalov@vsegei.ru)
ALEKSEI V. NASTAVKIN[2], Southern Federal University, Rostov-on-Don, Russia
EVGENY P. SHISHOV[3], A.P. Karpinsky Russian Geological Research Institute, Saint-Petersburg, Russia

Abstract

Russian coal is of commercial interest not only as a fuel. Trace elements in 11 brown coals of the Far East and the Arctic coast of Russia were analyzed (more than 1000 samples) using the method of mass spectrometry with inductively coupled plasma. It was possible to determine the reliable concentrations of a number of chemical elements (Ge, Sb, W, Ag, etc.). Coals contain high contents of Ge, Be, Sc, Mo, W, REE, U, Ag, Pd, etc. Content of metals in brown coals of Kamchatka: the Korfskoe deposit (content in ash/in coal, ppm): Ge (70-500/-), Li (-/43), REE (445.5 (max 1314)/161.7), Sr (425.1/154.3, Zr (261 (max 1570)/94.7), Mo (32.4 (max 219)/11.7), V (442 (max 3010)/161), Sc (22.3 (max 60)/8.1), Cu (-/79.4), Ag (-/3.9), Pd+Pt (0.13/0.05). Echvayamskoe deposit: Ge (-/max 372), In (max 10/-), REE (max 514/-), Cu (-/max 140), V (max 1020/-). Coal deposits with metals of the Magadan Region: Lankovskoe, Viliginskoe deposits: REE (to 549.1 – 691.3); Viliginskoe: W (to 381), Mo (to 106), V (to 1160), Pd (to 0.048) in coal ash. Coal deposits of the Amur Region (to/average, ppm, in ash): Erkovetzkoe (East part): REE (3813.4/ 490.9), V (to 1180), Zn (to 676); Hurmulinskoe: REE (2037.3/1095.8), Ni (480/230.4); Lianskoe: REE (1914.8/521.3); W (458.0/57.5), Mo (48.8), Cu (289.0/141.6); Ushumunskoe: REE (to 913.5/380.7), W (to 359), Nb (to 156), etc. Coal deposits with rare metals of Primorski Krai (ppm): Pavlovskoe deposit. Mean: Be (29.4), Ge (580), Sb (192.1), Y + REE (91.0), Cs (5.2), W (254.2), Rb (13.3) (in coal substance). Shkotovskoe brown coal deposit. Mean: Be (38.8), Ge (1484), Sb (598), REE+Y (83.3), Mo (14.4), W (341.4), Rb (12.5) (in coal substance). Rakovskoe deposit: max. concentrations: Be (338), Ga (96.4), Ge (1100), Sb (610), REE+ Y (2853), Mo (230), In (1.63), U (3670) in ash.

Rare metal resource potential of coals of Far East Federal District (the non-licensed 11 deposits): this resource of metals in coals has been assessed according to categories of prognosticated resources («P3» and«P2» according to Russian classification). The amount of rare metals prognosticated resources of category P2 is as follows: Ge – 7.18 thousand tons, Sc – 11.98 thousand tons, Ga – 10.94 thousand tons, Rb2O – 40 thousand tons, SrO – 137 thousand tons, Cs2O – 3.6 thousand tons, ZrO2 – 36.3 thousand tons, REE+Y – 212.8 thousand tons. Category P3: Ge – 9.8 thousand tons Sc – 14.4 thousand tons, Ga – 16.4 thousand tons, Rb2O – 46.3 thousand tons, SrO – 125.7 thousand tons, Cs2O – 9.16 thousand tons, ZrO2 – 135.6 thousand tons, REE+Y – 266.18 thousand tons. PGM (Pd+ Pt) of category P2 amount to 15.1 tons and those of category P3, 24.4 tons. All this, in total, forms a new considerable mineral-raw base of rare

metals and other valuable metals in brawn coal deposits of Far East of Russia.
This study was supported by the Russian Science Foundation project № 23-27-00427, https://rscf.ru/project/23-27-00479/

Rare metal (REE, Nb, Ta) deposits hosted by carbonatite and alkaline complexes: A Canadian perspective

Anne-Aurélie Sappin[1]*, Geological Survey of Canada (anne-aurelie.sappin@nrcan-rncan.gc.ca)
Paul Bédard[2], Université du Québec à Chicoutimi
Marc Constantin[3], Université Laval

Abstract

Carbonatite and alkaline igneous rocks are relatively rare on the Earth's surface, accounting for less than 1% of all the Earth's igneous rocks. However, they are the main hosts of rare metal (rare earth elements (REE), Nb, Ta) deposits and most of the world's rare metal production is associated with these igneous rocks. Alkaline-carbonatitic magmatic systems emplaced into intracratonic anorogenic or post-orogenic extensional settings, spatially related to major crustal structures. They generally crystallize from volatile-enriched carbonatite and alkaline parental magmas generated by low degrees of partial melting of metasomatized or crustally contaminated lithospheric mantle sources. Canada hosts many of these unusual magmatic systems. They range in age from Neoarchean to Mesozoic, albeit many are Proterozoic in age, and mainly occurred within the Canadian Shield (central and eastern Canada) and the Canadian Cordillera (western Canada). The country also has numerous examples of alkaline-carbonatitic magmatic systems mineralized in REE, Nb, and Ta, some of which are currently in production (e.g., Niobec Nb mine – 1.8 Mt at 0.61% Nb2O5, total production in 2010) or at an advanced-stage of development (e.g., Strange Lake REE deposit – 278.0 Mt at 0.93% TREO and 1.92% ZrO2, indicated mineral resources; Kipawa REE deposit – 13.4 Mt at 0.36% TREO, indicated mineral resources). Based on their main host rock-association, these rare metal deposits can be subdivided into 1) carbonatite-related deposit, 2) peralkaline intrusion-related deposit, and 3) peralkaline volcanic rocks-related deposit. They were mainly formed by magmatic (e.g., fractional crystallization, magmatic immiscibility), hydrothermal, or metasomatic processes, or a combination of these. Overall, REE ores in these alkaline-carbonatitic magmatic systems contain a range of REE-bearing fluorocarbonates (e.g., bastnaesite–Ce, parisite–Ce, synchysite–Ce), phosphates (e.g., monazite–Ce, xenotime–Y), oxides (e.g., aeschynite–Y, fergusonite–Y), REE-bearing silicates (e.g., eudialyte, mosandrite–Ce) and halides (e.g., gagarinite–Ce, fluorite). In contrast, Nb and Ta ores consist mainly of oxides (e.g., pyrochlore–Nb, columbite–Nb-Ta, and rutile–Nb-Ta).

Canada has some of the largest known high-grade, high-tonnage rare metal geological resources associated with carbonatite (e.g., Niobec, Aley) and alkaline (e.g., Strange Lake, Nechalacho) magmatism worldwide. Although many geological features of these deposits have already been documented, the critical processes responsible for their formation need to be better constrained in many cases. Improving our knowledge of rare metal-bearing carbonatite and alkaline complexes in Canada will therefore help refine the global petrogenetic and metallogenic models for this type of deposit.

Extreme low-T fractionation of felsic magmas and implications for rare-metal deposit genesis: analysis of regional thermal considerations and internal high heat production

David R LENTZ[1]*, University of New Brunswick (dlentz@unb.ca)

Abstract

The formation of very low temperature magmatic systems that are very highly enriched (extremely, i.e. > 1000 times) in key incompatible elements of interest are critical to both magmatic and magmatic hydrothermal deposits. A combination of selected partial melting and crystal fractionation are responsible for these levels of enrichment, although in many cases source protolith attributes are important as well. Like in most magmatic systems, the processes controlling fractionation to this degree are related to partitioning equilibria in the source and during ascent, emplacement, and locally even the eruption (tuff to flows) of these magmas. Other than the > 1000 times absolute enrichment values of metallogenic incompatible elements relative to the crust, key element ratios like Rb/Sr, Zr/Hf, Nb/Ta, Th/U etc. have long been applied to reflect degrees of differentiation to extreme fractionation levels, although some researchers have erroneously suggested that these indices can only reflect hydrothermal processes. However, the existence of virtually mineralized tuffs like the peraluminous Macusani (highly significant Li, U, Sn, Ta) and peralkaline Nb tuff (Brockman) (highly significant Nb, Ta, Zr, U) demonstrate these levels of differentiation can be entirely magmatic processes; numerous other examples are being realized worldwide. In addition, the saturation of ore minerals like spodumene, tantalite, cassiterite, uraninite, molybdenite, monazite, eudialyte etc. from extremely evolved magmas shows deep to shallow fractionation processes can occur, although are known to be extremely rare in nature. Published mineral solubility experiments show that these are reasonable saturation models as well. However, rheologic limitations coupled with limitations in crystal-melt separation mechanisms have cast doubt on extreme fractionation models. These specialized fractionation models have been termed boundary layer differentiation to solidification front fractionation, but none has solved the noted limitations to low-T crystal fractionation in felsic magmatic systems, even with high degrees of fluxing elements. Although typically neglected, the regional thermal environment of fractionating magmatic systems that can prolong selective partial melting through to extending fractional crystallization can extend these supra-solidus processes by up to 10 times. In addition, high U and Th (often > 10 times crustal values) in fractionating felsic magmatic systems, commonly termed high heat production (HHP), can also significantly extend the supra-solidus fractionation processes that will strongly affect very high degrees of fractionation. Although the absolute effects associated with significantly extending duration (t) of fractionation are not known, this is no doubt an important contributing factor in low-T fractionating magmatic systems. Also, metal endowment in these low-T fractionating felsic magmatic systems no doubt contributed to the relative fertility of these specialized felsic magmatic hydrothermal systems, although that remains quite controversial and vigorously debated.

Volcanic-hosted hydrothermal rare earth element (REE) mineralisation, West Musgrave Province, Australia

Ben James Kimpton [1]*, Caspin Resources Ltd (benkimptongeo@gmail.com)
Garry A Dick[2], Caspin Resources Ltd
Greg J Miles[3], Caspin Resources Ltd

Abstract

A unique style of hydrothermally remobilised, volcanic-related Rare Earth Element (REE) mineralisation is described at the Duchess Prospect in the Proterozoic West Musgrave Province of Western Australia. Mantle derived, highly fractionated felsic volcanics of the Warakurna Large Igneous Province (LIP) with significant background enrichment in REEs serve as the likely source and observed host of mineralisation. REEs are precipitated and transported by hydrothermal fluids and deposited in high concentration predominantly at rheological boundaries, principally the structural-stratigraphic contact between volcanic units. SEM mineralogy demonstrates that the majority of REEs are hosted within monazite and lesser xenotime, which are secondary in nature replacing primary minerals including titanite. Mineralisation includes a substantial proportion of both light and heavy REEs including the economically significant Pr, Nd, Tb and Dy.

Approximately 2 km to the northwest at the Handpump Prosect, hydrothermal fluids with analogous structural-stratigraphic controls are observed to host significant gold mineralisation. Handpump has previously been interpreted as a low temperature, low sulfidation epithermal deposit with mineralisation being broadly coaeval to the Lower Mt Palgrave Group at 1075±8 Ma. Fine grained gold is primarily hosted in quartz veins and breccias with associated hydrothermal alteration at the contact between volcanoclastic and rhyolite units. Systematic surface geochemistry along a 7 km strike extension of this contact identified significant and widespread base and precious metal anomalism which instigated further exploration at the greater Duchess Prospect. The discovery of high-grade REE mineralisation along this contact was a serendipitous outcome of reconnaissance aircore drilling principally targeting Cu-Mo-Zn-Pb-Au-Ag+ anomalism in the area. While significant Au-Ag, Cu and Mo values were observed in drill and rock chip assays, REE mineralisation represents the standout exploration result from the prospect. Coincident base, precious and REE enrichment serves to highlight the prospectivity of the West Musgrave region and the felsic components of the Bentley Supergroup and Warakurna LIP.

Abstract

Heima pegmatite-hosted lithium deposit is located in the Gaoligong Mountain area, close to the southern section of the Sanjiang region, Southwest China. There are more than 30 granite pegmatite veins developed in the ore district, most of which intrude into the metaquartzite hornblende schist of the Carboniferous system along the schistosity. The pegmatite veins are not well-zoned in the ore district, and the mother lode is mainly composed of quartz, zinnwaldite, albite, potassium feldspar, topaz, and apatite. The accessory minerals include niobium (tantalum) nigrine, garnet, tourmaline, beryl, cassiterite, zircon, and thorite. The rare metal ore-forming elements are mainly Li, as well as some Be, Nb, Ta, and Sn. Zinnwaldite is the main ore mineral in the ore district.

Apatite in the pegmatite of the Heima lithium deposit belongs to the fluorapatite and mainly occurs in zinnwaldite and mica fissuring, with a content of less than 5%. The apatite is colorless, transparent, and hypidiomorphic-xenomorphic granular, with a grain size of 0.2-2 mm, and some grains up to 10 mm. Commonly, it contains extremely small thorite inclusions. Under plane-polarized light, it is colorless and transparent, with a positive medium relief, while under cross-polarized light, the interference color appears as first-order gray, with parallel extinction.

The apatite in the pegmatite of the Heima lithium deposit exhibits uniform characteristics in both BSE and CL images and belongs to magmatic apatite. In this study, preliminary in-situ LA-ICP-MS U-Pb dating was analyzed on the 24 points of apatite. Results show that the 238U contents vary from 336.10 × 10-6 to 479.40 × 10-6, with an average of 386.40. The 238U/206Pb ratio ranges from 7.27 to 14.04, with an average of 11.41. The 207Pb/206 Pb ratio varies from 0.58 to 0.61, with an average of 0.59. The 238U/206Pb-207Pb/206 Pb age of apatite is 55 ± 4 Ma (MSWD=2.4), which could represent the diagenetic and ore-forming age of Heima pegmatite-hosted lithium deposit. Therefore, we can conclude that the rare metal mineralization was formed in the tectonic environment caused by the India-Eurasia collision which resulted in crustal thickening, which may be related to the crustal material remelting/deep melting caused by the India-Eurasia collision.

Abstract

Mongolia is divided into northern and southern domains by the main Mongolian lineament. The alkaline-carbonatite complexes are mainly distributed within the area of Southern Mongolia, which have a clear economic potential owing to their overall high content of rare-earth elements (REE). The Khotgor REE deposit located in the Gobi-Tien Shan fold belt in southern Mongolia and controlled by tectonic faults. Estimated resources in this deposit are 40Mt REO with an average content of 1.22 wt.% [1]. The alkaline-carbonatite complexes are mainly composed of nepheline syenite, carbonate breccia and carbonate dikes. Some of these dikes and breccia contain "apatite ore"[1]: magnetite-apatite or fluorite-celestine-magnetite-apatite associations. Previous studies have shown that the nepheline syenite age was 135 Ma[2].

At present, the study on mineralogy and geochemical of Khotgor carbonatite complexes are comparatively weak and not systematic. In our study, we analyzed the REE-rich carbonatite in Khotgor by SEM and TIMA. The carbonatites are, for the most part, medium-grained massive rocks composed of primary calcite, with different proportions of orthoclase, magnetite, dolomite, apatite, muscovite, biotite and barite. Accessory minerals are fluorite, quartz, zircon and chlorite. In some part of the carbonatite, calcite-dolomite-magnetite vein could be observed. Two REE minerals were identified: parisite and monazite. It is worth noting that the parisites are closely associated with calcite, orthoclase and other magmatic rock-forming minerals, with intact crystal form and mainly radially produced. Besides, most of the parisites are intergrown with or superimposed on barite (BaSO4), which also has a close relation with rock-forming mineral. All these mineralogical features show that the parisite and barite are mainly formed in the magmatic stage of carbonatite. The sulfate (SO42-) may be an important factor for rare-earth element migration and precipitation.

Abstract

Rubidium (Rb) is one of important rare metals and strategic emerging industry minerals, and it is anticipated to be of the focus of intrnational naturalresource competition in the future. South China is an important strategic mineral resource base in China, which has abundantly developed granites of multiple ages and gyres, and possesses large-scale mineralisation of rare and non-ferrous metals. The Miao'ershan-Yuechengling batholith (MYB) is one of the largest granitic batholiths in Guangxi Zhuang Autonomous Region, South China.

The Xianglushan rubidium-rich granite complex, which is mainly composed of alaskite and biotite monzonitic granite, is located at the northeastern part of the MYB. The content of Rb in granite body has exceeded the industrial grade. Alaskite has a concordant U-Pb age of 416.6±3.5 Ma (MSWD=0.15,N=12) of zircon and Tera-Wasserburg lower intercept ages of 415.9±2.4 Ma (MSWD=0.76,N=17) of cassiterite. All these new age data are indistinguishable within analytical uncertainty and, therefore, indicate the rubidium-rich granite complex formed in Caledonian. The εHf(t) values of zircon vary from -6.86 to -3.64 and calculated two-stage Hf model ages (TDM2) vary from 1.65 to 1.90Ga, indicating that the granites may have formed from partial melting of Paleoproterozoic basement rocks

The alaskite and biotite monzonitic granite have high SiO2 (74.58~80.71wt.%) and alkaline (K2O+Na2O=7.32~9.49wt.%), with a range of A/CNK ratios of 1.06~1.28. Both types of rock body have similar trace element characteristics, with relative enrichment in RbUThNb and Ta, and relative depletion in Sr and Ba. The mean value of the differentiation index (DI) is 93.93~98.03. All the geochemical features show that the Xianglushan rubidium-rich granite complex belongs to highly differentiated S-type granite.

Allanite crystallization inhibits economic rare earth element mineralization in carbonatites.

SOURAV BHATTACHARJEE[1]*, Indian Institute of Science Education and Research, Tirupati (souravbhattacharjee@students.iisertirupati.ac.in)
Monojit Dey[2], Indian Institute of Science Education and Research, Tirupati
Aniket Chakrabarty[3], Indian Institute of Science Education and Research, Tirupati

Abstract

Carbonatites are magmatic rocks with more than 50% primary carbonate minerals. Carbonatites host economic-grade rare earth elements (REE), and their demand is anticipated to surge amid the global shift toward green technology. Carbonatite-forming magma-derived carbohydrothermal fluids are rich in REEs, alkalis (Na and K) and REE-complexing ligands (CO32-, OH-, F-, SO42-, and Cl-), leading to widespread REE mineralization. Despite the presence of REE-carbonates (e.g., ancylite), REE-fluorocarbonates (bastnäsite, parisite, synchysite), REE-phosphates (apatite, monazite, xenotime) and accessory REE-silicates (allanite, britholite) in carbonatites, economically viable REE extraction is currently feasible only from bastnasite and monazite (Chakhmouradian and Wall, 2012). In contrast to silica-rich country rocks, the insufficiency of silica and alumina in carbonatite-forming magmas often results in wall rock assimilation. The influx of Si into such magmas prompts the early incorporation of REEs within apatite during magmatic stages, decreasing the overall REE budget in carbohydrothermal fluids (Anenburg et al., 2020). The persistent contamination by Si and Al in post-magmatic or carbohydrothermal stages stabilizes the formation of allanite (Bhattacharjee et al., 2024). Carbonatite-related allanite occurrences can be generalized into two broad types: a. confined within the carbonatites with profuse wall rock xenoliths, and b. at the interphase between the carbonatite and the Si-Al-rich country rock. Wall rock xenoliths within carbonatite facilitate prolonged assimilation and contamination through magmatic and carbohydrothermal stages. This process may sequester a major portion of the REEs within apatite and allanite, hindering the economic concentration of monazite and bastnasite within carbonatites. On the contrary, minimal assimilation and contamination within carbonatites might facilitate the formation of monazite and bastnasite. Additionally, carbonatites with wall-rock xenoliths show proximal allanite-(Ce) and distal REE-rich epidote in the metasomatized country rocks, governed by the allanite-epidote ($REE^{3+} + Fe^{2+} = Ca + Fe^{3+}$) and allanite-clinozoisite ($REE^{3+} + Fe^{2+} = Ca + Al$) substitution mechanisms. Thus, the spatial variation in allanite compositions further supports the decreasing REE budget in carbohydrothermal fluids with high degrees of wall rock contamination within carbonatites.

Abstract

The Jiufeng and Nandaoao tin deposits occur in the Jiufeng ductile shear zone that is developed on the western outer contact zone of the Neoproterozoic Sanfang granitic pluton of northern Guangxi, south China. The deposits and the shear zone are hosted by the Neoproterozoic Sibu Group sedimentary rocks. Tin was mainly sourced from Sanfang granite. The tin deposits were products of magmatic hydrothermal activities associated with granitic emplacement and are dated ~830 Ma by zircon U-Pb method. The tin orebodies are present as tourmaline-bearing quartz veins, cassiterite-bearing quartz veins, and greisen. The Jiufeng ductile shear zone strikes in NNE, dips to SE, and shows left lateral-reverse motion. The ductile shear zone is dated 440 Ma, indicating that the ductile shear zone postdated the tin mineralization.

The ductile shear zone superimposed the tin deposits and caused the S-shape bending of the deposits although the continuity of the deposits is not broken. The sheared deposits are characterized by pervasive mylonitic foliation. Cassiterite crystals in the sheared orebodies show

brittle deformation. In the high strain domains, the cassiterite crystals are broken into very small fragments that occur along the mylonitic foliation with pronouncing shape-preferred orientation. In the weak strain domains, the cassiterite crystals are also broken but the broken fragments have high angularity, show only slight dislocation, and can still be restored to their original shape. The correlation coefficient between the degree of AMS (P) of the ductile shear zone and the tin mineralization intensity (content of tin) for both deposits is only 0.2, too low to be metallogenetically related to the ductile shearing event.

This research was funded by the Natural Science Foundation of Guangxi, China (Grant Nos. 2019GXNSFDA245009, 2022GXNSFBA035463) and National Natural Science Foundation of China, China (Grant Nos. 42072259, 42162018).

THE ZONE OF JUNCTION OF OIL AND GAS BEARING STRUCTURES AND URANIUM PROVINCES

Rakhimjan TURSUNMETOV[1]*, State Establishment "Institute of hydrogeology and engineering geology" (tursunmetov45@mail.ru)
Valentin TYO[2], State Establishment "Institute of hydrogeology and engineering geology"
Aziz Ibragimov[3], State Establishment "Institute of hydrogeology and engineering geology"
Salim Sobirov[4], MINISTRY OF MINING INDUSTRY AND GEOLOGY OF THE REPUBLIC OF UZBEKISTAN

Abstract

Recent studies indicate a consistent increase in the depth of detection of hydrogenic uranium mineralization annually. Exploration efforts are not only focused within traditional uranium ore regions but also extend into areas where oil and gas structures intersect. Notable intersections have been identified in the usa (specifically wyoming) and china, the republic of uzbekistan (ziatdin and bukhara oil and gas structures). Consequently, there is a keen interest in enhancing the mobile radiogeochemical method to detect deeply buried uranium ores. This method relies on soliton transfer from deep-seated ore zones, facilitating the migration of radioactive elements to the surface through energy channels adjacent to the electrically negative surface near the earth's crust, which possess an accumulating capacity.

Soliton transfer occurs due to tectonodynamic movements induced by lunar-solar tides, fostering deformation phenomena that facilitate the migration of radioactive and geochemical elements. Diffusion processes are pivotal in the mass transfer of energy over uranium mineralization, accompanied by ionization processes forming ion pairs with opposite charges. Significant uranium concentrations (20-25 mg/l) have been observed in oil and gas structures at considerable depths. Therefore, the task at hand is to pinpoint the deposition locations of ore-bearing flows emanating from magmatic bodies.

The search for uranium deposits necessitates studying magmatic bodies associated with uranium, with methodology based on the congruence of radiometric indicators, radioactive, and geochemical elements under specific geostructural conditions linked directly to ore deposition. Generally, uranium mineralization originates from igneous bodies of granite or granite-porphyry composition. Tectonodynamic activation facilitates the release of uranium components in ion form, migrating towards artesian basins. Magmatic bodies exhibit local gravitational anomalies and reduced magnetic anomalies. The direction of ore-bearing flows is characterized by a gradual decrease in the gravitational field and an increase in the geomagnetic field, with the mineralization location indicated by gradient changes in these fields. Special attention is given to identifying paleochannels in deep horizons, along which uranium components migrate.

Furthermore, transverse neotectonic structures adjacent to magmatic bodies are considered, hosting paleochannels that discharge into artesian basins, leading to the formation of localized ore structures. Horizontal stretching and compression deformations develop in these structures under tectonodynamic forces. Monitoring reveals anomalous daily dynamics of gamma radiation during

this process. Organic substances like humic and fulvic acids significantly impact the uranium deposition zone, drastically reducing the redox potential (rp). Due to their high migration ability, these substances play a vital role in uranium mineralization. A similar scenario is envisaged in the junction zone of oil and gas structures and uranium provinces.
The radiogeochemical method serves to identify and study the aforementioned structures for detecting uranium mineralization. This method has been practically applied near oil and gas structures, resulting in the identification of uranium mineralization at depths ranging from 500 to 800 meters.

Beryl chemistry as a compositional framework for prospecting of rare-metal pegmatites in Nepal Himalaya

SUSHMITA BHANDARI[1]*, Department of Mines and Geology, Kathmandu, Nepal (sushgeo12@hotmail.com)
Kezhang Qin[2], Institute of Geology and Geophysics, University of Chinese Academy of Sciences, Beijing, China

Abstract

Beryl (Be3Al2Si6O18), being an important beryllium ore and valuable gemstone, is also an early rare-metal mineral crystallizing from fertile magma that potentially evolves to deposit Nb, Ta, Li, and Cs minerals. Although the highest concentration of aquamarines in South and Southeast Asia has been reported from Nepal, little is known about the geochemistry and mineralization characteristics of beryls from the Nepal Himalaya. This study presents major and trace element data for beryl from the recently discovered Yamrang pegmatite, aiming to elucidate characteristics of beryl and evaluate potential geochemical exploration tools for rare-metal pegmatites while also enhancing the prospects of other rare-metal commodities. Beryl mineralization was identified in zones 3, 4, and 5 out of the five mineralogical-textural zones within the Yamrang pegmatite. Two types of beryl, magmatic and hydrothermal, were distinguished based on their occurrences, mineral assemblage, texture, and geochemical properties. Magmatic beryls occur mainly in zones 3 and 4, mostly associated with blocky microcline and granular quartz. They are characterized by larger crystals (7-10 cm), prismatic to columnar habit, varying from opaque to translucent, and exhibiting green to bluish-white color. Their backscattered (BSE) images display homogeneous textures suggesting high Na and low alkali concentrations. In contrast, hydrothermal beryls are typically found in zone 5 miarolitic cavities, associated with smoky quartz crystals, albite (often cleavelandite variety), muscovite, and clay minerals. These beryls are smaller (1-3 cm), with tabular to acicular habit, ranging from colorless to deep blue, and exhibiting weak compositional zoning in BSE images, indicating alkali enrichment. Fe2+ is the main chromophore controlling the blue color of Yamrang aquamarines with up to 1.1 wt% of FeO. The octahedral Fe-Al substitution is the dominant element substitution mechanism in Yamrang beryls. The enriched Li + Cs + Rb and Fe, Mn, Rb concentration of beryl are the potential fractionation indicators. This study hopes to establish a fundamental compositional framework for future exploration of rare-metal pegmatites in the region.

Cycling of Uranium (U)-polymetals in Earth System and its Effect on Mineral Resources and Environment

Deru XU[1]*, East China University of Technology, Nanchang, China (xuderu@gig.ac.cn)

Abstract

In recent years, more and more exploration and exploitation have revealed that in many different types of metallic deposits with
various ages in the world, uranium (U), present either as main metal resource or as by-product, is often symbiotic or concomitant with other metals, such as REE, W, Sn, Bi, Mo, Re, Au, PGEs (Pa, Pt), Ga, Ge, In, Co, Ni, V, Nb, Ta, Cu, Pb, Zn, Mn, etc. Such the typical ore deposit-types include: (1) hydrothermal IOCG Fe-Cu-Au-U-Ag-Ba-REE, Fe-Cu-Mo-Au-Co-REE-U and Fe-Cu-Au-Ag-PGE-U deposits, represented by the supergiant Olympic Dam deposit in Australia, (2) quartz pebble-related Au-U deposit, represented by South Africa's Witwatersrand Basin, (3) metasedimentary rocks-hosted Cu-Co-(Ni-U-Cr-Ag-Au-PGE-Mo) or Cu-Co-(Ag-Bi-W-Ni-REE-U) deposits, (4) sedimentary-metamorphic and/or magmatic hydrothermally reworked U-Cu-Au-Te-Mo-Ni-Co-Ga-V-REE and Co-Cu-U deposits, represented by that in India‘s Singhbhum shear zone, (5) unconformity-related U-Mo, U-Cu-Au, U-REE and U-Ni-Co-As-PGE-Zn deposits, represented by those in Athabasca Basin, Canada, (6) volcanics- or intrusion-related U-Ni-Co-As-Ag/Bi or Ag–Bi–Co–Ni–As±U, U-Pb-Zn-REE-Mo-Cu-Au-Ag, U-Mo-W-Sn-Cu-Pb-Zn-Ag-Au, U-Be-Mo-Cu-Pb-Ag-Au and Au-PGE±U deposits, (7) carbonatite-type U-Nb-REE-Pb-Sr-Se-In-Te-Ge deposit, and (8) U-rich coal-type U-Se-Mo-V-Re or U-Se-Mo-V-Cr-Re-REE deposits. All these instances indicate that there are intrinsically genetic link of U to other metals, especially those critical metals in metallogenetic process(es), and that U shares similar geochemical behavour to associated metals. This fact is of important significance not only for prospecting much more U-bearing mineral resources but also for seeking more effective methods to disposal of nuclear waste. However, to that what mechanism(s) caused coexistence of U and associated metals in U-bearing deposits, how about the cyclic characteristics of U and associated metals in the earth system, and what kind of Resource-Environment effect was caused by such the cycling, has not been pay attention and thus not been possible to be unambiguously understood, up to now, although these topics should have become a hot spot and frontier scientific issue in international geosciences.

The present study aims at hunting the cyclic characteristics of U and associated metals in the earth system and then attempting to unravelling the Resource-Environment effect caused by such the cycling. To give a compelling answer to these issues, the authors, from the global vision, propose that the future work maybe focus on the following six key scientific Issues on U and associated metals in different mineral systems, that is: (1) geochemical behaviors, characteristics and mechanisms of the U and associated metals in the circulation of the earth system, (2) origination, occurrence, migration, interaction and accumulation of the U and associated metals in atmosphere, hydrosphere, biosphere and lithosphere, (3) mineralogical characteristics and formation

mechanisms of the U and associated metals in the circulation of the earth system, (4) key factors controlling the genesis and evolution of the different types of U-bearing rock series and U-polymetal deposits, (5) dynamic-chemical processes of mineralization for the U and associated metals, and their prospecting breakthrough, and (6) constraint of the U and associated metals cycling on Environment and Climate change.

Hao Song[8], Chengdu University of Technology

Abstract

Mineral deposits were formed at various depths in the upper crust, ranging from near surface to >10 km. The mineralization systems at different depths may be linked by a common hydrodynamic framework, even though the direct controlling factors and styles of mineralization are significantly different. This is particularly the case for mineralization systems in which structures exerted a major control. Understanding the genetic relationships between shallow and deep parts of the mineralization systems is critical for deep mineral exploration, which is increasingly important for finding new mineral resources. Since most mineral deposits formed from hydrothermal fluids, the hydrodynamic linkage between shallow and deep parts of a mineralization system, which controls the driving force, flow direction and velocity of the ore-forming fluids, plays a key role in determining whether or not, and where, mineralization is localized among the many seemingly similar structures.

The hydrodynamic relationships between shallow and deep parts of mineralization systems vary with the geologic setting, based on which the mineralization systems may be classified as magmatic-hydrothermal systems, structurally controlled hydrothermal systems with uncertain fluid sources, and hydrothermal systems associated with sedimentary basins. In the magmatic-hydrothermal systems, the difference in fluid pressure between the lithostatic or supralithostatic regime within the magmatic intrusions and hydrostatic or suprahydrostatic regime in the country rocks, is a major driving force for ore-forming fluid flow, in contrast to the shallow part of the system that is dominated by a hydrostatic regime. In structurally controlled hydrothermal systems, as typified by orogenic gold deposits, there is also a change from a lithostatic-dominated regime in the lower part to a hydrostatic-dominated regime in the shallow part. Similar fluid pressure profiles also occur in hydrothermal systems associated with sedimentary basins, although the lithostatic pressure regime may be developed in the basement far below the basin or within the basin, depending on the lithologies and sedimentation rate in the basin. In each of these systems, the structures that directly controlled the mineralization in the shallow part of the system may function as suction pumps during structural activity; however, such activities are likely linked to and regulated by those operating at depth by mechanisms such as described by the fault-valve model. Thus, the fluid flow related to structural activities at shallow depths actually resulted from

coupled suction pump (shallow) and fault-valve (deep) mechanisms. Whether or not a structure at shallow depth is linked to a deep-seated structure may be a determining factor for mineralization, not only for supply of ore-forming ingredients, but also for providing the driving force and pathways of ore-forming fluid flow. These hydrodynamic relationships between shallow and deep parts of mineralization systems and their implications for mineral exploration will be illustrated by several examples from South China and the Athabasca Basin in Canada.

Hydrodynamics of the Xiangshan volcanic-type uranium deposits in Jiangxi Province, South China

Zenghua LI[1]*, East China University of Technology (lizenghua@ecut.edu.cn)

Abstract

The Xiangshan volcanic Basin of the Jiangxi Province hosts the largest volcanic type uranium orefield in China. The formation of the uranium ore field was affected by many geological factors and/or processes. Firstly, uranium mineralization is almost consistent with the formation of the Cretaceous red beds in time and space. Previous studies suggest that the red beds might have played critical role in the ore-forming processes by providing oxidizing fluids. The meteoric water may have extracted Fe3+, Cl-, and other substances in the red beds and evolved into oxidizing brines, which are able to improve the activity of the uranium in the underlying uranium-rich rocks such as granites, volcanic and basement rocks. Many researchers have attempted to explain the genetic relationship between the red beds and U mineralization, but the dynamic flow pattern of the ore-forming fluids in the presence of the red beds and its significance for mineralization have not been specifically studied. In order to better understand the hydrodynamic mechanism of the ore-forming fluids and U mineralization processes in the Xiangshan U ore field, numerical models with different coupling mechanisms are established to simulate fluid flow patterns influenced by different factors on the basis of detailed field geological investigation and previous geological and geochemical data. Using the method of hydrodynamics and FLAC software, the modelling results are as follows: In the simulation results of the models that only have the topography-driven fluid flow, it is the slope gradient of the red beds that has a great influence on the fluid flow pattern in the Xiangshan Basin. Driven by topography, the fluid flows into the volcanic rocks or even into the basement at a high flow rate. The slope gradient of the red beds has a great influence on the velocity of the fluid in the shallow strata. In addition, the changes in the thickness and permeability of the red beds to a certain extent have little influence on the fluid flow pattern. In the results of the coupled hydro-thermal models, the fluid convection has formed in the model with a heat
source. It greatly changed the former fluid flow pattern and increased the flow velocity in the basement.
Meanwhile, it enhanced the temperature inside the volcanic rocks, which makes it easier to achieve for the
ore-forming temperature.This modelling is helpful to understand the effects of different geological factors on the fluid flow pattern in the shallow strata, and its implication for the Xiangshan ore-forming processes.

Genetic association between carbonates and gold precipitation

Teng Deng[1]*, East China University of Technology (dengteng2015@126.com)
Qingxiang Wang[2], East China University of Technology
Deru Xu[3], East China University of Technology

Abstract

Carbonates have been traditionally regarded as post-ore minerals in hydrothermal deposits, but they can also occur in pre- and syn-ore stages. However, the genetic relationships between multi-stage carbonates and gold precipitation mechanisms remain unclear. The gold deposits in the Jiangnan Orogen (JO), is characterized with the occurrence of abundant hydrothermal carbonates. The nature of the carbonates, especially their association with gold precipitation, is examined in this study through petrographic and geochemical analyses as well as geochemical modeling. Field and petrographic work recognizes four paragenesis stages, i.e., 1) quartz (Q1)-carbonate, 2) pyrite-quartz (Q2), 3) gold-polysulfide-quartz (Q3)-carbonate and 4) chlorite-quartz(Q4)-carbonate. Carbonates associated with gold mineralization are mainly present in the first and third stages. Among them, the first-stage carbonates are pre-ore Fe-bearing carbonate (ankerite and siderite), which are generally crosscut by syn-ore sulfides. Such carbonates mostly occur in altered host rocks that are characterized with bleaching. Mineralogical and geochemical analyses reveal that chlorite is consumed while pre-ore ankerite or siderite produced, and Fe contents of the host rocks remain generally unchanged during alteration. Consequently, pre-ore Fe-bearing carbonate is interpreted to be generated by the interaction of CO2-bearing fluids and chlorite in the host rocks. Geochemical modeling reveals that both chlorite and Fe-bearing carbonate can lead to gold precipitation by triggering sulfidation, but Fe-bearing carbonate has higher chemical reactivity and therefore is kinetically favorable for more efficient gold deposition. Syn-ore carbonates are mainly formed in the third stage, primarily consisting of ankerite with minor calcite, and is co-precipitated with native gold, galena, sphalerite and chalcopyrite. Two stages of carbonates share similar δ13CV-PDB values, Pb, Zn and Cu contents but different Ca, Mg, Mn and Sr contents, indicating they are formed at different stages of the same hydrothermal event. Geochemical modeling demonstrates that pH increases as indicated by the formation of syn-ore carbonates, together with the consumption of S due to the precipitation of pyrite and arsenopyrite in the second stage, results in the decrease of Au, Pb, Zn and Cu solubility in aqueous fluids. This would lead to the co-precipitation of native gold with galena, sphalerite and chalcopyrite, forming the general small-scale but commonly occurred native gold-polysulfide veins in hydrothermal gold deposits. Consequently, both pre- and syn-ore carbonates in the gold deposits in JO are genetically associated with efficient Au-polymetal deposition through distinct mechanisms. Pre-ore carbonates could cause the large-scale bleaching of the host rocks, while syn-ore carbonates are closely related to native gold-polysulfides, and they can both be used as exploration indicator for hydrothermal gold deposits worldwide.

Numerical modeling of the formation of ore shell by ore-forming materials enrichment in porphyry copper deposits

Changhua XIE[1]*, Sun Yat-sen University (xiechh23@mail2.sysu.edu.cn)
Fan XIAO[2], Sun Yat-sen University

Abstract

Porphyry deposits are the primary sources of copper and molybdenum globally, as well as significant sources of gold, silver, tin, tungsten, and other rare metals. In recent years, numerical simulation experiments have been extensively utilized to investigate the mechanisms of ore-forming dynamics, owing to their capability to effectively delineate crucial ore-forming processes through coupling physical-chemical processes and explore significant controlling factors. Furthermore, the study of porphyry deposits has been enduring, but there are still many scientific questions waiting to be answered, and one of the most important challenges is the unclear understanding of the dynamic mechanisms of ore metal enrichment and ore shell formation. Therefore, this study employs numerical simulation methods to quantitatively characterize the key process whereby ore-forming magma undergoes decompression boiling and crystallization differentiation boiling, resulting in "fluid exsolution" to form independent fluid phases, extracting ore-forming matels from the magma to create ore-forming fluids, transporting these matels to the shallow crust, and accumulating in a certain position to form ore shells. It elucidates the influence of key control factors such as magma temperature, intrusion periods of deep-seated magma, and deepth of upper crustal magma chambers on this process, yielding the following insights:(1) The magma temperature controls the interaction between the surrounding rocks temperature and fluid behavior by changing the permeability of the surrounding rocks, thereby causing ore-forming materials to accumulate to form a bell-shaped ore shell at about 1500 meters above the magma chamber, with most ore-forming materials accumulating at the bottom of the ore shell.(2) The most favorable temperature range of magma for the enrichment of ore-forming materials in magma is 850°C-900°C.(3) Deep-seated magma undergoing two upward intrusions is most favorable for the formation of the ore shell of porphyry copper deposits.(4) The temperature range for the formation of porphyry-copper ore shell (i.e., the mineralization temperature of porphyry copper deposits) is 450°C-200°C.This study effectively reveals the crucial factors and ore-forming response of porphyry copper deposits in terms of dynamic numerical simulation, providing new evidence for exploring the efficient enrichment mechanism of ore-forming materials in porphyry deposits through numerical simulation experiments. It supplements the theoretical model of porphyry copper mineralization and provides theoretical references for exploration of porphyry copper deposits.

The influence of basin fluid activity on the mineralization process of sandstone-type uranium deposits

Taping He HE[1]*, 710233010@qq.com (b22010021@s.upc.edu.cn)
Yaoqi Zhou[2], 13608969182

Abstract

Sandstone-type uranium deposits are the most significant industrial uranium deposit type globally and in China, each accounting for over 40% of the total. Exploration and research have revealed a close relationship between uranium enrichment in sandstone and basin fluid activity. In the presence of uranium-rich oxidizing fluids in the basin and interactions with reducing substances, soluble U(VI) is reduced to insoluble U(IV) through processes involving debris, plant fragments, humates, hydrocarbons, and sulfides. Therefore, a comprehensive exploration and analysis of the types of basin fluids and their impact on uranium mineralization play a crucial guiding role in prospecting. This paper examines the influence of basin fluid activities on uranium reservoirs and mineralization from both macroscopic and microscopic perspectives. Drawing on basin examples, this paper explores the mechanisms behind uranium enrichment. By categorizing basin fluids into two types, namely surface oxidizing fluids and deep-seated thermal fluids, this analysis examines the properties and origins of different fluids. It clarifies the transformative role of deep-seated thermal fluid activity on uranium reservoirs. The paper classifies and discusses the spatiotemporal coupling relationships between different fluids and uranium ore bodies. It further elaborates on the impact of basin fluid activities on uranium minerals, co-associated minerals, and biological activities. The results indicate that fluid-rock reactions occurring between deep-seated thermal fluids and rock particles have a significant impact on reservoir porosity structures, thereby controlling the permeability heterogeneity of surface oxidizing fluids. Basin fluids primarily influence the formation of uranium deposits by controlling ore-forming minerals and the ore-forming environment. In particular, deep-seated hydrocarbon fluids have a significant impact on mineralization processes and can effectively compensate for the insufficient reducing capacity of reservoirs. The reaction interface between oxidizing fluids and reducing fluids serves as the deposition site for uranium minerals and associated minerals. It is a favorable zone for the enrichment and mineralization of uranium deposits.

The Characteristics and Origin of Barite in the Giant Mehdiabad Zn–Pb–Ba Deposit, Iran

Yingchao LIU[1]*, Institute of Geology, Chinese Academy of Geological Sciences
(lychappy@126.com)

Abstract

Mehdiabad is the world's largest Mississippi Valley-Type (MVT) Zn–Pb deposit (394 Mt of metal ore at 4.2% Zn, 1.6% Pb) and contains significant barite resources (>40 Mt). Such large accumulations of barite are not common in carbonate-hosted Zn–Pb deposits. Therefore, the origin of the barite and its association with the Zn–Pb mineralization is of significant interest for further investigation.

Field work and petrographic studies indicate that the Zn–Pb–Ba ore bodies in the Mehdiabad are hosted by Lower Cretaceous carbonate units of the Taft and Abkuh Formations. Fine- to coarse-grained barite with lesser siderite formed in three stages (S1, S2, and S4), along with a quartz-sulfide stage (S3) with minor quartz, sphalerite, galena, chalcopyrite and pyrite, and the main Zn–Pb sulfide stage (S5) with massive sphalerite and galena.

The barites have δ34S values from 17.7 to 20.6‰, δ18O values from 13.2 to 16.8‰, △33SV–CDT values from –0.001 to 0.036‰, and initial 87Sr/86Sr ratios from 0.707327 ±0.000008 to 0.708593 ±0.000008. The siderites have δ13CV–PDB values from –3.8 to –2.7‰ and δ18OV–SMOW values from 18.2 to 20.9‰. These geochemical data and the barite morphology point to a diagenetic origin for all stages of barite. We suggest that S1 and S2 barite precipitated from pore fluids at the sulfate-methane transition zone (SMTZ) in a methane-diffusion-limited environment with increasing methane content. S4 barite precipitated when the methane and barium-bearing cold-seep fluid migrated to the shallow carbonate sediments and formed a methane-in-excess setting. For the three stages, the SO42– in barite came from the residual SO42– in pore fluids undergoing sulfate-driven anaerobic oxidation of methane, and the Ba2+ came from dissolved biogenic barite and terrigenous materials in the Taft and Sangestan Formations.

Primary fluid inclusions trapped in S3 quartz have salinities of 5.6 to 8.1 wt % NaCl equiv. and homogenization temperatures of 143.8° to 166.1°C. The quartz has δ18O values ranging from 9.8 to 22.5‰ and δ30Si values from –1.3 to –0.9‰. These data indicate hydrothermal fluid flow occurred between the diagenetic S2 and S4 events. Secondary fluid inclusions with salinities of 17.70 to 19.13 wt % NaCl equiv. and homogenization temperatures of 123.0° to 134.0°C are found in the S3 quartz, too. They might also represent the hydrothermal event formed by basinal brines in S5.

According to the ore textures and the comparison of the sulfur isotopes between S5 Zn–Pb sulfides and the digenetic barites, the barite provided a host and a sulfur source for the later Zn–Pb mineralization; the sulfate was reduced by bacterial sulfate reduction. The relationship between barite and the Zn–Pb mineralization indicates that significant accumulations of sulfates may be a

critical exploration target for this kind of giant deposit.

Low-crustal juvenility and continental-slab shallow subduction control the formation of post-collisional porphyry Cu systems in east Tibet

Zengqian HOU[1]*, Institute of Geology, Chinese Academy of Geological Sciences (houzengqian@126.com)

Abstract

Many large porphyry Cu deposits have been recently discovered in continental collision zones, yet it is unclear what controls their formation. Here, we aim to decipher the Sanjiang collisional orogenic belt (SCOB) formed by the Cenozoic Indo-Asian collision through better imaging of its lithosphere architecture by advanced seismic tomography methods and more detailed zircon Hf isotopic mapping. Seismic images show that the Indian continental slab is shallowly subducted northeastward beneath northern SCOB with many large Cenozoic porphyry Cu deposits and steeply subducted eastward beneath southern SCOB with few such deposits. This differential subduction resulted in the SCOB lithosphere with distinct thermal-stress states, i.e., cold upper mantle - thickened hot crust in the northern portion and hot upper mantle - thinned cold crust in the southern portion. The SCOB lithosphere shows significant heterogeneities, with its northern portion containing more juvenile mantle components in the lower crust, while the southern portion has limited crust juvenility. We argue that the collision-related ore-forming magmas were derived from partial melting of the juvenile mafic lower crust formed by underplating of previous arc mafic magmas. The Cu-Au refertilization within a low-crustal source and shallow subduction of a continental-slab during collision is critical for large porphyry Cu-(Au) deposits in a collisional zone.

W-Mo porphyry deposit Ochtiná-Rochovce (Western Carpathians, Slovakia) - lithological and mineralogical characterization

Peter Koděra[1]*, Department of Mineralogy, Petrology and Economic Geology, Faculty of Natural Sciences, Comenius University, Slovakia (peter.kodera@gmail.sk)
Diego Delgado Yáñez[2], Department of Mineralogy, Petrology and Economic Geology, Faculty of Natural Sciences, Comenius University, Slovakia
František Bakos[3], Green View, s.r.o., Bratislava, Slovakia

Abstract

The Ochtiná-Rochovce W-Mo deposit is located in the contact zone of Veporicum and Gemericum superunits in Western Carpathians. It is genetically linked to a Late Cretaceous monzodiorite to granodiorite intrusive complex (81.5 Ma) emplaced in the Lubeník-Margecany suture line in 3.7 to 7.5 km depth. The Gemeric Unit is represented here by Lower Carboniferous mylonitized schists with intercalated conglomerates and frequent metamorphosed basalts and basaltic pyroclastics (Ochtiná Fm). The Veporic Unit comprises Permian metasandstone (Rimava Fm) and underlying Carboniferous metamorphosed sandstone/graywacke and phyllite (Slatviná Fm). The deposit contains 50.9 Mt @ 0.097% Mo, 7.4 Mt @ 0.113% W, or 5.0 Mt @ 0.216% Mo, 2.4 Mt @ 0.22% W. Several small Pb-Zn, Au and Sb deposits and occurrences are present in the vicinity of the deposit. The deposit consists of two zones, which are partly overlapping. The lower Mo zone is ~400 m thick and occurs in 200 to 600 m depth, hosted partly by the endocontact of the granitoids, but mainly by the overlying Veporic unit. It is represented by molybdenite hosted by a stockwork of quartz veinlets. The upper W zone is ~100 m thick and reaches from surface to depths up to 300 m. It is represented by disseminated-stockwork and less frequent quartz veins in the Veporic and Gemeric units, while their contact zone is particularly W-enriched. Principal ore minerals are scheelite and less common wolframite in a quartz gangue. The intrusive complex generated a contact metamorphism aureole with cordierite, andalusite, biotite and chlorite zones, overprinting previous regional metamorphic assemblages.

Ore mineralization precipitated in four hydrothermal stages. The Mo-W stage is the earliest producing molybdenite, wolframite and pyrite. The W-Fe-Cu stage is developed above the Mo-zone, with scheelite replacing wolframite, abundant pyrite, minor chalcopyrite and rare arsenopyrite and tetrahedrite. The Bi-Pb-Sb stage is developed in external zones, represented by Pb-Bi-Sb sulphosalts and stibnite. The latest F-Pb-Zn stage minerals (galena, sphalerite, fluorite) occur close to the contact with the intrusion. Supergene zone reaches from 1 m to 20 m. It is enriched in W compared to primary ore and includes ferrimolybdite, tungstite and hydrotungstite. Hydrothermal alteration includes potassic alteration at the centre of the system (including intrusions), while the Mo-zone is accompanied be intense silicification, sericitization, pyritization and late carbonatization. In the upper part of the system (W-zone) alteration is restricted to narrow halos of veinlets, including biotite, K-feldspar, quartz, muscovite and pyrite. The earliest quartz veinlets parallel to the main foliation are related to regional metamorphism. Porphyry-related

veinlets are dominated by quartz gangue with variable proportions of ore minerals. Scheelite occurs in two generations: disseminated in rocks and veins as individual grains and replacing wolframite. Wolframite group minerals range from ferberite to rare huanzalaite. Tungsten is also variably enriched in rutile (up to 17.8 wt% WO3) but it represents a negligible fraction of W at the deposit. Veinlets also contain minor biotite, muscovite/illite, chlorite, calcite and fluorite.

Deep process and lithospheric architectural control of Cu-REE mineralization in the Gangdese and Sanjiang collisional belts

Rui WANG[1]*, CUGB (rw@cugb.edu.cn)

Abstract

Situated in an archetypal continental collision zone the Tibetan Plateau developed world-class porphyry Cu and carbonate REE metallogenetic belts, yet there is no scientific consensus about the mechanism of continental collision control of Cu-REE mineralization in the region. The outstanding issues include the exact trigger mechanism for melting of the thickened lithosphere, the relationship between the lithospheric framework and Cu-REE metallogenesis, and the source of Cu, REE and volatiles and their depositional processes. To better understand the deep process and lithospheric architectural control of Cu-REE metallogenesis, this paper summarizes the lithospheric architecture of the Gangdese forward and oblique collision zones had been imaged and analyzed using joint inversion of surface wave and satellite gravity data, combined with magnetotelluric (MT) array and geochemical data. During the India-Asia collision in the Cenozoic the subducting Indian lithosphere experienced significant tearing, allowing asthenospheric upwelling to rework the overlying Asian lithosphere and cause melting. The resulting ultrapotassic melt ascended and accumulated at the bottom of the crust, providing high heat flow and volatiles for the melting of the juvenile lower crust. In the hydrous melt, amphibole fractionation led to melt oxidation, promoting Cu recycling and enrichment. The above results revealed three key factors controlling the formation of collisional porphyry deposits: moderate-angle subduction, slab tearing, and reactivation of the sulfide-enriched juvenile lower crust. At the margin of the Yangtze craton, Sanjiang oblique collision zone, vertical upwelling and horizontal flow of asthenosphere, driven by subduction of the Indian plate or mantle convection, caused thermal erosion and partial melting of the cratonic continental lithosphere. The lithosphere beneath the craton margin was REE enriched due to prior metasomatism by REE/CO2-rich fluid from recycled oceanic sediment, and enriched REEs were carried by ascending carbonate melt along the lithosphere discontinuity (e.g., strike-slip fault, rift) to form large scale carbonate REE deposits. Without prior lithospheric metasomatism, carbonatic, ultrapotassic and mafic melts produced from the melting of the cratonic lithosphere had limited potential to form carbonate REE deposits.

Porphyry Copper Deposits Main Characteristics in Iran

Maryam AHANKOUB[1]*, Department of geology, Payame Noor university, tehran, Iran
(m.ahankoub@pnu.ac.ir)
shohreh hassanpour[2], department ofgeology, Payame Noor University, Tehran, Iran

Abstract

Late Mesozoic-Cenozoic was a time of active magmatism in Iran, represented by three major magmatic belts: 1) East-north (Kerman), 2) West-central (Kerman-Yazd), and 3) Northwest (Arasbaran). The magmatism started in the late Cretaceous-Paleocene, peaked in the Eocene, and extended into the Miocene and Quaternary, with periodic subvolcanic intrusions into the existing rocks. The Cenozoic magmatism in Iran is associated with the successive stages of Tethyan ocean closure in the Kerman and Yazd areas, and Mesothetys in the Arasbaran region, including subduction events from the late Cretaceous to Miocene. These magmatic events are associated with a wide range of mineralization deposits, including epithermal precious metal deposits, skarn-type metal ores, porphyry-type Cu-Mo-Au deposits, and various industrial minerals.

The majority of known porphyry-type mineralization in Iran occurs in the Kerman and Kerman-Yazd belts, ranging in age from 13-9 million years (Ma). The Arasbaran belt also hosts porphyry-type mineralization with ages (Ar-Ar and U-Pb methods) ranging from 27-10 Ma. On the base of the Ar-Ar and U-Pb datings, age of intrusion bodies, caused to Cu mineralization in kerman belt, are 7.2-29.2 Ma.

Shallow-level porphyritic intrusions with dominantly adakite-like signatures are characteristic features of these deposits. Copper mineralization primarily occurs within the porphyritic intrusions and into hosted Paleocene-Eocene-Oligocene volcanic-sedimentary rocks.

Most copper mineralization in these deposits is associated with well-developed alterations, including potassic (K-feldspar and biotite), and phyllic, propylitic, and locally argillic dominant alterations. Stockworks, various types of quartz veinlets (A to E), and sulfide disseminations are observed within the intrusive bodies as well as in the surrounding rocks. The main hypogene copper mineral is chalcopyrite, occasionally associated with minor bornite and subordinate molybdenite and/or gold. Supergene alteration zone are observed in some of them especially in Kerman belt porphyries. Magnetite is a common mineral associated with potassic alteration, while pyrite is a common phase in the hypogene ores. Gypsum/anhydrite also are common in the more oxidized porphyry systems.

Geodynamic settings of formation and metallogeny of gold in the Altai-Sayan folded area (Southern Siberia)

Alexandr CHERNYKH[1]*, PJSC "Polyus" (chaigeo@yandex.ru)

Abstract

Altai-Sayan folded area (ASFA) in the Southern Siberia is a part of the Central-Asian orogenic belt. ASFA is one of the oldest mining districts known since the mid 17th century where coal, iron, copper, zinc, lead, silver and gold were mined. For the past 15 years new digital technologies, innovative mineral prospecting techniques, instrumentation and analytical equipment have appeared. This provides further opportunities for mineral prospecting in well-studied mining districts such as ASFA.

Our metallogenic analysis of the western part ASFA is based on the contemporary methods and new data. Since gold is one of the Altai-Sayan top commodities, studies have been focused on gold mineralization and granitoid rock associations, which are essential for its formation.

The western part of ASFA can be divided into the three large Caledonian metallogenic subprovinces: Altai-Salair, Alatau-Tuva and West-Sayan. In addition, the Kuznetsk Mesozoic metallogenic zone is distinguished, the gold mineralization which is superimposed on more ancient rocks. All these metallogenic units are defined as they have the unique geodynamic settings and metallogenic specialization. The characteristic features of gold mineralization of these subprovinces are associated with the peculiarities of ore-hosted volcanogenic-sedimentary rocks and granitoid complexes.

Gold mineralization in the Altai-Salair subprovince are formed on the tow metallogenic epoch. Gold-bearing polymetallic mineralization (VMS-type) formed in the early Cambrian in an island-arc geodynamic setting. The Devonian metallogenic epoch is characterized by the formation of gold mineralization in the conditions of an active Andean-type margin. At this time gold-skarn (with Cu), gold-sulfide-quartz mineralization (intrusions related) and epithermal gold-silver mineralization were formed.

In the Alatau-Tuva subprovince gold-skarn and gold-sulfide-quartz mineralization was formed in an island-arc setting in the Early Cambrian. The gold ore deposits of the Late Cambrian-Ordovician metallogenic epoch is the most widespread. At this time gold-quartz and gold-sulfide-quartz (RIRG) and gold-skarn (with Fe) mineralization is formed in an accretion-collision setting.

Gold mineralization of the West-Sayan subprovince is confined to its marginal parts, which are represented by deformed Vendian-Early Cambrian ophiolites, including large ultramafic massifs. Gold-quartz-sulfide mineralization in metasomatites (listvenites and berezites) are found here.

Gold mineralization of the Kuznetsk metallogenic zone was formed in the Permian-Triassic stage of intraplate plume activation of the region. Here, gold-sulfide-quartz mineralization (probably the Carlin-type) was identified in low-temperature metasomatites (jasperoids) among Devonian-Carboniferous terrigenous-carbonate strata.

Eruption Style, Mineralization and Geohazard of Mt Popa Volcano, central Myanmar

Khin ZAW[1]*, CODES CENTRE OF ORE DEPOSIT AND EARTH SCIENCES, UNIVERSITY OF TASMANIA (khin.zaw@utas.edu.au)

Abstract

Mt Popa is located in the Central Magmatic-Volcanic Belt (CMVB) of Myanmar, and it is a dormant volcano rising 1518 meters above sea. The primary feature of the volcano is an exploded crater on its northern side. The volcano occurred on Pliocene sandstones of the Ayerwaddy Formation. Its complex volcanic edifice is composed of lava flows and domes; the composition ranges from basalts to dacites of calc-alkaline affinities and represents Holocene volcanological evidence of the ongoing subduction in this part of the collision zone between India and Asia. Laser ablation 40Ar/39Ar age dating of two hornblende from Lava flow, basalt, volcanic bomb, and andesite yielded 0.0 Ma and U-Pb zircon age of Lava flow, basaltic andesite from Taung Kalat gave 0.68 ± 0.04 Ma, and K-Ar age of biotite from the volcanic bomb, trachybasalt provided 4.4 ± 0.5 Ma (Belousov et al., 2018, https://doi.org/10.1016/j.jvolgeores.2018.06.010).Sano et al. (2022, https://doi.org/10.1038/s41598-022-07097-4) also indicated that the older volcanic rocks were formed in the Miocene, as indicated by U–Pb ages of zircon 19.7–10.7 Ma and also recorded a new U-Pb age for the Taung Kalat plug (0.82 ± 0.07 Ma) that is close to the zircon U–Pb age constraints (0.68 ± 0.04 Ma) given by Belousov et al. (2018) and their K–Ar and 40Ar/39Ar ages indicate that the beginning of the Taung-Ma-Gyi stratovolcano eruption is ~ 0.33 Ma. A local legend reported that Mt. Popa could have had an eruption at 800 BP and 442 BCE. The timing and type of the most recent eruptions of the volcano include several mild explosive eruptions probably of Vulcanian Type ~ 12700-8500 BP, followed by large-scale edifice collapse~ 8000 BP, then followed (probably immediately) by strong magmatic eruption with deposition of the pyroclastic flow (Belousov et al., 2018). Probably the edifice of Mount Popa was destabilized by the intrusion of magma and the collapse triggered explosive eruption. Additional research is necessary to understand the occurrences of crater wall collapses, mudflows, and volcanic facies in the region. This is crucial due to the potential for future eruptions and geohazards, particularly in light of the landslides reported in October 2017. The heavy monsoonal rains caused the problems as the volcano is composed of soft and loose volcanic sandstones, ash, and lahar as well as deforestation making the soil erodible and more susceptible to landslides. High-sulphidation epithermal Au deposit in silicified rhyolite and tuffs is recorded at Taungni Hill in the Mt Popa area similar to the high-sulphidation epithermal Cu deposits at Monywa along the CMVB. In current times, mining is not a viable option in the Mt Popa area due to the recent establishment of a Geopark and the existence of numerous Geoheritage sites both in the vicinity of Mt Popa and near the historical landmarks and tourist attractions at Bagan where devastating earthquakes occurred as recently as in 1975 (Khin Zaw et al., 2017, https://doi.org/10.1144/M48.24). Further academic studies should be conducted to comprehensively understand the tectonic and metallogenic evolution of the entire

CMVB.

Geodynamics of Late Mesozoic giant decratonization-related gold mineralization in the North China Craton

Jin-Hui YANG[1]*, Institute of Geology and Geophysics, Chinese Academy of Sciences (jinhui@mail.iggcas.ac.cn)
Lei Xu[2], Institute of Geology and Geophysics, Chinese Academy of Sciences
Jin-Feng Sun[3], College of Earth and Planetary Sciences, University of Chinese Academy of Sciences
Yu-Sheng Zhu[4], Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

Plenty of large and super-large gold deposits are widely distributed in the eastern North China Craton (NCC), which is suggested to be related to decratonization and termed as decratonic gold deposits. However, how the decratonization controls the formation and distribution of large-scale of gold and other metal deposits is not very clear. Late Mesozoic decratonization of the NCC triggered intensive magmatism, tectonism and hydrothermal activities. Here we systematically summarizes all of the data for the rock assemblages, chronology, geochemistry and petrogenesis of Mesozoic magmatic rocks, as well as for the mineralizing ages of gold and other metal deposits and the evolution of the Mesozoic basins in the eastern NCC to reveal the geodynamics of Late Mesozoic decratonization and related gold mineralization. After restoring the extensional rates of Mesozoic to Cenozoic basins and the strike-slip distance of the Tanlu Fault, the locations of the Paleo-Pacific plate subduction zone during the Mesozoic to Cenozoic is confirmed and the temporal and spatial distribution of Mesozoic gold and other metal deposits and magmatic rocks in the eastern NCC has been well reconstructed. The result shows that the magmatism and mineralization in the eastern NCC would westward migrate from east to west during the Early to Middle Jurassic, but they would eastward migrate from west to east during the Early Cretaceous. The mineralization of these deposits is genetically related to magmatism, and the magmas provided some ore-forming materials and fluids in the generation of metal deposits. Thus, the geodynamic mechanism of decratonization and related magmatism and mineralization can be proposed, i.e., the westward low-angle subduction of the Paleo-Pacific slab beneath the NCC formed continental magmatic arc with plenty of porphyry Cu-Mo-Au deposits in the Jurassic, similar to Andean continental arc in South America. The mantle wedge was metasomatized by the fluids/melts derived from the subducting slab, laying a material foundation for hydrothermal mineralization in the Early Cretaceous. While the rollback of the subducting slab with gradually increasing subduction angle and the retreat of the subduction zones during the Early Cretaceous induced strong destruction of the craton and the formation of extensive magmatic rocks and large-scale gold and other metal deposits.

Copper skarn mineralization related to reduced monzodioritic magma at the Huanren deposit, northeastern China

Hegen Ouyang[1]*, Institute of Mineral Resources, Chinese Academy of Geological Sciences (oyhg1984@163.com)
John Caulfield[2], Queensland University of Technology
Guiqing Xie[3], Institute of Mineral Resources

Abstract

Most known Cu skarns are associated with oxidized intrusions. In this contribution, we report a Cu skarn associated with a reduced monzodioritic intrusion at Huanren, northeastern China, which contains 0.41 Mt of Cu accompanied by economic concentrations of Zn, Pb, Fe, Mo, and Ag. Copper-polymetallic mineralization in the Huanren deposit is concentrated in skarns located between the contacts of the monzodiorite (SiO_2 = 52 - 55 wt. %) and the Cambrian carbonate rocks, with minor molybdenite-bearing veinlets/veins and dissimilated chalcopyrite mineralization hosted within the monzodiorite. Laser ablation inductively coupled plasma-mass spectrometer (LA-ICP-MS) U-Pb zircon geochronology indicates the monzodiorite crystallized at 125.4 ± 0.6 Ma (2σ). Isotope dilution inductively coupled plasma mass spectrometry (ID-ICP-MS) Re-Os molybdenite geochronology indicates mineralization at Huanren occurred at 125.3 ± 0.8 Ma (2σ). Whole-rock major and trace elements and zircon Hf isotopic compositions suggest enriched (subduction metasomatised) lithospheric mantle-derived sources for the parental magma of the monzodiorite without significant crustal assimilation. Zircon trace element and magmatic apatite major element compositions indicate the reduced nature of the monzodiorite, as evidenced by low magmatic oxygen fugacity (FMQ-1.09 ± 0.19) and negligible apatite SO_3 contents (< 0.05 wt. %). A reduced magmatic-hydrothermal system at Huanren is also supported by the predominance of magmatic ilmenite over magnetite in the monzodiorite, and the presence of pyrrhotite and the absence of anhydrite and hematite in the ore. Chalcopyrite from the Huanren deposit has an average $\delta^{34}S$ value of 4.34 ± 0.88 ‰ (1σ), which is clearly higher than those from most porphyry-skarn Cu±Mo±Au deposits. Accordingly, we suggest that interaction of (1) external oxidized fluids equilibrated with evaporite with (2) reduced Cl-bearing magmas and related exsolved fluids may have played a critical role in the formation of the Huanren Cu skarn by increasing the ability of fluids to scavenge Cu from the reduced magma and subsequently precipitate Cu in the carbonate rocks. This study defines a new type of Cu skarn and thereby opens new potential for Cu skarn exploration proximal to intrusives previously deemed too reduced to be Cu fertile, especially in non-arc settings. Moreover, we conclude that the availability of Cl and S in magmatic-hydrothermal systems may be as critical as fO_2 in facilitating the actual ore-forming event in Cu skarn systems.

Jincheng Song[4], China University of Geosciences Beijing

Abstract

Southeastern (SE) Yunnan contains one of the most economically important Mesozoic tungsten–tin metallogenic belts in East Asia. Several world-class tungsten–tin deposits (such as Gejiu tin, Dulong tin, and Nanyangtian tungsten deposits) have been identified in association with Late Cretaceous granites in these areas, although the geodynamics of the tungsten mineralization remain elusive and a subject of debate. On the other hand, more and more new metallogenic events have been revealed, and the overprinting of the multiple tungsten mineralization is especially prominent in the Nanyangtian tungsten deposit. The Nanyangtian tungsten deposit, which is located in the central of the Nanwenhe metamorphic core complex, consists of widespread subhorizontal skarn and overprinted localized steeply scheelite–mica–quartz (SMQ) vein mineralization. Structural analysis of the tungsten deposit and metamorphic core complex allows four stages of deformation that control multiple tungsten mineralization to be identified. Oriented quartz–orthoclase–microcline–plagioclase–amphibole–muscovite–biotite in the gneissic granites define the mylonitic foliations S1 and north-plunging mineral lineations L1 during D1. Asymmetric lenses, porphyroclasts, and intra-folial folds indicate a north-directed detachment (D1) under upper-greenschist- to low-amphibolite-facies conditions. Subsequently, the foliations S1 were asymmetric folded and overprinted by NE-striking subhorizontal foliations S2, indicating the northwest-directed thrusting (D2). Magmatic–hydrothermal fluid was channeled by these NE-striking foliations, and forming subhorizontal skarn mineralization after the peak of crustal thickening (D2). SMQ vein mineralization was occurred with the dextral transtensional faulting (D3). The final sinistral strike-slip faulting (D4) offset the pre-existing deformation and tungsten mineralization. Metamorphic zircon U–Pb and amphibole–mica 40Ar–39Ar ages (237–180 Ma) constrained the north-directed detachment (D1). In addition, the crystallization age of 162.5 Ma of zircons from undeformed skarn-related granitic dikes suggests the end of thrust deformation (D2) and the Late Jurassic skarn tungsten mineralization in the Nanyangtian deposit. 40Ar–39Ar isotope dating of biotite from the SMQ vein represent the Cretaceous vein mineralization and D3 in the deposit. By combining our new results with other research findings from SE Yunnan and East Asia, the inferred sequence suggests that the multiple stages of deformation and tungsten mineralization were influenced by geodynamic processes involving the Indochina and Paleo-Pacific blocks with the South China Block.

Gold Deposits of the Jiaodong Peninsula, Eastern China

Kunfeng QIU[1]*, China University of Geosciences (Beijing) (kunfengqiu@qq.com)
Haocheng Yu[2], China University of Geosciences (Beijing)
Shanshan Li[3], China University of Geosciences (Beijing)
Zhengyu Long[4], China University of Geosciences (Beijing)
Jingyuan Zhang[5], China University of Geosciences (Beijing)
Richard Goldfarb[6], China University of Geosciences (Beijing)
Jun Deng[7], China University of Geosciences (Beijing)

Abstract

The Jiaodong gold province, the third largest gold province globally, hosts gold resources of more than 5000 tonnes, with a present cumulative annual production estimated at 60 t Au. More than 90% of the Jiaodong gold resource is hosted by batholiths and related bodies of the Linglong (ca. 160–145 Ma) and, to a lesser degree, Guojialing (ca. 130–122 Ma) suites. The intrusions were emplaced into high-grade metamorphic basement rocks of the Precambrian Jiaobei (North China block) and Sulu (South China block) terranes during a 70-m.y.-period of lithospheric delamination, extensional core complex formation, and exhumation. The deposits are located about 20 to 200 km to the east of the continental-scale NNE-striking Tancheng-Lujiang (Tan-Lu) strike-slip fault system. They occur along a series of more regional NNE- to NE-striking brittle and ductile-brittle faults, which appear to intersect the Tan-Lu main structure to the southwest. This system of early to middle Mesozoic regional thrust faults, reactivated during Cretaceous normal motion and ore formation, tends to occur along the margins of the main Linglong batholiths or between intrusions of the two suites of granitoids. Orebodies are mainly present as quartz-pyrite veins and as stockwork veinlets and disseminated mineralization. The two mineralization styles are transitional and may be present within the same gold deposit. High-precision U-Pb dating on monazite yielded mineralization ages of ca. 120 Ma in the Jiaobei terrane and slightly younger age of 115 Ma in the Sulu terrane, which postdates the Paleoproterozoic high-grade metamorphism depriving the crustal basement of metal and volatiles. The comprehensive investigation of Ba-Li-Hg-S isotopes of mafic rocks and ores indicates that gold was released from continent-derived sediment and recycled into the subcontinental lithospheric mantle (SCLM) beneath Jiaodong during the Jurassic subduction of paleo-Pacific plate. Subsequently, the subducted carbonate-rich sediments oxidize SCLM, allowing the later mobilization of metal into magmas and/or fluids. Finally, the 120 Ma rollback of the paleo-Pacific plate induced upwelling of the asthenosphere and changes in the stress regime, triggering the release of metal from the SCLM in an extensional setting to form the giant Jiaodong gold deposits.

Exploration Potential of Antimony Deposits in Myanmar: Insights from Fluid and Stable Isotope Geochemistry of the Lyhamyar Sb Deposit, Eastern Myanmar

Aung Min OO[1]*, Department of Geology, Kyaing Tong University (granite.aungmin@gmail.com)
Lv Xinbiao[2], Institute of Geological Survey, China University of Geosciences, Wuhan 430074, China
Khin Zaw[3], Centre for Ore Deposit and Earth Science, University of Tasmania, Private Bag 126, Hobart, Tasmania 7001, Australia
Sakthi Saravanan Chinnasamy[4], Department of Earth Sciences, Indian Institute of Technology Bombay, Mumbai 400076, India

Abstract

Antimony is a critical metal in global markets (Kanellopoulos et al., 2024) with Myanmar emerging as a significant source, contributing 9000 metric tons of antimony ore (Gunn, 2014; Toe Aung Kyaw, 2017) in 2014, primarily exported to China. The country is a major metallogenic belt with various mineral deposits, including Pb, Zn, Ag, Fe, Sb, Au, and Mo. Most of the antimony ore is found in quartz-stibnite veins and breccias that form along fault zones in limestones and shales. Experts estimate that Myanmar has a total antimony resource of one million tons, with the possibility of additional deposits in areas near specific fault zones. In this study, we focus on the significant Lyhamyar Sb deposit, situated in the Southern Shan Plateau of Eastern Myanmar within the Early Silurian Linwe Formation, characterized by syntectonic quartz-stibnite veins. Based on the mineral assemblages and cross-cutting relationships, the deposit shows two mineralization stages: (1) the pre-ore sedimentary and diagenetic stage, and (2) the main-ore hydrothermal ore-forming stage (including stages I, II, and III), i.e., (i) early-ore stage (stage I) quartz-stibnite, (ii) late-ore stage (stage II) quartz-calcite-stibnite ± pyrite, and (iii) post-ore stage (stage III) carbonate. The study of primary fluid inclusions in quartz and calcite indicates that the ore-forming fluid had low temperatures (ranging from 144 to 260 °C) and moderate to high salinity (ranging from 2.9 to 20.9 wt. % NaCl equivalent). Hydrogen and oxygen isotopes suggest that the ore-forming fluids of the Lyhamyar deposit were derived from circulating meteoric water mixed with magmatic fluids that underwent isotopic exchange with the surrounding rocks. Sulfur in Lyhamyar was dominated by thermochemical sulfate reduction (TSR) with dominant magmatic source sulfur. The lead isotope compositions of the stibnite suggest that the ore-forming metals were a mixed source of the Late Proterozoic metasedimentary basement and the sedimentary host rocks. On the basis of the integrated geological setting, ore geology, fluid inclusions, (H-O-S-Pb) isotope data, and previous literature, we propose a new ore deposit model for the Lyhamyar Sb deposit: It was involved in an early deposition of pyrite in sedimentary and diagenetic stages and later Sb mineralization by mixing of circulating meteoric water with ascending magmatic fluids during the hydrothermal mineralization stage. The study highlights the need for further investigation into Myanmar's antimony deposits, suggesting future targets include geochronology, analysis of fluid characteristics and metal sources, and identifying exploration orientations. It also

recommends analyzing fluid inclusions, stable isotope analysis, LA-ICPMS analysis, and international research collaboration.

Mineralogy, Geochemistry, and Origin of Green Jasper in Northeastern Region of Cambodia

Seang Sirisokha[1]*, Institute of Technology of Cambodia (ssirisokha@yahoo.com)
Kret Kakda[2], 4Energy Technology and Management Unit, Research and Innovation Center, Institute of Technology of Cambodia
Khin Zaw[3], 3CODES Centre of Ore Deposit and Earth Sciences, University of Tasmania, Hobart, Tasmania, Australia
Kotaro Yonezu[4], Department of Earth Resources Engineering, Faculty of Engineering, Kyushu University
Koichiro Watanabe[5], Department of Earth Resources Engineering, Kyushu University, Fukuoka, Japan

Abstract

Green jasper can be used for jewelry, ornamental, carvings, cabochons, and home decoration. Green Jasper is a type of chalcedony that consists of a variety of micro-quartz crystals. Green jasper is found in the northeastern region of Cambodia. This research presents a new discovery of green jasper in Cambodia, and we investigated the formation environment based on the mineralogical and geochemical characteristics. Petrography, SEM-EDX, XRD, XRF, and LA-ICP-MS were used in this study. Based on the petrography and XRD, microcrystalline of quartz, k-feldspar, celadonite, chlorite, epidote, and magnetite were observed. Quartz is the main component of green jasper, occurs mainly as anhedral crystals ranging in size from cryptocrystalline to microcrystalline (<0.2mm). Silica and iron contents ranged from 78.7 wt.% to 90.8 wt.% as SiO2, and 4.63 wt.% to 7.87 wt.% as Fe2O3, respectively. This green jasper displays enrichment in concentrations of Rb, and K generally derived from hydrothermal fluid. In addition, the Al-Fe-Mn diagrams also confirm a hydrothermal origin. Total REE (ΣREE) contents are low in general up to 10.26 ppm, suggesting the possibility of the hydrothermal products due to its low REE contents. In addition, the chondrite-normalized rare earth element (REE) patterns of green jasper exhibit enrichment in LREE compared to HREE with values ranging from 1.30 to 7.17 for (La/Yb) N. Negative Ce anomalies are observed ranging from 0.49 to 3.10 negative Eu anomalies are also recognized ranging from 0.68 to 0.82. Various Ce anomalies suggest that green jasper is associated with hydrothermal alteration and the presence of oxidizing fluid or magmas. Negative Eu anomaly suggests that green jasper has undergone plagioclase feldspar fractionation. These mineralogical and geochemical results of this study provide significant potential for advancing the understanding formation and geological history of green jasper in Cambodia.

Characteristics and Timing of Migmatite Structures Exposed along the Kyaikkhami Beach area, Thanbyuzayat Township, Mon State, southern Myanmar

Zin Mar OO[1]*, Mawlamyine University, Mon State, Myanmar (zmo1984.geol@gmail.com)
Khin Zaw[2], Centre for Ore Deposit and Earth Science, University of Tasmania, Private Bag 126, Hobart, Tasmania 7001, Australia
Prinya Putthapiban[3], Geoscience, Mahidol University, Kanchanaburi, Thailand

Abstract

The Kyaikkhami area lies at the southwestern part of Thanbyuzayat Township, Mon State, southern Myanmar. The Three Padoda Fault is a major, large-scale, NW-SE strike-slip fault occurring in the Kyaikkhami area. The existing geological structures in the area are generally reflected in the shearing of the Three Pagoda Fault. The major structure of the Kyaikkhami area is the eastern limb of an overturned fold. This area is mainly composed of magmatic and metasedimentary rocks and forms a part of the Central Granitoid Belt of Myanmar (Khin Zaw, 1990). The metasedimentary rocks cover approximately 75% of the Kyaikkhami area. The dip angle of the quartzite unit (S0) which is greater than the phyllite unit (S1). Flow sturctures and many small-scale minor folds occur in migmatite units. Migmatites are well exposed at Kyaikkhami Pagoda, Sinpone Cave and Kayinthaung Daminseik. There is a sharp contact between biotite granite and migmatites. The structure of migmatite is stromatic migmatite which is one kind of metatexite migmatite. Biotite granite is a dome up intrusion that surrounds the migmatites and schists. Seven varieties of migmatite structures are classified by Mehnert classification (1968). In the Kyaikkhami Pagoda, migmatite structures such as phlebitic (vein) structure, stromatic (layered) structure, surreitic (dilation) structure, folded structure, ptygmatic structure, ophthalmitic (augen) structure and schlieren structure were recorded. In the Sinpone Cave, phlebitic (vein) structure, stromatic (layered) structure, surreitic (dilation) structure, folded structure, ptygmatic structure, and ophthalmitic (augen) structure were found. In the Kayinthaung Daminseik, stromatic (layered) structure, surreitic (dilation) structure, folded structure, and ptygmatic structure were also observed. Paleosome is mostly biotite schists, muscovite-biotite schists and biotite gneiss. Leucosome is aplite, leucogranite, biotite granite, granodiorite microgranite and other granitic materials. Melanosome is biotite gneiss, granite gneiss and contaminated granite. The age of granodiorite is 133±3.1 Ma and biotite granite is 123.4±52.1 Ma (CODES SE Asia database). In migmatites, one of the leucosome samples gives an Early Cretaceous by U-Pb zircon age determination indicating that the timing of migmatite formation is similar to the time of emplacement of the granitoid intrusion.

Origin of pegmatite-related gem deposits, northwestern part of Pyetkaywe Batholith, Myittha Townships, Mandalay Division, Myanmar

Yin Yin MYINT[1]*, Penta-Ocean Construction Co.Ltd (yym.geo@gmail.com)
khin Zaw[2], CODES Centre of Ore Deposit and Earth Sciences, University of Tasmania, Hobart, Tasmania, Australia 7001

Abstract

The studied area lies in the Central Granitoid belt which has a high endowment of Li and battery metals in Myanmar in addition to the presence of major W-Sn deposits, gem deposits, and other critical metals and REE mineral deposits. The Central belt granitoid are Late Cretaceous to Tertiary (Eocene and younger) in age and were emplaced during the eastward subduction of the Indian Plate (Khin Zaw, 1990, 1998, 2017). The area covers two peaks, East Pyetkaywe hill (1069m) and West Pyetkaywe hill (1031m). Two-thirds of the area is covered by igneous rocks of granitic composition with minor ultramafic intrusion. The rocks lie along the Jurassic to Miocene Mogok Metamorphic Belt (MMB) consisting of hornblende biotite gneiss, banded biotite gneiss, sillimanite schist, epidote quartzite, grossularite diopside marble and calc–silicate rocks as roof pendant. The exposed igneous rocks in the study area are porphyritic hornblende biotite granite, porphyritic biotite granite, biotite granite, diorite, meladiorite, and hornblendite. Meladiorite might have been formed by the magmatic differentiation of the dioritic magma and hornblendite as a segregated product. LA ICP-MS U-Pb zircon age of diorite exposed at the peak of west Pyetkaywe hill (Lat 21º13′ 15.2″, Long E 96º 12′ 17.5″) yielded 121±1.8 Ma (Early Cretaceous). The field evidence, together with petrological and geochemical analyses, indicate that the granite and diorite, of the northern Pyetkaywe area are calc-alkaline and are strongly peraluminous. Most granitoid rocks show S-type affinity and some fall in the I-type field. The granitic rocks are more akin to S-type due to the presence of tin and tungsten mineralization in the southern part. All the rocks, including the metamorphic rocks in the area, are transected by nearly N-S trending pegmatite dykes containing beryl and tourmaline crystals (Yin Yin Myint, Yin Yin Myint and Khin Zaw, 2014; MUIGC, Mahidol University, Thailand). The area is known for gem-bearing pegmatite deposits. The gems are beryl (aquamarine, goshenite, and yellow beryl), colourless topaz, schorl, and quartz (rock crystal and smoky quartz) are found along the streams of east Pyetkaywe Pagoda which attracted the locals for extraction. Aquamarine from the study area is locally known as Kume beryl which has much attention in the jewellery trade.

Graciano Jr. Yumul[7], Cordillera Exploration Co., Inc.

Abstract

The Mankayan Mineral District in Northern Luzon, Philippines is known for the world class Cu-Au mineralization of the Far Southeast porphyry copper deposit, Lepanto high sulfidation deposit and the Victoria-Teresa intermediate sulfidation deposits. South of this cluster of deposits is the lesser-known Suyoc epithermal prospect. Recent studies identified potential porphyry mineralization at depth, in addition to surface porphyry copper prospects in the vicinity. This study focuses on the igneous rocks in Suyoc to understand the magmatic evolution and related hydrothermal mineralization in the Mankayan Mineral District.

New U-Pb zircon ages, bulk geochemistry, and mineral chemistry results from igneous rocks in the area reveal three magmatic episodes. The Late Eocene (36.93–37.20 Ma) tholeiitic tonalite-granodiorite of the Bagon Intrusive Complex represents magmatism from a thin, nascent Luzon arc, which is barren of mineralization. In contrast, the Middle Pliocene (2.87–3.4 Ma) calc-alkaline hornblende quartz diorite of the Suyoc Diorite is closely associated with hydrothermal mineralization due to fertile melts associated with ridge subduction in the Manila Trench. The youngest magmatic episode is represented by the Bato Dacite Porphyry, dated Early Pleistocene (1.73 Ma). The calc-alkaline dacitic magmas reveal more fertile signatures and higher water content compared to the Pliocene magmas. The results of the study reflect the complex subduction dynamics in northern Luzon, which led to the shift from barren to fertile magmatism that caused the formation of porphyry-epithermal deposits in the district.

Bimodal volcanism and massive sulfide deposition in the mid-Miocene Hokuroku Rift of NE Japan

Andrea Agangi[1]*, Akita University (andrea_agangi@gipc.akita-u.ac.jp)

Abstract

Northeast Japan hosts important volcanic-hosted massive sulfide deposits that were deposited in the mid-Miocene during the final opening stages of the Japan Sea. These deposits formed in a similar tectonic setting and similar deep-sea environment to other massive sulfide deposits across the world, and serve as the type-locality of the Kuroko-type (1). The host-rocks of the deposits are composed of a bimodal, felsic-dominated deep-sea volcanic succession formed in a continental rift over stretched continental crust in a back-arc basin. A link between the composition of volcanic rocks, namely rare-earth element ratios, and the occurrence of massive sulfide deposits has long been proposed, implying large-scale effects of tectonic setting on magma composition and on ore deposition. However, the intensive parameters (magma temperature, pressure and depth of stalling and crystallization, water content, etc.) of host-rocks of the Kuroko of NE Japan are largely unknown, hindering attempts to link volcanism and hydrothermal activity (2).

This study focusses on a microtextural and microchemical approach to estimate some of the key magmatic parameters of the host volcanic rocks hosting Kuroko deposits of the well-studied Hokuroku District, historically one of the most important mining districts in Japan. Plagioclase-melt geothermometry in felsic tuff and lava samples collected from the foot-wall and hanging-wall of the Kuroko indicates temperatures of 880 – 940°C, and Fe-Ti oxide equilibrium indicates oxygen fugacity of ca. FMQ + 1.5. The melt inclusions have high-silica rhyolite compositions, suggesting low pressures of magma stalling and crystallisation (<1 kbar). Melt-plagioclase equilibrium indicates low water contents, mostly 1.0 – 3.3 wt% H2O and textural considerations suggest water-saturated conditions at the moment of melt entrapment. These water contents are compatible with pressures of 10 – 80 MPa, assuming solubility of pure water in rhyolitic melt (3). Because of these very shallow magma stalling pressures, the hydrostatic pressure imposed by the bathyal conditions (10 MPa/1000 m water depth) would have caused significant shallowing of the solidus, allowing magmas to migrate towards the sea-floor before freezing and caused efficient heat migration.

These results indicate that shallowly emplaced, hot (average temperature >900°C) felsic magmas provided heat necessary for vigorous sea-floor hydrothermal circulation, a pre-condition for ore deposition. Sea-floor depth may have played a key role in triggering ore-formation.

Magma fertility of the Wuntho–Popa arc belt: implication for porphyry Cu mineralization in Myanmar

Jing-Jing Zhu[1]*, Institute of Geochemistry, Chinese Academy of Sciences
(zhujingjing@vip.gyig.ac.cn)
Ruizhong HU[2], Institute of Geochemistry, Chinese Academy of Sciences
Xianwu BI[3], Institute of Geochemistry, Chinese Academy of Sciences

Abstract

Myanmar, situated within the significant Mesozoic-Cenozoic Neotethyan orogenic belt spanning from the Alps to Indochina, harbors an abundance of porphyry Cu deposits (PCDs). However, Myanmar has relatively fewer PCD occurrences, with the exception of the notable Monywa high-sulfidation Cu deposit. The Wuntho-Popa arc, a magmatic belt trending north-south and extending approximately 500 kilometers from Mount Popa to Wuntho in the West Burma terrane, represents a promising region for porphyry Cu mineralization.

To assess the magma fertility across the entire Wuntho-Popa arc belt, we employed a comprehensive geochemical analysis of whole-rock, zircon, and apatite samples. Our data reveals a systematic and continuous increase in La/Yb, Eu/Eu*, Dy/Yb, and Sr/Y ratios in the magmas from 100 Ma to the present. This trend indicates a transition from plagioclase-dominated to amphibole-dominated fractionation assemblages, suggesting higher pressure crystallization and/or an increase in hydrous water content during the late stages of arc evolution. This interpretation is further supported by zircon compositions, exhibiting rising Eu/Eu* and Ce/Nd ratios over time.

Moreover, our calculations of magma oxygen fugacity, based on zircon Ce, Ti, and U contents, reveal a progressive increase from FMQ-1 at ~100 Ma, to FMQ + 1 at ~40 Ma, and ultimately FMQ + 2 at ~18 Ma, coincident with the formation of the Monywa Cu deposit. This trend aligns well with variations in apatite sulfur content.

Collectively, our findings indicate that magmas younger than 40 Ma are more conducive to PCD formation, serving as potential indicators for future PCD exploration in Myanmar. Our study underscores the significance of high-pressure, water-rich, and moderately oxidized magma conditions in the generation of PCDs.

Role of chalcophile element fertility in the formation of post-collisional porphyry Cu deposits in the eastern Tethyan domain

Hongda Hao[1]*, Institute of Geology, Chinese Academy of Geological Sciences
(hongda.hao@hotmail.com)
Jung-Woo PARK[2], Seoul National University

Abstract

Porphyry deposits, the world's most significant source of Cu and an important source of Au, are generally associated with continental or oceanic arc magmas. Recently, many porphyry deposits have been found in post-collisional settings and they have become an increasingly important exploration target. The post-collisional ore-forming magmas, generated by partial melting of subduction-modified sulfide-bearing lithosphere, are suggested to be enriched in chalcophile elements. However, the chalcophile element contents in the post-collisional magmas and its role in controlling the porphyry ore formation remain unclear. We analyzed the platinum-group element (PGE) concentrations of representative post-collisional ore-associated and barren suites in the eastern Tethyan metallogenic domain. The ore-associated suites have moderate Pd and Pt contents ranging from ~0.05 to 0.5 ppb, which are systematically higher than the most of the barren suites that have Pd and Pt concentrations below ~0.1 and 0.05 ppb, respectively. Numerical models show that the ore-forming magmas have experienced early sulfide saturaiton and precipitated a small amount of sulfides during magmatic evolution, resulting in the moderate Pd and Pt contents in the ore-associated suites. Early sulfide segregation may have substantially depleted Au contents in the ore-forming magmas, remaining sufficient Cu to form porphyry Cu deposits. In contrast, the barren suites contain systematically lower Pd, Pt and Cu contents, unfavorable for porphyry Cu ore formation. We suggest that moderate chalcophile element content in the ore-associated magmas is sufficient to form post-collisional porphyry deposits in the eastern Tethyan domain and it plays an important role in controlling the ore-forming potential.

U–Pb and Hf-isotope analysis of zircons and Molybdenite Re-Os Dating in Gao'aobei Tungsten-molybdenum Ore, Southern Hunan Province , South China

Yanbin WANG[1]*, Institute of GeologyChinese Academy of Geological Sciences
(yanbinw@yeah.net)

Abstract

Gao'aobei tungsten-molybdenum mineral deposits , which are related genetically to granites , have been formed in the southern Hunan Province. , South China. However , the ages of W-Mo mineralization and granite crystallization are poorly understand at present. This study provides the first highly precise dating of the mineralization and rock-forming in the Gaoaobei W-Mo ore. The dating of zircon from Gaoaobei biotite granite determined by SHRIMP yield ages of 222.1±2.0 Ma. Hafnium isotope data was also acquired through laser-ablation multicollector ICP-MS analysis of zircon, with the aim of gaining insight into the age and nature of the source region of the pluton. The yield age (222±2 Ma) confirm that this biotite granite intrusion belongs to late Trassic. Hafnium analysis shows the biotite granite to have negative and variable epsilon Hf(t) values (-4.7 to -10.9) and Palaeo-Mesoproterozoic (1.6 to 2.0 Ga) depleted-mantle model ages, which is interpreted to reflect derivation from old crust source. The source region for these magmas may be tentatively correlated with Palaeo-Mesoproterozoic material of the South China Block, Which has been suggested to underlie the Hunan; however, further work is necessary to demonstrate this suggestion. Rhenium and osmium isotopic dating of molybdenite from the Gaoaobei tungsten-molybdenum ore by ICP-MS yields isochron ages of 157.3 ±6.6 Ma on the 187 Re versus 187Os correlation diagram. The result s suggest that the timing of W-Mo mineralization and granite crystallization are different period, W-Mo mineralization period is corresponding to the time of the largescale mineralization regionally in the Mesozoic. In addition , there exists an apparent time difference between W-Mo mineralization and granite crystallization.

BAO-QUAN ZHOU[5], Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China

Abstract

The lack of geochronological constraints on hydrothermal Au deposits results from their relatively simplified mineralogy (e.g., pyrite, pyrrhotite, arsenopyrite, sphalerite, and galena) and a general paucity of mineral phases suitable for geochronology. Fortunately, apatite has been recognized as a minor, very fine grained phase associated with ore-forming stage sulfide, e.g., pyrite and arsenopyrite in four Au ores collected from an IOCG deposit in the Rangnim Massif, North Korea. REE contents of apatites from Au ores are highly variable but lower than magmatic apatites from the intrusive rocks, suggesting that apatites from Au ores underwent hydrothermal evolution and are typical of hydrothermal apatite. That means, these hydrothermal apatites are clearly associated and provide information of hydrothermal gold mineralization. Apatite has been widely used as a geochronometer because it can preferentially incorporate U relative to Pb, which is requisite for successful U-Pb dating. Directly LA-SF-ICP-MS U-Pb dating of hydrothermal-apatite from four Au ores indicate ages of 113.1 ± 1.3 Ma, 111.6 ± 1.8 Ma, 109.1 ± 1.1 Ma and 110.8 ± 1.7 Ma, which can represent the gold mineralization age. Moreover, these ages are coincide with the 111-112 Ma zircon ages of the high-MgO diorites to granodiorites and porphyric granites that partially host mineralization. Innitial 87Sr/86Sr ratios and εNd(t) values of hydrothermal apatites ranging from 0.70893 to 0.71296 and -6.0 to -19.5, similar to whole rock Sr-Nd isotope of Ealy Cretaceous high-MgO diorites to granodiorites and granites (0.70876 to 0.71152; -14.5 to -16.9). Combined with U-Pb geochronology, trace elements and Sr-Nd isotope geochemistry, gold mineralization in the Rangnim Massif, North Korea is closely related to the Early Cretaceous magmatis which is generated by AFC of enriched lithospheric mantle-derived magmas. The magmatism and gold mineralization are the result of lithospheric delamination in North Korea during Early Cretaceous.

Chungwan Lim[2], Department of Geology, Kongju National University, Gongju, South Korea
Heejung KIM[3], Department of Geology, Kangwon National University, Chuncheon, South Korea

Abstract

Pyrite (FeS2) formations are occasionally mediated by sulphate-reducing bacteria (SRB) in the ore deposits. The origin of the Shinyemi Iron polymetallic ore field is related to the mineralization of skarn-type deposits. Shinyemi mine is one of the biggest polymetallic skarn-type Fe deposits in South Korea and contains Fe, Fe-Mo skarn, and Fe-Zn-Pb replacement skarn. Here, we investigated the SRB presence in these ores and reported the use of Raman spectrum features to distinguish the compositional characteristics of different types of pyrite (FeS2) from the deposit. The major types of pyrite can be identified by using transmission electron microscopy (TEM), and the major presence of organic carbon can be observed by using the Raman spectral pattern and peak positions. Pyrite sometimes occurs within the pyrrhotite, and two types of chalcopyrite occur: in stage 1 with a large proportion and in stage 2 with a small amount within either sphalerite or pyrite. Usually, pyrrhotite and pyrite are primarily observed in the range of 100–800 cm-1 peaks. The D1 peak and the G peak, which occur at 1301.04 cm-1 and 1608.43 cm-1, respectively, are the prominent peaks of pyrite that are associated with the presence of organic carbon. Only the D1 peak with the highest intensity was observed mostly, and the D1 and G peaks occurred together occasionally. Pyrite with no organic carbon peaks also occurred, which points out that there are two types of pyrite formation, biogenic and abiogenic, in the Shinyemi skarn deposit. The obtained results show that the use of Raman spectroscopy is an influential tool for the identification of all the minerals and biogenic trace which are usually found in pyrite. The optical absorption spectra of pyrrhotite exhibit low-frequency carbon-carbon (C-C) vibrations at approximately 800 cm-1. These C-C could result from the remnants of the organic carbon occurrence in the pyrite within the deposit. The secondary pyrite mineralization in the Shinyemi skarn deposit was probably precipitated with the help of sulphate-reducing bacteria.

Abstract

The Doi Ngom W-Sb deposit is located in the Sukhothai Fold Belt, a N-S trending volcanic arc extending from Yunnan, southern China to Myanmar, Laos, Thailand and peninsular Malaysia. This research aims to elucidate geochemical characteristics of the Doi Ngom deposit based on the mode of occurrence of ores and host rocks. On the basis of the field observation, wolframite (i.e., ferberite-hubnerite solid solution) occurs in the breccia, whereas stibnite occurs as dissemination in mudstone. We employed petrography, whole-rock geochemical analysis, and sulfur isotope analysis. The petrography showed that wolframite and fine-grained quartz with 10–20 μm in size occur as cementing materials of the breccia consisting of very angular to moderately rounded pebble-sized clasts. Subhedral to euhedral stibnite with 1–5 mm in size and euhedral fluorite with 10–50 μm in size are disseminated in the mudstone. The wolframite-bearing breccia contains 0.01 – more than 10 wt% W, up to 0.69 wt% Sb, 0.06–0.13 ppm Au, 0.17–0.93 ppm Ag, 54.4–145 ppm Cu, 7.87–564 ppm Pb, and 15.2–858 ppm Zn. The stibnite-bearing mudstone contains 0.07–1.42 wt% Sb, 0.07–0.54 ppm Au, 0.15–0.23 ppm Ag, 12.7–53.7 ppm Cu, 0.18–23.9 ppm Pb, and 0.20–80.6 ppm Zn. There are positive correlations ($r > 0.8$) of Au against Cr; Ag against Bi, V, Zn, Ge, In, and Pb; W against Ti, Cu, Nd, Sm, Eu, Tb, Dy, Ho, Er, Tm, Yb, and Lu. These correlations suggest a possible relationship of Ti, Cu, Nd, and REEs with wolframite. The $\delta 34S$¬CDT values of stibnite have a narrow variation, ranging from -10.6 ‰ to -8.8 ‰, suggesting possible sedimentary and metamorphic sources of sulfur for stibnite. There is no evidence of co-occurrence of stibnite and wolframite.

Linking two types of breccia bodies to sedimentary rock-hosted stratiform copper (SSC) and iron oxide-copper-gold (IOCG) deposits in the Kangdian metallogenic belt, SW China

Xue-Qing YIN[1]*, China University of Geosciences (xueqingyin@cug.edu.cn)
Xin-Fu ZHAO[2], China University of Geosciences

Abstract

Breccia bodies have been known to be spatially associated with diverse base metal hydrothermal deposits worldwide. Voluminous breccia bodies, regionally known as the Yinmin Breccia, are widely distributed in the late Paleoproterozoic Dongchuan Group in the Kangdian Fe-Cu metallogenic belt, Southwest China. However, the origin of these breccia bodies and their relationship to the SSC and IOCG deposits in the region remains highly controversial. The Yinmin ore district contains the Yinmin SSC deposit and Xikuangshan IOCG deposit, both of which display close spatial association with breccia bodies, providing an excellent opportunity to address such critical issues.

Detailed field mapping and petrologic observations suggest that the Yinmin Breccia contains two types of breccia bodies, namely monomict and polymict breccia. The monomict breccia is characterized by the clasts mostly from the fragments of the Yinmin Formation that cemented by hydrothermal mineral assemblages of quartz and carbonates, with locally pyrite and chalcopyrite, which are similar to the alteration phases of the SSC mineralization. In contrast, the compositions of polymict breccia are much more complicated and contain the fragments of the Yinmin Formation, monomict breccia, and minor other country rocks, all of which have been extensively albitized and transitioned to Ca-Fe, K-Fe, and Ca-Mg alteration. Such alteration phases share many similarities to the hydrothermal alteration of the Xikuangshan IOCG deposit.

Field evidence shows that the IOCG-type alteration was overprinted on the precursor SSC mineralization and monomict breccia. A dolerite intrusion crosscutting the SSC orebodies and monomict breccia yields a zircon U-Pb age of 1698±29 Ma, providing a low limit on the timing of the monomict brecciation and SSC mineralization. Combined with B-C-O-S isotope compositions, we propose that the monomict breccia was the product of salt halokinesis due to the dissolution of evaporites, whereas the polymict breccia formed in response to fluid overpressures by continuous influx of deeper magmatic-hydrothermal fluids during the IOCG mineralization. Although there are close spatial association between SSC and IOCG deposits in the Kangdian region, they are products of two separate mineralization events which are overprinted in a coincident location. This work also provides an excellent example for linking ore genesis to regional breccia bodies.

Robust age constraints on the Carlin-type gold and Skarn-type W deposits in the Youjiang basin of China: Implications for their genetic linkage and future exploration

WEI GAO[1]*, State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences (gaowei@mail.gyig.ac.cn)
SHANLING FU[2], State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences
RUIZHONG HU[3], State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences

Abstract

The Youjiang basin, located on the southwestern margin of the Yangtze block in southwestern China, represents the world's second-largest Carlin-type gold province after Nevada, USA. The limit availability of robust age determinations on gold deposits in this province has hindered understanding of their genesis and relation to the geodynamic setting. Hydrothermal apatite, rutile, and monazite that are coeval with gold mineralization have been identified in representative Carlin-type gold deposits. These hydrothermal minerals are characterized by intimate intergrowth with ore-stage gold-bearing sulfides, presence of primary two-phase fluid inclusions, composition affinities of hydrothermal origin, and highly variable concentrations of lattice-bound U and Th. In situ secondary ion mass spectrometry (SIMS) U-Th-Pb dating on these hydrothermal minerals yielded precise and reproducible U-Th-Pb ages of 150–140 Ma, representing the timing of Carlin-type gold deposits in the Youjiang basin, which are contemporary with the widespread felsic magmatism and associated high-temperature W-Sn mineralization to the east of the Youjiang basin. High-resolution nanoscale secondary ion mass spectrometry (Nano-SIMS) sulfur isotope analysis of gold-bearing pyrite and laser ablation inductively coupled plasma-mass spectrometry (LA-ICP-MS) composition analysis of individual fluid inclusion revealed that the Carlin-type gold deposits share similar geochemical fingerprints to the W-Sn deposits, indicating a common origin for the initial gold-bearing ore-forming fluids from deep magmatic-hydrothermal systems. Interestingly, in situ scheelite U-Pb dating conducted on the large Nanyangtian skarn-type W deposit in the southern margins of the basin has yielded robust mineralization ages of 155–145 Ma, confirming the scenario that there is indeed contemporaneous W mineralization occurring alongside with the Carlin-type gold deposits in the Youjiang basin. A vertical binary model has been established, characterized by lower high-temperature W mineralization and upper low-temperature Au mineralization. It can be predicted that there may exist high-temperature W deposits beneath the Carlin-type gold province in the Youjiang basin.

Metal sources of sediment-hosted antimony deposits: Evidence from antimony isotopes

Shanling FU[1]*, State Key Laboratory of Ore Deposit Geochemistry,Institute of Geochemistry, Chinese Academy of Sciences (fushanling@mail.gyig.ac.cn)
Wei GAO[2], Institute of Geochemistry, Chinese Academy of Sciences
Ruizhong HU[3], Institute of Geochemistry, Chinese Academy of Sciences

Abstract

Sediment-hosted antimony deposits are a major source of Sb, accounting for over 50% of global reserves and production. Although economically important, the genesis of sediment-hosted Sb deposits remains controversial due to the highly debated sources of metals in these deposits. The discovery by Rouxel et al. (2003) of significant Sb isotope fractionation in natural samples has led to numerous studies confirming the reliability of Sb isotopes as a geochemical tracer. However, the utilization of Sb isotopes as a tracer for source identification in Sb deposits remains limited due to ongoing debates surrounding Sb isotope fractionation models. The world's largest sediment-hosted Sb deposit, Xikuangshan, was studied to investigate the use of Sb isotopes as a tracer for identifying the metal source of such deposits. Investigation of Sb isotopic ratios of stibnite in the Xikuangshan deposit, altered and fresh host rocks, and metasedimentary rocks in Precambrian basement revealed that the Ediacaran and Banxi Group in the Precambrian basement may have served as the primary sources of Sb for the Xikuangshan deposit. The significant overlap of ε123Sb values in early-stage and late-stage stibnite suggest that the large variation of ε123Sb values from the early to late stages can be attributed to the episodic precipitation of multiple fluid batches that extracted Sb from the same source.

Trapping of uranium by organic matter within sandstones during mineralization process: A case study from the Shuanglong uranium deposit, China

Fan Fan Zhang[1]*, China University of Geosciences (1027728636@qq.com)

Abstract

Carbonaceous debris (i.e., CD), dispersed organic matter (i.e., DOM) within sandstones, has been studied in the Shuanglong uranium deposit of the southern Ordos Basin, northern China. Relations of uranium enrichment and organic matter (i.e., OM) were investigated through maceral analyses, proximate analysis, vitrinite reflectance measurements, and morphology analyses of uranium minerals. The results show that CD widely distributed in sandstones, is associated with pyrite and uranium minerals. Macerals are mostly composed of telinite, collotelinite, collodetrinite, semifusinite, and inertodetrinite, including that collotelinite is dominant (contents more than 60%). The CD is at the stage of medium coalification, and is of low moisture, high ash, high volatile matter, medium fixed carbon, and high sulfur. Uranium occurs in uranium minerals (i.e., pitchblende and coffinite) and amorphous uranium. Moreover, uranium minerals partly or completely replace macerals. Statistical analyses show that porous inertinite and higher organic matter maturity is more advantageous to uranium enrichment. Additionally, uranium is unevenly distributed in macerals along certain directions, which is related to the physicochemical properties of macerals. Porous inertinite could provide channel for uranium-bearing fluid migration and space for uranium preconcentration. The CD at the stage of gas coal is of reducibility to be favorable for the forming of uranium minerals. Moreover, the relative atomic content of uranium (IV) increases with the increasing organic matter maturity. Uranium-bearing fluid could permeate into macerals under certain physical and chemical conditions, and react, i.e., adsorption followed by reduction. It is beneficial to comprehend the mechanism of uranium mineralization, providing certain guides for prospection.

[Keynote] Unusual multi-metallic uranium deposits in India: Their potentialities.

DEEPAK KUMAR SINHA[1]*, AMD & GMDC (dksjai@gmail.com)

Abstract

Indian Plate provides varied litho-structural domains for hosting classical multi-metallic deposits. It contains Archaean to Recent geological environments established for minerallogenic provinces. Deep exploration carried out recently has resulted in the identification of multi-metallic uranium deposits in a few unusual host rocks. The recent additions like altered serpentinised peridotite in the Singhbhum copper-uranium province of Singhbhum Supergroup and uranium-REE in magmatic albitite in the Khertri-copper province of Delhi Supergroup have been established for opening new mining centres. The well-known strata-bound uranium deposit of Tumalapalli in the Vempalli Limestone Formation of Cuddapah Supergroup has reached the status of the highest tonnage discovered so far in India (Single largest uranium deposit -2,41,309t U3O8). It is classified under the low-grade category and proved up to a depth of 1km. The serpentinised peridotite and magnetic albitite at Geratiyon-ki-Dhani ranging from low to medium grade are emerging potentialities with 2000 tonnes U3O8 and 1000 tonnes U3O8 respectively. The continued exploration has paved the way to add 3000 tonnes in each deposit for the higher life expectancy of mine's life. The present paper discusses recently investigated geological and genetic aspects of these unusual multi-metallic uranium deposits for the identification of similar resources in other geological domains of the country and beyond the Indian Plate as well.

Sandstone-type uranium deposits hosted in the aeolian sandstone: Taking an example of the Pengyang-Jingchuan deposit in the Ordos Basin, China

YIN CHEN[1]*, Tianjin Center, China Geological Survey (chenyinchain@sina.com)
HUALEI ZHAO[2], Tianjin Center, China Geological Survey
LULU CHEN[3], Tianjin Center, China Geological Survey
QINGHONG SI[4], Tianjin Center, China Geological Survey
JIANGUO LI[5], Zhengzhou Institute of Multipurpose Utilization of Mineral Resources, Chinese Academy of Geological Sciences

Abstract

Sandstone-type uranium deposits have been regarded as the most significant uranium resources in the world, which has covered the uranium production to be up to 63.3 % and 72.0% in the global and Chinese market. Uranium deposits hosted in the aeolian sandstone were newly discovered in the Ordos Basin, China. Especially, petrology, mineralogy, geochemistry, geochronology, etc. have been invested in the Pengyang-Jingchuan uranium deposit located in the southwestern Ordos Basin. Uranium bodies are hosted in the Lower Cretaceous successions which are characteristic of the aeolian and shallow lacustrine sedimentary systems. Features of aeolian sedimentation (e.g., grain flow, wind ripple, and wind fall) were widely observed in the outcrops, drill cores or by the microscope. As there are less reduced materials in the red aeolian sandstone, hydrocarbon fluids uplifting along faults from the oil/gas preserves, act as the reducing agent for uranium mineralization, and alter the red sandstone to be gray. This has been proved by the fluid inclusions, ring-coating reduced alteration zone along the fissures, oil content tests and altered minerals. Anatase, pyrite, apatite, and clay minerals commonly spread in the uriniferous sandstone and played significant roles in the mineralization process. In-situ S isotope of the colloidal pyrites from the ore-bearing layers shows that the biological process is of great significance to the enrichment and precipitation of colloidal pyrite and uranium. Whole rock geochemistry analyses of samples from the ore-bearing layers also state a positive correlation between U and S. Furthermore, the uranium minerals are mainly pitchblende, with a small amount of coffinite. In-situ U-Pb dating of uranium minerals have recorded a mineralization stage during the Pleistocene. Tectonic events surrounding the southwestern Ordos Basin were analyzed based on the zircon and apatite fission trick, and five stages of tectono-thermal events since the Late Mesozoic were revealed: (i) the Late Jurassic–Early Cretaceous, (ii) the late Early Cretaceous, (iii) the Late Cretaceous, (iv) the Late Paleogene–Early Neogene, and (v) the Late Miocene–present. Combined with the former dating results of uranium mineralization in the western Ordos Basin, the latest activity since the Late Miocene is confirmed to drive the reactivation and re-enrichment of the uranium mineralization. Besides, most uranium mineralized drillcores were found to be located beside the faults spatially. In the end, the tectonic-driving and reducing-fluids-altering uranium mineralization model is set up, which has promoted the prospecting breakthroughs in the southwestern Ordos Basin and gave some key information for the uranium mineralization in the red beds.

Hongwei JI[9], Beijing Research Institute of Uranium Geology
Jian GUO[10], Beijing Research Institute of Uranium Geology

Abstract

The recently discovered uranium deposits occur in the red-mottled sedimentary sandstone system in northern basins of China, such as Hadatu deposit in Erlian basin and Hailijin deposit in south part of Songliao basin etc.. Unlike traditional sandstone-type uranium deposits, the uranium orebodies of these deposits exhibit multiple stratiform and tabular morphologies, which occur in grey-greenish sandstone layers within the red-mottled sandstone units, but do not appear to be controlled by a redox zone. The ore-bear grey-greenish sandstone layers display islet-, bead-like shapes in the bedding plane, and lens- and trumpet-like shapes in profile. These ore-bearing layers are associated with faults. The color of ores can be reddish to dark, which are geochemically rich in uranium, cobalt, nickel and zinc etc, showing similar element association of the source rocks rich in organic material below the ore beds. Uranium is closely related with organic material which is mostly determined to be bitumen. Multiple ages of the deposit have been determined to be Paleogene or Neogene, much younger than the hosted rocks. These signatures of these uranium deposits can not be explained in terms of the traditional infiltration (phreatic and interlayer oxidization-reduction) metallogenic theory.

based on the comprehensive studies on these deposits, a new exudation uranium metallogenic model for the formation of these deposits has been proposed. The ore-hosting red-mottled formation is evidenced to be syngenetic in origin, resulting from oxidization during primary sediment deposition. By contrast, the ore-controlling grey-greenish sandstone layers in the uranium-bearing formation are epigenetic in origin, resulting from secondary reduction by deep-seated reducing fluids that were mainly controlled by fault structures that connect the lower and upper parts of the sedimentary system. The uranium is believed to be from deep-seated dark sediments rich in various metals and organic materials. Uranium and other metals were transported by fluids originating from the same deep-seated source rocks, moving through faults and expelled during the sedimentary-tectonic evolution of the basin. The fluids were reducing in character, rich in organic acids, especially acetic acid and organic functional groups, and high in both temperature and pressure. These acids can leach and transport not only uranium, but also

zinc, cobalt, nickel, copper, and other metals. Furthermore, the functional groups can easily complex or combine with uranium and associated metals, which are soluble in those reducing fluids, and thus can migrate upwards into the overlying red-mottled sedimentary units. When the ore-bearing reducing fluids enter the red-mottled sedimentary units, the uranium complexes or compounds dissociate due to decreases in temperature and pressure, changes in pH and Eh values, oxidation, and other factors, resulting in precipitation of uranium and formation of the uranium deposit.

The new model has been applied to identify new prospective areas and a number of new discoveries on this new type of uranium deposit have been made in the red-mottled sedimentary formations of Meso- and Cenozoic basins in China for recent years.

Analysis on Uranium Metallogenic Conditions and Prospect Review of the Langka-Daladi Aera in Eastern Part of Southern Margin of Yili Basin, North China

SONG JI Jiye[1]*, Beijing Research Institute of Uranium Geology,CNNC (jessica_0@163.com)
QIN MING KUAN[2], BRIUG,CNNC

Abstract

Yili basin is an important uranium deposit base in China. So for, a series of large and medium-sized in-situ leachable interlayer oxidation zone sandstone type uranium deposits have been found in the middle and western part of the southern Yili Basin. However, there is no great breakthrough in the eastern part (Langka-Daladi area)of the basin south margin. Whether the area has the uranium metallogenic potential or not and how is the prospect is to be solved. In this paper, the uranium metallogenic condiontions (such as the metallogenic structure, sedimentry and palohydrodynamic conditions)and prospects in Langka-Daladi area have been studied detaily, through summarizing and analyzing the previous research results, making full use of drilling, geophysical exploration, field investigation and data collection, as well as indoor mapping study. The results show: the known uranium deposits area (Mengqiguer) and its eastern extention(Langka-Daladi area) are the favorable areas for the existing key exploration areas and the peripheral resources to increase and expand the deep prospecting space. The metallogenic scale of Kulusitai-Daladi compound syncline belt and its north area is limited compared with that of Meqiguer and its east extension, but it still has certain metallogenic prospect in the Almalai syncline and the area to the north of Almalai-Suaau.

Genesis of high-grade uranium deposits in Motianling Neoproterozoic granites from northern Guangxi Province, South China: Constraints from in situ micro-chronology, sulfur isotope and trace elements analysis

Yongjian WANG[1]*, Beijing Research Institute of Uranium Geology, China National Nuclear Corporation, Beijing, 100029, China (wangyongjian9818@foxmail.com)
Yaqing PANG[2], Beijing Research Institute of Uranium Geology, China National Nuclear Corporation, Beijing, 100029, China
Honghai FAN[3], Beijing Research Institute of Uranium Geology, China National Nuclear Corporation, Beijing, 100029, China

Abstract

The Neoproterozoic Motianling granite complex in northern Guangxi, South China, hosts a number of uranium deposits and occurrences. This region stands out from other hydrothermal uranium deposits in South China due to several distinct geological characteristics. The host rocks are notably ancient (730–828 *Ma*), *and there is a considerable temporal gap* (>400 *Ma*) *between the formation of ore-hosting granites and uranium mineralization. Additionally, the deposits exhibit high uranium grades* (>0.3%) *and a variety of mineralization types. Limited research and exploration in this area have led to considerable debate and discrepancies regarding the uranium mineralization age and the ore genesis.*

The Daliang deposit, a primary focus of this study, predominantly features uraninite-chlorite (pyrite) mineralization type. In these ores, uranium primarily occurs as pitchblende, and brannerite. Additionally, a small amount of uranium is found in the form of isomorphism or adsorption in hematite, illite, apatite, and xenotime. In contrast, the Xincun deposit primarily involves uranium-silicification and uranium-fluorite mineralization types, with a simpler uranium occurrence mainly in the form of uraninite and minor coffinite. Temperature estimations based on chlorite geothermometers suggest that the mineralization temperature of the Daliang deposit was between 218–243℃, *which aligns with previous findings derived from fluid inclusion homogenization temperatures, indicating a medium to low-temperature condition. In contrast, the pre-mineralization formation temperature of chlorite in the Xincun deposit was estimated to be* 219–243℃, *notably higher than the fluid inclusion homogenization temperature in the syn-ore stage. LA-ICP-MS uraninite U-Pb analysis indicates that the uraninite-chlorite mineralization type at the Daliang deposit formed around* 800-750 *Ma. The primary mineralization stage of uranium-silicification type at Xincun occurred at* 57 *Ma, followed by a later uranium-*

fluorite mineralization type at 50 *Ma. Microelemental analysis of pitchblende, along with H-O isotopic studies of quartz and chlorite and in-situ S isotope characteristics of pyrite in both deposits, indicate that the mineralizing fluids were primarily a mixture of deep-sourced fluids and meteoric water. The mineralizing components were predominantly derived from the granite body itself.*

Based on this research, a multi-stage and complex genetic model for uranium mineralization involving both deep-sourced fluids and meteoric water has been developed for the Motianling area. This model highlights the intricate interplay of geological processes in forming these unique and valuable uranium deposits.

Uranium mineralization age constraint by indirect dating of syn-ore gangue minerals: a case study from a Na-metasomatite uranium deposit in Northwest China

Jun ZHONG[1]*, Beijing Research Institute of Uranium Geology (zhongjun9818@163.com)

Abstract

Constraining the mineralization age of any mineral deposit is fundamental for understanding ore genesis and determining prospecting strategies. For uranium deposits, the commonly applied dating method used in recent two decades is uraninite (pitchblende) SIMS and/or LA-ICP-MS U–Pb dating. However, the determination of mineralization age for some low-grade uranium deposits (e.g. Na-metasomatite type and sandstone-type) with fine-grained uranium minerals remains difficult because these fine-grained minerals are difficult to date. Moreover, the dating results of some uranium deposits may be inconclusive and even confusing due to the easily reset characteristics of uraninite/pitchblende by post-mineralization tectonothermal events and/or fluids. Effective alternatives, therefore, are necessary for the mineralization timing constraint for the uranium mineralization systems. In this study, we present for the first time a case study of a Na-metasomatite uranium deposit in northwestern China (the Xinshuijing deposit), using the syn-ore hydrothermal zircon U-Pb and albite Ar-Ar dating methods to bracket the mineralization age. The syn-ore hydrothermal zircon U–Pb and albite Ar–Ar ages are consistent with each other (378–366 Ma; given analytic uncertainties), but also within the range of uraninite chemical U–Pb ages (approximately 370 Ma). The coupled application of hydrothermal zircon U–Pb and albite Ar–Ar age dating is thus regarded as a robust approach for constraining the age of mineralization for Na-metasomatite uranium deposits. An age gap of approximately 70 m.y. between uranium mineralization (~ 370 Ma) and host granitoid emplacement (about 440 Ma) suggests no direct genetic linkage between the two, and further exploration in the surrounding sedimentary and metamorphic units, rather than only focusing on the host granitoids, should therefore be considered, especially where intensive wallrock alteration and structural features are pervasive. Our study highlights the importance of selecting appropriate isotopic dating methods for the uranium deposits, which is informed by detailed paragenetic and geochemical analysis of dateable minerals formed before or coeval to the main-stage uranium mineralization.

Uranium mineral systems in Brazil

Hugo Jose de Oliveira POLO[1]*, Geological Survey of Brazil (hugo.polo@sgb.gov.br)
Anderson Dourado Rodrigues da Silva[2], Geological Survey of Brazil
Iago Sousa Lima Costa[3], Geological Survey of Brazil
Isabelle C.C.O. Serafim[4], Geological Survey of Brazil
Felipe Mattos Tavares[5], Geological Survey of Brazil
Lys Matos Cunha[6], Geological Survey of Brazil
Raul Eigenheer Meloni[7], Geological Survey of Brazil

Abstract

Brazil currently has one of the most extensive uranium resources in the world, with about 245 thousand tons of contained uranium. Besides, the country has the potential to be among the five largest resources globally due to its territorial extension, geological diversity, resumption of geological surveys, and prognosticated and speculative resources from a recently released IAEA report. Brazil has 36 uranium deposits in 9 different types, according to IAEA: 4 intrusive; 5 IOCG; 1 metamorphic; 15 metasomatic; 3 Paleo conglomerate with quartz pebble; 2 granite related; 3 sandstones; 2 phosphates; 1 superficial. In this work, we synthesize the current knowledge of Brazilian uranium deposits to obtain a macro-regional analysis. The deposit types are simplified into six sets of mineral systems: i) igneous, ii) metamorphic/metasomatic, iii) Proterozoic unconformity, iv) paleo conglomerate, v) sedimentary, and vi) superficial. There are 11 known igneous uranium deposits that account for between 38% and 48% of national reserves, the main ones are Salobo, Sossego and Pitinga, all located in Amazon Craton. Sedimentary deposits represent between 23% and 29% of reserves, with a total of 4 deposits, the most important being Amorinopolis and Figueira. There are 16 metasomatic/metamorphic deposits that represent between 27% and 31%, including Lagoa Real and Itataia/Santa Quiteria. The first is an active mine and the second is a project under development that should start production in 2026. Finally, paleoconglomerate and superficial deposits represent less than 2% of the total reserves, represented by Jacobina and Gandarela. We highlight that there are no Proterozoic unconformity uranium deposits described in Brazil, despite the high potential, due to the giant proterozoic basins that cover about 9% of crystalline terrain in Brazil. We also highlight that some of these deposits may represent the overlap of more than one mineral system. The sedimentary, metamorphic/metasomatic and igneous systems present best potential for new discovers based in the knowledge-driven analyses, and the airborne radiometric data, processed using artificial intelligence, are correlated to results for metamorphic/metasomatic and igneous systems. Due to the recent changes in the legal frameworks for uranium exploration in Brazil, it is necessary to publicise the Brazilian mineral potential widely. The mineral systems approach represents an important structure for the construction of prospectivity maps and other spatial data modeling products, which in turn assist in decision-making by public authorities and in the promotion of the mineral industry, by indicating priority areas for development of mineral exploration, thus reducing the risk and cost of exploration and consequently expanding national resources.

Late Cretaceous-Cenozoic tectonic-sedimentary evolution and U-enrichment in the southern Songliao Basin

Shaoyi WANG[1]*, Tianjin Center, China Geological Survey (1032668801@qq.com)

Abstract

Late Cretaceous-Cenozoic tectonic-sedimentary evolution is fundamental to U (Uranium) migration and U-enrichment in the southern Songliao Basin, northeast China. To establish the genetic connection between tectonic-sedimentary evolution and U-enrichment, this paper presents a mineralogical study, apatite fission-track (AFT) analysis, and SEM-CL analysis of quartz grains. Two stages of mineralization were proposed, including the U pre-enrichment stage during the Late Cretaceous, and the ore-forming stage during the Cenozoic. Based on the density plots of the AFT ages, paleoclimate studies, and SEM-CL analysis of quartz grains, it is inferred that the U pre-enrichment was closely related to the rapid uplift of the Great Xing'an Range and the Zhangguangcai Range, and the O2-rich atmosphere during 97–90 Ma in the southern Songliao Basin. The O2-rich atmosphere increased U mobility and led to the formation of red beds during the Late Cretaceous, which widely developed U pre-enrichment in the basins of Northeast China. The mineralogical study reveals that the Qianjiadian uranium deposit developed in two stages. The diagenetic process experienced the transition from early alkaline to late acidic conditions, to promote the Stage I mineralization (U pre-enrichment). The dominant occurrence spaces for U were the dissolution pores of quartz, tightly packed with calcite cement. U-enrichment during alkaline ambient conditions was mainly via adsorption. With the increase of the buried depth, the early alkaline diagenesis returned to acidic conditions due to the abundant organic material. U(VI) was reduced to pitchblende due to the reducing capacity of the organic matter (OM). Stage II (ore-forming stage) mineralization was strictly related to the hydrocarbon re-concentration. According to the thermal history study of the CC1 and Q2 boreholes, the southern Songliao Basin experienced four episodes of rapid uplift during the Cenozoic at 83–80 Ma, 68–52 Ma, 33–23 Ma, and −8 Ma, respectively. The Cenozoic uplifts led to hydrocarbon migration at 65 Ma, 23 Ma, and present. The re-concentration of hydrocarbon prompted the U mineralization in the Qianjiadian uranium deposit in the southern Songliao Basin during the stable period of tectonic movements. The reducing conditions caused by hydrocarbons promoted U mineralization. The dominant spaces of coffinite were intergranular dissolved pores, formed during the transformation from the feldspar to the kaolinite under acidic conditions. The post-rift phase and structural inversion phase directly controlled the U pre-enrichment stage and the ore-forming stage, respectively. Overall, the tectonic-sedimentary evolution played an important role in controlling the U leaching from granites, the dominant occurrence spaces, and U recycling.

Trans-strata mineralization of sandstone-hosted uranium deposits triggered by neotectonics

Yinhang CHENG[1]*, Tianjin Center, China Geological Survey (weicheng1858@163.com)

Abstract

Sandstone-hosted uranium deposits (SUDs) are hosted in different strata from Proterozoic to Cenozoic concentrated, with dominant ore-bearing of Mesozoic and Cenozoic. Traditionally, it is believed that uranium precipitation of SUDs is multi-staged. However, whether there is a dominant stage during the mineralization process still remains unclear. Here we show that the neotectonics could play a larger role than previously thought in generating SUDs in Ordos Basin, China, even in the world. Two main uranium-bearing strata, including the Middle Jurassic Zhiluo Formation (ZF) and the Lower Cretaceous Luohe Formation (LF) have been detected, and most of the uranium is present in pitchblende and coffinite. Relevant in-situ pitchblende U-Pb dating (1514 spots) and their chemical ages (145 spots) for ZF and LF ore deposits yielded ages range from 100 Ma to 0.1 Ma, while ca. 95% of their worldwide occurrences are concentrated in the 25-0.1 Ma. In addition, there are three mineralized stages with ages of 91-80 Ma, 70-68Ma and 37-30 Ma before the main stage. These early three staged residual uranium minerals have been increased exponentially as the younger age developed. The early three staged uranium ores even earlier have been almost redistributed by the latest regional oxidizing uraniferous fluids flow triggered by neotectonic events and rarely preserved. Though, the SUDs have been found to be hosted in different strata, it is considered that they have been formed in a same mineralized ages triggered by global neotectonics and climatic variations, and it could be defined as trans-strata isochronous mineralization.

Determination of radon exhalation rate of uranium ore samples from sandstone-hosted uranium deposits

Nanping WANG[1]*, China University of Geosciences (Beijing (npwang@cugb.edu.cn)
Ying JIANG[2], China University of Geosciences (Beijing

Abstract

Radon exhalation rate is the flux of radon produced by radium decay in solid media and released into the air. It is an important parameter for the study of underground radon transport, and is related to the radium content of the sample and its physical properties such as humidity, porosity and particle size. There are few data on radon exhalation rates of rocks and ores with different uranium and radium specific activity levels. In order to understand the law of radon transport in deep uranium deposits, the method of determining radon exhalation rate of uranium ore samples was studied.

A cylindrical closed chamber was used to collect radon released from core samplesand an AlphaGUARD radon detector and gas circulation system were used to measure the radon concentration released from the samples in the sealed chamber with different accumulation time, and then the radon exhalation rate of samples was calculated. The measurement results of radon exhalation rate of uranium core samples in Erlian Basin of Inner Mongolia show that the method effectively excludes the interference of radon-220, and the fitting R2 value, radon concentration growth curve at different accumulation time, is higher than 0.90. The average radon exhalation rate of uranium ore core samples is 380 times that of surface soil samples. The repeated measurement results of radon exhalation rate are stable and reliable. This method is suitable for the measurement of radon exhalation rate of uranium ore and rock.

This research was supported by the National Natural Science Foundation of China (U2067204).

Analysis and prediction of supply guarantee for the development of world nuclear power

SONG JI Jiye[1]*, Beijing Research Institute of Uranium Geology,CNNC (jessica_0@163.com)
QIN MING KUAN[2], Beijing Research Institute of Uranium Geology,CNNC

Abstract

The energy transformation by climate issues, coupled with the energy supply crisis, has led to the development of nuclear power being valued and re examined by many countries. It is expected that the demand for natural uranium will increase. The question of whether the development of world nuclear power can be guaranteed by 2050 urgently needs to be studied and analyzed.Based on the historical and latest data of nuclear power, uranium resources, mines, etc., this article comprehensively analyzes the new situation and historical changes in the demand and supply sides of nuclear power development, and quantitatively predicts the degree of guarantee of uranium resources and natural uranium supply for nuclear power development.The research results indicate that: a) On the demand side, the world's demand for nuclear power and natural uranium in nuclear power shows a concentrated pattern, while on the supply side, the total distribution of uranium resources in the world is uneven and highly concentrated, with a large overall economic gap. b) By 2035, low-cost identified (recyclable) uranium resources can basically guarantee the development of world nuclear power. From 2036 to 2050, 80% will be guaranteed by 55% of identified (recyclable) resources at medium to high costs, while medium to low cost resources can also meet nearly 20% of the world's nuclear power demand for natural uranium during this period. c) By 2035, the amount of natural uranium resources needed for nuclear power development can be guaranteed by 96% in terms of mining resources. However, from 2036 to 2050, on the basis of fully consuming the remaining resources in mining, all planned mines and nearly 90% of potential mine resources will be needed to supplement the needs. The overall resource guarantee situation is tense. d) By 2035, primary supply can only meet 78% -82% of the required natural uranium production under different production capacity scenarios, and the remaining shortfall cannot be fully satisfied by secondary supply. This will promote the increase of mine production capacity or the adjustment and supplementation of new planned mine operations. From 2036 to 2050, there is pressure to ensure the natural uranium production required for the development of nuclear power, and there is little secondary supply (which can be ignored). It is necessary to fully exploit and produce all resources in the production mines, and it is imperative to initiate plans and potential mine operations.

Thorium and Uranium ore occurrences of Georgia (The Caucasus): A comparative analysis and Prospects

Avtandil OKROSTSVARIDZE[1]*, Doctor of Geological Sciences (okrostsvari@gmail.com)
Avtandil Okrostsvaridze[2], 1 Institute of Earth Sciences, Ilia State University, 0177 Tbilisi, Georgia
David Bluashvili[3], 2 Faculty of Geology and Mining, Georgian Technical University, 0171 Tbilisi, Georgia
Franziska Wilke[4], 3 German GeoResearch Center, 14473 Potsdam, Germany
Rabi Gabrielashvili[5], 1 Institute of Earth Sciences, Ilia State University, 0177 Tbilisi, Georgia

Abstract

The Caucasus represents a Phanerozoic collisional orogen that extends for over 1000 km from the Caspian to the Black Sea. Georgia is located in the central part of the orogen and covers the southern part of the Greater Caucasus, the Transcaucasus and northern part of the Lesser Caucasus. Several ore occurrences of uranium and thorium have been identified on the Georgian territory: Shkhara U-Th, Stori Th-Bi, Vakijvari Th-Fe and Merisi Th-U.

Among them, the recently discovered Shkhara U-Th mineralization deserves significant attention [1]. It has been identified along the Main Thrust of the Greater Caucasus, in the Paleozoic Shkhara crystalline massif. The parent rocks of the mineralization are represented by biotite plagiogranites, zircon 206Pb/238U dating of which indicates 310.2±7.5 Ma. According to ICP-MS-ES analyses, in these rocks the Th content varies from ~25 ppm to ~90 ppm, and the U varies between ~20 ppm to ~390 ppm. The mineralization is represented ore veins and nests of the hydrothermal generation Their investigation on the JXA-8230 electron probe microanalyzer has shown that the mineralization is present by Th-bearing Uraninite, the overall chemical U-Pb ages of which corresponds to 291±14 Ma.

The analysis of the obtained data indicated that the Shkhara uranium mineralization was formed in the pos-orogenic extension regime of this Greater Caucasus crystalline basement (Late Carboniferous-Early Permian). This date is in full correlation with the vein-type uranium deposits similar to different regions of the world, including central and Western Europe. This mineralization has a special similarity to the uranium deposits of the Armorican Massif (France) and of the Iberian Massif (Spain)].

Unlike uranium, there are more thorium ore occurrences in Georgia. Among them, we can mention Merisi Th-U mineralization. It was formed in the active contact area of Late Eocene Merisi syenitic pluton, in the hydrothermally altered intermediate volcanic rocks. The thorium content ranges from 52.3 g/t to 147.7 ppm, and uranium from 6.2 ppm to 17.5 ppm in these rocks.

Among From thorium mineralization, it should also be noted the Stori Th-Bi ore occurrences. It is exposed within the Middle Jurassic Stori hydrothermal ore field, which is formed on the Southern Slope of the Greater Caucasus. In this zone, carbonate quartz-plagioclase veins of 30-40 cm thick, intersect the Plinsbachian clay-shales. In these veins, thorium content reaches 3880 ppm, and bismuth - 4800 ppm. Although generally in these rocks Th content varies within the range of 50-200 ppm, and Bi within the range of 55-880 ppm. Thus, as a result of our investigation we can

conclude that several prospective ore occurrence of thorium and uranium were revealed in Georgia, which require further detailed study

Sanghoon Lee[6], Korea Atomic Energy Research Institute

Abstract

The uraniferous black and coaly slates are developed in the Ogcheon metamorphic belt, South Korea. In Maninsan area, weathered soil fills along the fracture zone of the uraniferous hornfels, and fragments of coaly slate are found around the soil. This study compares the mineralogical and geochemical characteristics of these rock types to discuss potential processes leading to uranium enrichment in the soil. Uranium minerals predominantly occur as Th-V-Ca mineral and uranothorite for the hornfels, brannerite and coffinite for the coaly slate, and francevillite and uraninite for the soil. Their grain sizes are 7 μm in the hornfels on average, 23 μm in the coaly slate, and 29 μm in the soil. The uranium concentrations in these rocks vary from 5 to 14 ppm (av. 10 ppm) in the hornfels, 88 to 477 ppm (av. 277 ppm) in the coaly slates, and 290 to 832 ppm (av. 613 ppm) in the soils. In addition, the coaly slate and soils exhibit negative Eu and Ce anomalies and enriched V, Mo, and U, with depleted Mn concentrations. Carbon isotopic compositions and total carbon contents of the hornfels, coaly slates, and soils display a range of -24.7 to -24.1‰ (av. -24.5‰), -29.2 to -28.4‰ (av. -28.7‰), and -28.6 to -27.4‰ (av. -28.4) and of 1.8 to 5.2% (av. 3.6%), 9.7 to 28.4% (av. 16.5%), and 7.4 to 23.9% (av. 17.5%), respectively. Soil and coaly slates have similar characteristics, indicating that the soils are the weathered product of the coaly slate. The coaly slates were hydrothermally altered from hornfels and formed uranium-rich soils through weathering and secondary reconcentration processes.

Mineralogy of residual and redeposited uranium in the boreholes of in-situ leaching uranium mining

Anna Vladimirovna SASHCHENKO[1]*, Russian Mineral Resource Institute – VIMS (sashchenko@vims-geo.ru)
Gennady Ivanovich Avdonin[2], Russian Mineral Resource Institute – VIMS
Galina Alexsandrovna Tarkhanova[3], Tarkhanova

Abstract

Comparison was made between the natural composition of ore-bearing rocks and waters, contained in the ores, before ISL (in-situ leaching mining) and altered composition after ISL. The deposit studied belongs to sandstone type and is localized in Middle-Upper Jurassic paleo-alluvial deposits at depths of 480-600 meters. The mineralization is of infiltration-epigenetic genesis and is controlled by a wedging out oxidation zone.

The ore-bearing rocks are represented by gray-colored arenitic-argillitic formations with a significant admixture of vegetable detritus and iron sulfides, causing the reduction properties of the deposits. The arenitic part is composed of quartz and feldspar, the cement is of argillite – kaolinite composition. Pyrite of various morphologies is widespread in the ores. Pyrite content reaches 10%. Uranium mineralization is mainly in oxide form and is often associated with pyrite.

The uranium content in the ore-bearing horizon after 30 years after extraction ranges from 0.002 to 1%. The intervals with the maximum uranium content shows values of radioactive equilibrium ratio (RER) less than 1, which is typical for the conditions of its technogenic redeposition. In the same intervals, the content of pyrite reaches 16%. Two types of uranium mineralization of similar composition is associated with large nodules of pyrite.

The first type of uranium mineralization is confined to the central part of the nodules. According to laboratory studies, such mineralization is not leachable and represents a residual form. The second type is represented by films of multicomponent uranium-containing gels developed in the form of a thin rim in the marginal part of the nodule. Uranium mineralization of the second type often occurs together with small columnar gypsum aggregates, which are absent in natural ores. The indicated uranium mineralization is present in the form of a thin film with well-diagnosed shrinkage cracks, which indicates their fast formation. Given the absence of gypsum in natural ores, the morphology of uranium minerals, and its prevalence in ranges with RER values less than 1, it can be concluded that the mineralization is the result of redeposition during uranium extraction by the ISL method.

After 30 years since the completion of mining, the composition of waters has practically restored, along with the increase in the pH. the concentration of sulfate ions, sodium ions, uranium, as well as total mineralization decreased. The restoration of the initial composition of reservoir waters is associated with the neutralization ability of ore-bearing rocks.

Conclusion. Residual and redeposited uranium concentrations have been identified.

Felipe Mattos Tavares[5], Geological Survey of Brazil

Abstract

Brazil has the seventh-largest uranium resource in the world. However, the country appears to be outside the ranking of relevant producers of this commodity. The reason is the need for systematic mapping and the Brazilian laws related to uranium exploration in force until 2022. The changing of Brazilian Nuclear Policy aims to promote research, prospecting, and national production of uranium resources. Therefore, in line with its institutional mission to generate and disseminate geoscientific knowledge nationwide, the Geological Survey of Brazil (SGB) initiated a uranium potential assessment program in the national territory. Due to Brazil's vast dimensions, the resumption of systematic exploration poses a significant challenge. To address this challenge, technological advances in multi-scale uranium anomaly detection can significantly increase the number of discoveries and, consequently, the contribution of Brazil to the global nuclear sector. The uranium concentration in rocks varies due to primary and secondary factors. These primary variations are associated with pedogenesis, geomorphology, geochemistry, and lithological variations. In contrast, secondary variations may be related to processes responsible for forming ores, such as fluid migration or hydrothermal alteration. The most relevant uranium anomalies are related to the secondary variations; however, as primary variations are the most expressive, they must be suppressed before analyzing the effects caused by secondary processes. In this work, we use Artificial Intelligence (AI) to decompose the airborne radiometric data into a Uranium Expected map (Ui) and Uranium Deviation map (Ud). The first map corresponds to the contribution of primary variations and is predicted through other radiometric channels, such as eTh and the ratios eTh/K and eU/K. The Ud map is associated with secondary variations and is calculated by the deviation between the acquired airborne radiometric data and the Ui values The Ud interpretation of the Rio Cristalino and Itataia regions correlates the positive and negative values to uranium enrichment and depletion areas, respectively. The highest Ud values were well-correlated with the known uranium occurrences, with several other potential anomalies to follow up. However, we noted some positive anomalies without geological correspondence. These irrelevant positive anomalies were generated because the methodology calculates the relative uranium enrichment, and consequently, the interpretation of this map is not straightforward. For example, in regions where the background value of radioelements is meager, a slight change in content could generate a relative anomaly without relevance. To improve our interpretation, we also evaluated the map of uranium concentration before selecting areas to field

check. Finally, this work shows a possible workflow to interpret the Ud data for uranium assessment in brownfield and greenfield areas.

Abstract

With the continuous improvement of uranium exploration, the opportunities to find new outcrops and shallow deposits are gradually decreasing. As the main type of concealed uranium deposits, sandstone-type uranium deposits are mostly developed with thicker cover layers, and the surface anomaly information is weak, so the direct ore-hunting marks are not obvious. In recent years, studies on the theory and application of radon migration, geogas migration, and deep penetration geochemistry have shown that deep uranium mineralization can have weak anomaly information on the surface. However, how to identify and extract the weak airborne gamma spectrometry information on the surface of sandstone-type uranium deposits, and clarify their distribution characteristics, causes, and relationships with deep uranium ore bodies have become one of the key issues restricting the improvement of sandstone-type uranium exploration effects based on airborne gamma ray radiation data.

This study carried out profile measurements of five methods including geological observation, ground gamma spectrometry, soil radon concentration, geoelectrochemical and metal mobile state on known sandstone-type uranium deposits, typical aerial gamma spectrometry anomalies, and weak information of aerial gamma spectrometry in Erlian Basin of northern China. The point distance was 40m-80m, and the line distance was 100m-200 m. Based on the comprehensive study of the plan and profile maps of field geological observation, measured data and laboratory chemical analysis data, it was believed that the soil radon concentration above the sandstone-type uranium ore body or mineralization is mainly low, and the edge of the ore body often shows zonal or peak anomalies. The geoelectrochemical plane characteristics were high U and low Mo, and the profile characteristics were sawtooth U peak anomalies. Vertically along the ore body trend, the ground gamma spectrometry U content showed the characteristics of high on both sides and low in

the middle. The U extracted by metal mobile state presented irregular surface high values or anomalies and peak profile anomalies above the uranium ore body.

Therefore, aiming at the verification of the weak information of airborne radiation survey for the exploration of sandstone-type uranium deposits in the covered area, two kinds of effective combined methods and interpretation models have been established, including ground gamma spectrometry, soil radon concentration measurement, geoelectrochemical measurement or metal activity measurement. They can identify the spatial relationships between airborne radiation anomalies or weak information and deep uranium-rich geological bodies. In addition, in the future verification of airborne radiation anomalies and weak information in the covered area, as well as the exploration of concealed sandstone-type uranium deposits, priority should be given to analyzing the weak increase areas of surface gamma spectroscopy U content and the low-value areas near soil radon concentration anomalies. Attention should still be paid to the abnormal areas of airborne or surface gamma spectroscopy U content.

This research was supported by the National Natural Science Foundation of China (U2067204).

A Study on the Uranium-Radium Equilibrium Coefficient of Barun Sandstone-Hosted Uranium Deposit, Inner Mongolia

Aimin PENG[1]*, China University of Geosciences, Beijing (pengaimin126@126.com)
Nanping WANG[2], China University of Geosciences, Beijing
Mengke HAN[3], China University of Geosciences, Beijing

Abstract

The uranium-radium equilibrium coefficient reflects the post-formation migration and enrichment status of uranium in deposits and is a critical corrective parameter for estimating uranium reserves. However, it is susceptible to numerous factors, including the content of sample uranium and radium, as well as lithology. To investigate the characteristics of the uranium-radium equilibrium coefficient in sandstone-hosted uranium deposits, this study analyzed and researched the core samples from a drill hole in the Barun sandstone-hosted uranium deposit. The samples were divided into ore layer samples and non-ore layer samples. Uranium and radium contents in the samples were measured using an HPGe gamma-ray spectrometer, and their uranium-radium equilibrium coefficients were calculated. After using robust statistics to exclude outlier data, the average uranium-radium equilibrium coefficient was found to be 0.996 with a standard deviation of 0.293, indicating near equilibrium between uranium and radium in the samples. Further analysis on the distribution pattern of the uranium-radium equilibrium coefficient, considering influencing factors such as sample uranium content and lithology, showed that the coefficient negatively correlates with uranium content when categorized by uranium content. Except for conglomerates and medium sandstones, uranium and radium are essentially in equilibrium in other rock types. This research was supported by the National Natural Science Foundation of China(U2067204)

Types and spatiotemporal distribution characteristics of uranium deposits in China

Yuqi CAI[1]*, Beijing Research Institute of Uranium Geology, CNNC (caiyq1883@126.com)

Abstract

The Chinese Mainland is formed by many geobodies of different scales, with complex metallogenic geological background and various types of uranium deposits. According to the genesis of the deposit and the host rock, it can be divided into 4 major categories, 9 categories, and 21 subclasses. More than 350 uranium deposits have been discovered in China, with sandstone, granite, volcanic, and carbonaceous-siliceous-pelitic being the main types.Sandstone type uranium deposits are mainly distributed in northern terrestrial basins, with 7 major basins including Ordos Basin, Ili Basin, Tuha Basin, Erlian Basin, Songliao Basin, and Badain Jilin Bayingobi Basin accounting for over 85% of the total resources of this type. Uranium deposits have the characteristics of multiple periods and stages of mineralization, with mineralization ages ranging from 156 Ma to 2 Ma. The main mineralization periods are 85 ± 6 Ma, 65 ± 7 Ma, 49 ± 4 Ma, 8 ± 4 Ma, 21 ± 2 Ma, and 10 ± 2 Ma.Granite type uranium deposits are mainly distributed in uranium metallogenic belt of Taoshan-Zhuguan, Mount Wuyi and Chenzhou-Qinzhou in the south east China uranium metallogenic province. This type uranium mineralization period spans greatly from 1900-10 Ma, with the main mineralization periods being 82 ± 5 Ma, 74 ± 4 Ma, 64 ± 5 Ma, and 50 ± 4 Ma.Volcanic type uranium deposits are mainly distributed in Ganhang, Mount Wuyi, the middle and lower reaches of the Yangtze River, Guyuan-Hongshanzi, Xingcheng-Qinglong and Xuemishan uranium metallogenic belts. The uranium mineralization mainly occurred at 164 ± 12 Ma, 133 ± 9 Ma, 114 ± 3 Ma, 101 ± 2 Ma, and 85 ± 6 Ma.Carbonaceous-siliceous-pelitic type uranium deposits are mainly distributed in uranium mineralization zones such as the South Qinling, Xiushui-Ningguo, Central Hunan-Northwest Guizhou, Daming Mountains, the southern edge of the North China Block, and the northern edge of the Tarim Basin. The uranium mineralization period was later than the main rock formation period, concentrated in the Yanshan Himalayan period, with the main periods being 68 ± 16Ma and 31 ± 3Ma.

The complex origin of the Proterozoic Varena Iron Ore deposit in the SW East European Craton, southern Lithuania: implications from microstructures, mineral chemistry and isotope study

Grazina SKRIDLAITE[1]*, Nature Research Centre (grazina.skridlaite@gamtc.lt)
Laurynas Siliauskas[2], Nature Research Centre
Boguslaw Baginski[3], Faculty of Geology of the University of Warsaw
Olga Demina[4], Nature Research Centre

Abstract

The Precambrian Varena Iron Ore deposit (VIOD) is covered with 300-500 m thick sediments and is estimated to yield ca. 220 million tons of iron ore. The ores are assumed to be of metasomatic and hydrothermal origin, however, several other hypotheses of the VIOD origin, e.g. as a layered mafic, ultramafic or carbonatite intrusion have been suggested by different investigators.

The major iron ore bodies of the VIOD are hosted by former impure dolostones and are underlaid by ca. 1.90 Ga metamorphosed magmatic rocks of felsic and intermediate composition. In places, the ores are overlaid by mica schists and gneisses.

The SEM, EMPA, LA-ICP-MS as well as the phase diagram application allowed to distinguish high-grade skarns (forsterite, enstatite, spinel and diopside) produced during metamorphism of the dolostones and neighboring silicate rocks at 600-710o C. Only a small amount of magnetite has originated from metamorphic reactions at that stage. No reliable time constraints are available for the peak metamorphism so far. It was recently established that after the drop in pressure, an iron-rich, oxidised, Cl-bearing, water fluid influx has resulted in the formation of an abundant magnetite at T of 300-500o C together with intense secondary dolomitization, chloritization and serpentinization. Even though the part of iron might have been mobilised from the host rocks, some other sources, richer in iron, should be involved. It is likely that the neighbouring 1.79-1.76 Ga mafic magmatism was responsible for the metamorphism and Fe, Cl etc enrichment. Monazite, baddeleyite, and zircon have precipitated from the water-rich fluid together with the magnetite at an age of 1.71 Ga, which can be considered as the approximate age of major iron, phosphorus, and rare earth element mineralization.

Numerous veins cross-cutting the iron bodies were dated at ca. 1.50 Ga. A similar age of ca. 1.54 Ga was recorded by small homogeneous monazite grains in the studied calciphyre. coinciding with the emplacement of voluminous AMCG suites such as the Mazury complex and the Kabeliai intrusions further west and south. This second, younger magmatic and hydrothermal overprint has affected the VIOD rocks and remobilized Fe, P, RE elements.

Taking into account the temporary and spatial relationship between various mineralizations in the VIOD and the sulphide, iron oxide and REE enrichments in the neighbouring Mazury complex and Kabeliai granite intrusions, the potential of mineral resources in the region would increase considerably.

Abstract

The Triassic IOA-style mineralization at Yangyang located in the central-eastern Korean Peninsula occurs in the NW-and NS-trending boundaries between the Precambrian gneissic rocks and the Cretaceous Yangyang syenite complex. The IOA-style orebody at Yangyang can be divided into three areas as follows: the Northern, Central, and Southern, and this study area is located in the Northern orebody. IOA-style orebody strikes N70°E and dips to approximately 85°SE, and cuts across both rocks. It occurs as a discrete lenticular body, which is totally controlled by vertical fractures and has a maximum of approximately 20 m wide, 100 m long, and 40 m thick. The orebody consists of a similar proportion of magnetite and phlogopite with a lesser amount of apatite. Low-grade ore in wall-rock alteration was mainly controlled by foliation. The wall-rock alteration is zoned relative to the orebody, with an innermost part composed of amphibole, magnetite, apatite, and phlogopite, and an outer rich in phlogopite, amphibole, feldspar, and titanite. Within this zone, magnetite tends to be decreased forward wall-rock. The wall-rock alteration occurs both as pervasive and fracture-fill veins, the latter cutting the former. Magnetite both from orebody and wall-rock alteration is homogenous without undissolved, exsolution of other minerals, and overgrowth zoning. The Ti and V values for magnetite from the orebody range from 186 to 749 ppm (avg. 539 ppm) and from 0 to 911 ppm (avg. 548 ppm), respectively, whereas the Ti and V values for magnetite from wall-rock alteration range from 0 to 1,109 ppm (avg. 296 ppm) and from 0 to 1,788 ppm (avg. 711 ppm) one another. These magnetite compositions are plotted into the compositional field of magnetite from the IOCG and Kiruna-type deposit and also into the compositionally overlapped field of igneous and hydrothermal magnetite. Apatite in the study area is euhedral or subhedral, and less than 0.5 mm in size. These apatites have a fluorine ranging from 3.4 to 5.6 wt. %, whereas the content of chlorine is less than 0.01 wt. %. This feature is equivalent to those crystallized directly from the magmatic melt. Phlogopite also occurs in the orebody and alteration and is fine-grained in ore but coarse-grain in wall-rock alteration. Mg# of phlogopite tends to reduce toward wall-rock. Amphibole, the principal alteration mineral proximal to the orebody, is generally coarse-grained, dark green, and euhedral and is plotted into the compositional field of tremolite, actinolite, edenite, and magnesiohornblende. Amphibole partially altered to phlogopite and was also cut by fine-grained titanite veinlets. The euhedral or subhedral titanite is only disseminated in the wall-rock alteration. The δ56Fe values for magnetite from the orebody and alteration range from 0.03 to 0.16 ‰ and

from 0.05 and 0.25 ‰, respectively. The δ18O values for magnetite from the orebody and wall-rock alteration vary ranging from -0.3 to 1.8 ‰ and from -0.4 to 2.6 ‰ respectively. The Fe-O data for magnetite from the Yangyang deposit are also plotted into the compositional field for ortho-magmatic and common igneous magnetite.

Timing of iron skarn mineralization by U-Pb dating of Ca-Fe garnets

Ekaterina Borisovna SALNIKOVA[1]*, Institute of Precambrian Geology and Geochronology RAS, St.Petersburg, Russian Federation (katesalnikova@yandex.ru)
Maria Vladimirovna Stifeeva[2], Institute of Precambrian Geology and Geochronology RAS, St.Petersburg
Alexander Borisovich Kotov[3], Institute of Precambrian Geology and Geochronology RAS, St.Petersburg
Yulia Dmitrievna Gritsenko[4], Fersman Mineralogical Museum, Russian Academy of Sciences, Moscow

Abstract

Timing of ore deposits is of critical importance for understanding the origin of mineralization and related geological processes. However accurate and precise dating of hydrothermal ore deposits could be a challenge due to the lack of suitable minerals directly related to ore formation. Ca-Fe garnets are the main minerals in large diversity of hydrothermal deposits where they growth coevally with ore minerals. Numerous recent studies have focused on the application of the U–Pb system of calcic garnets, where uranium is controlled by isomorphic incorporation, to accurately and precisely date alkaline and carbonatitic intrusive rocks and skarn deposits.

This study presents results of U-Pb ID TIMS dating of garnets from four iron skarn deposits of different age and location namely the Dashkesan (Lesser Caucasus), the Gavasay (western Tian Shan), the Shalym deposit (Gornaya Shoriya) and Leglier deposit group (Siberian craton). Relative timing of the magmatic–hydrothermal events at the Dashkesan mines was previously documented whereas no precise emplacement ages of ore-related intrusions available for the Shalym Gavasay and Leglier deposits.

Studied skarn garnets are characterised by andradite and grossular components predominately, high U concentrations (8-40 ppm), low common Pb and yield the concordant ages. The U–Pb age obtained for skarn garnet from iron deposit of the Dashkesan is at 147 ± 2 Ma, the Gavasay 306±3 Ma, the Shalym is at 499 ± 1 Ma and the Leglier deposit is 1901±5 Ma allows to constrain the absolute timing of ore formation. The geochronological data reported for the Leglier deposit are the first “direct” age of the ore-bearing iron–magnesian metasomatic rocks of the Aldan Shield. These data demonstrate that U-Pb isotopes of Ca-Fe garnet from iron deposits is extremely resistant relatively to later superimposed processes.

The study was supported by grant No. 22-17-00211 from the Russian Science Foundation and FMUW-2022-0003.

BIF-hosted iron ore: A mineral system review

Steffen Gerd HAGEMANN[1]*, Centre for Exploration Targeting, UWA
(steffen.hagemann@uwa.edu.au)

Abstract

The BIF-hosted iron ore system represents the world's largest and highest grade iron ore resource. BIF, the precursor to low- and high-grade BIF hosted iron ore, consists of Archean and Paleoproterozoic Algoma-type BIF (e.g., Serra Norte iron ore district in the Carajás Mineral Province), Proterozoic Lake Superior type BIF (e.g., deposits in the Hamersley Province and craton), and Neoproterozoic Rapitan-type BIF (e.g., the Urucum iron ore district).

The BIF-hosted iron ore system is structurally controlled, mostly via km-scale normal and strike-slips fault systems, which allow large volumes of ascending and descending hydrothermal fluids to circulate during Archean or Proterozoic deformation zones including early extensional fault zones. Structures are also (passively) accessed via downward flowing supergene fluids during Cenozoic times.

Hypogene alteration of BIF and surrounding country rocks is characterised by: (1) changes in the oxide mineralogy and textures, (2) development of distinct but variable distal, intermediate and proximal alteration zones defined by distinct oxide–silicate–carbonate assemblages, and (3) mass negative reactions such as desilicification and de-carbonatisation, which significantly increase the porosity of high-grade iron ore, or lead to volume reduction by textural collapse or layer-compaction. Supergene alteration, up to depths of 200 m, is characterised by leaching of hypogene silica and carbonates, and dissolution precipitation of the iron oxyhydroxides.

Four discrete end-member models for Archean and Proterozoic hypogene and supergene-only BIF hosted iron ore are proposed: (1) granite–greenstone belt hosted, strike-slip fault zone controlled Carajás-type model, sourced by early magmatic (±metamorphic) fluids and ancient “warm” meteoric water; (2) sedimentary basin, normal fault zone-controlled Hamersley-type model, sourced by early basinal (±evaporitic) brines and ancient “warm” meteoric water. A variation of the latter is the metamorphosed basin model, where BIF (ore) is significantly metamorphosed and deformed during distinct orogenic events (e.g., deposits in the Quadrilátero Ferrífero and Simandou Range). It is during the orogenic event that the upgrade of BIF to medium- and high-grade hypogene iron took place; (3) sedimentary basin hosted, early graben structure controlled Urucum-type model, where glaciomarine BIF and subsequent diagenesis to very low-grade metamorphism is responsible for variable gangue leaching and hematite mineralisation. All of these hypogene iron ore models do not preclude a stage of supergene modification, including iron hydroxide mineralisation, phosphorous, and additional gangue leaching during substantial weathering in ancient or Recent times; and (4) supergene enriched BIF Capanema type model, which comprises goethitic iron ore deposits with no evidence for deep hypogene roots. A variation of this model is ancient supergene iron ores of the Sishen-type, where blocks of BIF slumped into underlying karstic carbonate units and subsequently experienced Fe upgrade during deep lateritic

weathering.

High-tech metals are key elements for future technologies – What are the challenges and how are their global market situations ?

Volker STEINBACH[1]*, Federal Institute for Geosciences and Natural Resources
(volker.steinbach@bgr.de)

Abstract

Low-carbon technologies such as wind energy, photovoltaics and energy storage batteries for e-mobility are key for a shift to a low-carbon future. The expected dynamic change towards renewable energy systems will have a major impact on the mineral raw material markets in the next decades. The demand for base and minor metals for clean energy technologies is expected to rise substantially – e.g. lithium, cobalt, germanium, gallium, tantalum, graphite, rare earth, osmium, iridium and indium.

Primary raw material production needs to provide most of the metals for low-carbon technologies, at least for the upcoming decade, because secondary raw material supply alone cannot accommodate the future demand. Therefore, upstream and end-of-life activities of low-carbon technologies must be taken into account to ensure firstly that the mining industry can meet the increasing demand using sustainable and responsible practices and secondly that the products can be recycled in the best possible way.

Hence, reliable estimates of potential future raw materials for emerging technologies are imperative to avoid negative economic impacts and supply shortages. Therefore it is a) necessary to analyze the recent situations and trends in their global markets, b) to carry out research on primary mineral deposits and secondary deposits (recycling) containing these high-tech metals and c) to develop concepts for due diligence in their supply chains.

[Keynote] Envisioning 2050: Strategic Scenarios for the Global Raw Materials Landscape

Christopher KEANE[1]*, American Geosciences Institute (keane@americangeosciences.org)

Abstract

To forge a pathway toward a sustainable mineral resource framework for the future, a comprehensive understanding of potential external factors—those that may expedite or impede the advancement of society's raw material utilization—is crucial. In this context, INTRAW, SAFE, and Fraunhofer have engaged in a collaborative effort to redefine raw material scenarios for 2050, employing a Delphi-method-inspired analysis. This methodical approach yielded four distinct scenarios that delineate the extremities of potential outcomes and the most plausible trajectory given the contemporary socio-political milieu as of 2023. Central to this endeavor was the creation of a detailed fact book. This compendium explicates the rationale behind each scenario, drawing upon insights from a global spectrum of experts spanning government, industry, and academia within the raw materials sector.

This discussion will encompass these four scenarios: an optimistic, idealistic projection; a markedly pessimistic outlook; and two intermediary scenarios that organically evolve from the nascent political, social, and economic currents, particularly the rise of trade blocs and the ambiguous commitment to sustainability investments. These carefully crafted scenarios, along with the accompanying fact book, serve as strategic instruments for policymakers, investors, and corporate leaders. They provide a foundational framework for future strategic planning and offer a versatile toolkit to navigate and respond to the evolving global landscape marked by technological breakthroughs, social and economic upheavals, and shifts in both domestic and international political arenas. These tools are designed not only for foresight but also for readiness, equipping stakeholders to adeptly manage the dynamic interplay of forces shaping the future of raw materials.

Mining to meet the challenge of Net Zero

David MANNING[1]*, Newcastle University (david.manning@ncl.ac.uk)

Abstract

The production of minerals as raw materials to meet the needs of the Green Transition has tended to focus on the metals and non-metals that are required for energy, catalysts, and novel products (especially IT and transport). In addition, there is a huge increase in growth projected for mining the minerals used to remove CO2 from the atmosphere through the process of Enhanced Rock Weathering (ERW). This rapidly-growing business sector poses specific challenges in the context of this session.

ERW is a nature-based solution that involves the spreading to land of crushed silicate rocks, especially basaltic rocks. Within the soil these weather, releasing cations which are counterbalanced by bicarbonate ultimately derived from photosynthesis. The biogeochemistry of the process is well understood. A critical aspect that remains to be explored is the implications for the minerals industry of the supply chain that underpins the process at scale.

Based on its chemical analysis, a typical basalt is able to remove approximately 230 kg CO2 per tonne of rock through ERW. This capacity is exploited by companies that are rapidly increasing in both size and number especially since COP26 (Glasgow, 2021). It is not uncommon for publicly-stated targets or aspirations for CO2 removal to be given as ‘1 billion tonnes by 2030’. The corresponding target for the amount of basaltic rock mined is around 5 billion tonnes.

Mining such a large volume of rock challenges society and environmental stewardship. However, the ERW industry is able to take advantage of existing strategic management of minerals mined for construction, for example as established in Europe since the end of World War II for urgent reconstruction. The construction industry globally requires of the order of 22-36 billion tonnes of crushed rock, perhaps 20% of this being basaltic. It is reasonable to assume that this industry operates at a capacity appropriate for the needs of ERW, although it may need to double in size. What is critical, however, is that the extraction of crushed rock for construction is a highly regulated activity, especially as mining takes place close to where materials are needed for construction, so close to population centres.

For the extraction of crushed rock by quarrying, existing regulation and processes for gaining societal consent, through partnership, are established, although there remain challenges and room for improvement. Ideally, extraction is regulated and permitted through well established processes that provide (often local) government with the assurance that sufficient permitted reserves exist to meet the needs of planned construction, with a 10-20 year horizon. In partnership, the extractive industries ideally work closely with local communities and Non-Governmental Organisations to

improve biodiversity and to create infrastructure that improves quality of life for those who live close to a mine. There are many examples of good practice internationally, which suggest that the challenges of meeting the needs of ERW can be met at scale, to help this new industry mitigate the effects of climate change. However, these examples need to be widely disseminated, with global adoption of good practice.

Critical raw materials extraction in environmentally protected areas

Vitor Correia[1]*, INTRAW (vcorreia@intraw.eu)
Eberhard Falck[2], INTRAW
Marko Komac[3], INTRAW

Abstract

The European Commission identified in its Action Plan on Critical Raw Materials (CRM) and the 2020 CRMs list those materials that are particularly exposed to supply shortages and disruptions due to their sourcing or processing outside the EU. Without metals such as Li, Co, and Cu, the move away from the use of fossil fuels to renewable source of energy and a large-scale electrification to reduce direct carbon emission currently would not be conceivable. Before this background, the EU-funded project CIRAN (https://ciranproject.eu/) is developing strategies to reconcile society's desire to protect environmentally sensitive areas with society's growing need for such CRMs, while ensuring the resilience of supply through EU domestic sourcing. The project explores ideas for improved permitting procedures based on systemic approaches to policy-making that balance interests and novel social contract frameworks. CIRAN brings together external expert and public stakeholders and aims to advance the development of an inclusive community of practice (CoP) on permitting that is designed to remain active after the funding of the project ends in 2025. The invited stakeholders assist in analysing policies, economic drivers, technology options, mining technology, local governance, social capital, as well as nature conservation and biodiversity protection needs.

The project employs a ‘logical framework’ approach to arrive at a well-founded justification for extraction, based on a system-oriented assessment of all relevant dimensions, including projected raw materials needs, environmental and societal impacts, spatial planning, technological options, and national/international regulatory frameworks. A strong co-creation of knowledge component ensures that the proposed strategies are tested and validated in communities located in or nearby environmentally protected areas. This will stimulate the development of novel social contract models based on identified rights, obligations, and responsibilities of governments (national/regional), communities, and mine operators, capable of dealing with socio-economic transformations and challenges due to climate change. For this purpose, a team of 25 external stakeholder representatives on the environmental, political, societal, economic, and technological dimensions that shape the responses to energy transition needs and the demand for CRMs is brought together. These stakeholders, organised in four Expert Groups (EGs), work with project partners, conveying insights on policy-making and -implementation, economic drivers, technologies, mining, local governance, social capital, nature conservation and biodiversity. The EGs actively engage in CIRAN through synergetic processes combining analysis and deliberation, and participation in project workshops and structured consultations, such as focus groups and foresight analysis.

The CIRAN Consortium is geared to develop proposals for inclusive policy-making instruments that support the EU Green Deal and UN-led reforms to reach the climate commitments and sustainable development goals.

Ukrainian Salt Sector: Strategy for Post-War Recovery, Sustainable Development, and Advancement of Salt Resources as Input in Green Transition Technologies

Larysa BOSEVSKA[1]*, Ukrainian Salt Research Institute (lara.bosevskaya@gmail.com)
Yuliia DUDCHENKO[2], Institute of Geological Sciences of National Academy of Sciences of Ukraine

Abstract

Ukraine is very rich in fossil salt resources, represented by five salt-bearing formations in the eastern and western parts of the country, corresponding to five geological regions, namely, the Dnieper-Donetsk depression, North-Western Donbass, Carpathian Foredeep, Transcarpathian depression, and Dobruja Foredeep (Khrushchev D., Bosevska L., Environmental problems of salt mining in Ukraine, 2014).

Before the war, salt resources (rock salt deposits and natural brines) were primarily used as the raw material base for chloride-sodium raw materials to produce a variety of salt, including food salt and road salt as the primary de-icing material, as well as salt for chemical production.

For many years, the giant of Ukraine's salt industry has been the state mining enterprise "ARTYOMSOL", which operated based on the reserves of the Artemivsk rock salt deposit located in the eastern part of Ukraine within the North-Western Donbass. This deposit is one of the largest in the world, with estimated reserves reaching 15 billion tons of high-quality salt. Currently, the enterprise is in a combat zone and requires restoration because its surface complex has been significantly destroyed due to military aggression.

The Carpathian region of Ukraine, besides the well-known unique deposits of potassium-magnesium salts (Stebnyk and Kalush-Golyn), is characterized by numerous scattered deposits of rock salt of smaller size and natural saturated chloride-sodium brines. The latter have been extracted in small quantities by the Drohobych salt mining plant for a few centuries. Transcarpathian internal depression is also extremely rich in rock salt resources, where the powerful Baden salt-bearing formation is developed. Under the conditions of applying the geotechnological method of extraction, the resources of rock salt of the Ukrainian Carpathians can become a significant source of table salt and salt for industrial processing.

However, in light of Ukraine's chosen European path, global trends in green transformation, and green energy transition, the further use of Ukraine's salt resources should be considered not only in terms of obtaining salt raw materials but also as an opportunity for addressing green transformation issues. It has already been proven that salt is an excellent geological barrier for creating underground gas storage facilities (e.g., hydrocarbons, hydrogen, and other volatile gases), and large salt arrays will certainly be a key component of the green energy transition.

In the aspect mentioned above, a general strategy for using Ukraine's salt resources is proposed to make a significant contribution to global trends in sustainable development and green energy transition.

Mechanochemical processing of silicate rocks to trap CO2

Mark Stillings[1], University of Strathclyde
Zoe SHIPTON[2]*, University of Strathclyde (zoe.shipton@strath.ac.uk)
Rebecca Lunn[3], University of Strathclyde

Abstract

Milling minerals rich in magnesium and iron within CO2 gas has been proposed to capture carbon as metal-carbonates, for instance through injection of CO2 into basalt. We conduct milling experiments in CO2 and show that polymineralic rocks such as granite and basalt, whether high or low in carbonate-forming metals, are more efficient at trapping CO2 than individual minerals. This is because the trapping process is not, as previously thought, based on the carbonation of carbonate-forming metals. Instead, CO2 is chemically adsorbed into the crystal structure. Additionally, this occurs predominantly at the boundaries between different minerals, which explains why trapping on rock is more effective that trapping within single crustal experiments.

Leaching experiments on the milled mineral/rock powders show that CO2 trapped in single minerals is mainly soluble, whereas CO2 trapped in polymineralic rocks is not. Indeed, under ambient temperature conditions, polymineralic rocks can capture >13.4 mgCO2 g−1 as thermally stable, insoluble CO2.

Polymineralic rocks are crushed worldwide to produce construction aggregate. More than 50 billion tonnes of rock is crushed worldwide every year and the materials and construction industry accounts for 11% of global carbon emissions. If crushing processes could be conducted within a stream of effluent CO2 gas (for instance waste gases produced from cement manufacture), our findings suggest that for every 100 Mt of hard rock aggregate sold, 0.4–0.5 MtCO2 could be captured as a by-product. We estimate that if the technology was adopted worldwide in aggregate production, it could potentially capture 0.5% of global CO2 emissions - 175 million tonnes of carbon dioxide annually.

Abstract

The industrial and technological revolutions over the last few centuries have been accompanied by a substantial improvement of the living environment, while at the same time the consumption and therefore the exploitation of mineral resources, which are globally non-renewable on a human-scale. This ever-increasing use of mineral resources in many industrial sectors has over the past 30 years contributed to the definition of the concept of sustainable development. Many industries aim to achieve a "sustainable" economic growth that is respectful of the environment and human beings. Supporting a rational use of mineral resources while developing economic activity with respect to the environment and social well-being are contributing to sustainable development. Industry has to limit the impacts of all its activities on climate, water, biodiversity and natural resources. These impacts can be also considered in terms of the planetary boundaries. Consequently, sustainability of mineral resources and, in particular their abundance, is a topic of growing interest. Nevertheless, mineral abundance is an extremely complex notion as it not only encompasses geological considerations but also environmental, technical, economic, and social constraints. In addition, to the best of our knowledge, no tools are currently available to allow a comprehensive evaluation of mineral abundance for downstream industries.

This study therefore aims to present an innovative and unique methodology to evaluate the abundance of non-energy mineral resources, and determine a, so-called, Mineral Abundance Index (MAI). Based on a multi-criteria analysis, MAI considers natural abundance of a mineral in the Earth crust (geosphere), its availability on the market (technical-economic sphere) and integrate the influence of factors that could constraint or promote future market changes (socio-epistemic sphere). In that way, the MAI aims to integrate the notions of intrinsic natural abundance and economic abundance, and through innovation, to reconcile the fixed-stock and opportunity-cost paradigms. This index can cover all non-energy mineral resources (metals, industrial minerals and rocks). The MAI, ranging from 0 (very scarce) to 100 (very abundant), aims to qualify the abundance of minerals in a simple and rapid manner, based on published and reliable data. This new methodology could be a powerful decision-making support tool for any downstream

industrials and end-users making use of mineral resources. MAI could be used as one of the criteria to consider in Life Cycle Assessment (LCA) and initiatives by end-users aiming at ensuring that the minerals used in the production of their goods are genuinely abundant.

Origin of carbonate cements and their control on sandstone reservoir quality in the First Member of the Eocene Shahejie Formation, Bohai Sea, East China

Xiaojun PANG[1]*, School of Geosciences, China University of Petroleum (East China) (pangxiaojunupc@163.com)
Guanmin WANG[2], School of Geosciences, China University of Petroleum (East China)
Xiaobo HUANG[3], CNOOC China Limited, Tianjin Branch, Tianjin
Xuefang ZHANG[4], CNOOC China Limited, Tianjin Branch, Tianjin
Li ZHANG[5], CNOOC China Limited, Tianjin Branch, Tianjin

Abstract

The widespread presence of carbonate cements in the sandstones of the First Member of the Eocene Shahejie Formation has been regarded as a major diagenetic process leading to strong heterogeneities in reservoir quality. Therefore, understanding the origin of carbonate cements is critical for the prediction of high-quality reservoirs.

Petrographic and geochemical analyses, including helium porosity and permeability, thin sections, cathodoluminescence, scanning electron microscopy, carbon and oxygen stable isotopes, as well as fluid inclusion microthermometry, were conducted to decipher the origin of carbonate cements and understand their influences on reservoir quality.

Physical properties show that the sandstone porosity is typically smaller than 15%, and the permeability is typically smaller than 10 mD. However, some samples have porosity greater than 15% and permeability greater than 50 mD.

The petrography indicates that the samples with high porosity and permeability develops pore types such as biocoelom pore and intergranular dissolution pore. A large number of bioclastic particles, as well as cements such as micrite dolomite coats, pore-filling dolomite and calcite, were developed in the reservoir.

The carbonate cements can be divided into four stages based on the precipitation temperature. Stage 1 consists of bioclastic and micrite dolomite. Micrite dolomite exhibits as grain coats on the particle surface and is in dark red under cathodoluminescence. Stage 2 consists of powdery dolomite, exhibiting as grain coats on the surface of micrite dolomites. They showed the orange under cathodoluminescence. Stage 3 consists of pore-filling powdery dolomite, showing orange under cathodoluminescence. Stage 4 consists of pore-filling sparry dolomites, showing orange under cathodoluminescence.

The carbon isotope range from -4.1‰ to 1.6‰ and the oxygen isotope ranges from -18.2 ‰ to -0.5 ‰. The calculated precipitation temperature ranges from 36.3 ℃ to 109.4 ℃.

The results indicate that the carbonate cements are derived from multi-stage fluids, including saline lake water, saline water at early diagenetic stage, meteoric water and decarboxylation of organic acids. Among them, the intact spiral shells and micrite dolomite coats resisted mechanical compaction during burial process. Early dolomitization preserved primary pore spaces. A large number of secondary pores were generated through the dissolution of dolomite by acidic fluids. Bioclasts preserved a large number of biocoelom pores, which increased the primary porosity. The

early carbonate cements resisted mechanical compaction, preserved primary porosity and therefore protected the reservoir quality. In conclusion, bioclastic and early carbonate cements have positive effects on the reservoir quality.
A number of sandstone reservoirs characterized by bioclastic and early carbonate cements have been found in the First Member of Eocene Shahejie Formation. The daily oil and gas production of wells in these reservoirs exceed 1000 tons, demonstrating an excellent exploration prospect of these reservoirs. The results of this study can provide theoretical supports for the exploration and evaluation of oil and gas resources in Bohai Sea.

Influence of diagenetic fluid on glutenite reservoirs: a case study of the Junggar Basin, China

Zhiguo MAO[1]*, Petrochina (owenmao@126.com)
Zhanguo LIU[2], PetroChina Hangzhou Research Institute of Geology, Hangzhou, Zhejiang 310063, China
Xiangchao MENG[3], PetroChina Hangzhou Research Institute of Geology, Hangzhou, Zhejiang 310063, China
Jian ZHU[4], PetroChina Xinjiang Oilfield Company, karamay, Xinjiang 834000, China

Abstract

In the formation process of oil and gas reservoirs, the properties of the formation fluids and the diagenetic environment have a significant impact on the quality of the reservoir. Junggar Basin is an important oil and gas bearing basin in northwest China. Multiple strata have developed glutenite reservoirs from Permian to Paleogene in Junggar Basin. In this study, the Upper Wuer Formation (P3w) of the Permian in the western depression and Badaowan Formation (J1b) of the Jurassic in the eastern depression of the the Junggar Basin are selected for comparative analysis of the impact of diagenetic fluids on glutenite reservoirs.

The facies of the P3w is fan delta front subfacies, characterized by mixed sand and gravel, large lateral thickness variation and low maturity. The reservoir has poor physical properties, complex pore structures and medium-alkaline formation fluid environment. The P3w belongs to an ultra-low porosity ultra-low permeability reservoir. Its porosity ranges from 0.81% to 15.5%, with an average of 7.31% and a permeability of 0.02%×10-3-3.15×10-3μm2, average 0.06×10-3μm2. However, the facies of the J1b is braided-river delta, characterized by the development of coal seams. The reservoir belongs to low porosity and ultra-low permeability reservoirs, with medium-acidic formation fluid environment. Its porosity ranges from 3.80% to 16.30%, with an average of 9.68% and a permeability of 0.014%×10-3-33.80×10-3μm2, average 1.26×10-3μm2.

Through microscopic observation, electron probe energy spectrum and elemental analysis, it has been found that the fluid environment of the formation determines the quality and intensity of reservoir transformation in the later stage. The medium-alkaline formation fluid mainly dissolves the volcanic ash among sand and gravel particles in the P3w, On the contrary, the medium-acidic formation fluid mainly dissolves calcium interstitial materials in the J1b. Due to the differences in the stages of action, there are also differences in the formation of reservoirs between the two types of dissolution mentioned above. The P3w dissolution mainly occurs in the intermediate diagenetic stage, which helps to develop reservoir pores. However, the J1b dissolution mainly occurs in the early diagenetic stage, making the reservoir easier to compact and not conducive to reservoir development.

Lamina-scale diagenetic mass transfer in lacustrine organic-rich shales and the impacts on shale oil reservoir formation

Kelai Xi[1]*, China University of Petroleum (East China) (xikelai@upc.edu.cn)
Miruo LIN[2], China University of Petroleum (East China)
Yingchang Cao[3], China University of Petroleum (East China)
Xiaobing Niu[4], China University of Petroleum (East China)

Abstract

Lacustrine organic-rich shale has become the important petroleum exploration target in recent years. Reservoir is the crucial factor to determine the potential of shale oil exploration and development. In order to fully understand the shale oil reservoir formation processes, it is essential to be engaged in fluid-rock interaction and diagenetic mass transfer in organic-rich shales. Based on the detailed petrographic investigation, in-situ element and isotope testing as well as organic geochemistry analysis, diagenetic mass transfers and the related organic-inorganic interactions were performed on a suite of organic-rich shales from the Triassic Yanchang Formation of the Ordos Basin. The organic-rich shales consist of silt-grained felsic lamina (SFL) and organic-rich lamina (ORL). The SFL is mainly dominated by K-feldspar, while illite is the most abundant mineral in the ORL. Authigenic quartz and euhedral pyrite are the major diagenetic minerals in the ORL, and K-feldspar dissolution extensively occurred in the SFL. It is the first time to find that siliceous resting cyst of algae can play significant roles on silica nucleation, which determines the occurrence and distribution of authigenic quartz. The smectite to illite reaction plays significant role on diagenetic alterations in the organic-rich shales. This reaction not only induced overpressure to generate micro-fracture for authigenic quartz growth, but also provided the major silica source for authigenic quartz precipitation. Petrographic and geochemistry evidence have surely confirmed that organic acids migrated from ORL to SFL, while K+ and aqueous SiO2 from K-feldspar dissolution transported from SFL to ORL. According to organic-inorganic interactions related to authigenic quartz formation, we further conclude that lamina-scale open diagenetic system allows mass transfer occurring at micro-scale inside shales, nevertheless, the buried shale perform as a closed diagenetic system respect to surrounding formations. The lamina-scale diagenetic mass transfer and by-products redistribution significantly contributed to the effective pores formation in shales. This study helps us to better understand the fluid flow and mass transfer process in a mass balance diagenetic system of organic-rich shale formation.

[Keynote] Mixing processes and patterns of fluids in alkane-CO2-water systems under high temperature and high pressure—Microscopic visual physical thermal simulations and molecular dynamics simulations

Guanghui YUAN[1]*, China University of Petroleum (East China) (yuan.guanghui@upc.edu.cn)

Abstract

Various types of geofluids exist in deep and ultra-deep layers in petroliferous basins. The geofluids are much more active under high-temperature and high-pressure (HTHP) conditions, but their properties are unclear. We simulated the mixing of different fluids in CH4/C3H8/C6H14/C8H18-water systems and C6H14/C8H18-CO2-H2O systems at temperatures of 25°C to 425°C and pressures of 5 MPa to 105 MPa, using an in-situ micron quartz capillary tube thermal simulation system and molecular dynamics numerical simulation software. The mixing processes, patterns, and mechanisms of various fluids were analyzed at
microscale under increasing temperature and pressure conditions. The results show that the miscibility of fluids in the different alkane-H2O and alkane-CO2-H2O systems is not instantaneous, but the miscibility degree between different fluid phases increases as the temperature and pressure rise during the experiments. The physical thermal experiments (PTEs) show that the mixing process can be divided into three stages: initial miscibility, segmented dynamic miscibility, and complete miscibility. The molecular dynamics numerical simulations (MDNSs) indicate that the mixing process of fluids in the alkane-H2O and alkane-CO2-H2O systems can be divided into seven and eight stages, respectively. The carbon number affects the miscibility of alkanes and water, and the temperature and pressure required to reach the same miscibility stage with water increase with the carbon number (C3H8, C6H14, CH4, C8H18). CO2 has a critical bridge role in the miscibility of alkanes and water, and its presence significantly reduces the temperatures required to reach the initial, dynamic, and complete miscibility of alkanes and water. The
results are of great significance for analyzing and understanding the miscibility of geofluids in deep and ultra-deep HTHP systems.

Diagenetic Processes and Low-Permeability Tightening Mechanisms of Reservoirs in the Paleogene Deep Layers under High-Temperature and High-Variability Conditions in the Baiyun Sag, Pearl River Mouth Basin

Xiaoyang Zhao[1]*, China University of Petroleum (East China) (B22010052@s.upc.edu.cn)
Guanghui Yuan[2], China University of Petroleum (East China)
Hui Sun[3], Shenzhen Branch of CNOOC Ltd.
Guangrong Peng[4], Shenzhen Branch of CNOOC Ltd.

Abstract

The oil and gas exploration in the Baiyun Sag of the Pearl River Mouth Basin is gradually shifting from conventional reservoirs in the shallow Hanjiang-Zhujiang Formation to low-permeability to tight reservoirs in the deep-ultra-deep Zhuhai-Enping Formation. The distinctive high-variable geothermal background results in significant differences in the diagenetic stages and compactification mechanisms between these reservoirs and conventional ones..

This paper comprehensively utilizes techniques such as cast body thin section identification, scanning electron microscopy observation, physical property testing, diagenetic process reconstruction, and physical property restoration. It systematically analyzes the differential diagenetic processes of sandstone reservoirs in the lower section of the Paleogene Zhuhai Formation to the Enping Formation in the northwest low uplift to the central depression belt of the Baiyun Sag, under the high-variable geothermal background. By integrating the tectonic evolution background, stratigraphic burial history, and current physical property data, the study explores the main factors influencing the relationship between reservoir properties and elucidates the densification process and mechanism.The results indicate that the reservoirs in the lower section of the Zhuhai Formation to the Enping Formation underwent significant compaction, two stages of carbonate cementation, three stages of siliceous cementation, and three stages of feldspar dissolution to create pores. The variation in geothermal gradients during the reservoir formation process led to different compaction rates, and the water-rock interaction processes in open-closed systems played a crucial role in the differences in physical property relationships in different zones.. Compaction is the main factor to the formation of tight reservoirs, while cementation further strengthens the densification process, and dissolution improved reservoir properties to a certain extent. Additionally, during the reservoir formation process, the transition between open and closed systems and an increase in geothermal gradient leading to an accelerated compaction rate are the primary reasons for variations in physical properties among different structural units in the reservoir .With increase of geothermal gradient and burial depth, diagenetic stages gradually increase from the middle diagenetic stage A2 in the low uplift zone to the middle diagenetic stage B in the slope zone and the late diagenetic stage in the depression zone. The different diagenesis processes lead to significant differences in the evolution of reservoir properties. The reservoirs in the depression zone have already undergone densification before late-stage hydrocarbon charging, the reservoirs in the slope zone gradually densify during the late-stage hydrocarbon charging

stage, while the reservoirs in the low uplift area still exhibit low-permeability characteristics. Matching favorable cap layers, the slope zone with burial depths shallower than 5 km is the key area for exploration in the lower section.

Oxidation of hydrocarbons in deep strata of continental sedimentary basins: Evidences, mechanism, and geological implications

Xun KANG[1]*, Central South University (xunkang@csu.edu.cn)

Abstract

Oxidation of hydrocarbons including methane is part of interrelated hydrogeochemical reactions, and affects the carbon budget in the Earth's crust. To unravel such processes in deep siliciclastic strata, we analyzed core samples from Lower Triassic red beds in the Mahu Sag (Junggar Basin, NW China) by coupling petrological observations with high resolution in situ SIMS stable carbon and oxygen isotopes, and clumped isotopes (Δ47) of authigenic calcite. The strata contain a variable oil and gas content as well as abundant high-valence Fe/Mn oxide. Three generations of cement occur which are characterized as: (i) non-luminescent, early diagenetic calcite (MnO < 0.3%, δ13CVPDB of –5.6 to –4.1‰); (ii) bright-orange luminescent late-stage I calcite (0.75–5.23% MnO, δ13C: –51.4 to –25.8‰), and (iii) dull-orange late-stage II calcite (4.10–12.93% MnO, δ13C: –91.4 to –30.9‰). Clumped isotopic thermometry reveals that their precipitation temperature increases successively from <40 °C, 81–107 °C to finally 107–132 °C, corresponding to three precipitation time slices: (i) before the Late Triassic, (ii) from the Early Jurassic to the Early Cretaceous, and (iii) from the Early Cretaceous to the present, respectively. The δ13C values as low as –91‰ indicate that late-stage II calcite is mainly derived from the thermochemical oxidation of methane (δ13C: –46.8 to –39.3‰) induced by high-valence Mn/Fe oxide, whereas late-stage I calcite is the final product of both oxidation of methane and C2+ hydrocarbon. For late-stage I calcite, hydrocarbon oxidation was most likely promoted by high temperature, though microbial oxidation can’t be totally ruled out. The higher precipitation temperature of late-stage II calcite demonstrates that the oxidation of methane requires higher activation energies than C2+ hydrocarbons. Besides time as a factor, constrained by varying oil and gas emplacement, this sequential oxidation of hydrocarbons is also well visible laterally and vertically in the investigation area.

Due to the pervasive distribution of high-valence Mn/Fe in the analyzed rocks, we suggest that TOH is a common process in the deep crust and has important geologic implications. Within oil or gas reservoirs, the TOH reactions at 81–132 °C alter the chemical and isotopic composition of hydrocarbons, but also modify reservoir quality via mineral dissolution and/or precipitation. Importantly, the consumption of hydrocarbons including CH4 in sedimentary basins and hydrothermal systems reduces CH4 emissions into the atmosphere. This study also highlights the scientific applicability of combining in situ isotope and clumped-isotope thermometry of carbonate in solving complex and interrelated hydrogeological processes with hydrocarbons as educts.

ZHENGXIN SHEN[7], Hebei Key Laboratory of Airborne Survey and Remote Sensing Technology, Shijiazhuang, Hebei,050002

Abstract

Erlian Basin is an important base for the exploration of sandstone-type uranium deposits in China. As the exploration work of uranium deposits continues to deepen, the opportunities to discover new outcrops and shallow deposits gradually decrease. The Bayanwula uranium metallogenic belt is located in the eastern part of the basin, and the ore body has a large burial depth. Studying its airborne magnetic, airborne gamma spectrometry, and gravity response characteristics is of great significance for establishing a method for quickly delineating favorable areas for sandstone-type uranium deposits based on 1:50,000 airborne magnetic, airborne gamma spectrometry, and regional gravity data.

The study shows that the anomalous characteristics of radioactive elements in the surface sediments of the uranium mineralization belt are not obvious, mainly showing weak increase. The boundaries of the ancient river channels on the surface often present high-value or anomalous belts of airborne uranium. Based on the fine partition of surface sediment properties and radioactive element distribution characteristics, the active uranium in the sandstone-type uranium mining area is mainly introduced. In addition, irregular annular and banded anomalies of airborne active uranium entropy, uranium increment, uranium migration enrichment coefficient, and geochemical activity index are mainly presented on the surface above the ore bed. Uranium mining areas or ore deposits are mainly located in stable magnetic fields or magnetic gradient zones, as well as the moderate apparent magnetic susceptibility gradient zone where the northeast direction intersects with the northwest direction. The regional gravity field characteristics effectively reflect the undulating shape of the basement in the mineralization belt, and uranium mining areas or ore deposits are mainly located in the gradient-dense zone or the intersection of gradient bands of Bouguer gravity residual anomalies, as well as the intersection of moderate and higher apparent densities.The different burial depth contour lines of apparent magnetic susceptibility and apparent density from 3D gravity and magnetic inversion can effectively reflect the spatial distribution characteristics of the cover layer structure, providing a basis for the

analysis of the genesis of weak uranium information from airborne gamma spectrometry. Based on the comprehensive study of airborne magnetic, gravity, and regional geology, the favorable areas for uranium mineralization can be quickly identified. The information of airborne active uranium, uranium increment, active uranium entropy, and geochemical activity index in the favorable areas can be extracted and identified, which can further delineate the favorable areas for uranium exploration.

Therefore, this study suggests that the sandstone-type uranium deposit detection technology based on airborne gamma spectrometry and 3D gravity and magnetic inversion can quickly identify the sandstone-type uranium ore-forming environment and delineate favorable areas for exploration, which is beneficial for the uranium exploration effect of sandstone-type uranium deposits in airborne geophysical prospecting.

This research was supported by the National Natural Science Foundation of China (U2067204).

Fluid-rock interaction of deep hydrothermal fluids and its reservoir response in carbonate rocks: A case study from the Ordovician in the Tarim Basin

Jian WANG[1]*, School of Geoscience, China University of Petroleum (East China) (wangjian8601@upc.edu.cn)
Yingchang CAO[2], National Key Laboratory of Deep Oil and Gas (China University of Petroleum (East China))
Dongping TAN[3], National Key Laboratory of Deep Oil and Gas (China University of Petroleum (East China))

Abstract

Hydrothermal process is one of the common diagenetic transformations in carbonate strata, which has a significant impact on carbonate reservoirs. The transformation effect of hydrothermal fluids on reservoirs is a controversial hot topic. One viewpoint holds that hydrothermal fluids have a constructive effect on reservoirs, mainly manifested as hydrothermal dolomitization, hydrothermal fracture and hydrothermal dissolution. Another viewpoint suggests that hydrothermal fluids have a destructive effect on reservoirs, mainly manifested as hydrothermal mineral precipitation and recrystallization. This study takes Ordovician carbonate reservoir in Tabei-Tazhong area of Tarim Basin as the research object. Based on core observation, thin section analysis and relevant geological data, through geochemical tests and numerical simulation methods, the types, characteristics, fluid rock interactions and reservoir responses of hydrothermal fluids are defined.
Research has shown that the hydrothermal fluids developed in the Ordovician strata in the study area mainly include Mg-rich hydrothermal fluids and Si&F-rich magmatic hydrothermal fluids. The main activity period of Mg-rich hydrothermal fluids is from the late Caledonian to early Hercynian period, with characteristics of moderately negative carbon and oxygen isotope values, δEu positive anomaly and δCe negative anomaly. Si& F-rich magmatic hydrothermal fluids are controlled by tectonic movements in the late Hercynian and magmatic volcanic activities in the early Permian, with characteristics of more negative carbon and oxygen isotope values and strong δEu positive anomaly δCe negative anomaly. The comprehensive analysis of geological data and numerical simulation results shows that the diagenetic response of the Mg-rich hydrothermal fluid in the study area to Ordovician carbonate reservoirs is mainly manifested by dissolution, hydrothermal dolomitization, and filling. It has both constructive and destructive transformation effects on the reservoir space, but mainly constructive effects. The diagenetic response of Si&F-rich magmatic hydrothermal fluids to Ordovician carbonate reservoirs is mainly characterized by fracturing, dissolution, metasomatism, and filling, with destructive effects being the main ones. The hydrothermal transformation of carbonate reservoirs is constrained by the strike-slip fault system, and the calcite precipitation filling zone formed in the upper part of the hydrothermal transformation reservoir also plays a certain sealing role.

The influence of microscopic petrological characteristics on fracability of tight sandstone in the Yanchang Formation of the Longdong Area, China

Xiaoming SHI[1]*, China University of Petroleum (East China) (shixiaom@126.com)
Guanmin WANG[2], China University of Petroleum (East China)

Abstract

The fracability evaluation of clastic rock is significant for reservoir modification and providing guidance for oil and gas development. The fracability can be characterized by mechanical parameters, but it is essentially determined by petrological characteristics. In this study, we focused on tight sandstone in the Chang 7 member of the Upper Triassic Yanchang Formation in the Longdong area of the Ordos Basin, China. Based on crack propagation mechanism and stress-strain behavior, we propose a method for evaluating fracability using the ratio of strain parameters brittleness index and stress parameters triaxial compressive strength. We analyze the controlling effect of microscopic petrological characteristics such as mineral content, occurrence state, texture, etc., determined by X-ray diffraction analysis and thin sections, on fracability. Regarding composition, the content of brittle mineral quartz has a positive effect on fracability. Feldspar alteration gradually converts the brittle fresh feldspar into plastic altered feldspar, which has a negative impact on fracability. Carbonate minerals are not always beneficial to fracability. Carbonate minerals in the form of particles or debris (mainly dolomite rock debris in this paper) are beneficial to fracability, while dispersed carbonate cementation (mainly ankerite in this paper) is detrimental to rock fracability. Clay minerals with various occurrence states have a weak negative relationship with fracability. In terms of texture, the average particle size and the grain median diameter calculated by Friedman Moment Methods are positively correlated with the fracability, indicating that coarser particle size leads to better fracability. The standard deviation calculated by Friedman Moment Methods shows a positive correlation with the rock fracability, implying that rocks with worse sorting degrees have better fracability. The influence of texture on fracability largely reflects the importance of brittle particles in crack formation. The interplay between composition and texture determines the internal mechanism of rock fracability.

Impact of CO2 influx on sandstone reservoir quality: A case study of the Quantou Formation, southern Songliao Basin, China

Zheng Cao[1]*, Chongqing University of Science and Technology (caozheng_upc@126.com)
Chengyan Lin[2], China University of Petroleum (East China)
Keyu Liu[3], China University of Petroleum (East China)
Karem Azmy[4], Memorial University of Newfoundland
Hairuo Qing[5], University of Regina

Abstract

The CO2-gas reservoirs have been recorded in many petroliferous basins worldwide. However, the impact of deep inorganic CO2 influx on reservoir quality has received little attention. Here, a new set of mineralogical and geochemical data collected from the Lower Cretaceous Quantou Formation sandstones in the southern Songliao Basin are presented to address this issue. The sandstones were broadly subdivided into two zones based on their mineralogical compositions: (1) a “normal” zone with higher porosity (av. 13.7%) and permeability (av. 3.27 mD) that is located > 10 km away from the Gudian Fault (composed of ferrocalcite, ankerite, quartz, mixed-layer illite/smectite (I/S), kaolinite, illite, and chlorite), and (2) a “dawsonite-bearing” zone with relatively poor reservoir quality (av. 10.1% and 0.4 mD) adjacent to the Gudian Fault (consisting of dawsonite, ankerite, quartz, I/S, and illite). The carbon sources for dawsonite and ankerite in the dawsonite-bearing zone (13C= -5.7‰ to -0.8‰ and 18O= -20.6‰ to -17.1‰, and Sr= 0.710216 to 0.712472) are mostly a mix of mantle magmatic CO2 and crustal CO2, with a small amount of organic CO2, which is the opposite for the ferrocalcite and ankerite in the normal zone (13C= -10.5‰ to -2.3‰, 18O= -19.3‰ to -14.9‰, and Sr= 0.712060 to 0.714030). Observations of the dawsonite-bearing zone demonstrate higher contents of carbonate and quartz cements, specific clay mineral types (mixed-layer I/S with Reichweite order of R = 3 and illite), and poor reservoir quality and oil productivity due to the influx of deep inorganic CO2 dating back to around 65-44 Ma.

Characteristics and origin of deep and ultra-deep high-quality clastic reservoirs in the steep slope zone of the Minfeng sub-sag, Dongying Sag, China

Jiageng LIU[1]*, China University of Petroleum (East China) (wyzh@upc.edu.cn)
Yanzhong WANG[2], China University of Petroleum (East China)
Yingchang CAO[3], China University of Petroleum (East China)
Shuping WANG[4], China University of Petroleum (East China)
Xuezhe LI[5], China University of Petroleum (East China)

Abstract

Deep and ultra-deep layers within petroliferous basins have emerged as new targets in global oil and gas exploration. However, the characteristics and origin of the high-quality clastic reservoirs within these layers remain poorly understood, posing challenges for effective exploration. This study focuses on the coarse-grained clastic reservoirs in the nearshore subaqueous fan in the lower sub-member of the 4th member of the Shahejie Formation in the steep slope zone of the Minfeng sub-sagDongying Sag. By combining methodologies including casting thin section observation, scanning electron microscopy (SEM), cathodoluminescence microscopy-based identification of minerals in thin sections, fluid inclusion thermometry, and paleopressure reconstruction, as well as the analytical results of the burial and thermal history, the reservoir characteristics, hydrocarbon charging history, pressure evolution and genetic mechanism of the high-quality reservoirs were comprehensively investigated. The coarse-grained clastic reservoirs in the study area are predominantly lithic arkoses and feldspathic litharenites. They exhibit medium to strong compaction and are dominated by ankerite cementation, followed by quartz overgrowth. Dissolution is overall weak and is dominated by feldspar dissolution. The reservoir spaces comprise mostly primary poresalong with some others developed from feldspar dissolution. Two oil charging stages and one natural gas charging stage were identified: an early mature-oil charging between 37.225.8 Ma and a later highly-mature-oil charging from 12 Ma onwards. The natural gas charging has lasted till now since 3.6 Ma. The reservoirs have experienced two distinct pore pressure-increasing cycles: 4524.6 Ma and from 24. 6 Ma to present, corresponding to the two hydrocarbon charging stages. Favorable lithofacies lay the foundation for the development of high-quality reservoirs dominated by primary pores in the study area. The inhibitive effects of overpressure hydrocarbon charging on compaction and cementation are crucial to the development of high-quality reservoirs. The weak dissolution of feldspar and carbonate minerals in the deep closed system leads to a low increment in porosity. However, the reduction rate of the reservoir porosity with depth declines significantly at burial depths beyond 3 750 mand the development of deep high-quality reservoirs dominated by primary pores expands the lower limit of depth for exploration.

Study on the Main Controlling Factors of Effective Reservoirs in Tight Beach Bar Sand Oil Reservoirs in the Dongying Depression

Huafeng ZHANG[1]*, 1.School of Geosciences, China University of Petroleum (East China), Qingdao 266580; 2.Exploration and Development Research Institute of Shengli Oil Field, SINOPEC, Dongying 257100 (zhanghuafeng1984@sohu.com)

Abstract

The Dongying Depression, located in Eastern China, is a prominent example of an oil and gas-rich geological depression. During the deposition of the Sha-4 upper sub-member, beach bar sands in shallow lake environments were the primary deposits, covering more than one-third of the depression's total area. Since the Ninth Five-Year Plan, the Shengli Oilfield has identified multiple beach bar sand oil reservoirs in Dongying Depression’s regions, including Liangjialou, Zhenglizhuang, Wangjiagang, Boxing, and Daluhu. As of 2023's end, the Shengli Oilfield reported 426 million tons in proven geological reserves in these reservoirs, marking a significant contribution to the oilfield's reserve augmentation and production. The urgent geological challenge lies in identifying the oil-bearing properties of beach bar sand reservoirs. Currently, the most effective methods, onsite coring and field testing, are also the most costly. Electrical logging interpretation can yield results in identifying effective reservoirs. Beach bar sand reservoirs typically enter production post-fracturing, which can also enhance development in some dry layers. Therefore, accurately determining the main factors controlling the oil-bearing nature of beach bar sands is crucial. This study focuses on the sub-member of the Sha4 member in the Dongying Depression. This study examines factors including micro-pore structure, reservoir thickness, depositional microfacies, diagenesis, and fracture systems. It aims to assess their impact on the effectiveness of thin interlayered beach bar sand reservoirs, offering a geological basis for evaluating sweet spots and predicting favorable reservoirs. Bar sands exhibit superior physical properties and oil-bearing capacity compared to beach sands.Well logging and core data indicate a positive correlation between the oil-bearing capacity of beach bar sand reservoirs and their thickness. Thicker layers are associated with better reservoir properties and higher effectiveness.The closer the beach bar sand reservoir is to the sand-mudstone interface, the more abundant the supply of pore fluid ions from the mudstone, the stronger the diagenesis, and the higher the degree of reservoir compaction. The quality of bar sand concentrated type reservoirs is the highest with the best oil-bearing capacity, followed by the beach bar interlayered type with moderate quality and oil-bearing capacity, and the beach sand dispersed type with the poorest quality and lowest degree of hydrocarbon enrichment.It is important to note that most beach bar sand oil fields currently employ fracturing for production. Additionally, some dry layers achieve increased productivity post-fracturing. Establishing accurate criteria for the lower limit of effective reservoirs under reservoir modification conditions is a key.

Mixing processes of the oil-water-CO2 systems in different fluid phases: Insights to CO2 sequestration in depleted hydrocarbon reservoirs

Zihao JIN[1]*, China University of Petroleum (East China) (1325022832@qq.com)
Guanghui Yuan[2], China University of Petroleum (East China)
Yingchang Cao[3], China University of Petroleum (East China)

Abstract

The dissolution of supercritical carbon dioxide (scCO2) in saline formation water and remaining oil is a crucial trapping mechanism for geological carbon storage in depleted hydrocarbon reservoirs. Therefore, understanding the physics behind dissolution trapping and mass transfer among scCO2, resident brine and remaining oil is essential to evaluate CO2 storage capacity. During trapping, the dissolved scCO2 in oil leads to oil swelling, viscosity reduction, wettability alteration, and ultimately leads to the miscibility between the scCO2 and oil. However, previous studies have often overlooked the potential of CO2 dissolution trapping in oil as well as the interactions between different phases of mixed fluids. To address this gap in knowledge, we simulated the mixing of different fluids in crude oil (light oil and heavy oil), water (distilled water, various saline solutions), and CO2 at temperatures of 32 ℃ to 200 ℃ and pressure of 5 MPa to 60 MPa, using the in-situ micron quartz capillary tube thermal simulation system along with PVT cell simulation systems equipped with gas chromatograph (GC) and mass spectrometer (MS), as well as Material Studio molecular dynamics numerical simulation software.

The results indicate that the miscibility or dissolution process of mixed fluids were not instantaneous, but rather a result of a series of physical interactions occurring near the interface between oil and scCO2. This process was governed by the solubility between the two phases, and influenced by factors such as temperature, pressure, oil properties, and scCO2 content. The solubility of scCO2 in oil decreased with increasing reservoir temperature, and increased with increasing reservoir fluid pressure. As the temperature approached the two-phase miscibility temperature, changes in pressure will have a more pronounced effect on the solubility of scCO2 in oil. Increasing pressure promoted oil-CO2 miscibility and could even achieve miscibility at relatively low temperatures. For various crude oil types, scCO2 exhibited higher solubility in light oils characterized by low viscosity and density, enabling miscibility to be achieved at relatively low reservoir temperature and pressure conditions. Conversely, scCO2 can effectively extract heavy oils with high viscosity and density while partially forming a miscible fluid zone with the extracted light hydrocarbons, thereby promoting two-phase complete miscibility between heavy oil and scCO2. In closed or slow fluid flow systems, the degree of oil-CO2 miscibility is governed by the scCO2 content; achieving miscibility is easier at lower scCO2 concentrations compared to higher ones. Additionally, the miscibility or dissolution processes of oil-scCO2 near the interface induced density convection, thereby enhancing the interaction between dissolved and incompletely miscible carbon dioxide with oil and gas, ultimately promoting the process of miscibility. These findings hold significant implications for analyzing and comprehending the

mechanism of CO2 dissolution trapping in depleted hydrocarbon reservoirs.

Study on Diagenetic Fluids and Reservoir Evolution of Near Source Glutenite Reservoirs, Bozhong Depression Paleogene

Jin HU[1]*, China University of Petroleum(East China) (18706488715@163.com)
Shouyu Xu[2], China University of Petroleum(East China)
Guanmin Wang[3], China University of Petroleum(East China)

Abstract

The resource potential of the Paleogene reservoirs in the Bozhong Depression is great, and the development laws of the reservoirs are complex. The properties of the diagenetic fluids have an important impact on the diagenesis and physical properties of the reservoirs.

Based on the core observation, impregnated thin section, fluorescence thin section, cathodoluminescence observation and analysis, scanning electron microscope observation, fluid inclusion homogenization temperature test, carbon and oxygen stable isotope analysis, X-ray diffraction, formation hydrochemistry analysis, combined with the burial history and thermal history of the study area, the diagenetic fluid properties and diagenetic characteristics of the reservoir in the study area are analyzed and discussed in detail.

In a relatively closed diagenetic fluid system. In the early and middle stages of early diagenesis where the formation temperature is below 80 degree Celsius and the burial depth is less than 2000m, the formation fluid tends to be alkaline. Pore water mainly inherits the ion composition and chemical characteristics of sedimentary water, with stable clay mineral composition. Bright calcite and dolomite cementation occur in sandstone, and the carbon source is CO2 with heavy carbon isotopes generated by microbial fermentation. The particles rarely undergo dissolution. In the late stage of early diagenesis and the middle diagenetic stage A1, where the formation temperature is between 80-120 degree Celsius and the burial depth is 2000-3500 meters, multiple layers of source rocks have successively entered the stage of thermal evolution and acid generation. Organic acids and CO2 enter the reservoir, and the formation fluid rapidly turns acidic, greatly changing the ion composition of the reservoir. Feldspar and detritus undergo widespread dissolution under H+ substitution and carboxylic acid anion complexation, resulting in secondary pores and improving reservoir properties. Simultaneously, common siliceous cementitious materials and authigenic minerals of kaolinite are produced, while carbonate cementitious materials undergo minor dissolution, resulting in changes in the composition of clay minerals. In the middle diagenetic stage A2, When the ground temperature exceeds 120 degree Celsius and the burial depth is greater than 3500m, the oxygen to carbon ratio in the source rock has decreased to a lower level, and the acid generation ability has been depleted. The organic acids in the formation decarboxylate and decompose with increasing temperature, and their concentration gradually decreases. During this stage, the pore water is mainly alkaline. K+ released by feldspar dissolution and enriched in pore water is fixed in clay minerals, and the relative content of illite increases rapidly. Calcite, ferrocalcite, dolomite, and ferrocalcite are commonly cemented in sandstone, and the carbon source mainly comes from CO2 with lighter

carbon isotopes produced by the thermal evolution of organic matter. There are also phenomena such as cementation of sodium feldspar, dissolution of quartz particles and enlarged edges, and cementation of pyrite. In relatively open diagenetic fluid systems, atmospheric freshwater leaching plays a strong role in transformation.

Synergistic diagenesis and shale oil enrichment patterns in the Chang 73 sub-member of Triassic Yanchang Formation in the Ordos Basin

Xiaobing NIU[1]*, Key laboratory of deep oil and gas, China University of Petroleum (east china) (likea0619@163.com)
Yingchang Cao[2], Key laboratory of deep oil and gas, China University of Petroleum (east china)
Kelai Xi[3], Key laboratory of deep oil and gas, China University of Petroleum (east china)
Ke Li[4], Key laboratory of deep oil and gas, China University of Petroleum (east china)
Miruo Lin[5], Key laboratory of deep oil and gas, China University of Petroleum (east china)

Abstract

This study of the Chang 73 sub-member of Triassic Yanchang Formation in the Ordos Basin used an integrated approach of core observation, thin sections analysis, XRD analysis, AMICS mineral analysis, SEM, and vitrinite reflectance analysis to clarify the diagenesis characteristics of thin sandstone interlayers and mudstones. The Chang 73 sub-member is mainly composed of thick mudstone interbedded with thin sandstone. Among them, the mudstone exhibits various types of laminae, including silt-grained feldspar-quartz lamina (SFL), tuff-rich lamina (TL), organic-rich lamina (OL), and clay lamina (CL). Different combinations of these laminae vertically form massive mudstone, “organic-rich + silt-grained feldspar-quartz” laminae combination shale (Type A shale) and “organic-rich + tuff-rich” laminae combination shale (Type B shale). Based on different types of shales, the shale strata of Chang 73 sub-member mainly develop three main types of sandstone-mudstone combinations. Type I is massive mudstone and low-density turbidite sand body combination, whose mudstone are characterized by strong compaction and have little effect on sandstone. The sandstone interlayers have strong compaction and poor reservoir properties. Type II is composed of type A shale and hyperpycnal flow deposited sandstones, which have medium reservoir properties. In this type, strong dissolution of potassium feldspar occurred in the SFL, and provided materials for the authigenic quartz in the OL. Mass transfer occurred inside the shales and have limited influence on sandstones, which have medium compaction and weak feldspar dissolution. Shale oil is mainly enriched in the dissolution pores of the SFL. Type B shale and hyperpycnal flow deposited sandstones combination is another type (Type III1). Abundant tuff can catalyze the earlier hydrocarbon generation of type B shale to accumulate in intergranular pores of the interbedded sandstones, which inhibits the latter diagenesis of sandstone. Shale oil is mainly enriched in the primary pores of sandstones and the reservoir properties is best. Type B shale and sandy debris flow deposits sandstones combination is also a type (Type III2). The evolution of type B shale provides calcium rich fluid to promote the formation of calcite cemented crust at the edge of sand body. The reservoir properties in the middle sand body are better, and shale oil is mainly enriched in the sandstones.

The impact of burial dissolution on the development of ultra-deep fault-controlled carbonate reservoirs: Insights from high-temperature and high-pressure dissolution kinetic simulation

Xiaolin TAN[1]*, College of Geoscience, China University of Petroleum (Beijing)
(txl2021310053@163.com)
Lianbo Zeng[2], College of Geoscience, China University of Petroleum (Beijing)

Abstract

Burial dissolution is a critical diagenetic process influencing ultra-deep carbonate reservoir development and preservation. Artificial carbonate samples with different internal structures were prepared, and high-temperature and high-pressure dissolution kinetic simulations were conducted. The results demonstrate that temperature and pressure exert a significant influence on the intensity of buried dissolution processes. After the experiment, an overall decrease occurred in the intensity of buried dissolution processes in conventional porous-type samples while the reservoir capacity was reduced. Within the faulted samples, there was an overall decrease in the intensity of buried dissolution processes while the reservoir capacity increased. Within the different structural locations of faults, the intensity of dissolution processes exhibits a marked variation. In both fault types of the samples, dissolution expands predominantly along the fault surfaces. The larger the scale of the faults, the more pronounced the dissolution process becomes. Within the special porous-type samples, a three-tiered "string-bead-like" fault-cave structure manifests vertically within SP1. In the case of SP2, an internal fault forms, giving rise to extensive dissolution cavities at the fault's tip. The intensity of burial dissolution is controlled by temperature and pressure, while tectonic-fluid activity influences the development pattern of burial dissolution. Extensive burial dissolution is likely to occur primarily at relatively shallow depths. The development of faults facilitates the maintenance of the intensity of burial dissolution. The maximum intensity of burial dissolution occurs at the tips and overlap zones of faults and intersections of multiple faults. The larger the scale of the faults, the more conducive it is to the development of burial dissolution. Burial dissolution fosters the formation of fault networks characterized by enhanced reservoir capacity and permeability. Burial dissolution controlled by episodic tectonic-fluid activity is a plausible explanation for forming the Tarim Basin's ultra-deep fault-controlled "string-bead-like" reservoirs.

The Stability of the CO2-H2O-Dawsonite-Bearing Sandstone Reaction System: Experimental Study And Thermodynamic Simulation

Kaining WANG[1]*, China Univ Petr East China, Natl Key Lab Deep Oil & Gas, Qingdao 266580, Peoples R China (kningwang2022@163.com)
Fulai Li[2], China Univ Petr East China, Natl Key Lab Deep Oil & Gas, Qingdao 266580, Peoples R China

Abstract

CO2 monitoring constitutes a crucial component of CCUS (Carbon Capture, Utilization, and Storage) technologies, serving as an indispensable tool for ensuring the safety and viability of sequestration projects. This study systematically investigates the reaction system of CO2-H2O-dawsonite-bearing sandstone, clarifying the stability of CO2 reservoirs after mineral trapping, thereby providing significant insights for CO2 monitoring techniques. Experiments and thermodynamic simulations of CO2-H2O-dawsonite-bearing sandstone interactions were conducted under various temperature and pressure conditions using high-temperature, high-pressure autoclaves. A total of 18 physical experiments were carried out at different temperatures and pressures, employing techniques such as scanning electron microscopy, energy-dispersive spectroscopy, and X-ray diffraction to analyze the dissolution and precipitation characteristics of sandstone samples post-reaction and to quantitatively detect the elemental composition changes in key minerals (such as dissolved dawsonite and newly formed minerals). The post-experimental liquid samples were quantitatively analyzed for pH, major ion concentrations, and trace element concentrations. Thermodynamic analysis of the reaction system was performed using the Peng-Robinson equation of state and the van der Waals one-fluid mixing rules to calculate equilibrium state parameters such as pH, CO2 fugacity, ion concentrations, and Gibbs free energy. Thermodynamic simulation experiments on CO2-H2O-dawsonite-bearing sandstone interactions were conducted using Phreeqc, along with the creation of mineral dominance diagrams, to analyze changes in the types and concentrations of ions in the liquid phase at equilibrium, as well as variations in the saturation index of various minerals. The experimental results indicate that the stability of dawsonite decreases under lower CO2 partial pressures, leading to elemental loss and structural transformation into gibbsite and boehmite, with the elemental composition evolving to an O:Al ratio between 3:1 and 2:1, ultimately transforming into gibbsite and boehmite. It is inferred that temperature and CO2 pressure have a comprehensive impact on the stability of the CO2-H2O-dawsonite-bearing sandstone reaction, where high temperatures reduce the system's stability, whereas high CO2 pressures enhance it. An increase in temperature diminishes the inhibitory effect of CO2 pressure on the CO2-H2O-dawsonite-bearing sandstone interaction, necessitating a higher CO2 pressure to maintain system stability, i.e., a lower CO2 pressure is required to preserve system stability under low-temperature conditions. The stability of various minerals changes significantly under different CO2 partial pressures, with quartz, feldspar, and siderite experiencing greater dissolution at 4.3MPa, while remaining stable under other pressures,

and the stability of calcite decreasing with increasing CO2 partial pressure, in contrast to dawsonite and siderite, which increase in stability with higher CO2 partial pressures. Under high CO2 partial pressure conditions, quartz, feldspar, siderite, and dawsonite are relatively stable, indicating a strong "carbon fixation capacity" of the system. This study integrates experimental and thermodynamic simulation data of CO2-H2O-dawsonite-bearing sandstone under various temperatures and CO2 partial pressures, thoroughly investigates the dissolution mechanisms of dawsonite, discusses the stability impact modes of the CO2-H2O-dawsonite-bearing sandstone reaction system under different conditions, and provides a reference for the feasibility and safety analysis of CO2 geological storage.

The use of Airborne Geophysics in Mineral Exploration

Alla DIAW[1]*, National Geological Survey in Senegal (alla.diaw@sgns.gouv.sn)
Rokhaya Samba DIENE [2], Organisation of African Geological Survey
Raymond SAGNA [3], National Geological Survey in Senegal

Abstract

It is essential for a government to play a significant role in attracting foreign investments in the mining and the geology sectors, with a clear legal framework and quality information on the country's potential.

In Africa, mining and geology sector is underexplored, which is why it is important to use much more appropriate techniques that will allow a better understanding of a country's geological and mining potential, hence the interest in airborne geophysics in exploration.

The objectives of airborne geophysics in exploration are:

• Improve the knowledge of the country's natural resources;

• Attract investments in the natural resources sector;

• Identify opportunities related to natural resources in the Energy and Environment sector (water, geothermal);

• Improve the visibility and reputation of the country among investors and multilateral organizations.

Thus, the methodology of airborne geophysics consists in:

• The acquisition of data by overflights following well-defined lines;

• The processing of data by appropriate software (Leapfrog Geo, Oasis montaj or Geosoft);

• The interpretation of data to produce reports and geophysical maps.

The result of this study: Airborne geophysics provides detailed information to reduce the risks, time, and costs of subsequent exploration. Among others, we can mention:

• Integration of data from airborne geophysical surveys (RAD-MAG, EM, gravimetry) with geological data to better identify future prospecting areas;

• Elaborated geological maps defining faults, geo-structures, intrusive dykes, litho-stratigraphy or vein-layers, produce a GIS database containing the targeted minerals with their priority and their attributes;

• Final interpretation reports include all databases: geophysical maps, geological maps, and 2D / 3D modeling of target anomalies to extract geometric information (size, shape, depth, physical properties).

Finally, it is important to note that:

• Airborne geophysics is the initial activity aimed at providing valuable information over vast territories to detect areas of interest;

• Advanced airborne geophysics associated with geology and geochemistry, will have an impact in target areas to maximize the efficiency of investments.

• And the results of these actions will be a set of data for potential investors interested by the

mining sector.

Abstract

The potential of ultra-deep ancient marine carbonate rocks for oil and gas resources is tremendous, becoming an important direction for oil and gas exploration. During the diagenetic development of ultra-deep carbonate rock reservoirs, as burial depth increases, the reservoir undergoes multiple stages of fluid injections including atmospheric freshwater, seawater, organic acids, hydrothermal fluids, and fluids rich in CO2/H2S. This triggers fluid-rock interactions, accompanied by mineral dissolution, precipitation, and transformation, gradually forming porosity, which is then either destroyed or preserved by infilling. The transformations induced by fluid-rock interactions, such as "dissolution porosity increase" and "cementation porosity reduction," play a crucial role in the formation and evolution of porosity, and are key to the development of high-quality reservoirs. Identifying the fluid-rock interactions and the mechanisms of mineral dissolution, precipitation, and transformation during the lengthy and complex diagenetic process of ultra-deep carbonate rock reservoirs, and elucidating how porosity forms and evolves, are critical for revealing the formation mechanism of high-quality ultra-deep reservoirs. This study innovatively introduces temperature-fluid-chemical multi-field coupled multiphase, multicomponent reactive solute transport simulation technology, based on petrological testing and physical simulation experiments, to deeply investigate the fluid-rock interactions during the represented diagenetic process of ultra-deep carbonate rock reservoirs, clarify the mechanisms of mineral dissolution, precipitation, and transformation, simulate the cumulative transformation effects of multiple types of fluids on reservoir porosity during different diagenetic stages, and establish a temperature-fluid-chemical multi-field coupled diagenetic physical-numerical simulation system to quantitatively represent the diagenetic-porosity evolution process on a geological timescale, thereby revealing the formation mechanism of high-quality ultra-deep carbonate rock reservoirs. The research shows that the formation of porosity is closely related to the properties of underground fluids. In fluid-rock interactions, the dissolution of minerals releases ions, which recombine in the solution to form new minerals. Therefore, the concentration of ions in the fluid largely determines the trend of mineral dissolution/precipitation and its degree of transformation of the reservoir porosity. The

fluid types experienced during the diagenetic process of ultra-deep carbonate rock reservoirs are complex and numerous, and the secondary porosity, vugs, and caves formed by the dissolution action of different types of fluids are the main spaces for oil and gas accumulation.

The role of transient processes in the generation of giant uranium deposits

Patrick LEDRU[1]*, University Lorraine (patrick.ledru@univ-lorraine.fr)
Julien Mercadier[2], University Lorraine
Guoxiang Chi[3], University Regina

Abstract

The concept of metallogenic system highlights the notion of favorable geodynamic context and self-organized hydrothermal systems. The formation of such systems requires a source of energy which sustains a hydraulic gradient, controls fluid circulation, and allows accumulation of metals in localized traps. These geologic elements are considered critical for the formation of mineral deposits, and the understanding of their functioning is important for identification of the controlling factors of mineralization. Their thermal, hydraulic and mechanical properties are comparable to the parameters involved in the stimulation of fractured reservoirs in geothermal systems. The application of these concepts to the metallogeny of uranium leads to a better understanding of the possible role of transient processes in the formation of giant deposits and in particular unconformity-related uranium deposits.

The location of high-grade uranium deposits in the Proterozoic Athabasca Basin within or near fault systems that have been reactivated multiple times suggests that these faults have propagated within the basin and have guided the circulation of fluids, testifying to the structural control of the mineralization. The coincidence between this reactivation, induced permeability enhancement and the generation of uranium deposits is the first evidence of transient events as illustrated by the relative chronology between deformation, alteration and mineralization. The thermal conditions indicated by mineralogical and fluid inclusion studies and the observation of dissolution and recrystallization phenomena suggest that the leaching of considerable volumes of rocks in the basement and the basin is related to the mineralization system. The system involved fluid reservoirs within the basement derived from accumulation of brines from the basin and fluids of deeper origin. The study of graphite in basement faults hosting uranium deposits suggests that the faults may be reactivated due to the fault-valve mechanism ~5 km below the unconformity surface, in relation to far-field tectonic stresses and/or over-pressured fluids whereas the upper tip of the faults may attracts fluids both from the basement and basin via the suction pump mechanism. According to this model, the formation of these deposits may result from coupled fault-valve and suction pump mechanism. The alternating seismic and interseismic periods associated with this mechanism would thus be entirely comparable to the self-organized hydrothermal systems described for gold deposits or geothermal reservoirs and could correspond to a succession of very short-lived events in the history of the basin. Although no geochronological constraints exist on the time required to form the Athabascan unconformity-related uranium deposits, first-order approximation from Thermal Hydrological Mechanical and Chemical modeling suggest that 0.1–1Myr is a viable estimate for the duration of the mineralizing event. Translation of the new understanding of these geologic processes that are critical for

mineralization into recognizable or mappable geological features or footprints is important for continued exploration for new giant deposits.

The relationship between Meso–Cenozoic tectonic-fluid evolution and sandstone type uranium mineralization in Kuqa Depression, Tarim Basin, western China

NIAN LIU[1]*, Beijing Research Institute of Uranium Geology (liuniancup@163.com)
Mingkuan QIN[2], Beijing Research Institute of Uranium Geology
Qiang GUO[3], Beijing Research Institute of Uranium Geology
Qiang XU[4], Beijing Research Institute of Uranium Geology
Jing XIAO[5], Beijing Research Institute of Uranium Geology

Abstract

The apatite fission track, apatite (U-Th)/He, balanced section and organic-inorganic geochemistry are used to recover the Meso–Cenozoic tectonic-fluid evolution of Kuqa Depression in this paper. The relationship between tectonic-fluid evolution and sandstone type uranium mineralization is also discussed. The results show that the tectonic deformation strength of the Kuqa Depression is characterized by “strong in the west and weak in the east”, and there are three tectonic uplifting events: Late Jurasic–Early Cretaceous, Paleogene–Miocene and Pliocene–Quaternary. It is caused by the collage of the Lhasa terrane and the Eurasian plate, the accretion of the Kohistan-Dras island arc and the progressive collision between the Indian and the Eurasian plate, respectively. From Paleogene to Miocene, slow regional uplift and denudation occurred in the study area, and the uplifted and exfoliated marginal strata suffered from surface weathering and leaching and developed large-scale interlayer oxidation, and early uranium mineralization occurred in the Middle and Lower Jurassic and Lower Cretaceous. From Pliocene to Quaternary, the infiltrating fluid penetrated deep into the basin and the temperature rose, forming high temperature hydrothermal water. Due to tectonic extrusion in the later period (Quaternary), the hydrothermal fluid mixed with oil and gas continuously extracted uranium, copper, lead, zinc and other ore-forming materials in the surrounding strata during upward migration, forming the fluid rich in metal ore-forming materials. Due to the change of temperature and pressure conditions, ore-forming fluids are enriched and uranium mineralization occurs in Pliocene. The Meso–Cenozoic tectonic-fluid evolution controls the sandstone type uranium mineralization in the Kuqa Depression, which is generally characterized by “early interlayer oxidation and late exudation relay mineralization”.

Abstract

Since 2000, the significant theoretical and technological innovations in the field of uranium geological exploration in China have greatly changed the prospecting ideas and directions for sandstone-type and hydrothermal-type uranium resource exploration. These innovations have led and supported a series of major prospecting breakthroughs, reshaping the new pattern of uranium resource exploration in China. This paper firstly analyzes the overall ideas and evolution directions of China's uranium geological research layout over the past 20 years. It then summarizes the progress in major basic geological and metallogenic theories of uranium ore formation, systematically condenses technological innovations and core exploration equipment development achievements that including fields of geology, physical and chemical exploration, remote sensing, drilling technology, analysis and testing, and reviews the progress and application effectiveness of uranium resource prediction and evaluation techniques. Lastly, this paper proposes the main development trends and directions for the next 10-15 years in the areas of major basic geology frontier and metallogenic theories, which including advanced research and development of uranium resource exploration technology, unconventional nuclear energy fission resource exploration technology, and digital uranium resource exploration technology. The authors points out that under the background of the 'dual carbon' goals, the development of nuclear energy and demanding security of uranium resource, it is necessary to strengthen the innovation of uranium geological science and technology, and drive the prospecting breakthroughs in 'new areas, new stratigraphic positions, new types, and new depths'.

Progress in the extraction and integration of uranium mineralization information in the basin

Yu RENG-AN[1]*, China Geology Survey (yurengan@163.com)
Chen Yin[2], China Geology Survey

Abstract

Comprehensive information of prospecting sandstone type uranium in the basin is a specific reflection of the phenomenon of uranium mineralization. Because of complex uranium mineralization mechanism, prospecting indicator, deep buried and less differences in physical properties of ore-bearing, etc., the extraction of comprehensive information on uranium mineralization is an important part of uranium exploration. As a radioactive logging method, natural γ logging is one of the main means of geophysical logging in the exploration of oilfields and coalfields. Based on the study of the principles and working methods of natural gamma logging and quantitative gamma logging, combined with the comparative analysis of the natural gamma logging of coal field and oil field holes and quantitative gamma logging data of uranium mines, the empirical equation between the natural gamma and radioactive gamma values of the study area and the logging response of different lithologies are fitted, and the ore body's grade, and other more accurate measurement information modules are established, so as to make a more accurate measurement information module for the unvalidated oil field logging Numerical prediction of grade, lithology and other attributes of the oilfield logging data was carried out, and a preliminary index system for discriminating potential uranium ore layers based on the natural gamma logging data, as well as circling prospective zones and target zones for finding minerals, was established. At the same time, we collected and analyzed geological data, heavy magneto-electricity, remote sensing and borehole logging data of the study area, analyzed and processed them for interpretation, compiled and drew different kinds of basic maps of the study area, combined with relevant drilling and seismic data to speculate on the fracture tectonic system of the study area and discuss its geological significance; the characteristics of the geophysical field of the study area and the relationship between fracture uplift tectonics and sandstone uranium in the study area were created, then the geological background of uranium formation and predicted the prospective uranium prospecting areas were analysed and summarized. This study might be profit to analysis of the geological background of uranium formation and the uranium exploration in the study area.

[Keynote] IAEA activities supporting capacity building and innovations in uranium resources, processing and mining

Adrienne Hanly[1]*, IAEA (A.Hanly@iaea.org)

Abstract

The IAEA provides various forms of support for capacity building in countries engaged in uranium exploration, processing, and mining. This support includes technical meetings, training workshops, symposia, review and expert missions, publications, databases, e-learning, fellowships, scientific visits, and procurements.

The IAEA produces publications covering diverse topics in uranium production cycle activities that are an excellent source of recent and historical information, and many are available free of charge as a downloadable PDF file on the IAEA website. To complement publications on uranium and thorium deposits there are databases on uranium (UDEPO) and thorium (THDEPO) deposits.

An IAEA Nuclear Energy Series document (NES No. NF-G-1.1) titled 'Milestones in the Development of National Infrastructure for the Uranium Production Cycle' offers guidance to countries currently undertaking or considering programmes in uranium exploration, production, processing, decommissioning, and remediation of uranium mines and processing facilities.

To assist countries in understanding this guidance, the IAEA is developing a series of e-learning modules. One e-learning module will provide an overview of the Milestones approach in developing national infrastructure for the uranium production cycle. Two additional e-learning modules, one focusing on stakeholder engagement and the other on conventional safety and radiation protection, will further expand on the Milestones approach. A fourth e-learning module will concentrate on uranium exploration, offering a solid foundation in the principles of conducting uranium exploration systematically, safely, and sustainably. This will complement an IAEA Technical Document currently in draft form titled 'Exploration Planning, Management and Practise.'

Ore mineralization of some gold deposits of Mongolia: Gold mineralization linking to the crystal forms

MUNGUNTULGA PUREVSUREN[1]*, National University of Mongolia (munguunup@gmail.com)
OYUNGEREL Sodnom[2], National University of Mongolia
YEONGMIN Kim[3], Korea Basic Science Institute
ALTANZUL Chikalov[4], Sudaltmana LLC
ERDENEJARGAL Choindonjamts[5], Institute of Geology, Mongolian Academy of Sciences

Abstract

The gold deposits and occurrences in Mongolia are separated into 23 metallogenic belts with enormous potential for gold mining. These gold deposits and occurrences are genetically classified into many types such as porphyry, VMS, orogenic, intrusion-related and epithermal vein types. In this study, we tried to compare the ore minerals and gold mineralization with their crystal form of a few main gold deposits in Mongolia such as Tavt deposit, Gatsuurt, Ereen, Sujigtei deposits of the Boroo-Dzuunmod ore district, Khan-Altai deposit and North Eagle deposit. In these deposits, the gold mineralization might be related to sulfide minerals whose crystals mostly belong to the cubic crystal system. Arsenic (As) and gold (Au) concentrations in some gold deposits in Mongolia are positively correlated and both arsenopyrite and pyrite occur together. The analyses of ore minerals in these deposits indicate that Au may be found in ore minerals in As-bearing pyrite as well as tennantite (Cu12As4S13), arsenopyrite (FeAsS), enargite (Cu3AsS4) and other ore minerals. Pyrite in a pentagonal-dodecahedral (210) crystal stably holds a larger amount of gold than two primary crystal forms of pyrite such as hexahedron (100), and octahedron (111). Because the pentagonal-dodecahedral (210) pyrite is widely distributed in Mongolian gold deposits pyrites could be used as a mineralogical criterion in exploration survey to prospect gold.

The role of mineral-related industries in Chinese industrial pattern

Weidong LI[1]*, Institute of Mineral Resources, Chinese Academy of Geological Sciences (wadeli55@outlook.com)

Abstract

Mining industry provides raw materials for economic development, and is a basic industry with strong correlation with other industries. Meanwhile, mining industry possess the feature of “high energy consumption, high pollution and high emissions”. Especially in today’s society where environmental protection is increasingly becoming the main theme, it has become an important issue for people to actively coordinate the relationship between mining and environmental protection, and promote the green transformation of mining industry. Combining industrial relationship and complex network, industrial complex network is applied to explore the industrial relevance, which is a perfect method to research industrial pattern. Based on the input-output data of China (1990–2018), this paper constructed the industrial complex network model to describe the evolution characteristics of Chinese industrial pattern. Then we focused on the mineral-related industries, to explore their role and position in Chinese industrial pattern by analysis of network overall and individual indicators and community division. The results show that Chinese industrial network has small world property, and the closeness of various industries is increasing, and the characteristic of industrial clusters ais obvious; The system of Chinese manufacturing industry is becoming more and more perfect and remains an important pillar and foundation of the national economy; Smelting and processing of metals industry plays an important role in connecting the preceding and the following. This paper provides a new perspective for the study of China’s mining industry pattern and puts forward corresponding policy suggestions for the adjustment of industrial structure. At the same time, relevant development experience can also serve as a reference for subsequent countries.

Simulation Analysis of Supply Crisis Propagation Based on Global Nickel Industry Chain

Xingxing WANG[1]*, Chinese Academy of Geological Sciences (xiaoxing0523@126.com)

Abstract

Nickel is a key metal in the low-carbon transition. The industrial chain is a chain network organization system composed of various layers from the initial production of raw materials to the final product sales. The intensified contradiction between supply and demand can easily lead to the problem of resource supply security, and the occurrence of supply shortages will endanger the healthy and orderly development of the whole industrial chain. Therefore, from the perspective of the industrial chain and based on the trade data related to the nickel industrial chain, this study first constructs a multi-layer network model of the nickel industrial chain, and analyzes its trade structure characteristics and the correlation between different layers. It is found that the export policies of resource exporting countries may influence trade structure characteristics. On this basis, a multi-layer network crisis propagation model of the nickel industrial chain is constructed to simulate the impact and its propagation path of Indonesia supply shock on the entire industrial chain. With the increase of supply shock in Indonesia, the impact of crisis gradually concentrates to the downstream. Along the industrial chain, the number of affected countries gradually increases, but the difference in the impact degree gradually decreases. In addition, there are certain differences in countries affected by crisis at different layers of the industrial chain, and the crisis spreads mainly from China and Japan to the countries in midstream and downstream. The research results can provide corresponding policy suggestions for countries involved in the nickel trade.

GEOLOGICAL-GEOCHEMICAL MODEL OF THE DAUGYZ GOLD DEPOSIT (SOUTHERN TIEN SHAN, CENTRAL KYZYLKUM)

JAKHONGIR MOVLANOV[1]*, University of Geological Sciences (ugs.cgt2020@gmail.com)

Abstract

The geochemical model of the Daugyz deposit represents a generalized multicomponent, spatially ordered image of the above-background contents of ore elements of a typomorphic complex from above-ore to sub-ore levels. The formation of the Daugyztau gold-sulfide deposit took place in several stages. During the exogenous-diagenetic stage, the accumulation of ore-hosting terrigenous-flyschoid formation, enriched with dispersed ore mineralization, occurred. During the final stages of diagenesis and the elision-catagenetic stage, sediment compaction and initial redistribution of matter occurred as a result of the movement of fluids from the center and depths of the system to its periphery. The thermofluidic impact of large masses of granitoids and tectonic dislocations caused regional metamorphism of strata, regeneration and redeposition of primary dispersed mineralization from gold-bearing sulfide horizons into subconformable rock bedding and cutting zones. This contributed to the local concentration of disseminated ore mineralization. During the metamorphogenic-hydrothermal stage in tectonic zones, further metamorphogenic-metasomatic transformations of mineralized rocks and deposition of hydrothermal mineralization into steeply dipping veinlet-disseminated ore deposits occur in metasomatites of the beresite and argillicite formation. A paragenetic connection of hydrothermal processes with a large massif of granitoids, the roof of which is located at a depth of 3-5 km from the surface, is assumed.

In the Daugyztau ore field, intense and contrasting primary halos of Au, Ag, As, Sb have a correlated distribution, forming a generally complex geochemical field with concentrations on objects of gold-silver mineralization. Based on the correlation in the primary aureoles, two ore-geochemical associations were identified: Au+As+Sb+Ni (gold-pyrite-arsenopyrite veinlet-disseminated ores) and As+Ag+Sb+ Pb +Ba+Cu+Zn (polysulfide-sulfosalt-silver ores). The association of coherent elements Ni+Co+V+Mn+Cr+(Cu+Zn) is represented by fields of removal from ore-bearing positions and accumulation in their frontal parts in the form of a discontinuous ring. The through elements in the ore and metasomatic associations are Cu, Zn, Ni.

The typical chemical accumulation complex of the Daugyztau deposit is Au, Ag, As, Sb and Hg. The maximums of their concentrations are located near fault zones. Transverse zoning is manifested by a contrasting distribution of the contents of these elements in the footwall, while in the hanging wall there is a wider halo zone with a gradual decrease in the intensity of the haloes from the axis of the ore-hosting fault. Longitudinal geochemical zoning of the deposit - in the direction from north to south there is a consistent increase in the thickness and intensity of the halos of Ag, Cu, Pb, Sb, As, Hg. Ore deposits coincide with halos of Au, As, Ag. Small low-intensity tungsten halos are characteristic of the recumbent side of ore deposits. The vertical zoning of mineralization at the Daugyztau deposit is expressed by various complexes of indicator elements representing lower ore, subore (W, Zn, Cu, Mo), ore (As, Au, Ag), supra-ore and upper

ore (Sb, Hg, Pb, Ag,) sections .
The results were used to assess the prospects for gold mineralization on the flanks of the ore field and at depth.

Research on the impact of global mineral trade structure on national economy

XIAN XI[1]*, Research Center for Strategy of Global Mineral Resources, Chinese Academy of Geological Sciences (xixianer01@163.com)
Xiangyun Gao[2], School of Economics and Management, China University of Geosciences, Beijing

Abstract

Mineral resources are considered the upstream raw materials of the industrial chain and represent an important material basis for economic sustainable development. Countries have different mineral resource endowments promote trade development. According to the theory of resource dependence and interdependence, countries have close trade relations, through which they can exchange resources to meet domestic needs and economic development. Different countries have different trading partners, media capabilities and importance in the networks, which make them different in the ability to obtain and provide resources, thus leading to different roles of countries and different influences on their GDP. Therefore, we construct global mineral trade networks and analyze their overall characteristics; we use network parameters to represent the roles of the countries and apply the panel quantile regression method to test the relationship between the roles of the countries and the GDPs. We find that a country's media capacity is beneficial to economic growth, and when a country's resources are readily accessible, it is adverse to the economic development; export is conducive to economic growth, while high dependence on external resources is not conducive to economic growth and it is good for a country's economy to have many important trading partners. In addition, countries with a high economic level should attach more importance to the strategic reserve of mineral resources, while countries with a low economic level should attach more importance to the development of an international market.

Reinterpretation and 3D visualization of Pine Creek Orogen (NT, Australia)

Gemma Mitjanas[1]*, Sustainable Minerals Institute (Univ of Queensland)
(g.mitjanascolls@uq.edu.au)
Steven Micklethwaite[2], Sustainable Minerals Institute (The University of Queensland)

Abstract

The Paleoproterozoic Pine Creek Orogen (PCO; Northern Territory, Australia) is a multi-commodity province rich in resources, including minerals crucial for the energy transition (1). The large spectrum of metals, the range of rock types of different litho-geochemistry, the presence of Archean basement, and the complex structural and metamorphic patterns, make the PCO an attractive exploration target. However, considering the 15 critical minerals and 13 emerging critical minerals included in the Northern Territory's lists, only 5 commodities are currently being produced (2).

We reviewed and integrated open-source data to provide an updated geological map and a 3D geological model of the Central Domain of the PCO. We used regional geological and geophysical maps to build cross-sections and a preliminary 3D geological model, which was iteratively refined using 2D and 3D geophysical forward and inverse modelling.

Our results underscore the region's geological complexity, particularly in terms of its structural evolution and the spatial distribution of mineral systems. The structural geometries revealed in the final interpretations are suggestive of the possibility that salt tectonics played a role in Paleoproterozoic orogenesis, and the Cullen Supersuite unit and main faults appear to have a key role in the distribution of critical minerals.

The applied methodologies and workflow prove the value of the use of open-source data during the preliminary phases of exploration, thereby, enhancing sustainable practices. In addition, the outcomes of this project provide the basis for stimulating exploration and investment in the Northern Territory, with the opportunity of leveraging the results for mineral systems analysis and informed exploration targeting strategies.

Abstract

Hydrothermal-type mineralisation is the most abundant genetic types of fluorite mineralisation so far reported in the literature. Characteristically, the involved fluid is consistently low to moderate in temperature (<300°C) however extensively varied in salinity and chemical composition. Sources of dissolved solutes such as calcium, fluorine, rare earth elements etc. are reported from diverse geological reservoirs in varied geological settings. Dissolved solutes are the main constituents of ore deposit formation therefore constraining it's sources will be helpful for understanding the genesis of mineralisation and also for further exploration of deposit.

Dongargaon fluorite (±barite) deposit is situated in the Chandrapur district of Maharashtra, India. Geologically, the Archaean Bengpal gneissic complex forms a basement for all overlying sediments. The sedimentary strata are part of the Gondawana Supergroup, Vindhyan Supergroup, Sulluvai Group, Pakhal Supergroup and Penganga Group. The Sahyadri Group's Deccan Basalts are overlying these sedimentary layers. Fieldwork carried out in the Dongargaon fluorite (±barite) mine area reveal that the dominant lithology of the local area is Penganga chert and a lesser amount of Penganga limestone. At the same time, phyllitic rock materials were highly weathered. The unconformity between Penganga sediments and Gondawana sediments is marked by the presence of a Conglomerate. Penganga chert and limestone are extensively brecciated indicating past fault activity in the area that has created open spaces for hydrothermal fluid circulation. Fluorite mineralisation is hosted within Penganga chert however Penganga limestone is devoid of fluorite mineralisation. The fluorite mineralisation is dominantly botryoidal (stage-1) and developed as radiating crystals perpendicular to the brecciated chert. As per the field observation feeble mineralisation is also observed as alternate chert and fluorite bands and cubic fluorite (stage-2). The veins of cubic fluorite cut across the botryoidal type fluorite indicating the late stage of fluorite mineralisation.

Previously carried out petrography suggests hydrothermal assemblage as fluorite+quartz+baryte. Reported fluid inclusion study of late-stage fluorite mineralisation reveals involvement of low salinity (<1.5 wt.% NaCl equivalent)-low temperature (<180°C) hydrothermal fluid that was probably sourced from meteoric water.

To constrain the sources of dissolved solutes and physico-chemical condition of mineralisation, pure phases of hydrothermal minerals and associated rocks were separated, digested and analysed for major, trace and REE concentration using ICPMS. The fluorites are low to moderate (12—195 ppm) in REEs concentration and consistently show PAAS normalised HREE enriched (NdSN/YbSN= 0.23—0.28) REE+Y patterns. The limestone and host chert shows the PAAS normalised HREE enriched to flat (NdSN/YbSN= 0.58—1.20) REE+Y patterns. Both botryoidal fluorites and host rock show similar Y/Ho ratios (30—49), however the late-stage cubic fluorite shows a high degree of fractionation (Y/Ho =69). Fluorites of both stages show typically positive europium anomaly (1.2—4.3). The cerium anomaly of botryoidal fluorites is negative (CeSN/CeSN* = 0.73—0.76) however that of cubic fluorite is neither positive nor negative (CeSN/CeSN* = 1.0). Lithologically, limestone is the possible source of Ca2+ as chert is devoid of Ca2+. As per the available literature fluorine content is much higher in clastic rocks than the limestone therefore it is suggested that the source of fluorine is dominantly

Ultramafic-Hosted Magnesite Deposits in Southern Peninsular India: Spectral and Stable Isotopic Insights

HARITHA A[1]*, Department of Earth and Space Sciences, Indian Institute of Space Science and Technology, Thiruvananthapuram 695 547, India (harithaanil1994@gmail.com)
Rajesh V.J[2], Department of Earth and Space Sciences, Indian Institute of Space Science and Technology, Thiruvananthapuram 695 547, India
Satish-Kumar M[3], Department of Geology, Faculty of Science, Niigata University, 2-8050 Ikarashi, Nishi-ku, Niigata 950-2181, Japan

Abstract

Magnesite (MgCO3) is a major carbonate mineral that forms through the alteration of magnesium-rich rocks within diverse marine and non-marine geological environments. Magnesite deposits of southern India are mainly confined to the ultramafic rocks and are characterized by intricate network of veins and fractures. The main objective of the study is to investigate the source of the mineralizing fluid and the prevailing physico-chemical conditions that controlled the formation of magnesite deposits, in particular those hosted within the Archean to Neoproterozoic ultramafic rocks. Ultramafic-hosted magnesite is found at several locations within the Archean greenstone belt of the Dharwar craton such as Doddakanya, Jambur, Karya, and Nuggihalli region. These magnesites are confined to ~3.3 Ga-old ultramafic bodies belonging to the Sargur group supracrustals especially, highly weathered dunite. Similarly, magnesite occurrence of southern granulite terrane is observed in the ultramafic of Attappadi, and serpentinized dunite of the Salem mafic-ultramafic complex (SMUC). Mineralization in all these occurrences is restricted up to an average depth of 25m below the surface and within the soil horizon.

We conducted a spectral characterization of magnesite mineralization using various techniques. The hyperspectral data revealed paired absorption at 2.3 and 2.5 μm, attributed to C-O bond vibration overtones and combination tones of C-O stretching and bending. FTIR analysis identified characteristic vibrational frequencies in the spectral ranges of 1434, 880, and 747 cm−1, while laser Raman data showed peaks at or near 212, 332, 735, 1096, and 1460 cm−1. The C-O isotopic data obtained from magnesite samples in Karnataka indicate average 18O(V-SMOW) values of 30.6‰ and 13C(V-PDB) values around -2.6‰ while the isotopic composition of magnesite is δ13C =-3.6‰ and δ18O = 25.5‰ from Salem. Meanwhile, stable isotope analysis of the magnesite samples from Attappadi yielded a δ13C and δ18O value in the range of -5 to -0.6‰ and 26‰ to 28‰ respectively. The stable isotopic values, characterized by lighter carbon and heavier oxygen, imply that the mineralizing fluid cannot be solely sourced from the deep mantle, with the heavier oxygen indicating a meteoric/atmospheric origin. The oxygen isotopic composition depicts the precipitation temperature of magnesite from all the study areas of southern peninsular India indicating a low-temperature replacement reaction. We estimated the formation temperature of magnesite between 23 to 49ºC based on the oxygen isotope thermometry using a fractionation factor from Aharon, 1988. Based on all these observations, we propose a

model of the genesis of the magnesites that invokes the percolation of meteoric water through weak planes and fractures into the ultramafic rocks. The plausible source of the mineralizing fluid involves a combination of surficial reservoirs and carbon produced by the decarbonation of marine carbonates.

Nanoparticles Observed by TEM from Gold, Copper-Nickel and Silver Deposits and and Their Significance for Mineral Exploration in Covered Terrains

Bimin ZHANG[1]*, Institute of Geophysical and Geochemical Exploration, CAGS
(zbimin@hotmail.com)

Abstract

Geochemical exploration for concealed deposits covered by thick rocks overlying, transported soils present special problems. Geochemists conjectured that ultrafine metal particles or metal elements could be carried onto bubbles or micro-flow of geogas and migrate upward to the surface and ultrafine metal particles or metal elements transported to the surface by gases could be trapped by soil geochemical barriers. After years of study, ultrafine metal particles as nano-scale have been extensively observed in the geogas samples. In this study, nanoscale particles were observed in soils over three concealed ore deposits by using transmission electron microscope (TEM). The particle characteristics in sizes, shapes and chemical compositions are compared for study on the three types of Au, Cu–Ni, Ag Deposits. The results show that (1) nanoparticles of native metals or alloys widely occur in soils, geogas, and ores in the three mineral deposits; (2) nanocrystals occur in soils, geogas, and ores; (3) the sizes of nanoparticles are similar in diameter from 5 nm to 100 nm; (4) the particles tend to agglomerate into clustering forms; (5) the most obvious difference among nanoparticles collected from the three types of deposits is the chemical compositions that nanoparticles at Au and Ag-polymetallic deposits have Au element, while nanoparticles at Cu–Ni deposit have Ni and Cr elements; (6) nanoscale metal particles are not discovered in the samples collected from the background zone. The results indicate that nanoparticles of metals have good inheritance relationships with the deposits. The nanoscale particles of native metals or alloys from the ore body can migrate with the ascending flow of gases through structural fissures or rock pores upwards to the surface. On arriving at the surface, some of the particles persist in the soil, whereas gases and other particles are trapped by soil geochemical barriers. The discovery of nanoscale particles in geogas and soils over concealed ore bodies also provides direct observation evidence for deep-penetrating geochemistry using soil and geogas as sampling media to search for deeply concealed ore deposits.

Analysis of the Safety Situation of Potash Resources in China and Suggestions for Global Cooperation

YAN ZHANG[1]*, Institute of Mineral Resources,Chinese Academy of Geological Sciences (398232175@qq.com)
YANSONG ZHANG[2], Chinese Academy of International Trade and Economic Cooperation

Abstract

Potassium salt is mainly used to produce potash fertilizer, which is an essential material basis for agricultural production and has important strategic significance for ensuring food security. The distribution of potassium salt in the world is extremely uneven, and a large number of resources are concentrated in a few countries, making it a natural monopoly. Major countries in the world have included it in the list of strategic minerals. At present, the global population continues to grow, national protectionism and local geographical conflicts intensify the food crisis, and the demand for potash will continue to grow in the future, which may become the focus of international competition. As the world's largest potassium salt consumer, China relies on international imports for nearly half of its resources. Under the new situation, the safety of China's potash mineral resources must be considered in the global resource governance system, systematically plan the layout of overseas resources, continuously deepen international cooperation, and use political, diplomatic, economic and technological projects to ensure the safety of China's potash supply system. In this regard, this paper puts forward the following suggestions: first, deepen the innovation of potash mineralization theory, broaden the scope of potash resource prospecting, and at the same time carry out technological innovation in potash mining; At the same time, carry out technological innovation in potash mining; third, promote the construction of a resource cooperation system, and promote cooperation in politics, diplomacy, capital, technology, engineering, etc.; fourth, strengthen industry cooperation, form industry alliances, and enhance international competitiveness; The fifth is to improve the construction of relevant service guarantee organizations and expand the communication and exchange mechanism.

First row transition metals deportment in Cretaceous karst bauxite: the case of the southern Italy and Sardinia Island deposits

Roberto BUCCIONE[1], Department of Sciences, University of Basilicata, viale dell'Ateneo Lucano 10, 85100 Potenza, Italy
Paola MAMELI[2], Department of Chemical, Physical, Mathematical and Natural Sciences, University of Sassari, Via Piandanna 4, 07100 Sassari, Italy
Giovanni MONGELLI[3]*, Department of Sciences, University of Basilicata, viale dell'Ateneo Lucano 10, 85100 Potenza, Italy (giovanni.mongelli@unibas.it)
Giacomo OGGIANO[4], Department of Chemical, Physical, Mathematical and Natural Sciences, University of Sassari, Via Piandanna 4, 07100 Sassari, Italy

Abstract

In the last decade an increasing interest has been paid to the distribution of critical metals and critical raw materials in karst bauxite deposits. Great interest has been devoted to Rare Earth Elements although some deposits show remarkable enrichment in other critical metals including, for instance, W, Ta , and some first row transition metals such as V, Cr, Co, and Ni.

Here we explore the deportment of V, Cr, Co, and Ni in five karst bauxite deposits in southern Italy (Apulia and Campania Districts) and Sardinia Island. These areas are located in the converging zone between the African and Eurasian plates since Cretaceous. Sardinia is a microplate which was part of the southern margin of the European plate whereas Adria is considered a single plate separated from the African plate by the Ionian basin .

According to the Al2O3-SiO2-Fe2O3 diagram the karst bauxite of the Campania and Apulia district are mostly Fe-rich bauxites and bauxites. The Sardinian ores are bauxites and Fe-poor bauxites, although several samples fall in the clayey bauxite field. The ores show larger median values of first row transition metals with respect to the average Upper Continental Crust. Sardinian ore is enriched in V (median value 623 ppm) whereas in the Apulia District are observed the highest median values for Cr (Otranto site: median value 1005 ppm) and Ni (Spinazzola site: median value 470 ppm). Further, the distribution of both Co and Ni is characterized by the presence of several outliers.

R-mode Factor Analysis was performed on each of the five datasets including SiO2, Al2O3, Fe2O3 TiO2, V, Cr, Co, and Ni, devoid of the outliers and after Varimax rotation. Multivariate statistics indicate that three factors always explain more than 84% of total variance. In some deposits Co and Ni share significant weights in the same factor suggesting common fate. In the ores from the Apulian district, Fe2O3 and V share significant weights in the same factor indicating Fe-oxyhydroxides play a role in controlling V. Al2O3 and TiO2 in four deposits show significant weights in the same factor confirming Al-hydroxides and Ti oxide accumulate during bauxitization. In several cases Al2O3 and TiO2 share significant weights with transition metals such as Cr and Co suggesting that Al-hydroxides and Ti oxide may also play a role in distributing these elements.

Potential Natural Hazards of Mineral Facility and Effect of Mineral Production Using Geospatial Data for Asia-Pacific Region

Jaewon CHUNG[1]*, National Minerals Information Center, U.S. Geological Survey (jchung@usgs.gov)
Ji Won Moon[2], National Minerals Information Center, U.S. Geological Survey
Sean Y. Xun[3], National Minerals Information Center, U.S. Geological Survey
Steven D. Textoris[4], National Minerals Information Center, U.S. Geological Survey

Abstract

The U.S. Geological Survey (USGS) has recently updated a geodatabase containing mineral facility (mines and plants) data for countries in the Asia-Pacific region. The geodatabase contains data on about 2,410 mines and 3,320 mineral processing plants with the respective annual production capacity of mineral commodities. This study attempted to assess the risk of mineral supply disruption on a regional scale and at a facility level by overlaying the subset (selected mineral commodities, such as lithium-ion battery minerals and tin) of the geodatabase with natural hazards maps showing designated susceptibility of floods and landslides and the severity of probabilistic earthquake. In particular, earthquakes may cause damage to mineral facilities and related infrastructure and trigger earthquake-induced landslides and -fires, which can hinder mineral production and supply availability. Preliminary analysis shows that about 50 bauxite-tin mines and plants in Sumatra, which dominate such mineral output in Indonesia, would be prone to strong-to-severe seismic damages. The ground motion in Sumatra near the subduction zone ranges from 0.3 g to 0.6 g for the peak ground accelerations for 10% probability of exceedance in 50 years (or 475-year return period). Meanwhile, the ground motion in the Malaysian peninsula within the stable tectonic plate is likely to be low, implying facilities in the area are not prone to seismic damage.

The impact of oil decoupling between EU and Russia on the pattern of global oil trade under the Russia-Ukraine military conflict

Xiu WANG[1]*, +86)15210984055 (wangxiucugb@163.com)
Chonghao LIU[2], +86)13811900135

Abstract

Oil plays an important strategic role in the global economic system and is a strategic resource related to national security. The ongoing conflict between Russia and Ukraine is not only a military conflict, but also another kind of "war" in the field of oil and other energy, which has brought an impact on the global oil supply pattern. The study of the influence of the Russo-Ukrainian military conflict on the pattern of global oil supply is of great significance to the study of oil situation and strategic decision of various countries. This paper simulates the oil decoupling between the EU and Russian by using scenario sham, and uses the method of complex network to analysis the impact of the decoupling on the global oil supply pattern under the background of the military conflict. Before the EU-Russia oil decoupling, the oil consumption of the EU was heavily dependent on Russia, and the EU members and Russia were divided into a same trade group. After the decoupling, the trade group is disintegrated, and Russia enters another trade group where China is the main importer. European countries mainly enter the groups where North America or the Middle East countries are the main exporters. The EU-Russia oil decoupling will lead to a decline in the status of Russia in the global oil trade, while the status of some countries in North America and the Middle East will increase.

Copper-Gold Mineralization in a Covered Basement Complex of North Delhi Terrane, Rajasthan: Implication towards Mineral Potential of Basement Rocks

Arindam MISRA[1]*, Geological Survey of India (arindam.misra@gsi.gov.in)
Debapriya Chatterjee[2], Geological Survey of India
Avik Manna[3], Geological Survey of India

Abstract

The basements rocks of Mangalwar Complex are rarely exposed in the northeastern part of Jaipur and surrounding areas along with Proterozoic cover sequence of Delhi Supergroup within North Delhi Terrane. Limited information on mineral potentiality and nature of mineralization in basement complex is due to paucity of outcrops in this terrain. The present study with geological, geophysical and geochemical mapping followed by targeted drilling has resulted in identification of copper-gold mineralization in the partly covered areas of Dausa district of Rajasthan.

The boreholes drilled in the study area intersected sulphides at different drilled depth in the form of pyrite, pyrrhotite, and chalcopyrite as major sulphide phases whereas bornite, covellite, cubanite and sphalerite are present in minor concentration. At shallow level the primary sulphide association includes bornite-chalcopyrite whereas bornite-covellite-digenite occurs as secondary (supergene) type. The ore association at depth includes only primary ore minerals like chalcopyrite, cubanite and minor bornite and sphalerite. The chalcopyrite-cubanite solid solution is well preserved with blebs and laths of cubanite occurring within host chalcopyrite. At deeper level, chalcopyrite dominant association with minor pyrite and cubanite is present. The chalcopyrite-sphalerite with rare pyrite is another important assemblage. The sphalerite grains show mutual boundary with chalcopyrite in most cases and with pyrite in rare cases.

The textural study of ores shows presence of chalcopyrite with serrated margins and also occupy interstices of silicate grain boundaries whereas pyrite grains are often shattered with healing of cracks by pyrrhotite. At many places, sphalerite occurs as islands within the chalcopyrite host or is being embayed by chalcopyrite. Well-developed chalcopyrite disease has been observed in few sphalerite crystals occurring in association with large chalcopyrite. The mineral chemistry analysis of Cu-ore minerals shows presence of silver and bismuth suggesting hydrothermal activity as possible source of ore fluid generation.

The study of sulphide ores suggests a) the chalcopyrite-cubanite association formed due to probable intermediate composition of hydrothermal ore fluid at 350º-400°C and b) a metamorphism-induced partial melting of sulphide ores facilitates the formation of chalcopyrite disease by producing a Cu-enriched but S-deficient melt phase and Fe- and S-enriched sphalerite. Presence of broken pyrite and pyrrhotite crystals followed by development of chalcopyrite disease indicates towards metamorphism, culminating in sulphide partial melting as one of the mechanism of ore fluid formation.

The observations made in the present study indicates hydrothermal activity as plausible mechanisms for ore generation followed by later metamorphism induced partial melts, producing

chalcopyrite disease which often indicate towards presence of massive sulphide deposits. The discovery of Cu mineralization in a concealed basement complex in North Delhi Fold Belt has opened up a new horizon in context of mineral potentiality of northeastern part of Rajasthan.

Genesis of Gold mineralization in Sonakhan Greenstone Belt, Bastar Craton, India: constraints with fluid inclusion studies.

Sathyavani C[1]*, Geological Survey of India (sathyavani.c@gsi.gov.in)
Aneesh SS[2], Geological Survey of India
MM Korakoppa[3], Gelogiacal Survey of India

Abstract

The Neo-Archean Sonakhan Greenstone Belt (SGB) located in the north-eastern fringes of Bastar craton, Central India, is dominated by Basalts, Andesites, Dacites and Rhyolites association. Gold mineralization within Sonakhan schist belt has been studied in terms of its mode of occurrence, structural association, metamorphic setting, metal association, geochemistry of host rocks, nature and source of ore fluids, hydrothermal alteration and tectonic setting. Sulphide mineralisation is more abundant in metabasalt, Quartz-carbonate veins and BIF. Sulphide minerals are pyrrhotite pyrite, arsenopyrite, chalcopyrite with occasional sphalerite. Other associated mineral phases identified in the rocks are cobaltite, tellurobismuthite, lollingite, galena, REE and Pd-Bi-Teluride mineral phase. Gold grains identified within carbonate vein is associated with chalcopyrite and lollingite. PGE (Pd-Bi-Teluride) grain associated with pyrrhotite in metabasalt.

Fluid Inclusion studies of wafers of mineralised quartz and calcite veins indicate the presence of primary and secondary mono-phase/bi-phase aqueous and carbonic inclusions. The major component in aqueous phase is NaCl in the fluid system. The fluid inclusion studies show a low salinity NaCl±KCl±MgCl2 along with H2O fluid which is associated with mineralization in this area. The trends of inclusion plots indicate the Isothermal mixing, boiling and cooler less saline fluids. Homogenization temperature vs. salinity diagram for inclusions with fields for various fluid types shows the fluid source is metamorphic water indicated by the salinity ranging from 1.32 - 12.96 wt.% NaCl equivalents. The inclusions plotted mainly fall in Lode Au, epithermal and massive sulphide type of deposit indicating the field of dominant sulfide complexes which were responsible for carrying epithermal gold which precipitated along with silica in the veins. The two-phase fluid inclusions of L + V having homogenization temperatures from 175˚C to 321˚C (average homogenization temperature is 231.16°C) and salinities from 1.32 to 12.96 wt% NaCl equivalent (average salinity was 7.14 wt% NaCl equivalent). The Lack of gases like CH4, N2, H2, Ar, and H2S indicates the loss and release of such gases during boiling, which is one of the typical characteristics of epithermal mineralization. The intrusion of plutonic bodies together with presence of volcanic rocks like andesite, trachyandesite, basalt, and dacite have provided the conditions required for circulation of mineralizing fluids. The free flow of hydrothermal fluids with intermediate temperatures close to the surface have caused the occurrence of silica veins together with anhydite indicate hydrothermal origin of gold mineralization.

Combined Study of Gold-Bearing Arsenopyrite of Orogenic Gold Deposits: High Resolution 3D X-ray Computed Tomography, LA-ICP-MS and EMPA Analyses

Evgeny NAUMOV[1]*, Central Research Institute of Geological Prospecting for Base and Precious Metals (naumovevg@gmail.com)
Yuri Kalinin[2], Sobolev Institute of Geology and Mineralogy of Siberian Branch of Russian Academy of Sciences
Galina Palyanova[3], Sobolev Institute of Geology and Mineralogy of Siberian Branch of Russian Academy of Sciences
Lyudmila Kryuchkova[4], St. Petersburg state university
Viacheslav Voitenko[5], Geological Center of SPbSU
Vera Abramova[6], Institute of Geology of Ore Deposits, Petrography, Mineralogy and Geochemistry Russian Academy of sciences

Abstract

Using high resolution 3D X-ray Computed Tomography (HRXCT) and LA-ICP-MS and EMPA analyses the distribution and composition of gold in acicular arsenopyrite of a pyrite-arsenopyrite association from Suzdal (East Kazakhstan), Olympiada (Yenisei Ridge, Russia) and large pseudorhombic arsenopyrite crystals from Bazovskoe (Yakutia, Russia) orogenic-type deposits were investigated. HRXCT allow to reliably identify dense phases, such as inclusions of native gold in crystals of a mineral-concentrator (arsenopyrite, pyrite) without destroying the hosted mineral grains. But, HRXCT study is most effective when it is used together with other studies such as SEM, EMPA, LA-ICP-MS, etc. The combination of HRXCT with the traditional methods of the analysis made it possible to establish that the content of "invisible" gold in the acicular arsenopyrite of the orogenic deposits (Suzdal and Olympiada) vary within 195-1185 ppm. The gold content in arsenopyrite is quite reliably determined by various methods such as atomic absorption, EMPA and LA-ICP-MS. Three-dimensional HRXCT reconstruction revealed micro-inclusions of native gold in the central parts of the acicular crystals and aggregates of the arsenopyrite of Suzdal and Olympiada deposits, although previously researchers assumed the presence only of “invisible” gold in unspecified form in such acicular crystals.

The LA-ICP-MS study for arsenopyrite of the Olympiada deposit determined the contents of other impurity components (Co, Ni, Cu, Zn, Sb, Te, Ba, Pb) and established a uniform distribution of gold within the analyzed grains. Also, in some arsenopyrite grains, regular variations in Sb content were revealed. The distribution of antimony does not correlate with the distribution of other elements, and SEM studies did not show the presence of micro-inclusions of Sb-bearing minerals. This is possibly caused by the zonal structure of arsenopyrite grains.

According to HRXCT studies of gold distribution in large crystals of arsenopyrite from ores of the Bazovskoye deposit (Yakutia, Russia) it was found that gold shows selective crystallization not only within the aggregate of arsenopyrite crystals in the ore zone, but also among the crystallographic directions of a single arsenopyrite crystal.

After research performed, we can suggest that HRXCT technique permits:

1. To do preliminary estimation of the amount of gold inclusions in minerals or host rocks and draw reasonable conclusions about the gold content of the ores.
2. To study in detail the distribution patterns of metal inclusions (associated with certain minerals, cracks, crystal growth faces, etc.) and to evaluate the morphology of grains and veinlets without destroying the matrix.
3. Applying complex methodologies (HRXCT combined with quantitative analysis of gold content) to determine the form of the metal; to define which type of gold makes the greatest contribution to the economic productivity of mineralization - the inclusion of native gold or “invisible” gold in the form of nanoparticles or structural impurities.
4. HRXCT studies offer new opportunities for the development of efficient technologies for ore processing in order to maximize the extraction of the gold, silver and PGE minerals.

Jose Manuel Plastov[8], IGEO

Abstract

The National Geological Plan of Angola (PLANAGEO) has been one of the most significant african geothematic projects of recent decades. The Government of the Republic of Angola launched the project through Presidential Resolution 52/09. The project was implemented by the Geological Survey of Angola (IGEO) under the supervision of the Angolan Ministry of Mineral Resources, Petroleum and Gas (MIREMPET). The main objectives of PLANAGEO were to deepen the knowledge of Angola's geological resources, to foster the diversification of the national economy, and to attract foreign investment to promote the socio-economic development of the country. The PLANAGEO consortium, consisting of the Geological and Mining Institute of Spain (IGME), the National Laboratory of Energy and Geology of Portugal (LNEG), and the company Impulso Industrial Alternativo (IIA), was awarded to execute the project in southern Angola, covering an area of approximately 480,000 km2. The contract, worth USD 115,312,500, was signed in October 2013 following an international call for tenders by IGEO. The work was carried out between July 2014 and the end of 2022. The project involved a regional aerogeophysical survey (magnetic/radiometric) and geological mapping at a scale of 1:250,000, along with other detailed geological mapping at a scale of 1:100,000. Additionally, synthesis mapping was carried out at scales of 1:500,000 and 1:000,000. Geochemical prospecting campaigns were conducted at a scale of 1:250,000, and other specific studies were made at a scale of 1:50,000. These studies included Metallic Minerals Mapping (CRMMA) and Rock and Industrial Minerals Mapping (CARMINA) in areas of special interest, for investigation of the potential of metallic and non-metallic mineral resources; as well as hydrogeological studies in the Angola´s Kalahari basin very much needed to relieve the present drought in the basin where underground water reservoirs are poorly known.

Mineral chemistry of tourmaline associated with the Zawar Zn-Pb deposit, Rajasthan, India

ARKODEEP SENGUPTA[1]*, Department of Geology and Geophysics, Indian Institute of Technology Kharagpur (reach.arko.sg@gmail.com)
SOUMI CHATTOPADHAYA[2], Department of Geology, Banaras Hindu University
KUMARI MEENU SINGH[3], Department of Geology, Banaras Hindu University

Abstract

Tourmaline occurs in diverse types of hydrothermal mineral deposits and can be used to constrain the nature of ore-forming fluids as a reliable indicator of the mineralizing processes. It occurs as an accessory phase associated both with the mineralized vein and stratiform-banded type pyritic Zn-Pb ore. The tourmaline grains mostly occur within bands of phyllite intercalated with dolomite as dispersed subhedral to euhedral, rod-shaped isolated grains aligned sub-parallel to the foliation along with pyrite and sphalerite. The grains are typically 50 μm in size, with a few exceeding 250 μm. They are often fragmented but corrosion-free. It most probably represents a relict detrital and/or early-formed metamorphic mineral. The grains are commonly zoned with blue or dark-brown cores surrounded by a light-brown rim of varying thickness. The colour change from the core to the rim is generally gradational and occasionally involves sharp optical discontinuities. Electron microprobe analysis on the tourmaline grains reveals that those with diffuse optical zonation have an apparently homogenous compositional pattern. In contrast, those with a sharp contact display a core-to-rim compositional variation where Al, Na, K, and Ca increase as Fe, Mg, and Si typically decrease. The most prominent change from the core to the rim is an increase in the Al and a decrease in the Fe and Mg. Thus, Fe and Mg substitution for Al is most likely. Microprobe analysis of tourmalines reveals that the FeO and MgO contents vary between 3.3 to 6.6 wt% and 7.8 to 11.70 wt%, respectively. The average Fe/Fe+Mg ratio of 0.42 for the analyzed tourmalines indicates they can be considered intermediate between the dravite and schorl species. The points on the Fe/Fe+Mg vs Na/Na+Ca plot demarcating the fields of dravite, schorl, uvite and feruvite confirm the same. This is in conjunction with available chemical data, which suggest two major compositions for tourmaline associated with sedimentary and metamorphic terranes: one being uvite and the other being intermediate between schorl and dravite. Identifying the usual occurrence of tourmaline in association with the sulfide ore from the deposit suggests that tourmaline can be considered useful horizon markers for hydrothermal activity and a potential prospecting guide for geochemical exploration.

Abstract

The ultra-deep Cretaceous Bashijiqike Formation (K1bs) sandstone reservoir developed on the Kelasu thrust anticline is the main production layer (>6000m) in the Kuqa Depression, Tarim Basin. The development and preservation of primary pores play an important role in predicting reservoirs under ultra-deep burial conditions. Through thin section observation, cathodoluminescence, SEM, and physical property evolution, the development patterns and main controlling factors of primary pores in ultra-deep clastic rock reservoirs have been clarified. The primary pores of K1bs sandstone reservoir have the distribution characteristics of high in the south and low in the north, high in the extensional zone and low in the compressive zone of the anticline, and high in the middle of the sand body and low at the top and bottom. The original sedimentary components fundamentally control the physical properties of the reservoir. Sandstone reservoirs with better sorting, rounding, and large particle size have the highest initial porosity. The higher content of rigid particles protects the primary pores. The vertical compaction effect is the most important factor in reducing primary pores, with an average porosity reduction rate of 24.42%. Under the control of regional compressive stress, lateral compaction further reduces the primary pores average of 4.97%, and the lateral compaction effect is greater in the high stress area of the northern piedmont. In reservoirs within the same anticline, due to the different horizontal principal stresses intensities in the extensional and compressive zones, the distribution and reducing of primary pores are more complex. Cementation is another destructive factor for primary pores. In the same phase sequence, stronger cementation at the sandstone-shale boundary fills the primary pores in the reservoir. In the middle of the weakly cemented sand body, the primary pores are well preserved. Overall, sandstones with good sorting, large particle size, and more rigid particles have higher initial primary pores. Weak lateral compaction (far from the anticlinal extensional section of the piedmont) and weak cementation (in the middle of the sand body) control the development and distribution of high-quality primary pore type reservoirs.

Xianfeng LIU[4], School of Geosciences, Yangtze University
Qinghai XIU[5], School of Geosciences, Yangtze University

Abstract

The Yinchuan Graben is an important potential exploration area that is located on the western margin of the Ordos Basin. Over 8000 m of Cenozoic strata have been formed since the Cretaceous. With an integrated approach of cores observation, logging analysis, and geochemical analysis, we analyzed the characteristics of the Cenozoic source rocks in the Yinchuan Graben and determined the formation and destruction of the fossil oil reservoirs. With type III kerogen, the TOC of the dark mudstone in the Qingshuiying Formation is up to 7.5%, and the Ro is 0.95~1.04%, indicating the source rocks have entered the mature stage but the hydrocarbon generation potential is insufficient. A quantity of reservoir bitumen and oil-bearing fluid inclusions (GOI=1.67~4%) were found in the Qingshuiying Formation sandstone in Well YQ-1, which indicates a fossil oil reservoir had existed. The fossil oil reservoir and reservoir bitumen were generated by the unexplored pre-Cenozoic strata under the Qingshuiying Formation in the Yinchuan Graben. The reservoir bitumen has high maturity and is associated with many fluid inclusions with a high homogenization temperature or CO2. This indicates that the bitumen was formed by the pyrolysis of the oil which was caused by the hot fluid migrating along with the deep fault belts.

Cross-layer propagation of natural fractures in finely laminated shale

huawei LI[1]*, China University of Petroleum (East China) (lhwvinsmokes@163.com)
qingfeng Meng[2], China University of Petroleum (East China)

Abstract

We conducted quantitative characterization, scanning electron microscopy and geochemical analyses of shale samples from the fractured intervals of the Eocene Shahejie Formations from the Dongying Depression, Bohai Bay Basin, China. The aim is to investigate the cross-layer propagation mechanism of natural fractures in finely laminated shale and elucidate the controlling factors. We found that high angle fractures exhibit different features in argillaceous laminae from calcite laminae. The fractures are largely arranged as a network in argillaceous laminae. The average thickness of argillaceous laminae is 0.18 mm with the average fracture density of 0.96 fractures/mm and an average aperture of 0.1 mm. The fractures in the calcite lamina are mainly vertical. The average thickness of calcite laminae is 0.1 mm with the average fracture density of 1.22 fractures/mm and an average aperture of 0.22 mm. High-angle fractures are highly affected by laminae and characterized by strata-bound development in the strata. The fractures mostly terminate at or near such interfaces. The high-angle fractures in the adjacent calcite laminae are connected by shear fractures developed in the mudstone laminae to form a highly-interconnected fracture network. Our study provides a general model for cross-layer fracture propagation and linkage in finely-laminated shale and carbonate, and yields important implications for fluid flow in low-permeability shale systems.

Fluid migration through an intensively overpressured diapir in the Yinggehai Basin, South China Sea

zhifeng GUO[1]*, China University of Petroleum (East China) (s22010056@s.upc.edu.cn)
qingfeng MENG[2], China University of Petroleum (East China)

Abstract

Multiple mud diapirs have been identified in the Yinggehai Basin, where intensive overpressure is widespread. Here, we present a representative example of the diapirs, namely the DF29-1 diapir, to demonstrate the fluid migration pathways through typical mud diapirs by using integrating analysis of seismic reflection and fault likelihood attribute. We also investigated fluid overpressure mechanisms by logging and MDT data. The diapir is characterized a seismic blank zone beneath a crestal graben developed in the overburden strata. We found that the position of the crestal graben is in the Two-Way Travel Time 280 to 1960ms (Quaternary to Early Pliocene) and is in a hydrostatic pressure environment. The position of the diapir and fractures are in the Two-Way Travel Time 1950 to at least 6000 ms (Early Pliocene to Late Miocene) and are in an overpressure pressure environment. The genetic mechanism chart of overpressure strata shows that the overpressure mechanism are mainly disequilibrium compaction and external fluid injection. While the range of C1 / ∑ C1 ~ 5 of natural gas in the shallow strata is 0.879 - 1, and the range of δ13C1 is -29.09 - -48.69 ‰. Most of them are high maturity coal-formed gas formed in deep strata. So we conclude that the vertical migration path of fluid in the diapir area of the Yinggehai Basin is diapir and its associated fractures and faults. Our results provide important implications for vertical fluid migration pathways in deep overpressure environment.

Miao Laicheng[5], Institute of Geology and Geophysics, Chinese Academy of Science

Abstract

Located in North Mongolia, the Erdenetiin Ovoo porphyry copper-molybdenum ore field was discovered in the early 1960*th. The ore field comprises* 4 *deposits, from NW to SE namely Northwest, Central, Intermediate, and Oyut. These deposits are distributed along the NW-striking faults and extend about* 12 *km. The Northwest deposit has been exploited since* 1976 *and presently reaches to a depth of* 440 *m beneath the surface, and the Central deposit was started to mine in* 2014*. No activity for the Intermediate deposit at the moment, while detailed exploration work for the Oyut, the southern end of the ore field started in* 2023*. These deposits are hosted in the Triassic Erdenet porphyry complex, which is composed mainly of granodiorite porphyry intruding into the middle Permian – early Triassic Selenge intrusive complex of diorite and granodiorite. These intrusive rocks show geochemical features of LILE enrichment and HFSE depletion, consistent with those of I-type, calc-alkaline, and subduction-related arc igneous rocks. SHRIMP and LA-ICPMS zircon U-Pb dating suggest that the Erdenet porphyry complex was formed at* 235-248 *Ma and* 243-265 *Ma for the Selenge intrusive complex* (*Munkhtsengel*, 2007; *Munkhtsengel et al*., 2018, *Munkhtsengel et al*., 2020). *Among the deposits, only the Northwest one is well-studied in terms of geology, mineralization, and geochronology, with a molybdenite Re-Os age of* ~240 *Ma having been reported* (*Watanabe and Stein*, 2000). *In this paper we present the new Re-Os molybdenite ages for the Central, Intermediate, and Oyut deposits. Two molybdenite samples of the Central deposit yielded Re-Os ages of* 233.1±3.5 *Ma and* 233.9±3.5 *Ma, respectively. The Intermediate deposit gives a molybdenite Re-Os age of* 222.9±5.3 *Ma, and the Oyut deposit has an age of* 228.9±3.7 *Ma. These age data indicate a southeastward younger tendency for the Cu-Mo mineralization in the ore field. The mineralization period somehow correlates with the span of magmatic activity of the Erdenet Porphyry complex.*

Element Distribution and REE Dispersal in Sandstone-Hosted Copper Mineralization within Oligo-Miocene Strata, NE Iran: Insights from Lithostratigraphy and Mineralogy

MOSTAFA FEIZ[1]*, Geological Survey of Iran (mostafa_feiz1979@yahoo.com)

Abstract

The lithostratigraphy and mineralogy of the Oligo-Miocene strata in NE Iran warrant particular interest due to the presence of sandstone-hosted copper mineralization. Comprehending the element distribution and mass change within these strata is vital for evaluating the potential for economic mineral deposits. Moreover, the dispersal of rare earth elements (REE) within the mineralization can offer valuable insights into the geological processes influencing these deposit formations. Our objective is to scrutinize the lithostratigraphy, mineralogy, and element distribution in the sandstone-hosted copper mineralization in the Nasar-Chalpo-Sangerd area of NE Iran. Our findings aim to enhance understanding of the geological processes shaping the mineralization in this region.

The Chelpo copper deposit is situated in northeastern Iran, within the structural zone of central Iran and the Sabzevar back-arc basin. The Oligo-Miocene sedimentary strata, which we refer to as the Nasr-Kadkan-Sangerd (NKS) basin, host this copper mineralization. This basin comprises red bed strata, such as red marl, red siltstone, and interbedded sandstone layers. These layers are primarily deposited on the Upper Cretaceous ophiolitic rocks and the intermediate to mafic-post ophiolitic volcanic rocks, forming a nonconformity. The mineralized sandstone layers contain leached zones (5 to 8 meters thick) and mineralized zones with a thickness of 0.5 to 0.7 meters. The ore minerals include sulfide minerals, such as chalcocite, chalcopyrite, and pyrite, as well as secondary minerals (covellite, digenite, malachite, and azurite) that formed during the supergene stage. The primary factors controlling the mineralization in the sandstone layers are the permeability of the sandstone, the presence of fault zones acting as conduits for copper-bearing solutions, and the significant amounts of plant fossils, which create a reducing environment for deposition. Statistical studies on copper layers indicate that Ag, Cd, Mo, and S have the maximum positive correlation with Cu, whereas TiO2, Fe2O3, Al2O3, Sc, Tm, Sn, and the REMs exhibit a negative correlation. Mass change calculations on copper-bearing layers and primary sandstone layers reveal that Pb, As, Cd, Te, and Mo are enriched in the mineralized zones, whereas SiO2, TiO2, Fe2O3, V, Sr, and Ba are depleted. Copper and silver deposited in the sandstone layers may encounter reducing conditions due to abundant organic matter. The sandstone layers bearing copper have been depleted of Fe2O3, TiO2, SiO2, and REEs through leaching processes. The results indicate that during the main mineralization stage, LREEs and MREEs were depleted, but Cu, Ag, and S were enriched.

Relationship between vegetation canopy and selected ore bodies of Iran

Shahindokht ABOLMAALI[1]*, geological Survey of Iran employee (abolmaali50@yahoo.com)
Kambiz RANA[2], geological Survey of Iran employee

Abstract

Shahin Dokht ABOLMAALI
Faculty of Science, University of Tehran (abolmaali50@yahoo.com)

The scope of this study is to discover the concentration of selected elements (As, Ag, Au, Ba, Cr, Cu, Fe, Hg, K, Mn, Mo, Sb and Pb-Zn) in vegetation canopy of Iran. Three data layers including mines and ore indications, High potential areas of above elements and vegetation canopy provided by Forests, Range and Watershed Management Organization (FRWO) are used. Vegetation canopy is divided into 75 genera and their dispersion and areas were determined. The related canopies were introduced by intersecting and buffering vegetation canopy layer with mines and ore indication layer and high potential layer in GIS environment with following results. Artemisia Sieberi and Artemisia Aucheri for As, Astragalus sp. and Artemisia Sieberi for Ag, Astragalus Microcephalus, AstragalusGossypinus, Astragalus Eirosphaerus, Astragalus Yueksekovae and Artemisia Sieberi for Au, Artemisia Sieberi and Astragalus spp. for Ba, Artemisia Aucheri, Artemisia Sieberi and Astragalus spp. for Cr, Artemisia Aucheri, Artemisia Sieberi and Artemisia Lehmanniana for Cu, Artemisia Sieberi Juniperus Excelsa and Juniperus Polycarpus for Fe, Astragalus Microcephalus, Astragalus Carduchorum, Astragalus Eriophaerus, Astragalus Persicus and Austragalus Yueksekovae for Hg. Artemisia Sieberi, Hammada Salicornica, Salsola Tomentosa, Seidlitzia Rosmarinus, Suaeda Fruticosa and Tamarix Kotschi for K, Juniperus Excelsa and Artemisia Sieberi for Mn, Artemisia Sieberi and Artemisia Aucheri for Mo, Artemisia Sieberi, Artemisia Aucheri, Juniperus Excelsa, Juniperus Polycarpus and Astragalus Gossypinus for Pb-Zn and Artemisia Lehmanniana for Sb.

Abstract

Detecting heat treatment of sapphire has been a challenging issue for several decades. High-resolution optical microscopy, optical absorption (UV-VIS-NIR) spectroscopy, Fourier-transform infrared (FTIR) spectroscopy, Raman spectroscopy, and photoluminescence (PL) spectroscopy and imaging were applied in testing natural unheated sapphire before and after heat treatment. Three groups of sapphire (high-density-silk, low-density-silk, and silk-free) were investigated. Most unheated sapphire specimens (except the high-density-silk group) showed orange to red luminescence under long-wave ultraviolet (LWUV) light, whereas under short-wave ultraviolet (SWUV) light, all specimens appeared inert. After heating at 1,650 °C for 10 hours under atmospheric conditions using an electric furnace, most of the sapphire specimens (except the high-density-silk group) showed strong purplish red luminescence under LWUV as well as blue luminescence under SWUV illumination. UV-excited PL indicated a link between the broad emission spectrum of the orange to red region and the orange to red luminescence presented in unheated sapphire under LWUV, as well as a link between the emission band of the green region and the blue luminescence of heated sapphire under SWUV illumination. Consequently, occurrences of the orange to red emission band center around 630-650 nm and orange to red luminescence under LWUV that appeared in unheated sapphire specimens may serve as novel evidence of unheated sapphire, whereas the occurrence of the green emission band at the center around 525 nm and blue luminescence under SWUV that appeared in heated sapphire specimens

may serve as crucial evidence of sapphire that has undergone heat treatment. It is worth mentioning that the luminescence of purplish red under LWUV observed in heated sapphire specimens (except the high-density-silk group) could potentially function as an alternative means of detecting heated sapphire. It is noteworthy that sapphire belonging to the high-density-silk group appeared inert under LWUV and SWUV illumination, both before and after heating. This may be attributed to the abundant presence of ferrous Fe (a luminescence quencher) derived from ilmenite. However, a more detailed investigation is recommended for the exact cause of such mechanism. In addition, fluid inclusions within dissolved silks may indicate high-temperature heat treatment of sapphire. It is also suggested here that applying Fourier-transform infrared (FTIR) spectroscopy alone is inadequate for distinguishing heated and unheated sapphire. Consequently, utilizing orange to red and blue luminescence, both prior to and after heat treatment, together with fluid inclusions, presents a novel and practical method for accurately distinguishing unheated sapphire and heated sapphire.

ANCIENT NEPHRITE QUARRY NEWLY DISCOVERED: CHARACTERIZATION OF NEPHRITE FROM SANWEI MOUNTAIN, GANSU PROVINCE, WESTERN CHINA

YUE SU[1]*, China university of Geosciences (gemlabmem@163.com)
Mingxing Yang[2], China University of Geosciences

Abstract

The newly discovered nephrite deposit in Sanwei Mountain, Dunhuang City, Gansu province, China, is an ancient jade quarry dating back to the Xichengyi Culture to the Qijia Culture, approximately 4000 years ago. It is recognized as the earliest archaeological jade mining site in China and holds significant archaeological and gemological value. However, there is limited information available on the gemological properties of nephrite from Sanwei Mountain. This paper provides a detailed investigation into the gemological, photomicrographic, spectral, and chemical composition features, as well as hydrogen and oxygen isotopic characteristics, and methods for distinguishing it from other major nephrite sources. The nephrite from Sanwei Mountain exhibits various colors, including white, green-white, yellow-white, green, and brown. Chemical composition analysis classified all the nephrites as dolomite-related (D-type) nephrites. Furthermore, the common secondary alteration of nephrite materials in Sanwei Mountain constitutes a distinctive feature of this deposit. Additionally, to differentiate the Sanwei Mountain nephrite from other deposits and establish a basis for tracing ancient jade artifacts, we used chemical composition and linear discriminant analysis (LDA) to construct the origin determination model. Hydrogen and oxygen isotope measurements were also performed and compared with data from other nephrite deposits. The results demonstrate that trace elements and H, O isotopes effectively distinguish Sanwei Mountain nephrite from other high-quality deposits.

Ageing Characterization and Origin Traceability of archaeological amber artifacts via FTIR spectroscopy and Pyrolysis-gas chromatography/mass spectrometry (Py-GC/MS)

Yan LI[1]*, China University of Geosciences, Wuhan (yanli@cug.edu.cn)
Jiarong Li[2], China University of Geosciences, Wuhan
Qi Liu[3], Hunan Key Laboratory of Archaeometry and Conservation Science, Hunan Museum

Abstract

Amber (fossil resin) is a complex biogenic polymer originated from ancient plant resin buried underground through many various geological periods and fossilized over tens of millions of years of geological process[1]. The archaeological amber artifacts unearthed from different time periods in China offer significant historical insights into the international trade networks and cultural interactions among ancient civilizations[2]. This research investigated three archaeological amber artifacts (labelled as Arc 1-3) provided by the collection of the Hunan Museum originating from different historical periods in China. The objective of this study aims to demonstrate the aging characteristics of the artifacts and determine their provenance.

The examination of the aging characteristics of the cross-section and weathered surface was carried out using scanning electron microscopy (SEM). Fourier Transform Infrared (FTIR) spectroscopy and Pyrolysis-gas chromatography/mass spectrometry (Py-GC/MS) were utilized to investigate the functional group and chemical composition of amber artifacts. SEM analysis conducted on historical amber has revealed a clear differentiation among different degrees of aging. As the aging process, there were changes in the chemical composition and degradation in the physical properties, manifested as a distinct boundary between the aging and core layers, as well as the presence of deeper cracks. The occurrence of these features indicates that FTIR was ineffective for determining provenance. The results obtained through Py-GC/MS analysis indicate that three amber artifacts were from Baltic amber. Additionally, a set of compounds obtained from Py-GC/MS analysis could act as biomarkers for the identification of Baltic amber. The findings of this study demonstrate that Py-GC/MS was an accurate and effective method to confirm the origin of severely degraded amber artifacts. Additionally, it provided a reference to evaluate the extent of deterioration in archaeological amber collections. Identification of the archaeological amber also provides clues to the trade routes and cultural exchanges on Silk Road during ancient time.

Chemical Composition and origin of color in Black and Black Cyan Nephrite from Margou Deposit, Qiemo county, Xinjiang, China

Ting FANG[1]*, China University of Geosciences(Wuhan) (funtyfang@163.com)
Mingxing Yang[2], China University of Geosciences(Wuhan)

Abstract

The nephrite belt in the Altun Mountain–Western Kunlun Mountain region, spanning approximately 1300 km in Xinjiang, NW China, constitutes the world's largest pre-eminent nephrite deposit. The Qiemo region in the Altun Mountains is a crucial nephrite-producing area in China, with demonstrated substantial prospects for future exploration. While existing research has extensively investigated secondary deposits in the Karakash River and native black nephrite deposits in Guangxi Dahua, a comprehensive investigation of black nephrite from original deposits in Xinjiang is lacking. Margou nephrite has been found in recently discovered black-toned nephrite deposits in Qiemo County, Xinjiang, warranting comprehensive investigation of this primary source of black nephrite within the region. For this scholarly inquiry, a suite of sophisticated analytical methods were employed, including the use of a polarizing microscope, an electric microprobe, back-scattered electron image analysis, X-ray fluorescence, and inductively coupled plasma mass spectrometry. A rigorous experimental test was conducted to elucidate the chemical and mineralogical composition, further clarifying the genetic types of the black and black cyan nephrite from Margou deposit in Qiemo, Xinjiang. The results reveal that the nephrite is mainly composed of tremolite–actinolite, characterized by Mg/(Mg + Fe2+) ratios ranging from 0.86 to 1.0. Minor minerals include diopside, epidote, pargasite, apatite, zircon, pyrite, and iron hydroxide. Bulk-rock rare earth element patterns exhibit distinctive features, such as negative Eu anomalies (δEu = 0.00–0.17), decreasing light rare earth elements, a relatively flat distribution of heavy rare earth elements, and low total REE concentrations (1.6–38.9 μg/g); furthermore, the Cr (6–21 μg/g) and Ni (2.5–4.5 μg/g) contents are found to be conspicuously low. The magmatic influence of granite emerges as a pivotal factor in the genesis of magnesia skarn hosting the Margou nephrite. The distinctive black and black cyan colors are attributed to heightened iron content, mainly associated with FeO (0.08~6.29 wt.%). The discerned chemical composition characteristics place the Margou nephrite as an exemplary magnesia skarn-type nephrite deposit.

The Structure of Natural Opal-A: An Insight through Synchrotron X-ray Diffraction and Pair Distribution Function Analysis

Seungyeol LEE[1]*, Chungbuk National University (slee2@cbnu.ac.kr)
Huifang Xu[2], Department of Geoscience, University of Wisconsin–Madison
Hongwu Xu[3], School of Molecular Sciences and Center for Materials of the Universe, Arizona State University

Abstract

Opals, historically valued for their unique optical properties and extensive use in jewelry and decorative arts, are classified gemologically into precious, common, and hyalite types based on their color play due to light diffraction. From a mineralogical perspective, opals are categorized into opal-A, opal-CT, and opal-C, according to their X-ray diffraction (XRD) patterns, with 'C' and 'T' representing cristobalite and tridymite, respectively. The structural comprehension of opals is challenging due to the broad and weak peaks in their XRD patterns, suggesting short- and medium-range ordered structures. This research aims to clarify the structure of naturally occurring opal-A using synchrotron X-ray pair distribution function (PDF) analysis, synchrotron XRD, and transmission electron microscopy (TEM). Opal-AN primarily consists of various sizes of nanospheres (<5 nm) forming banded features, while opal-AG exhibits closely packed silica nanospheres about 400 nm in diameter. XRD patterns of both samples reveal one significant peak at approximately 4.0 Å, along with broad peaks at around 2.0, 1.45, and 1.2 Å. PDF patterns of opal-AN and opal-AG show short-range atomic pairs (<15 Å). Our PDF analyses suggest that the opal-A structure can be primarily described as disordered inter-growths of cristobalite- and tridymite-like domains composed of 6-membered rings of [SiO4] tetrahedra, aligning with the previously reported cristobalite/tridymite stacking (interstratification) model. Additionally, our synchrotron X-ray PDF analysis indicates the presence of 4-membered [SiO4] rings in the opal-A structure. The existence of four-membered silica rings in the opal-A structure is attributed to twinning, stacking faults, and interface boundaries of six-membered rings. Trace elements such as K, Na, Al, and Ca can be incorporated into the four-membered silica rings, similar to the feldspar framework, in opal. Indeed, to gain a deeper understanding of the natural structure of opals, it's crucial to conduct additional research on other opal structures, such as opal-CT and opal-C, using a combined XRD/PDF method. For instance, in sedimentary cherts like the Monterey formation, the silica in the sediment undergoes a steady transformation from opal-A (diatomaceous clay) to opal-CT, and finally to chert during the process of diagenesis. This combined methodology can offer in-depth structural data about the phase transformation of opal, which can have significant implications for its stability in geological settings.

Unusual Synthetic Overgrowth on Natural Rose-Quartz Crystal Aggregate

Thanapong LHUAAMPORN[1]*, The Gem and Jewelry Institute of Thailand (Public Organization)
(lthanapong@git.or.th)
Waratchanok Suwanmanee[2], The Gem and Jewelry Institute of Thailand (Public Organization)
Bhuwadol Wanthanachaisaeng[3], The Gem and Jewelry Institute of Thailand (Public Organization)

Abstract

Rose quartz is a pink-colored variety of quartz mineral (SiO2) and commonly used as a trade name in gem market. Because of its charmingly pink color, rose quartz usually conveys an impression of love and has become one of popular gemstones until now. The GIT Gem and Precious Metal Testing Laboratory received an aggregate (108.2 x 71.9 x 44.0 mm,) of pink-colored crystals for identification in November 2023. Initial observations of the uncut specimen revealed typical large-quartz crystals exhibiting a short six-sided prism with pyramid-like rhombohedral faces at each end. We also noticed color zoning, a distinct boundary between the colorless overgrowth containing breadcrumb-like inclusions and natural pink crystal cores.

Further investigation involved isolating the upper parts of crystals from the rose quartz aggregate and then slab-cut into several pieces. These representatives, colorless overgrowth, and inner pink core, were used for determining their properties and characteristics by employing both basic and advanced gem instruments.

The standard analyses of the polished slabs revealed the following basic gem properties: double refraction. uniaxial positive with RI of 1.552–1.543 (birefringence 0.009), inert to long and short-wave UV radiation, and SG of 2.65, corresponding quite well with those of quartz. Again, the slabs displayed a sharp contact boundary between the natural pink-colored seed crystal at the inner core, and colorless overgrowth zone at the outer rim. The contact boundary is better visible when using immersion with diffused light. Microscopic observation of the synthetic overgrowth zone revealed the following internal features; irregular two-phase inclusions, fluid leaf-like inclusions, breadcrumb-like inclusions and heal fissures, whereas the natural, pink-colored core showed only healed fractures. The true nature of natural pink core was confirmed by the presence of a ~3595 cm-1 peak on the FTIR spectra, while the synthetic overgrowth was also reaffirmed by the existence of a prominent band at ~3585 cm-1 and, especially, a small band at ~3543 cm-1. Overall, this study identified the sample as an aggregate of natural (pink-colored) rose quartz crystals with synthetic colorless overgrowth, highlighting the importance of comprehensive gemological analyses in distinguishing the natural and synthetic materials.

Fast identification of imitation pearls against cultured pearls using hyper near-infrared spectroscopy

JINHEE LEE[1]*, HANYANG UNIVERSITY (lindapark8464@gmail.com)
Jin hee Lee [2], Hanyang University
Sanghoon CHO[3], Hanyang University
Hoeil Chung[4], Hanyang University

Abstract

Pearls are one of the gemstones that have been loved by everyone for a long time. Cultured pearls are produced by the secretions of shellfish that leading to form a thin film of artificial nuclei in the body and layers. Aragonite (CaCO3) and conchiolin (protein) form a layer outside the nucleus, and are being stacked during the growth. Materials adopted to make imitation pearls are typically including glass, plastic, and mollusc shells. Meanwhile, plastic beads coated with a pearlescent substance to imitate the natural iridescence of nacre or mother of pearl are rather popular in actual markets. Visual discrimination of imitation pearls against cultured pearls is somewhat feasible due to their differed colors and shapes; however, a method able to provide more objective compositional information of a pearl and analyze a large number of pearls in a short period is practically beneficial. For this purpose, hyper near-infrared (Hyper-NIR) spectroscopy enabling the fast mapping of many pearls was adopted, and the discrimination of imitation pearls against fresh/sea water cultured pearls was attempted. Initially, the NIR spectral features of samples were comparatively analyzed according to the types of pearls and discrimination accuracy was finally assessed using diverse chemometric discriminant methods.

Unusual mixed characteristics of sapphires from magmatic deposits in Muling, Northeast China

Yimiao Liu[1]*, China University of Geosciences (Wuhan) (yim2015@163.com)
Ren Lu[2], China University of Geosciences (Wuhan)

Abstract

Muling area in the Heilongjiang province of northeastern China produces sapphires with a full range of hues and saturations. The gem quality of these materials rivals those of world-class sapphires commonly found only in marble-hosted environments. Muling corundum deposits lie in the intraplate basaltic fields of the West Pacific continental margins (Graham et al., 2008), from where classic magmatic sapphire deposits emerged. However, Muling sapphires show unusual mixed characteristics typical of both alkali basalt- and marble-hosted sapphires. Internal features, spectral analyses, and geochemical data provide evidence that the true origin of Muling sapphire is consistent with a mixture of geological formation environments. Inclusion characteristics suggest that Muling pink and light blue sapphires may have crystallized from a silicon-rich environment while part of deep blue sapphires showed a closer relationship with alkali basaltic origin. Spectral analysis further reveals the diverse formation environment among deep blue sapphires. These mixed characteristics are further evidenced in the FeO-Cr2O3-MgO-V2O3 vs. FeO+TiO2+Ga2O3 chemical classification diagram (Giuliani et al., 2015). Combined with the specific geological background, it can be found that alkali basalt may act as a "carrier" in the formation of Muling sapphire as well as an integrated participant in the formation of these gem corundum to some extent. These findings certainly enriched our knowledge of basalt-related gem corundum with various gemological and geological characteristics.

Beyond Jewelry: The Quantum Realm of Diamonds

Hyunmin CHOI[1]*, Hanmi Gemological Institute & Laboratory (hmcgem@hanmail.net)
Youngchool KIM[2], Hanmi Gemological Institute & Laboratory
Jaeeun KIM[3], Hanmi Gemological Institute & Laboratory

Jeongwon SEOK[5], Dongshin University

Abstract

Known for their exceptional physical properties and beautiful gemstones, diamonds have a wide range of applications in existing industries. Diamonds have a variety of defects that are responsible for their color. NV defects give diamonds their pink color and also give diamonds their quantum properties.

There is current research to use diamonds with NV centers for applications in technologies such as quantum sensing and quantum computing.

The use of NV diamond centers in quantum sensing demonstrates a significant sensitivity to tiny magnetic fields, which shows significant potential. This sensitivity has the potential to bring innovation to medical diagnostics, navigation systems, and precise defect detection in battery manufacturing. At the same time, the stable quantum state maintained by NV diamond centers positions them as ideal candidates for quantum computing.

High purity single crystal diamonds are essential for quantum research using NV centers. There are two main methods of artificially producing diamonds: Chemical Vapor Deposition (CVD) and High Pressure-High Temperature (HPHT).

Initially, synthetic diamonds grown by the HPHT method were used in quantum research. However, this method is now rarely used in quantum research due to challenges in controlling impurity concentrations (NV defects) and a lack of cost competitiveness.

While the CVD method has the disadvantage of slow diamond growth, it has the advantage of producing large areas of high-purity diamond. In addition, the 13C isotope concentration can be controlled and NV centers can be generated during the diamond growth phase, making CVD grown diamonds the most widely used for quantum research today.

The future of diamond quantum technology cannot be defined with precision, but advances in quantum sensing and computing are expected to impact fields as diverse as healthcare, energy and computing. This study looks at quantum technology research using diamonds beyond their beauty as jewelry.

The Special Color Effect in “Chameleon” Amber and its main Fluorescence Component

Yan LI[1]*, China University of Geosciences, Wuhan (yanli@cug.edu.cn)
shiyi li[2], China University of Geosciences,Wuhan
Guanghai Shi[3], China University of Geosciences, Beijing

Abstract

One special variety of Burmese amber is “chameleon” amber, named for the bluish green color that appears to float on its surface. This material is found in the famous Tengchong market in Yunnan Province, China’s largest Burmese amber market. Its bodycolor ranges from golden brown to brownish red or even red. When exposed to sunlight or strong white light against a black background, its surface shows a uniform green color. Chameleon amber is rare and expensive compared to regular Burmese golden or brownish amber, especially with the severe reduction of exports from Myanmar.

This research presents the gemological properties, spectral characteristics and organic components of Burmese 'chameleon' amber. The samples were then examined with 3D fluorescence spectroscopy under the excitation of a continuous-wavelength excitation light source. The three-dimensional (3D) fluorescence spectral showed that Burmese 'chameleon' amber had fluorescence centres near 433,465 and 470 nm, and the excitation wavelengths of the fluorescence centres of Burmese 'chameleon' amber were shifted from the ultraviolet region (380 ± 10 nm) to the visible region (410 ± 10 nm), with the emission wavelengths concentrated in the bluish-green region. Through the colour simulation and superimposition, the phenomenon of floating bluish green fluorescence colour of Burmese 'chameleon' amber is not only derived from bluish-green fluorescence centres, but also enhanced by the mixture of surface fluorescence and its bodycolour. Headspace solid-phase microextraction gas chromatography-mass spectrometry (HS-SPME-GC-MS) analysis demonstrated the variety of aromatic compounds in Burmese 'chameleon' amber was related to geological process and the presence of fluorescent components. The High-performance liquid chromatography-fluorescence detector obtained some fluorescent aromatics, particularly benzo[a]anthracene with yellowish-green fluorescence, which is responsible for the fluorescence characteristics of Burmese 'chameleon' amber.

Observation of characteristics of synthetic diamonds in ultraviolet illuminating

EUNOK JO[1]*, Seoul Jewelry Industry Support Center (jo@sjc.or.kr)
KYUNGJU NAM[2], Seoul Jewelry Industry Support Center

Abstract

The Korean jewelry market is witnessing a rapid increase in the distribution of synthetic diamonds known as "lab-grown diamonds." In the early days of synthetic diamond distribution in Korea, CVD synthetic diamonds were the majority, but recently, the proportion of imported HPHT synthetic diamonds has more increased. Diamonds exhibit fluorescence and phosphorescence in response to high-energy short-wave ultraviolet light. This is one of the visible characteristics of diamonds, and natural diamonds are generally reported to exhibit blue fluorescence and poor phosphorescence. Synthetic diamonds, on the other hand, exhibit distinctive fluorescence, phosphorescence, and growth patterns that are not found in natural one, depending on the synthesis method and growth conditions. Therefore, the observation of fluorescence, phosphorescence and growth patterns is a very useful method for the identification of synthetic diamonds.

This study collects images of different fluorescence, phosphorescence and growth patterns of synthetic diamonds to discuss about their characteristics. The samples analyzed in this study are Type II natural and synthetic diamonds, which contained no nitrogen. Spectroscopic characteristics of diamonds were identified by FT-IR. The fluorescence, phosphorescence, and growth patterns were observed using a fluorescence imaging device based on a 255 nm shortwave ultraviolet source. Experimental results, the HPHT synthetic diamonds exhibited a mixture of Type IIa and IIb characteristics by infrared spectroscopy due to the boron content. In addition, since natural diamonds crystallize as octahedrons, while HPHT synthetic diamonds grow as cubo-octahedral with a mixture of cubic and octahedral forms, this structure is partially observed in the fluorescence images, mostly showing strong fluorescence and phosphorescence. In the case of CVD synthesis, it can be seen that somewhat less consistent of characteristics when compared to HPHT synthesized diamonds. Since CVD synthesis is grown by depositing carbon seeds onto a diamond substrate, it is characterized by striped or concentric growth lines, irregular fluorescence in color and intensity and often absent phosphorescence.

Wiwat Wongkokua[5], Department of Physics, Faculty of Sciece, Kasetsart University

Abstract

The blue color in sapphire is caused by Fe3+ and Ti4+ impurities replacing two adjacent Al3+ in the Al2O3 structure. Based on experimental results, Fe2+ has never been measured by any method. Hence, the intervalence charge transfer theory between Fe2+ and Ti4+ has been proposed to be replaced by the Fe3+ and Ti4+ mixed acceptor states. For over two decades, beryllium-assisted heat treatment has been introduced not only to produce padparadscha, yellow and orange sapphires but also blue sapphires. In this work, we investigate the roles of beryllium atoms in the corundum structure responsible for the blue color of blue sapphire. The chemistry and spectroscopic properties of the light blue samples were collected using EDXRF, LIBS, polychromatic UV-Vis-NIR, monochromatic UV-Vis-NIR, and XAS techniques. The samples were Be-heat treated to yellow with ground BeO mixing in an alumina crucible introduced into an electric furnace then heating up to 1715 °C under an oxidizing atmosphere for 80 h. The yellow beryllium-treated sapphires were later heated under reducing atmospheric conditions at 1680 °C for 10 h and analyzed. The results show that the samples turned blue, although beryllium is still detected. The oxidation state of iron (Fe) is Fe3+ as determined by XANES for both before and after the treatments. The absorption bands of Fe3+/Ti4+ pairs in monochromatic UV-Vis-NIR spectra appear after the latter heat treatment, corresponding to the blue color caused by Fe3+/Ti4+ mixed acceptor states, as observed in natural blue sapphires. Conversely, the Fe3+/Be2+ mixed donor states detected at 425 nm in polychromatic UV-Vis-NIR spectra continue to be present after the reducing heat treatment. As a result, the polychromatic UV-Vis-NIR spectroscopic technique could be used to differentiate between the natural and beryllium-treated blue sapphires. An energy band model is discussed to explain the color mechanism.

Abstract

Wiwat Wongkokua1, Natthapong Monarumit2, Thanapong Lhuaamporn3, Phongsakorn Kajornboonsook1, Pornsawat Wathanakul2
1Gem & Mineral Sciences Special Research Unit, 1Department of Physics and 2Department of Earth Sciences and, Faculty of Science, Kasetsart University, Bangkok 10900, Thailand; 3The Gem and Jewelry Institute of Thailand

Causes of coloration in gem corundum varieties have been reported and followed by gem scientists since several decades by using different concepts; Red color in ruby caused by Cr3+ based on the crystal field; Yellow by absorptions of Fe3+ and Fe3+ pairs, as well as color center; The blue by Fe2+-Ti4+ intervalence charge transfer (IVCT); Green by Fe2+ or the yellow mixed with the blue. The UV-Vis-NIR absorptions have been mainly used for those explanations.
The in-depth research on gem corundum samples of different varieties has been conducted using quantitative analyses (LA-ICP-MS, EDXRF), spectroscopic methods (poly- and monochromatic UV-Vis-NIR, FTIR), synchrotron techniques (XANES, EXAFS) for the trace element oxidation states as well as their environments. Cr(III), Fe(III) and Ti(IV) are the results obtained regarding the trace element oxidation states. None of the experiments showed Fe(II), except those contaminated by containing Fe(II)-bearing inclusions. Hence, the causes of sapphire colorations have been reviewed based on the experimental results. The chemistry defects produced by those trace elements exist in the real space, whereas the kinds of excited states are thus introduced in the energy space, resulting in optical properties, i.e., absorptions, emissions, and overall luminescence. As the average energy gap of gem corundum varieties containing those chemistry defects has been calculated for about 4eV, covering the range that can be measured by the UV-Vis-NIR for both the poly- and monochromatic ones. The new explanations based on the defect chemistry of trace elements, i.e., Cr, Fe or Ti in corundum structure have been proposed by using the energy space model of the Band Theory. The UV-Vis-NIR and FITR absorptions have been newly designated and explained for the blue and green sapphires of both and basalt and metamorphic rock related ones. The blue coloration is proposed to be caused by the Fe3+/Ti4+ mixed acceptor states in the energy gap. The new concept has been well fitted with the

experimental results and makes more senses to be understood by young gem research scientists. Besides, heat treatment detections by using FTIR absorptions based on molecular water and hydroxyl ions in corundum structures are experimented and reviewed. Though before their trace element chemistry as well as their spectroscopic characteristics for both UV-Vis-NIR and FTIR have been well documented, nevertheless, their crystal chemistry has not been well touched in research, leading to the non-conclusive explanation and confusion on heat treatment determination by using those spectroscopic techniques.
Hence, the chemistry defect is not only the vital clue responsible for coloration of gem corundum, but it also helps determinations and understanding the complexity of treatment as well. Some unveiled research topics related to chemistry defect will be raised and suggested.

Comprehensive Spectral and Chemical Characterization of Amber from Xixia, Henan Province

Yan LI[1]*, China University of Geosciences, Wuhan (yanli@cug.edu.cn)
Yilei Feng[2], China University of Geoscience, Wuhan

Abstract

Amber, a fossilized tree resin with geological origins spanning millions of years, encapsulates essential paleoenvironmental information[1]. Xixia amber is produced in Xixia, Henan Province, China. Despite the fact that the largest known amber deposit in China is located in Xixia [2], the spectral studies on Xixia amber are limited. This study fills the gap in systematic spectral characterization of Chinese amber, with a focus on Xixia amber. Employing a combination of microscopic observation, infrared spectra, three-dimensional fluorescence spectra, and pyrolysis gas chromatography-mass spectrometry (py-GC-MS), we comprehensively analyze Xixia amber and compare it with counterparts from the Baltic region, Burma, and Fushun.

Results indicates that Xixia amber, though exhibiting similar gemological traits to other ambers, displays distinctive infrared spectral features, especially in the fingerprint region. Based on the carbonyl band morphology and the doublet signal (1023 cm-1 and 974 cm-1) [3], two varieties of Xixia amber were suggested. Each series encompasses both relatively fresh and oxidized samples.

Three-dimensional fluorescence spectra further differentiate Xixia amber, aligning it more closely with Burmese and Fushun amber than Baltic amber. A detailed examination of peak wavelengths facilitates further differentiation, following the sequence Xixia > Burma > Fushun. The two series of Xixia amber also exhibit subtle differences in fluorescence characteristics.

Using py(HMDS)-GC-MS, the molecular-level similarities between Xixia amber and Burmese amber were investigated. By comparing the test results of individual samples with the co-pyrograms of Burmese amber, it was determined that Xixia amber belonged to Class I b, characterized by a regular configuration and the absence of succinic acid [4]. This result aligns with previous studies suggesting that Xixia amber is most likely contributed by the conifer family Araucariaceae [5].This research significantly advances our understanding of the unique spectroscopic properties of Xixia amber, distinguishing it from other globally distributed ambers.

Figure 1. Amber samples used in this study. Eight amber samples from Xixia, Henan Province: two yellow samples, Y-1 and Y-2, one light brown sample, LB, three orange samples, O-1, O-2 and O-3, and two brown samples, B-1 and B-2 (A is the interior, and B is the crust). Three amber samples of other origins: E-1 from the Baltic Sea, E-2 from Burma, and E-3 from Fushun, China.

Figure 2. FTIR spectra of ambers from the Baltic Sea, Burma, Fushun and Xixia

Figure 3. Three-dimensional fluorescence spectra of yellow amber samples from the Baltic Sea (a), Burma (b), Fushun (c) and Xixia (d).

Figure 4. Total ions chromatograms of Xixia amber (a) and Co-pyrogram of Xixia amber with Burmese amber(b). Framed areas (12-18 min) show partial pyrolyzates of esterified communol and communic acid. Labelled peaks and the corresponding chemical structures are also listed.

Abstract

Since 2008, the Baw Mar gem deposit located in Mogok Township has become well-known for its exceptional quality blue sapphires within Myanmar's gem industry. The primary production of sapphires has been continually and mainly extracted from the southern part of the deposit. Most mining sites are situated at the northwest of Kyat Pyin, approximately 12 miles (19 km) from Mogok. The finest blue sapphires are primarily found in pegmatitic syenites, intruding into highly weathered gneiss with pocket-like leucogranites. Some sapphires are nestled in clay lenses resulting from the kaolinite alteration from feldspar of the syenite pegmatites. The sizes of the sapphires vary from 2 to 8 millimeters, reaching up to 15 centimeters. Gem-quality blue sapphires typically exhibit distinct pleochroism, ranging from greenish to violet-blue, and are relatively free of inclusions under a microscope. Through observations with high-powered gem microscopes, some show multiple twinning and are associated with whitish needle-like tiny inclusions such as boehmites. Unlike sapphires from other Mogok locations, rutile needle-like inclusions are infrequent in the Baw Mar sapphires. Common internal features include surface-reaching healing fissures, small platelets and needle-like particles (probably ilmenites), negative crystals, and unidentified dark crystal inclusions. Occasionally, mineral inclusions of K-feldspar, mica, and zircon are identified using high-powered gemological microscopes and Raman analysis. EPMA analysis reveals the trace element geochemistry of the Baw Mar sapphires, showing a relatively high iron content, very low titanium percentage, and gallium. The Ga/Mg ratio ranges from 0.5 to 18, indicating that most Baw Mar sapphires originate from both magmatic and metamorphic sources. The findings of this research suggest that the Baw Mar sapphires exhibit distinctive features when contrasted with the other Mogok blue sapphires by the trace element compositions, as well as microscopic and spectroscopic characteristics.

Mahan Carnelian beads production techniques and sociopolitical significance of long-distance trade

JINA HEO[1]*, Chonnam National Univ. (jina3152@gmail.com)

Abstract

In world archaeology, long-distance trade has received attention as an essential element in understanding the sociopolitical development of complex societies. Recently, Korean archaeology has revealed that from the early Iron Age to the Three Kingdoms period, polities on the ancient Korean Peninsula imported beads from various regions of East Asia. In ancient societies, long-distance trade goods included expensive luxury goods, not produced in local societies, or rare goods, such as beads.

On the other hand, studies of social complexity in different parts of the world tend to view long-distance trade and prestige-good economies as one and the same. According to this view, long-distance trade in ancient societies required both the economic ability to pay high transportation costs and the political power to control the distribution and allocation of trade goods. As such, long-distance trade goods such as beads were often used as "prestige goods," with limited access and control over their distribution granted to a certain class of individuals (i.e., elites) who had the political and economic power to do so. As a prestige good, beads may have served to define socioeconomic relationships within a community or symbolize individual power. It is also possible that they were used as an exchange of wealth, a status symbol, a display of limited goods, or as gifts to expand alliances.

In this light, the nearly 50,000 glass and stone beads found in Mahan (100 BCE-300 CE) tombs can be interpreted as suggesting that Mahan elites used beads as prestige goods and were active participants in long-distance trade networks. To test this hypothesis, this study examines the production techniques of carnelian beads, which the ancient Mahan people considered more valuable than gold and silver, to understand the maritime trade network. First, I review ancient bead-making techniques in South and Southeast Asia. Next, I conduct a quantitative analysis of the perforation size of the carnelian beads and a scanning electron microscope (SEM) analysis of silicon samples that molded the interior of the perforations. Based on the analytical results, the origin and trade routes of the carnelian beads are estimated. Finally, I discuss the implications of the carnelian bead trade for the sociopolitical development of Mahan.

Hauyne of an Unusually Rare Green Color

BUDSABAKORN SRISATAPORN[1]*, The Gem and Jewelry Institute of Thailand (Public Organization) (sbudsabakorn@git.or.th)
WASSANA CHONGRAKTRAKUL[2], The Gem and Jewelry Institute of Thailand (Public Organization)
CHEEWAPORN SUPHAN[3], The Gem and Jewelry Institute of Thailand (Public Organization)

Abstract

Haüyne, a member of the feldspathoid group, derives its named after Rene Just Hauy, who is considered to be the father pioneer of mineralogy and crystallography. It is a constituent mineral of lapis lazuli, sodalite, and lazurite, and belongs to sodalite group. Gem-quality haüyne, renowned for its typically intense blue color, is a rare stone. Recently, GIT's Gems and Precious Metal Testing Laboratory (GIT-GPTL) has identified two green stones facetted as 0.83 ct cushion and 1.19 ct round-brilliant. These stones were examined for their gemological properties by standard and advanced testing instruments. The stones possess attractively bright and unusually rare green color. Both stones are single crystals and singly refractive having a similar RI of 1.498, and specific gravity (SG) of about 2.45. The stones displayed moderate orange fluorescence under long-wave ultraviolet (LWUV) and inert to weak orange fluorescence under short-wave ultraviolet (SWUV). Microscopic observation showed several features, such as crystals, minute particles, needles and liquid inclusions of natural origin. The Raman spectra of both stones showed dominant peaks at 442, 544, 988 and 1089 cm-1 that were perfectly matched with the haüyne reference spectrum from the RRUFF database. The FTIR reflectance spectra showed peaks at 429, 461, 609, 638, 648, 698, 726, 1018 and 1145 cm-1 resembling the spectrum of a typical haüyne sample. The chemical analyses of two stones by EDXRF gave SiO2, Al2O3, SO3, CaO and Na2O as their major components that are consistent with the haüyne chemical formula of Na6Ca2(Al6Si6O24)(SO4)2. Minor components included Cl and SrO with traces of MgO, K2O, MnO, Fe2O3 and TiO2. The chemical comparison results among the samples of green haüyne, blue haüyne, and green-yellow haüyne revealed no significant differences, except for somewhat lower Na2O and higher CaO concentrations in the green samples. Consequently, it is observed that the chemical analysis conducted through EDXRF is unable to distinguish the haüyne samples of various hues. The distinctive coloration of haüyne is attributed to the idiochromatic nature of differing sulfide radical anions in its structure. The UV-Vis spectra displayed a strong absorption band at ~400 nm and a small broad absorption band at ~600 nm that was quite contrast with the spectrum of blue haüyne (i.e., a strong broad absorption band at ~600 nm and a weak absorption band at ~400 nm). In conclusion, based on our comprehensive study of the basic gemological properties and advanced analyses, the gem-quality stones are identified as natural haüyne possessing an exceptionally rare green hue.

Thanong Leelawatanasuk[5], The gem and jewelry institute of Thailand (Public organization)
Chakkaphan Sutthirat[6], Chulalongkorn University

Abstract

Sodalite [Na8Al6Si6Cl2] is a feldspathoid, a tectosilicate found in more restricted occurrences, such as in undersaturated igneous rocks of both intrusive (e.g., nepheline-syenites, monzonites) and extrusive (e.g., phonolites, trachyte), also in metasomatized limestone (marble). Transparent or translucent gem-quality sodalite specimens are extremely rare. Recently, the GIT Gem and Precious Metal Testing Laboratory (GIT-GPTL) received a 0.21 ct greenish blue stone facetted as triangular modified brilliant for identification. The stone was characterized by using both basic and advanced gem equipment. The stone possesses an extremely rare transparent to somewhat translucent diaphaneity and attractively bright greenish blue hue. Its basic gem properties are single refraction with RI of 1.495, SG of 2.241, fluorescence/phosphorescence reaction as weak orange in short-wave UV and moderate orange in long-wave UV without tenebrescence effect, in agreement with those of sodalite. Microscopic observation revealed many prominent internal features including curved hollow tubes, fingerprints, fluid inclusions, crystals, and fractures with iron stain. The UV-Vis-NIR spectrum showed two board bands peaked at ~380 and ~606 nm, typical of blue sodalite. The FTIR spectra in the mid-infrared region showed the most prominent peak at 990 cm-1with shoulder 1036 cm-1 and other smaller sharp peaks at 732, 711, 664, 475 and 437 cm-1 that are slightly different from our reference spectra of blue sodalite and hackmanite. The semi-quantitative chemical components of the greenish blue stone obtained by EDXRF are 51.43%SiO2 , 29.88%Al2O3, 8.68%Na2O, 6.11%Cl, 2.34%SO3, 1.02%K2O, 0.36%CaO, 0.08%TiO2, 0.02%Mn2O3 and 0.06% MgO that are fairly consistent with the compositions of our blue sodalite and hackmanite reference samples. Traces of Li (305.3 ppmw), Be (23.2 ppmw), Cr (0.9 ppmw), Co (0.1 ppmw), Ni (0.5 ppmw), Cu (0.4 ppmw) and Zn (0.2 ppmw) were also found in the by LA-ICP-MS. In conclusion, this stone is identified as an extremely rare transparent, attractively bright greenish blue, gem-quality sodalite that deserves a comprehensive documentation.

Influence of Electron Radiation on Colour Modification and Colour Stability of Pink Sapphires: A Preliminary Study

WARATCHANOK SUWANMANEE[1]*, The Gem and Jewelry Institute of Thailand (Public Organization) (swaratchanok@git.or.th)
THANAPONG LHUAAMPORN[2], The Gem and Jewelry Institute of Thailand (Public Organization)
NONGNUCH JANGSAWANG[3], Thailand Institute of Nuclear Technology (Public Organization)

Abstract

Padparadscha are a rare and highly desired variety of corundum, prized for their unique coloration that falls somewhere between pink and orange. Most Padparadscha sapphires in the recent market undergo various treatments to enhance their beautiful colour through heat treatments. The heat-treated Padparadscha sapphires are exposed to high temperatures to improve their colour and clarity. This process makes the gemstones more vibrant and brighter in appearance. Another treatment often used is adding beryllium to the gemstone during heating, which can create a more desirable colour. In addition to heating, there is also irradiation treatment. Nowadays, irradiation has increasingly become a concerning issue in corundum enhancement. Recently, some entrepreneurs attempted to irradiate corundum such as yellow sapphire, pink sapphire, and purplish ruby to enhance the color and add value to the gemstone, significantly. It is well-known that the yellow colouration after irradiation of corundum is related to defect structures (colour centres) that are unstable when exposed to daylight or heated for a long time and faded back closer to their original colour.

In case of pink sapphires, their colour was treated to resemble a Padparadscha-like colour due to the addition of yellow shade, the samples were sold to the market without disclosing the treatment. Therefore, the authors have investigated the representative of irradiated pink sapphires to better understand the effect of an electron irradiation treatment and to develop potential detection methods for gem testing laboratories. In this study, pink sapphires were selected from Madagascar and Tanzania to investigate. An electron irradiation experiments on our samples were carried out in a specialized facility in Thailand . All samples were subjected to a colour stability test after being irradiated. The colour modification of the pink sapphire was investigated by UV-Vis absorption spectra and color grading was also subjected to color grading using the Munsell color chart under a lightbox with a 5000K color temperature. In addition, samples were photographed to compare their color before and after irradiation, as well as after the color stability test.

Baddeleyite SK10-2 and Rutile KNW: Two natural reference materials for microbeam U-Pb geochronology

Shitou WU[1]*, Institute of Geology and Geophysics, Chinese Academy of Sciences (shitou.wu@mail.iggcas.ac.cn)
Yueheng Yang[2], Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

Microbeam U-Pb geochronology by LA-ICP-MS and SIMS requires matrix-matched reference materials for the correction of elemental fractionation and matrix-induced mass bias. In this study, we presented two natural reference materials SK10-2 and KNW for baddeleyite and rutile U-Pb geochronology, respectively. Baddeleyite SK10-2 is separated from a gabbro rock collected from Northeast China, while rutile KNW is a gemstone quality megacrystal from North Europe. CL and SEM images illustrated these two materials are relatively clean without inclusions and secondary minerals. Baddeleyite SK10-2 and rutile KNW contain U contents of ~500 ug g-1 and 20 ug g-1, respectively. A large multiple spot analyses (n > 150) using LA-ICP-MS demonstrated the homogeneity of U-Pb age at tens um level for both materials. ID-TIMS analyses yielded a weighted mean 206Pb/238U ages of 31.592 ± 0.035 Ma (2s, n = 10) and 1088.1 ± 1.5 Ma (2s, n = 9) for baddeleyite SK10-2 and rutile KNW, respectively. Baddeleyite SK10-2 is a reference material for Hf isotope ratio analysis with the mean MC-ICP-MS 176Hf/177Hf value of 0.282742 ± 0.000008 (2SD, n = 9). Rutile KNW is a reference material for Zr content analysis with the mean LA-ICP-MS and EPMA value of 1252 ± 45 ug g-1. These two reference materials might be useful for the baddeleyite and rutile microbeam U-Pb geochronology.

Agrominerals and food security in Africa

Olugbenga Akindeji Okunlola[1]*, university of Ibadan/AGID (gbengaokunlola@yahoo.co.uk)

Abstract

AGROMINERALS AND FOOD SECURITY OF AFRICA
Olugbenga A Okunlola
Department of Geology University of Ibadan, Ibadan, Nigeria
Food security, a situation in which people, at all times, have physical and economic access to sufficient, safe and nutritious food to meet their dietary needs and food preferences for an active healthy life is in three aspects, availability, access and adequacy. Achieving food security in its totality continues to be a challenge for Africa worsening over the years. One of the major challenges to food security in Africa is low fertility soils as a result of severe nutrient depletion ranging between 30 to over 60kg/ha, leading to low crop yields. Agro-minerals which are minerals of importance to agriculture and horticulture are usually essential plant nutrients. Strategic planning to explore and exploit these minerals as main raw materials in additive fertilizers and or direct application to soils will lead to enhancement of soil nutrient status.
The study aims at elucidating the significant agro-minerals of Africa, which includes Phosphate, Limestone (Marble), Potash, Gypsum, Feldspar, and Sulfur, with a view to reveal distribution, mode of occurrence origin occurrence and application
Phosphate deposits found in 41 African countries are mainly of igneous apatite and Sedimentary carbonate-fluorapatite mineralogical varieties. Tonnage varies across Africa with significant occurrence mainly in North Africa which accounts for over 55% of all the phosphate resource. P2O5 content varies from 9.25 % to 30 % across the continent. The main gypsum deposits in sub-Saharan Africa are associated with Mesozoic to Recent sediments and evaporative crusts. They are found in many coastal basins and in various localities in continental basins in West-Central Africa and the Rift valleys. Gypsum as by-product from the phosphate industry (phosphogypsum) is found in large amounts in Senegal and Zimbabwe. In Africa, the most commonly used form of K input in agriculture is potassium salts (potash). Pegmatitie and leuco granites of the Eburnean and Pan African Orogenic origin hosts K-feldspar, leucite, K-micas such as biotite, phlogopite, and glauconite, and are in places weathered into clays such as illite. Leucite-bearing volcanics occur within the volcanic regions of Central Africa. Sulfur as elemental Sulfur is found in relatively small amounts in many volcanic terranes of Africa, but also as part of sedimentary gypsum-(CaS04 2H20) and anhydrite-(CaS04) bearing sequences. Pyrite, (FeS2) occur in areas of mixed sulfide mineralization in countries of East and West Africa and can provide Sulfur to plants. Sulfur deficiencies have been studied in soils of Parts of Africa and are partially due to depletion of S through heavy crop removals, intensive cropping and lack of organic matter recycling.
Improvement in soil nutrient status is essential to achieving soil food security in Africa. Development of strategic approach to exploration and development of a data bank and inventory of agromineral resources of Africa is of necessity. Agrominerals should be treated as critical and

strategic minerals and prioritized. Integrated regional agronomic, agrogeological and a needs assessment study for the development of soil nutrient enhancement through agrominerals should also be

Geochronology of diamond formation in the mantle and its relation to geodynamics

Felix V. Kaminsky[1]*, Russian Academy of Sciences (kaminsky@geokhi.ru)

Abstract

The ages of diamond formation are determined by the ages of their syngenetic mineral inclusions (garnet, pyroxene, sulfide, and rutile). Rb-Sr, Sm-Nd, Re-Os, and U-Pb isotope systems are most common for this purpose. They show a much earlier formation of diamonds than their host kimberlites and lamproites, confirming the xenogenic nature of diamonds in these rocks. The established diamond ages are distributed through the entire Earth's history from 100 Ma to 4.16 Ga (Smit et al., 2022). Most diamond formation ages are usually connected to lithospheric slab subduction into the Earth's mantle. However, geological data do not support such a conclusion. First, the uncertainties in all analytical methods are many hundreds of millions of years, especially for eclogitic inclusions in diamonds. This creates uncertainties in the geological interpretation of data. Second, most of the analyzed inclusions in diamonds belong to the eclogitic association, considered a priori due to the subduction of lithospheric plates. For some kimberlite pipes, several (up to 5-7) epochs of diamond formation are determined from 140 Ma to 4 Ga. These specified diamond formation periods cover the entire evolution of cratons. A large data scatter makes it formally possible to tie almost any diamond age with some subduction event. Meanwhile, a detailed study of eclogitic inclusions in diamonds shows that they initially belong not to subduction products of the oceanic crust but to mantle igneous rocks. There are "eclogites and eclogites". Bimineral (garnet-omphacitic) eclogites of group A (according to the Strekeisen classification) have a mantle formation. They are magmatic due to the formation of "eclogitic magma", in the terminology of Escola, from the mantle melt. For example, among eclogitic xenoliths in the Roberts Victor kimberlite pipe, located in the central part of the Kaapvaal Craton. Two types (I and II) of eclogites are distinguished among them, formed at depths of 120-200 km, which differ in mineralogical and isotopic compositions (Huang et al., 2012). They have different ages of formation: 103 ± 10 Ma (Sm-Nd) and 132 ± 16 Ma (Lu-Hf) for type I, and 738–1,143 Ma (Sm-Nd) and 1,148–1,544 Ma (Lu-Hf) for type II; and no subduction processes of these ages are known in the region. As Huang et al. (2012) conclude, eclogite xenoliths from the Roberts Victor pipe were originally igneous rocks crystallized at depth, not products of oceanic crust subduction. Thus, the ages of most eclogitic inclusions in diamonds cannot be considered chronological indicators of hypothetical subduction processes. It can be assumed that the formation of diamonds with eclogitic inclusions is associated not with tectonic processes in near-surface zones but with the episodic formation of eclogite melts in the mantle caused by deep geodynamic processes. Most peridotitic inclusions are older than 2.5 billion years, corresponding to areas of the most ancient mantle. The ages of both peridotitic and eclogitic inclusions in diamonds can serve as indicators of deep geodynamic processes (mantle convection currents, primary and secondary plumes, etc.).

Trace element in blue sapphire: Challenge or potential of element analyses by LA-ICP-TOF-MS for origin determination?

Wei ZHOU[1]*, SSEF Swiss Gemmological Institute (wei.zhou@ssef.ch)
Michael S Krzemnicki[2], SSEF Swiss Gemmological Institute
Hao Wang[3], SSEF Swiss Gemmological Institute

Abstract

In this study, we present trace element data of gem quality sapphires showing distinct chemical fingerprint. Sapphire samples which originating from two metamorphic deposits, Kashmir (Zanskar Range, India) and Madagascar (possibly Andranondambo) has been chosen. The analyses have been performed by LA-ICP-TOF-MS (LA-ICP Time-of-Flight mass spectrometry), which specifically adapted to analyze zoning with unexpected trace elements (e.g. from nano-inclusions) by simultaneous multi-element detection.

For several years, the data collection and study on LA-ICP-TOF-MS data of gem-quality sapphires have revealed that the presence and content of elements which known as high field strength elements (HFSE, Zr, Nb, Zr, Hf, Ta, Th, U…) with Ni, Pb are indicative of the origin determination of the host sapphire. In sapphire from Kashmir, part of the light-colored stones with pronounced color zoning often has more noticeable occurrences of HFSEs; the similar situation occurs in sapphires from certain regions of Madagascar. Although these group of elements are present only at levels of a few to a dozen ppm, they are hardly ever encountered in sapphires from other places that have been also tested at SSEF by LA-ICP-TOF-MS. The ultra trace elements occurring in groups are enriched in sapphires from specific origin, in order to address this meaningful phenomenon, in this study the geological and lithological conditions of these two regions, Kashmir and Andranondambo, Madagascar, are further characterized and discussed.

In addition, although similar enrichment of elemental compositions occurs, the content of specific elements is not the same in sapphires from Kashmir and Madagascar. The geochemically significant elements Th and Pb are particular important. According to the classical Th/Pb isotope dating method, the geologic ages of sapphires from the two origins with similar chemical composition and similar inclusions are quite different. By using this direct age dating, the geological ages obtained from sapphires of Kashmir origin are in the approximate range of 25-50 Ma, whereas ages on sapphires from Madagascar exceed 500 Ma. Considering the testing requires only very small amount of samples to obtain the data and the testing is rather performed by a “random” sampling, the direct age dating conclusions, which are highly in line with the geological background of the origin, are more than just acceptable.

By using only 4-8 analytical spots (as commonly applied in commercial gemstone analyses), the presence and variability of certain trace elements already are helpful for origin determination of sapphires.

Three natural reference materials for in situ andradite U–Pb geochronology

Yueheng Yueheng YANG[1]*, Institute of Geology and Geophysics, Chinese Academy of Sciences (yangyueheng@mail.iggcas.ac.cn)
Shi WU[2], Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

Grandite garnets are a solid–solution series of andradite and grossular, and occur widely in a variety of alkaline magmatic rocks, carbonatites and skarn deposits typically associated with economic Fe, Cu, W, Sn and Mo mineralization. Andradite–rich garnet, a common mineral in various rocks such as alkaline and skarn rocks, could have high U/Pb ratios and is suitable and preferable for in situ U–Pb dating. Nevertheless, very limitedly available U–Pb andradite reference material hindered its widespread application for microanalysis. In this study, three new natural andradite (MKWB, DGS and Stanley) have been characterized and evaluated as potential reference material for in situ U–Pb geochronology. We performed U–Pb age measurement in four different laboratories using isotope dilution TIMS and laser ablation (SF, Q)–ICP–MS, to check the homogeneity of euhedral andradite crystals. The ID–TIMS results of MKWB, DGS and Stanley andradite are reported for the first time in this study. We presented ID–TIMS 206Pb/238U age of 264.9 ± 5.8 Ma (2s, n=6, MSWD=3.4), 139.42 ± 0.36 Ma (2s, n=5, MSWD=1.9) and 23.28 ± 0.38 Ma (2s, n=3, MSWD=1.9) for MKWB, DGS and Stanley, respectively. These three new natural secondary reference materials are to contribute significantly to rapidly developing in situ U–Pb andradite–rich garnet geochronology.

Different origins of garnet in high-grade metamorphic rocks

Qiong-Xia XIA[1]*, University of Science and Technology of China (qxxia@ustc.edu.cn)

Abstract

Garnet in high-grade metamorphic rocks, including high temperature (HT), high pressure (HP), to ultrahigh-temperature (UHT) and ultrahigh-pressure (UHP) metamorphic rocks of subduction zones commonly shows considerable zonation in major and trace elements as well as mineral inclusions, which bears information on its growth mechanism via metamorphic or peritectic reactions in coexistence with relic minerals and metamorphic fluids or anatectic melts at subduction-zone conditions. It provides an important target to retrieve physicochemical changes in subduction-zone processes, including those not only in pressure and temperature but also in the durations of metamorphism and anatexis. Garnet from different compositions of HT-HP to UHT-UHP metamorphic rocks may show different types of major and trace element zonation, as well as mineral inclusions. Discrimination between the different origins of garnet provides important constraints on pressure and temperature and the evolution history for the HP to UHP metamorphic rocks. Magmatic garnet may occur as relics in granitic gneisses despite metamorphic modification at subduction-zone conditions, with spessartine-increasing or flat major element profiles from inner to outer core and exceptionally higher contents of trace elements than metamorphic mantle and rim. Metamorphic garnet can grow at different metamorphic stages during prograde subduction and retrograde exhumation, with spessartine-decreasing from core to rim if the intracrystalline diffusion is not too fast. The compositional profiles of metamorphic garnet in the abundances of grossular, almandine and pyrope are variable depending on the composition of host rocks and co-existing minerals. Peritectic garnet grows through peritectic reactions during partial melting of HT to UHT rocks, with the composition of major elements to be controlled by anatectic P-T conditions and the compositions of parental rocks and anatectic melts. Trace element profiles in garnet with different origins are also variable depending on the coexisting mineral assemblages, the garnet-forming reactions and the property of metamorphic fluids or anatectic melts. Mineral inclusions not only present key clues to identify the different origins of garnet, but also serve as sound candidates for the temporal constraint on garnet growth.

Paragenesis of Alteration/Zoning in Meta-Sedimentary Chromite from the Singhbhum Craton, Eastern India.

Asish Kumar DAS[1]*, CSIR-Central Institute of Mining and Fuel Research
(asiskumar.ctc@gmail.com)
Birendra Kumar Mohapatra[2], CSIR-Institute of Minerals and Materials Technology
Somnath Khaoash[3], Ravenshaw University
Patitapaban Mishra[4], Ravenshaw University

Abstract

The chromite occurrences present in southern fringe of Singhbhum Craton, shares a unique position in the mineral map of the world because of its sedimentary genealogy which is a notable divergence from the world's well-established orthomagmatic deposits. However, the altered chromite grains are heterogeneous that are associated with quartzites as host rock and demonstrates a different compositional trend. The change is erratic, generally consisting of two optical zones (bright and dull). Chromite grains often have a high reflectivity core (brighter zone) encrusted by a low reflectivity surrounding zone (dull zone). This change in zoning is in sharp contrast to other chromiferous ores reported from various regions of the world, where the chromite grain has greater marginal reflectivity.

Although the avg. Cr and Al content remains almost same (Cr# 0.78 in core and 0.77 in rim), there is a considerable rise in Fe composition and decline in Mg content from the outer peripheral zone (avg. Mg# 0.24) to the core zone (avg. Mg# 0.48). In the current setup, the chromite alteration essentially represents the outcomes of compositional zoning. The altered chromite exhibits an aluminium trend, with Fe being enriched in the spinel's core zone while Al, Mg, Mn, and Co concentrations are greatest in the periphery zone. The difference in composition suggests that such zoning may have resulted through chromite alteration via solid-state diffusion, in which Mg-Al ions migrate out of the core area and Fe ions diffuse into the core. The plots of many key elements in triangular diagrams, such as Cr-Al-Fe(T) and Cr-Mg-Fe(T) as end members, also show clear patterns from the core to the rim and indicates that there is a process of leaching of Cr and Fe ions from the core, followed by their precipitation in the rim during alteration.

Petrological and structural characterisation controlling gold mineralization in the northern part of the Kon Tum massif, Central Highlands of Vietnam

THÀNH VŨ-TIẾN[1]*, Official of Center for Information, Archives and Museum of Geology, Vietnam Geological Department (tienthanhvudgmv@gmail.com)
VƯỢNG NGUYỄN-VĂN[2], University of Science, Vietnam National University
HOÀI LƯỜNG-THỊ-THU[3], University of Science, Vietnam National University

Abstract

The northern Kon Tum massif, the Central Highlands of Vietnam, has the largest concentration of gold deposits in the country and the Southeast Asia region. However, the relationship between the geological structures controlling gold mineralisation in the area has not yet been fully elucidated. Our study is based on the tectonic movement characteristics, indicating the relationship between gold mineralisation and geological structures. Five structural subzones are divided by several shearzones in the north of Kon Tum massif. They result from tectonic deformation processes occurring around 250 to 230 million years ago (MA), forming interleaved anticlines and synclines. The older structures only leave residual traces. From south to north, the local melting degree of migmatite gradually decreases to zero, and the metamorphic grade transitions from amphibolite with strong migmatization to greenschist. Spatially, gold mineralisation within the study zone is distributed in various formations. Hence, lithological factors do not play an important role in shaping the space and positions of gold mineralisation deposits. In fact, gold mineralisation is found conformably within metamorphic foliation planes or distributed on surfaces of mylonite zones. Dome-shaped structures with brittle deformation at the top create fractures and faults, facilitating ore concentration due to pressure differences. The domes of the anticlines and along the shearzones are potential areas that need to be expanded to research for gold mineralization.

Age of the South Ural mines: U-Pb ID-TIMS garnet dating

Yulia PLOTKINA[1]*, Institute of Precambrian Geology and Geochronology RAS (jplotkina@yandex.ru)
Maria Stifeeva[2], Institute of Precambrian Geology and Geochronology R
Ekaterina Salnikova[3], Institute of Precambrian Geology and Geochronology R
Olga Yakubovich[4], Institute of Precambrian Geology and Geochronology R
Alexander Kotov[5], Institute of Precambrian Geology and Geochronology R

Abstract

Skarn mineral associations of the South Ural mines (Eremeevskaya, Zelentsovskaya, Nikolae-Maximilianovskaya, Akhmatovskaya, Perovskite and Shorlomite) are famous mineralogical objects full of amazing variety of minerals which attract researchers as well as simply stone amateur. All mines are located along the western contact of the Mesoproterozoic Kusa–Kopan intrusive complex with country carbonate rocks. About 100 different minerals founded in these deposits including colored tourmalines, green beryl, morganite, topaz, pollucite, perovskite, vesuvian, olivine, tantalum-niobates etc. At this moment interpretation of the origin and age of these deposits are controversial. Some researchers suggest multi-stage mineral formation of skarn mineral association, some authors imply carbonatite origin of these rocks with unique mineralization (Popov, 2010; Stepanov et al., 2020).

U–Pb perovskites ages from silicate-calcite vein rocks from the South Ural mines range from 468 ± 6 Ma (Zelentsovskaya mine) to 497 ± 4 Ma (Perovskite mines) (Stepanov et al., 2020) and are significantly younger than the Kusa–Kopan intrusive complex (1379 ± 8 Ma).

We present U-Pb ID-TIMS ages of the andradite from the Shorlomite mine located in vicinity of Zelentsovskaya and Perovskite mines. Ca-Fe garnet is common in magmatic and metasomatic rocks. Garnet usually forms large (about 5 cm) black single crystals. Studied andradite is characterized by high level of andradite component (up 60 to 80% of andradite component). Numerous recent studies demonstrate the robustness and utility of garnet U–Pb system for precise dating of ore-forming processes as well as compositionally diverse alkaline and carbonatitic intrusive rocks of different ages.

Composition and high U abundance in garnet from the Shorlomite mine may suggests its magmatic rather scarn origin.

Three homogeneous garnet fractions were selected for analysis. The studied sample is characterized by high U contents (19-21 ppm) 275 and low levels of common Pb (Pbc/Pbt = 0.1-0.2). The data points are concordant or slightly discordant and yield an age of 505±15 Ma.

This U-Pb garnet age is in a good coincidence with previously reported perovskite age for neighbor Perovskite mines and confirms the Cambrian age of at least part of famous South Ural Mines.

The study was supported by grant No 22-17-00211 from the Russian Science Foundation and FMUW-2022-0003.

Review on geochemical, metallogenesis, and geodynamic studies for the origin and mineralisation potential of rare metal pegmatites of Côte d'Ivoire (West Africa).

Felix Oufouet KONAN[1]*, Pan African University, Life, earth and Science Institute (felixhouphouetkonan@gmail.com)

Abstract

Côte d'Ivoire's pegmatite occurrences have been the subject of a limited number of studies. Fifteen (15) zones of interest have been identified, of which only those in the Issia locality have been the subject of rigorous and detailed study, revealing them as columbite-tantaliferous (coltan) deposits. Recent investigations have revealed the numerous rare metal potentials of the pegmatite, particularly in the Boundiali region (north-west of the country) and the Comoé basin (south-east of Côte d'Ivoire), highlighting the significant potential of pegmatites. The pegmatites of the Boundiali region, and more specifically those of the Touvré-Kouto area, appear to be the most interesting in terms of rare metal enrichment. These pegmatites are intrusive into birimian (Palaeoproterozoic), either in parametamorphic formations (mainly amphibolites) or in granites, and are characterised by two main series. The first series, by far the largest, contains volcanic and volcano-sedimentary formations, affected by general greenschist-type metamorphism and general sub-vertical schistosity N20 to N30. The second series made up of detrital sediments, is undeformed and non-metamorphic, also deposited unconformably on the first series. The Boundiali region is characterised by five main types of pegmatites: the lepidolite-muscovite-spodumene-colombo-tantalite type, the green muscovite, and colombo-tantalite type, the green beryl type, muscovite-beryl type, and the biotite-magnetite type. Mainly peraluminous, it is not uncommon to find some of metaluminous origin, showing the pegmatitic diversity of this region. A recent study classified these pegmatites as LCT, based on lithium anomalies identified from soil sampling analyses (14,000 samples, sent for pXRF and LIBS analysis). Purplish lepidolites and spodumene were also identified in isolated blocks of pegmatite, leading to the discovery of a lithium deposit. Also characterised by rocks of Birimian age (Eburnian orogeny), the Comoé region is known for its occurrences of later-stage pegmatitic rocks associated with leucogranite plutons. Recent studies carried out in the Agboville region have identified several pegmatite outcrops with interesting rare metal potential (lithium, tantalum +/- niobium, and beryllium). Four groups of pegmatites are identified based on their mineralogy: beryl-muscovite pegmatite (Aboisso-Comoé), albite-tourmaline pegmatite (Aboisso-Comoé), micas-tourmaline pegmatite (Alosso), and muscovite-garnet pegmatite (Songan). The pegmatites in this region show signatures suggesting a para-derivative origin and are close to the Lithium-Cesium-Tantalum (LCT) type, with diagrams indicating the probable presence of beryl and spodumene-type mineralisation in the muscovite-garnet pegmatite. Overall pegmatite occurrences of Côte d'Ivoire deserve to be further studied and explored for further elucidation of their economic potentials.

MINERALOGICAL FEATURES OF GOLD ORES OF THE SARYJAY AREA (BUKANTOU MOUNTAINS, CENTRAL KYZYLKUM)

SHOKHIDA SAMANDAROVA[1]*, MINEROLOGY, PETROLOGY, CRYSTALLOGRAPHY (Sshoxida90@gmail.com)

Abstract

In order to identify typomorphic minerals and their characteristic features, we studied the main ore minerals of the Saryjay gold ore field in the Bukantou Mountains using electron microprobe analysis. Productive parageneses and typochemical features of individual minerals are identified.

The Sarijoy prospective area is located in the eastern part of the Bukantou Mountains in the Uchkuduk district of the Navoi region, belongs to the Bukantou structural-formational zone, and the research area is composed of Meso-Cenozoic deposits, which appear in the form of a platform cover, as well as Precambrian layers and Paleozoic formations that form the lower structural layer [1].

The main part of the studied areas consists of Precambrian rocks, represented by Riphean sediments of the Kyrkkuduk and Kokpatas formations [2].

Mineral rocks are represented by shales, carbon-silica shales, sandstones, siltstones, and carbonate. Shales consist of albite-chlorite-silica-sericite rocks that differ from each other in composition. It has a layered, sometimes striped structure with a distinct texture.

Vein-shaped and lens-shaped quartzization zones are observed in carbon-silicon shales.

Zones of sulfide mineralization form medium to coarse-grained, veined and aggregated textures at rock contacts (predominantly in carbonaceous-siliceous shales) with predominantly quartz veins. In gray and black shales, sulfide minerals are predominantly fine-grained, less often medium-grained, forming a scattered, disseminated texture.

As a result of research, the main types of ores of hypogene minerals are gold, electrum, kustelite, silver, argentite, pyrite, pyrrhotite, arsenopyrite, sternbergite, chalcopyrite, chalcocite, covellite, sphalerite, galena and fahlores; non-metallic minerals are quartz, plagioclase, sericite, chlorite and carbonates (calcite, dolomite), accessory minerals are apatite, alamazite, ashirite, monocyte, rutile.

Ore-forming minerals are found predominantly in hypideomorphic and xenomorphic structures, sometimes in euhedral structures.

The productive ore-forming paragenesis is represented by gold-silver-quartz-pyrite-chalcopyrite and silver-gold-quartz-pyrite-arsenopyrite associations.

The origin of olivine in kimberlite inferred from variably compositional zoning in kimberlite from Karowe mine, Botswana

Wentao Cao[1]*, State University of New York at Fredonia (cao@fredonia.edu)
Tingting Gu[2], Purdue University

Abstract

Olivine, a common crystal in kimberlite, is a critical mineral to interpret the kimberlite petrogenesis, ascent, and evolution. However, the origin of olivine, mantle-derived vs. melt-derived, remains largely disputed. In this study, we examined the olivine macrocrysts or phenocrysts in kimberlite from the AK6 Karowe mine in Botswana with petrography and mineral chemistry, attempting to address its origin in the specimen. The study sample was collected from the Karowe AK6 south lobe in the Orapa kimberlite field. The volume percentage of olivine in the specimen is ~40%, with perovskite, spinel, magnetite, serpentine, and solidified melt as the other major constituents. The olivine crystals are predominantly subhedral along with euhedral to anhedral crystals, with crystal sizes varying from megacrystic (>5 mm) to mesocrystic (<5 mm). Grain-scale cracks commonly filled with serpentine are common in the specimen. Perovskite, large or small, is typically present along with the major olivine phase. Spinel is typically found in the rim of olivine or the matrix.

Backscattered electron (BSE) images of olivine crystals show that the olivine crystals are variably zoned, with either Fe-rich or Mg-rich core of anhedral to subhedral shape. The rims display a variable thickness from ~10 to 100 um, with diffused or sharp transitions. Electron microprobe analysis of different olivine crystals shows that two distinct types of compositional zoning are present. The first and primary type olivine crystals show reverse zoning (i.e. increasing Mg# = Mg/(Fe+Mg)). The analyzed composition shows an Fe-rich core with a Mg# at 82 and low CaO (0 – 0.23 wt%), Cr2O3 (0 – 0.03 wt%) and NiO (0.10 – 0.25 wt%) values, followed by an Fe-poor rim with Mg# at 84 – 90 and higher CaO (up to 1.07 wt%), Cr2O3 (0.02 – 0.09 wt%) and NiO (0.08 – 0.34 wt%). The second and normal (ie. Decreasing Mg#) type olivine crystals display an Fe-poor core, Mg#) at 89 – 94, variable CaO (0 – 0.14 wt%) and Cr2O3 (0.03 – 0.08 wt%) and high NiO (0.32 – 0.47 wt%), along with an Fe-rich rim (Mg# = 88 – 89, CaO 0.02 – 0.08, Cr2O3 0.02 – 0.07 and lower NiO 0.28 – 0.38 wt%). Considering the shape of olivine, compositional boundaries and, these two types of olivine reflect the complicated evolution of kimberlitic magma along with subsequent diffusional modifications.

Enhancing Ceramic Quality through Mineralogical Adjustments in Highly Silicic Clays: A Case Study from Brunei Darussalam

Yussif IDDRISU [1], Department of Design & Creative Industries, Faculty of Arts and Social Sciences, Universiti Brunei Darussalam
Elena IFANDI[2]*, University Brunei Darussalam (elena.ifandi@ubd.edu.bn)
Rui Oliveira LOPES [3], Department of Design & Creative Industries, Faculty of Arts and Social Sciences, Universiti Brunei Darussalam

Abstract

The sedimentary deposits in Brunei Darussalam are highly silicic, with quartz dominating both the coarser and the finer fraction of the sediments. The focus is on locally sampled clay material, specifically those with a significant quartz content (70-80%), which hitherto were deemed unsuitable for ceramic production. We assessed the mineralogical and geochemical characteristics of the local clay sediment that lead to failures during ceramic firing. This study involved in-depth analysis of the clay deposit's chemical composition, shrinkage percentage, plasticity, and other key factors relevant to earthenware production. The results on the physical analysis of the selected clay show a good plasticity quality, shrinkage percentage of about 2% on average, and a bulk density of 1.57% on average. Thermogravimetric analyses (TGA) result revealed a weight loss of 8.68% on heating and 93.32% undecomposed value after degradation which indicates that the clay sample is thermally stable at high temperature. Furthermore, X-ray diffraction (XRD) analyses showed that the clay contains high amount of quartz (75.3%), with minor occurrence of illite (16.4%), kaolinite (7.3%), and potentially trace amount of the iron hydroxide goethite (0.7%) and vermiculite (0.3%). The TGA and XRD results indicated the need to modify the firing temperature towards the stability limit of quartz. Thus, ceramic samples prepared from the local clay were fired in range of different temperatures, between 573oC to 1196oC. The colours changes before and after firing ranged from terracotta to dark brown. Post-firing XRD analysis of the ceramic samples indicated phase transformations from kaolinite to mullite, and of illite and quartz to melt and form a glassy matrix which results to increase in the ceramic cohesion. The observed densification of the ceramic after firing is assigned to the oxidation of the iron species coupled with the reported colour changes. The ceramic fired in optimised temperature had a good cohesion and developed the characteristic metallic sound used by potters to evaluate the quality of the ceramics. Our comprehensive investigation of the physical, geochemical and mineralogical characteristics of locally sampled clay material allowed us to fine tune the firing temperature and create good quality ceramics. Our study highlights the potential of local clay for earthenware production, suggesting a reevaluation of previously undervalued clay deposits in Brunei Darussalam and elsewhere. Further experimentation with a variety of local clay types is essential for a more comprehensive understanding.

Abstract

Molecular-scale understanding on the interactions between Sb oxyanions (Sb(III)/Sb(VI)) and aluminum (oxyhydr)oxides is of great environmental importance. Despite the natural abundance of boehmite (γ-AlOOH), however, the adsorption behavior of boehmite toward Sb oxyanions and their interfacial interaction mechanisms have not been yet studied. We systematically investigated the adsorption behavior of Sb oxyanions on boehmite with defined facets via batch adsorption experiments, spectroscopy-based techniques and theoretical calculations. Considering the Sb-contaminated environmental condition (e.g., acid mine drainage), boehmite sample was synthesized under weak acidic condition through hydrothermal method and the mineralogical properties were characterized using XRD, TEM, SEM/EDS and FT-IR. The synthesized boehmite showed the nanorod morphology and consisted of four crystal facets with the following order: 48.4% (010), 27.1% (101), 15.0% (001), and 9.5% (100). Adsorption behavior of the boehmite sample towards Sb(III) and Sb(V) was different depending on pH and ionic strength. The combined results of X-ray absorption spectroscopy (XAS) analyses and density functional theory (DFT) calculations revealed that Sb(III) formed hydrogen-bonding outer-sphere complexation on the (100), (010), and (001) facets, whereas Sb(V) preferred to form bidentate inner-sphere complexation via mononuclear edge-sharing configuration on the (100), (001), and (101) facets and binuclear corner-sharing configuration on the (010) facet. Furthermore, (010) facet was the most sensitive binding site to changes in environmental factors and favorable for the outer-sphere complexation. These results indicated that the facet-mediated thermodynamic stability of surface complexation determined the interaction affinity towards Sb species, resulting in the different adsorption behavior. Our study will provide a valuable reference for understanding the role of boehmite in Sb-contaminated environments and its impact on the fate of Sb oxyanions.

Atomistic structure models of nanocrystalline vernadite mineral

Gerica Joie Placido CASTRO[1]*, Kangwon National University (gpcastro@kangwon.ac.kr)
Kideok D. Kwon[2], Kangwon National University

Abstract

Vernadite, a turbostratic nanocrystalline phyllomanganate, is ubiquitous in the environment and a key player in the (bio)geochemical cycling of trace metals. Its high redox and sorption capacity is a result of the high amount of defects in its structure and its nanometer dimensions. However, due to its poor crystallinity, vernadite's detailed structure has been challenging to characterize using traditional diffractometric and spectroscopic techniques. To address these limitations, in this study, for the first time we utilized molecular dynamics (MD) simulations to investigate the structure of nanocrystalline vernadite using Zn(II) as the probe sorptive ion. The MnFn force field, interatomic potentials optimized for manganese oxides, were used and modified for atoms at the lateral edges. Vernadite nanoparticles with diameters of ~3 or ~6 nm and with variations in the number of stacked sheets were simulated in vacuum and in an aqueous phase. MD simulation results showed that vernadite is composed of non-uniformly curved sheets instead of flat or uniformly curved sheets. The degree of vernadite nanosheet curvature depended on the lateral size and number of stacked sheets, with the 6 nm models being more curved compared to the 3 nm models, and the monolayer models had a considerably more curved surface in comparison to the layered models. Vacancy-free models collapsed when placed in aqueous phase, highlighting the importance of octahedral vacancies adsorbed with cations in the stability of vernadite's structure. A minimum of 4.9-6.5% vacancy content was required to ensure vernadite layer stability in aqueous phase. Zn complexes at the exposed basal planes transformed to tetrahedral coordination in vacuum but remained octahedral in aqueous phase. While at the lateral edge surfaces, Zn cations were found to change the coordination and speciation depending on the presence or absence of surrounding water, suggesting that the environment and water play a key role in influencing the coordination geometry of Zn cations adsorbed at vernadite surfaces. These atomistic simulations reveal the details of vernadite structures, offering valuable insights for the experimental exploration of vernadite's chemical reactivity. This understanding is crucial for unraveling the fate and transport of trace metals in the environment by providing a dynamic view of how they interact with Mn oxide surfaces which could aid in the development of environmental remediation strategies.

Effect of Ca-containing byproducts generated during interzeolite transformation on the sequestration and release of Cs

Seokju HONG[1]*, POSTECH (frederic@postech.ac.kr)
Wooyong Um[2], POSTECH

Abstract

Hydrothermal interzeolite transformation, which can give a strategy for the synthesis of specific zeolite structures often with shorter reaction times, can be applied to the sequestration of radionuclides. Natural zeolites, as well as synthetic zeolites, are frequently used as parent zeolites in the hydrothermal interzeolite transformation because they are inexpensive and abundant in quantity. However, our study revealed that minor amounts of charge-compensating Ca ions present in parent natural zeolites can affect adversely the sequestration of radionuclides (especially Cs-137) by the final byproducts during the hydrothermal interzeolite transformation.

Our study prepared pollucite from natural Korean zeolite by hydrothermal interzeolite transformation without using organic structure directing agents. Only the presence of pollucite was confirmed by XRD, IR, and Raman analyses. However, in pore characteristics and scanning/transmission electron microscopic analysis, we could observe the existence of Ca-containing byproducts other than pollucite. These byproducts showed a wider pore size distribution in the mesopore range and a higher specific surface area compared to the pollucite. Furthermore, these byproducts showed an acicular shape at the hydrothermal temperature of 453 K, which distinguishes them from pollucite.

After the characterizations, we designed our experiment by dividing parent zeolites into three types: Na-exchanged type (NaNZ), original type (OrNZ), and Ca-exchanged type (CaNZ), each of which was used to suppress, proceed, and activate the generation of byproducts. In the Cs release tests, the pollucite made from NaNZ showed less release of Cs compared to pollucite made from OrNZ or CaNZ, and this indicates the presence of byproducts negatively affects the sequestration of Cs. Interestingly, the interzeolite transformation rates of NaNZ, OrNZ, and CaNZ were all different, although the structures of natural zeolites and hydrothermal reaction conditions were the same. The rate of interzeolite transformation slows down when the Ca content of parent zeolite is high, because the dissolved Si should be consumed first for interzeolite transformation to pollucite, resulting in the generation of Ca-containing byproducts.

To the best of our knowledge, we demonstrated the presence of byproducts during the hydrothermal interzeolite transformation, which can cause the negative effect on the Cs-sequestering performance of pollucite for the first time. Our study highlights that trace amounts of byproducts present in the process of mineral transformation for radionuclide-sequestration may cause fatal failure in the long-term (or permanent) immobilization of radionuclides.

On the crystal structures and thermodynamics of Sr-bearing calcite

Sanggeon KIM[1]*, Kangwon national university (cjsekfdl97@naver.com)
Sangbo SON[2], Kangwon national university
Sung Pil HYUN[3], Korea Institute of Geoscience and Mineral Resources
Kideok D KWON[4], Kangwon national university

Abstract

Calcium carbonates containing diverse divalent metal cations are widely found in rock fractures and fault zones. Experimental studies on Sr-bearing calcite have been prompted by its potential role in mitigating the mobility of radioactive 90Sr dissolved in groundwater. While chemical analysis has identified the presence of Sr in calcite crystals, the elucidation of their crystal structures and thermodynamics remains elusive. This knowledge gap is attributed in part to the natural occurrence of SrCO3 with an aragonite-like structure (strontianite) whereas a calcite-like structure for SrCO3 has not been observed. Herein, we report the examination of the crystal structures and solubility product constants of Sr-bearing calcite using density functional theory (DFT). Geometry optimization well reproduced experimental data, encompassing lattice parameters, Sr coordination numbers, and solubility products of Sr-bearing aragonite. Contrary to expectations, we found a deviation from the conventional six-fold coordination of Sr in calcite to a seven-fold coordination. We also explore the potential use of Sr *K*-edge absorption near edge structure (XANES) spectra as an indicator for the coordination number of Sr in calcite through the analysis of spectra generated by DFT for various Sr coordination. DFT predicted an increase in the solubility product constant of Sr-bearing calcite with rising Sr content, indicating a higher stability of Sr in aragonite than in calcite. These results imply that Sr-bearing calcite within rock fractures may be apt to release Sr, potentially augmenting Sr mobility, an aspect critical in predicting the fate of 90Sr in subsurface environments.

Abstract

The main objective of the presented research was to investigate the sorption processes of thorium, lead and cesium onto synthetic secondary iron minerals (K-jarosite, goethite, schwertmannite) and natural clay minerals (mixed-layer illite-smectite ISCz-1) under conditions corresponding to the environment affected by the acid mine drainage (AMD). The specific aim of the project was to examine the effect of pH (pH range from 2 to 6) and ionic strength (0.1, 0.5, and 1 M NaNO3) on the sorption of Th, Pb, and Cs onto selected mineral phases. Element concentrations were measured using a multimode microplate reader, ICP-OES, and HR-ICP-MS. The zeta potential and specific surface area (BET) of the minerals were also investigated. Furthermore, the morphology, mineralogical composition, and chemical composition of these minerals before and after sorption experiments were analyzed using a scanning electron microscope coupled with energy dispersive spectrometers (SEM-EDS) and a powder X-ray diffractometer (PXRD). The results of laboratory experiments indicated that an increase in pH enhances the sorption of the studied elements. Sorption of Pb was observed onto all minerals, similarly to Th (except K-jarosite). In the case of Cs, sorption was observed only onto K-jarosite and clay minerals (ISCz-1). An increase in ionic strength resulted in a decrease in sorption in all cases. The research demonstrated that schwertmannite obtained by Fe2+ oxidation has significantly worse sorption properties compared to that obtained by Fe3+ hydrolysis. The parameters of adsorption isotherms and adsorption kinetics under selected pH conditions were also determined for the tested elements.

This work was funded by the National Science Centre (NCN) under the Preludium-20 Project (number: 2021/41/N/ST10/02759) led by I. Sekudewicz.

Abstract

Manganese (Mn) is a prevalent metal in acid mine drainage (AMD) and poses a challenge for remediation because of its high mobility across a wide pH range. This research was conducted at a mine treatment facility in Japan, which treats acidic mine water (pH~2.9) associated with high dissolved metal concentrations. Soluble manganese (Mn2+) is inefficiently removed from acidic mine water at the thickener when other toxic metals (Fe, Cu, and Zn) are removed with sludge. As a result, untreated Mn2+ precipitates on the sand in the filtration tank. However, the Mn concentration is negligible in the effluent upon discharge from the filtration tank. This study investigates the mechanisms of manganese oxidation and removal promoted in a sand filter and the Mn2+ removal process facilitated by naturally formed/precipitated manganese oxides on the sand in a filtration tank.

X-ray diffraction (XRD), X-ray fluorescence (XRF), and scanning electron microscopy (SEM) analyses were conducted for the solid characterization of clean/unprecipitated sand (UNS) and manganese precipitated sand (MPS). Batch experiments were conducted to simulate the Mn oxidation and removal conditions that occur in the sand filter. Manganese-precipitated sand [MPS], unprecipitated sand [UNS], and commercial dioxide powder [MnO2] were compared in removing Mn from the mine water [MW] collected from mine thickener and pure water [PW] prepared in the laboratory. MPS was treated by UV irradiation to inhibit bacterial activity.

Solid characterization of MPS indicated poorly crystalline birnessite and manganite. UNS showed no presence of Mn minerals. The results show that MPS rapidly decrease the Mn concentration in MW within 3 hours, while UNS decreases it slowly, leaving most of the Mn dissolved after 96 hours. This suggests that birnessite and manganite on MPS act as a catalyst for Mn oxidation and removal. MPS rapidly decreases the Mn concentration in both MPS + PW (treated) and MPS + MW (untreated), suggesting that physicochemical processes dominate the Mn2+ oxidation and removal at the mine treatment facility. MPS rapidly reduced Mn conc from PW faster than MnO2, demonstrating that MPS is an effective catalyst for Mn2+ oxidation even in abiotic processes. This study sheds light on the role of naturally formed manganite and birnessite on the sand (MPS) in controlling Mn removability from MW in the filtration tank of the mine treatment facility. MPS could be used to optimise Mn removal from the mine water at the treatment facility.

Molecular-scale understanding of the sorption structure and reactivity of heavy metals at mineral-water interfaces

Sang Soo LEE[1]*, Argonne National Laboratory (sslee@anl.gov)

Abstract

Sorption of metal ions on mineral surfaces controls the mobility and bioavailability of the toxic chemicals in natural environments. Direct visualization of the sorbed ion distribution can provide a fundamental understanding of molecular-scale mechanisms at the interfaces. In this talk, I will present how the affinity and speciation of metal ions vary depending on the type of sorbent minerals to emphasize the role of mineralogy over the interfacial structure and reactivity: The basal surface of muscovite mica has a structural negative charge, which can electrostatically attract metal cations in solution. Cation adsorption on the mica surface occurs as a mixture of inner-sphere (IS) and outer-sphere (OS) complexes whose proportions are controlled by ion charge and hydration [1, 2]. For example, divalent metal Sr(II) adsorbs to the mica surface in nearly equal proportions of IS and OS complexes, although its adsorption is significantly stronger than monovalent metal Rb that adsorbs predominantly as an IS complex. When both Rb and Sr compete for sorption on the mica surface, we observe dramatic changes in adsorbed metal speciation, resulting in changes in the sorption free energy for the metal ions [3]. When individual metal ions Pb(II) and Cd(II) interact with the (104) surface of calcite, the most dominant surface of the ionic compound mineral, their sorption behaviors are largely controlled by the dynamic fluctuation of surface morphologies. In particular, metal uptake occurs predominantly via incorporation in the calcite crystal structure even during active dissolution of the host mineral under acidic far-from-equilibrium conditions. The degree of this metal uptake appears to be systematically controlled by the similarity in crystal structure and lattice match between the substrate and incorporated metal-bearing carbonate phases (i.e., cerussite and otavite, respectively) [4]. Experimental observations are made through the application of in-situ synchrotron-based X-ray scattering and imaging techniques. The chemical and structural characteristics obtained from these measurements will be discussed in the context of their impacts on emerging environmental and energy issues including metal contamination, water remediation, and carbon sequestration.

Efficient Seawater Splitting with Ni-based Oxyhydroxide Catalysts: A Computational Perspective

Sooyeon KIM[1]*, Korea Institute of Science and Technology (KIST) (skim5520@gmail.com)
Sang Soo Han[2], Korea Institute of Science and Technology (KIST)

Abstract

Electrochemical water splitting is one of the most eco-friendly methods for hydrogen production. However, the reliance on pure fresh water as a proton source increases overall costs and hampers widespread adoption of this process, particularly in water-scarce regions. Consequently, direct seawater splitting has gained significant attention as a promising alternative because of its abundant availability on Earth. Nonetheless, its utilization remains still challenging due to the presence of impurities and detrimental chlorine species, which induce corrosion and compete with the oxygen evolution reaction (OER) of water splitting. In this study, we systematically investigated the catalytic performance of Ni-based oxyhydroxide catalysts for seawater splitting using computational methods. Specifically, we focused on comparing their catalytic activities for both the OER and the chlorine evolution reaction (CER) to determine which reaction would favorably occur. Additionally, we explored the impact of various transition metal dopants on selectivity between OER and CER to provide fundamental understanding in a molecular level necessary for the development of efficient new catalysts for seawater splitting. Our comprehensive analysis not only highlights the suitability of Ni-based oxyhydroxide catalysts for efficient and sustainable seawater splitting, but also offers insights for the development of robust and cost-effective technologies for harnessing hydrogen from seawater.

Replacement of Calcium Carbonate (CaCO3) Polymorphs by Cerussite (PbCO3)

YoungJae KIM[1]*, Pukyong National University (youngjkm@pknu.ac.kr)

Abstract

Calcium carbonate (CaCO3) polymorphs, calcite, aragonite, and vaterite, serve as a major sink to retain various metal ions in natural and engineered systems. Here, we visualize the systematic trends in reactivities of calcite, vaterite, and aragonite to Pb2+ dissolved in acidic aqueous solutions using in situ optical microscopy combined with ex situ scanning electron and transmission X-ray microscopies. All three polymorphs undergo pseudomorphic replacement by cerussite (PbCO3) but with distinct differences in the evolution of their morphologies. The replacement of calcite and aragonite occurs through the formation of a pseudomorphic cerussite shell (typically 5−10 μm thick) followed by a slower inward propagation of reaction fronts through a thin solution gap (∼0.1 μm wide) between the shell and the CaCO3 substrate. The replacement of vaterite is characterized by the formation of a thinner cerussite shell (≤1 μm thick) and a larger cavity between the shell and the host mineral. These systematic differences in cerussite morphology for different CaCO3 polymorphs are explained by the relative dissolution and precipitation rates of the reactant and product minerals, coupled with the role of ion transport through the cerussite shells. We also find that the replacement of calcite by cerussite is the slowest when all three polymorphs coexisted. Our results provide mechanistic insights into the growth mode of cerussite on dissolving calcium carbonate and demonstrate these CaCO3 polymorphs as promising substrate materials for removal and recycling of Pb from acidic polluted water and industrial effluents.

Solid Substrate-Induced Variations in the Heterogeneous Formation of Mn Solid Phases

Seonyi NAMGUNG[1]*, Korea Atomic Energy Research Institute (synamgung@kaeri.re.kr)
Sungsik Lee[2], Argonne National Laboratory
Giehyeon Lee[3], Yonsei University

Abstract

Understanding the geochemical cycling of manganese (Mn) is pivotal, especially regarding the formation of its various solid phases, such as oxides and carbonates. These processes profoundly affect the environmental fate of essential elements and are reciprocally influenced by the cycling of these elements, thereby contributing to the dynamic transformation of Mn phases. While the importance of various formation processes of Mn oxides in both biotic and abiotic processes is well-recognized, the genesis of Mn carbonates in nature has typically been attributed to the reduction of Mn oxides, a process closely linked with microbial activity and organic matter decomposition. This study seeks to explore the competitive formation of Mn carbonates and oxides under oxic conditions in aqueous Mn(II) solutions, aiming to uncover how solid substrates influence these processes. By examining the impact of different substrates, our research demonstrated that the presence and type of substrate play a critical role in determining the pathway of Mn solid phase formation. In homogeneous oxic conditions, Mn carbonate was initially formed, becoming the dominant Mn solid phase alongside the minor oxides. This indicates a preference for Mn carbonate precipitation over Mn(II) oxidation in the absence of a solid substrate. However, the presence of a goethite (α-FeOOH) substrate distinctly promotes the oxidation of Mn(II) to form groutite (α-MnOOH), while the rhodochrosite ($MnCO_3$) substrate inhibits further Mn(II) oxidation. The results highlight the intricate mechanisms that govern the heterogeneous formation of various Mn solid phases, determined by the combined effects of two factors associated with nucleation and electron transfer processes.

Insights into the Origin of Pyrite in the Sediments of Brunei Darussalam

Azrina BOEY[1], Universiti Brunei Darussalam
Basilios TSIKOURAS[2]*, Universiti Brunei Darussalam (basilios.tsikouras@ubd.edu.bn)
Elena IFANDI[3], Universiti Brunei Darussalam

Abstract

Disseminated pyrite occurS in the sedimentary formations throughout Brunei Darussalam. Despite its common occurrence, the exact formation mechanisms of pyrite are understudied. This study focuses on the morphological and physicochemical properties of the pyrite and its host sediments to elucidate its genesis and distribution. Furthermore, it aims to reveal the role of pyrite in various geological processes and its potential impact to the environment. Besides, pyrite often serves as an essential pathfinder, for gold and hydrocarbons, while its association with elevated acidity raises environmental concerns. Secondary electron imaging revealed that the pyrite in clay sediments is of authigenic origin characterised by euhedral, octahedral microcrystals and framboids. The formation of pyrite involves complex water-rock and microbial interactions under highly acidic and anoxic conditions. Diagenetic processes play a pivotal role in pyrite formation, particularly the generation of the required sulphides by bacterial-mediated sulphate reduction. The availability of dissolved ferrous ions and organic matter further contributes to pyrite growth. Framboids ranging from 2 to 7 microns, suggest an early diagenetic formation, whereas larger euhedral microcrystals approximately 5-10 microns in size, are consistent with a syngenetic formation. The surface occurrence of pyrite presents significant challenges to environmental integrity and sustainability. In tropical areas, pyrite weathers rapidly when exposed to oxidising conditions. Its dissolution results in the formation of highly acidic leachates containing sulphuric acid and hydrogen sulphide. This elevated acidity facilitates mobilisation of heavy metals into the ecosystems which may be detrimental to public health and biodiversity. Anthropogenic activities, such as excavation and water-flooding, can exacerbate the oxidation of pyrite promoting its dissolution and enhancing the acidic conditions. The absence of carbonate rocks to buffer the acidity contributes to widespread soil acidification in Brunei Darussalam, negatively impacting soil fertility and agricultural productivity. Given these concerns, it is imperative to evaluate the distribution of pyrite, as well as to identify and map regions that are highly susceptible to acidification and other potential environmental risks. This knowledge is crucial for implementing targeted mitigation strategies to protect and safeguard Brunei's biodiversity and people while promoting sustainable economic growth.

Abstract

Atmospheric deposition of phosphorus (P) serves as an important nutrient input for many terrestrial, marine and freshwater ecosystems, influencing their bio-geochemical cycling of phosphorus/carbon and primary production. Excessive phosphorus input has the potential to accelerate eutrophication and climate change. Phosphorus occurs in nature primarily in its fully oxidized form as orthophosphate (represented here by PO_4 to encompass the range of protonation states and ion pairs). Phosphorus has no significant gas phases, and is conventionally thought of as having no significant redox chemistry in low-temperature natural environment (< 70°C).

While most of the atmospheric-P are mineral airborne particulate matter (PM) that originated in soils/sea salts (32% of total global P-budget), recent estimations of global P-budget have shown that both anthropogenic combustion of fossil fuels, biomass and biofuels (51% of total global P-budget) and biogenic airborne PM (e.g., plant pollen; 17% of total global P-budget) have significant roles as well (Wang et al., 2014). In agricultural regions, the soil/mineral airborne PM were shown to be enriched in phosphorus, because of their high sorption capacity of anthropogenic phosphorus (e.g., fertilizer-P, livestock excrement-P) (Granger et al., 2018).

In this study, airborne total suspended particles (TSP, size: <ca.50 μm in diameter) were collected over one month (May 7th – June 6th, 2019) in urban region at the Eunpyeong-gu, Seoul, Republic of Korea. The concentration of water-soluble ions (NO_3^-, SO_4^{2-}, NH_4^+, Ca^{2+}, Mg^{2+}, Na^+, K^+, Cl^-, F^-, Br^-), water-soluble organic carbon (WSOC) and elements were measured on TSP using IC, TOC and ICP-MS/OES, respectively. We developed a sequential extraction method for five different forms of phosphate (PO_4) in TSP, including water soluble-PO_4, adsorbed-PO_4, solid-PO_4 (less-crystalline), solid-PO_4 (crystalline) and organic-PO_4. The concentration of PO_4 and elements in the sequentially extracted fractions were determined by UV-Vis spectrophotometer and ICP-

MS/OES, respectively.

The total-PO_4 mass fraction against TSP is very low as 0.6 % of TSP, including water soluble-PO_4 (0.12 %), adsorbed-PO_4 (0.14 %), solid-PO_4 (0.18 %) and organic-PO_4 (0.16 %). Good positive correlations were observed for PO_4 species (total-PO_4, adsorbed-PO_4, solid-PO_4 and organic-PO_4) with TSP ($r > 0.7$) but, no statistically significant correlations were observed with PM2.5 ($r < 0.3$). The water soluble-PO_4, on the other hand, has a good positive correlation with PM2.5 ($r > 0.6$) and other anthropogenic tracers (e.g., NO_2, SO_2, SO_4^{2-}, NH_4^+, WSOC, S, As, Cd, Mo), implying that water soluble-PO_4 is a good tracer of secondary PM2.5 associated and anthropogenic P-sources. Importantly, the input of water soluble-PO_4 through atmospheric deposition can be a major source of bio-available P to the environment. The data we present demonstrates a new application of PO_4 species for the potential use to trace atmospheric-P sources.

Effects of different tunnel cations on adsorption, occurrence, and mobility of water in palygorskite

Jinhong ZHOU[1]*, Nanjing University (zjh12387@126.com)
Xiancai Lu[2], Nanjing University

Abstract

Palygorskite is a fibrous magnesium-rich clay mineral with a typical tunnel structure, and its adsorption properties make it an ideal adsorbent for broad applications. Thus, revealing the confinement effects on tunnel species can help in understanding its adsorption properties. Grand canonical Monte Carlo and molecular dynamics simulations were performed to analyze the effects of different tunnel cations of palygorskite on the adsorption, occurrence, and mobility of tunnel water. Water adsorption isotherm, distribution models, and mobility were achieved from these systematic simulations. Compared with neutral palygorskite, the influences of tunnel cations on water distribution and mobility are obvious. The occupation of Na+Ca2+ or Li+ ions in tunnels can reduce the maximum water amount and affect the spatial distribution of zeolitic water. The water distribution in tunnels can be described by a two-zeolitic water-site model for neutral palygorskite and a one-zeolitic water-site model for the charged one. The zeolitic water confined in the tunnel presents very low mobility, and the appearance of cations in the charged palygorskite further reduces the mobility of zeolitic water. Compared with other clay minerals, the much lower water mobility of palygorskite implies that it may have a more efficient fixation on foreign molecules or ions in environmental applications.

Investigation of characteristic heavy metal contamination of roadside dusts in Daejeon, Korea: Impacts of car tire, brake pad and traffic paint on the elevated levels of Zn, Cu, Sb and Cr

Seon Yong LEE[1]*, Korea Institute of Geoscience and Mineral Resources
(seonyonglee@kigam.re.kr)
Pyeong-Koo Lee[2], Korea Institute of Geoscience and Mineral Resources
Sangwoo Ji[3], Korea Institute of Geoscience and Mineral Resources
Dong-Wan Cho[4], Korea Institute of Geoscience and Mineral Resources
Gil-Jae Yim[5], Korea Institute of Geoscience and Mineral Resources
Jeong-Ho Lee[6], Korea Institute of Geoscience and Mineral Resources

Abstract

Road dust has the potential to contribute to transport hazardous pollutants, fugitive emissions, and release toxic trace elements into various components of the ecosystem, encompassing water, air, and soils. Many studies consistently report elevated concentrations of heavy metals in road dust, the heavy metal types and chemical forms of which vary depending on contamination sources. The mobility and availability of toxic heavy metals hinge significantly on their chemical species. Therefore, comprehending the fate of harmful heavy metals in urban areas and establishing fundamental pollution prevention strategies necessitate identifying the characteristics and causes of heavy metal pollution in roadside dusts. In this study, we investigated the characteristic heavy metal contamination (especially, Zn, Cu, Sb, Cr, and Pb) in roadside dusts collected in Daejeon metropolitan city, Korea, and the contribution of three anthropogenic traffic sources such as car tire, brake pad and traffic paint to the heavy metal contamination. Roadside dust samples were collected from a total of 120 points in the Daejeon area divided into 72 districts. Additionally, background soil samples were collected from a total of 20 sites within the granitic and metamorphic rock region to take geological origin factors into account. Overall, heavy metals in road dust samples showed a wide concentration range of hundreds to thousands of mg/kg in Zn, tens to hundreds of mg/kg in Cu, Cr, and Pb, and several to tens of mg/kg in Sb. Although concentrations were generally elevated in the vicinity of industrial areas, notable levels were also identified in certain residential or commercial zones, suggesting the significant contribution of other contamination sources, such as traffic. Therefore, we analyzed seven car tires (tread part) and ten brake pads, which are known as representative traffic-related pollution sources, using XRD, EPMA, XRF and ICP-MS. In addition, XPS analysis were further performed on several roadside dust samples with high Cr concentrations to confirm the oxidation state. Characterization analyses revealed that in comparison to other heavy metals, a relatively higher concentration of Zn was detected in tire treads, while particles containing Cu or Sb were found in brake pads. Moreover, Cr in the roadside dust samples predominantly existed as Cr3+ in the industrial zones and Cr6+ in road areas. These findings indicate that Zn in roadside dust may originate from car tires, whereas the presence of Cu and Sb could be attributed to brake pads. Furthermore, traffic paint containing Cr6+ as well as industrial can contribute to the Cr contamination of roadside

dusts. This understanding is useful for devising effective measures to mitigate the environmental impact of heavy metal contamination in road dust and safeguarding public health and ecological integrity.

Molecular simulations of CO2 and H2 insertion into palygorskite

Juhyeok KIM[1]*, Kangwon National University (juhuyg@kangwon.ac.kr)
Kideok D Kwon[2], Kangwon National University

Abstract

Palygorskite, a clay mineral with a ribbon-like structure, possesses nanopores that offer a large surface area, making it a promising adsorbent for greenhouse gases and reactive gas molecules. Studies have shown that palygorskite's CO2 adsorption capacity is approximately twice that of montmorillonite, with additional advantage of lower production costs. There is potential for use in the capture and storage stages in the processes of carbon capture, utilization and storage (CCUS). Palygorskite is also being explored as a potential storage material for hydrogen gas. In this study, the adsorption isotherms of palygorskite for gas molecules were obtained using grand canonical Monte Carlo (GCMC) simulations. Molecular-level insight into the adsorption of CO2 and H2 to palygorskite were obtained using molecular dynamics (MD) simulations. Our findings indicate that with increasing partial pressure, the adsorption of CO2 and H2 increases, although H2 intercalation requires higher pressure compared to CO2. The mean squared displacement was also higher for H2 than for CO2, suggesting that intercalation of H2 is comparatively less favorable. At completely saturation, CO2 molecules exhibited the lattice structures akin to one of the dry ice phases at high pressure (>10 GPa). These atomistic simulation results enhance our current understanding of mineral-fluid interactions and will guide the development of materials for the capture and storage of gas molecules.

Changsoo Lee[4], Korea Atomic Energy Research Institute
Dong-Keun Cho[5], Korea Atomic Energy Research Institute

Abstract

Since bentonite as an engineered buffer material for High-Level radioactive Waste (HLW) disposal, understanding mineral transformation at high temperatures is essential. In this study, Bentonil WRK, Ca-type of bentonite, was utilized. A long-term experimental setup has been established to investigate the transformation (alteration) of bentonite when it reacts with potassium ions at temperatures exceeding 100 degrees Celsius. To clarify the estimation of clay mineral types, Ethlyne Glycol (EG) treatment was also conducted alongside EG-dry treatment at 550 degree Celsius. Additionally, to estimate the water layer content, the sample was saturated with deionized water (DIW) was saturated before XRD analysis. From the XRD results, the transformation from bentonite to illite was investigated, with a focus on the illite-smectite (I-S) mineral. There is no clear evidence of bentonite transformation below 175 degrees Celsius during the 6-month experimental period. However, under the same temperature conditions, the solid-to-solution ratio appears to have greater effect on altering bentonite. For example, at temperatures below 150 degrees Celsius, samples with a 10-fold reduction in solid-to-state ration exhibited narrower interlayer spacing (d-001). While the qualification and quantification of clay minerals from XRD analysis remain challenging, we have attempted to understand the possibility that bentonite in deep HLW disposal sites may transform into illite due to the high temperatures.

Youngseuk Keehm[4], Department of Geoenvironmental Sciences, Kongju National University, Republic of Korea
Hyun Na Kim[5], Department of Geoenvironmental Sciences, Kongju National University, Republic of Korea

Abstract

Smectite is a primary consideration as a buffer material to delay radionuclide migration in the event of a High Level Radioactive Waste(HLW) repository leak, due to its high swelling and adsorption capacity and low permeability. In nature, smectite in sediment basin transforms over time into smectite-illite mixed layer minerals, thereby used as a geothermometer. The potential for similar smectite-illite transformations in bentonite at HLW repositories requires an understanding of the transformation mechanism and rate. However, laboratory-scale research is not yet sufficient. The aim of this study was to reproduce the smectite-illite transition on a laboratory scale using Bentonil-WRK (Clariant Korea), a candidate buffer material for waste repositories in Republic of Korea.

The hydrothermal experiment was conducted with 1 M KCl to accelerate the smectite-illite transformation reaction by variation of temperature and reaction time. X-ray diffraction (XRD) results show that the S(001) peak decreased while the I(001)/S(002) and I(003)/S(005) peaks increased with increasing temperature up to 250 °C, indicating the progress of I-S transformation. The I-S mixed layer samples of R0 and R1 were obtained after 7 days and 21 days of reaction, respectively, as analyzed by NEWMOD. However, above 330 °C, the smectite disappeared and new minerals such as quartz, illite, Kfs were observed, indicating the dissolution of smectite.

In this study, we confirmed the proper experimental conditions for the reproduction of the I-S transformation in the laboratory. Further research involving ICP-MS, Si-29 and Al-27 NMR, and SEM are currently undergoing to enhance the understanding of I-S transformation mechanism.

The Alteration of Fault Gouge with Supercritical CO2: Changes in Fault Stability by Carbon Sequestration

Yuna LEE[1]*, Department of Geoenvironmental Sciences, Kongju National University, Republic of Korea (sharon1224@naver.com)
Insun Song[2], Korea Institute of Geoscience and Mineral Resources, Republic of Korea
Hyun Na Kim[3], Department of Geoenvironmental Sciences, Kongju National University, Republic of Korea

Abstract

The injected CO2 for Carbon capture and storage (CCS) increases the pore pressure within the storage formation, inducing potential leakage along faults in the cap rock. Leakage alters the frictional properties and change the fault behavior. The fault gouge, one of crucial factors determining the frictional behavior of fault, altered by the chemical reaction with CO2 leaked from carbon sequestration formation. Therefore, understanding the interaction between fault gouge mineral and leaked CO2 is crucial for assessing the fault slip behavior at the cap rock. A systematic lab-scale investigation on fault gouge and CO2 interaction, considering varying particle size, crystallinity, and mineral composition is necessary to evaluate the long-term geological stability of CCS. In this study, various synthetic fault gouges ware produced to simulate the characteristics of natural fault gouge and investigate the effect of mineralogical alteration resulting from CO2 reaction on the fault stability.

The series of fault gouge are synthesized with varying composite minerals; quartz, feldspar, illite, and montmorillonite. Additionally, the crystallinity and particle size were controlled using high energy ball mill: non-pulverized and pulverized. The fault gouge reacted with scCO2 for six weeks using a multiphase fluid flow test apparatus under 75 bar and 40℃.

In pulverized fault gouge with low grain size and crystallinity, significant changes in mineral composition and structure were observed. Depending on the mineral composition, remarkable mineralogical differences occurred due to CO2 interaction, and more clearly in fault gouge with clay minerals. Alteration such as reduction in particle size and acceleration of the dissolution rate of the mineral, was found to be greater in fault gouge containing montmorillonite, a clay mineral with high swelling properties. Therefore, when the CO2 leaks and reacts through the fault, the type of clay minerals present has a crucial influence on the alteration of fault gouge than the grain size and crystallinity. This suggests that the mineral composition acts as a key factor in changing the characteristics of the fault plane.

As a result, the clay-ultrafine particles of the fault gouge generated by fault slip can enhance the reactivity with CO2. Furthermore, the properties of the fault gouge are not fixed and can vary over time and geochemical conditions. Therefore, this study is expected to contribute to understanding the diverse mineral alteration generated by CO2 reactions in a fault.

An improved structural model of silicate melts and magmas probed with NMR spectroscopy: implications for planetary sciences

Jeongjae LEE[1]*, Seoul National University (jl635@snu.ac.kr)
Sung Keun LEE[2], Seoul National University

Abstract

The macroscopic properties of silicate melts such as viscosity and diffusivity depend critically on the microscopic short-range structures (interaction radius of <5 Å) and the mesoscopic medium-range (structural features within 5–20 Å) order in these glasses, which is in turn governed by how metal ions distribute within the silicate framework. Information on the nature of such distribution on a varying length scale is therefore crucial for better understanding the dynamics of silicate melts and magmas in the Earth's crust and mantle. While the distribution and local structure of oxygen and silicon atoms in these glasses are relatively well known, such information for metallic ions such as sodium are still poorly understood. In particular, the distribution of sodium with respect to two distinct types of oxygen atoms, namely the bridging (Si–O–Si) and nonbridging (Si–O–Na) oxygens, has remained a controversy for over a century since the introduction of continuous random network by Zachariasen; the conventional modified random network (MRN) model suggests completely segregated Na-rich and silicate-rich regions, while previous NMR data suggested otherwise.

Following this line, here we provide a clear experimental evidence for bonding between the bridging oxygen and sodium atoms through 17O→23Na triple quantum heteronuclear correlation (3QHETCOR) NMR experiments in multiple different sodium silicate compositions. Through 3QHETCOR experiments, we demonstrate the ability to resolve the bridging/non-bridging (vide infra) oxygen NMR signals as well as the capacity to probe the close-by quadrupolar 23Na–17O (I=3/2 and 5/2, respectively) spin pairs simultaneously; this method unambiguously shows the existence of Na atoms in the first coordination shell of bridging oxygen atoms. Our result suggests a more homogeneous Na distribution than that expected from the conventional MRN model, which we name as a perturbed random network (PRN) model; it also illustrates the powerful capability of heteronuclear correlation experiments in advancing our understanding of glass structures. While further confirmations remain, we discuss the potential implications of our perturbed structural model for explaining a number of puzzling phenomena in planetary sciences such as decrease in elastic constants upon densification and an increase in configurational entropy of magmatic melts, highlighting improved prospects for modelling the non-linear changes in viscosity and seismic wave velocity of molten silicates.

[Invited] How do transition elements influence viscosity of glasses, melts and lavas?

Daniel R. NEUVILLE[1]*, CNRS IPGP UP (neuville@ipgp.fr)

Abstract

Transition metals such as iron, chromium, nickel, titanium, copper, … are common minor components of aluminosilicate glasses and melts, with concentrations ranging from ppm to some wt%. The effects of transition metals on the properties of glasses and liquids are relatively poorly understood, with the exception of the role of iron, which has been well investigated. However, there is a lack of data on their structural role in glass and how it affects properties such as viscosity.

In order to better understand the role of transition elements on the structure and properties of glasses and melts, we present several new glass compositions with different amounts of Fe, Ti, Cu, Cr, Ni.... Measurements of density, viscosity at high and low temperatures and heat capacity have been carried out on these glasses, and their structure investigated using Raman spectroscopy and XANES spectroscopy at the different K-edge.

As a first approximation, IVFe2+, Cu2+ can be considered as network modifiers, while IVFe3+, Ti4+, Ni2+, Cr3+ seem to play the role of intermediate cations in the glass structure. It seems that element coordination plays a key role in understanding the role of an transition element. We will present and discuss these new results.

[Invited] A multiscale simulation study of supercritical geofluids

Xiandong LIU[1]*, Nanjing University (xiandongliu@nju.edu.cn)

Abstract

With increasing temperature and pressure, solubility of silicate in aqueous fluids increases as well as the solubility of water in silicate melts. When silicate melts are completely miscible with aqueous fluids, i.e. the phase boundary disappears, a single phase is formed, that is termed as supercritical geofluid or supercritical fluid. The unique properties and behaviors of supercritical fluids have attracted great attentions. For example, supercritical fluids have compositions close to those of hydrous silicate melts but have high diffusivity and low viscosity, that is close to aqueous fluids. Aiming at a molecular level view of these properties, we have carried out systematic molecular simulations. To overcome the temporal and spatial scale limitation of FPMD (first principles molecular dynamics), we have developed a general purpose ReaxFF force field (i.e. a reactive force field based on bond order) for simulating silicate materials. This force field was validated against experimental and DFT data on a wide range of systems including minerals, interfaces and melts. We applied this force field to perform molecular dynamics simulations to investigate supercritical fluids. The derived results of microscopic structures, speciation and transport properties will be presented. The future application and further development of the force field will also be discussed.

The pyrolite melts of the early Earth: structure, compressibility, viscosity, volatile content

Razvan CARACAS[1]*, CNRS, IPGP (caracas@ipgp.fr)
Adrien Saurety[2], IPGP
Anne H Davis[3], University of Oslo, PHAB

Abstract

As the protolunar disk formed by the giant impact with the incoming asteroid Theia started to cool, the Earth condensed in its center as a molten planet. The outer layer, rich in lithophile oxides, formed the magma ocean, whose dynamical behavior heavily influenced the entire evolution of the early Earth. Here, we employ first-principles molecular dynamics simulations to characterize the magma ocean in its initial stage. We compute the compressibility and the viscosity of the molten pyrolite, which best approximates the bulk silicate Earth composition. With an extensive set of calculations, we span the entire relevant pressure-temperature range. We provide a detailed analysis of the athermal and thermal equations of state in various formulations. We also establish the position of the critical point around 6000K and at pressures of about 1.1-1.2 kbars, at conditions hardly attainable experimentally.

We analyze the evolution of the structure of the liquid as a function of pressure and temperature. The melt structure is formed on a backbone of silica and alumina polyhedra. The other cations, like Na, Mg, and Ca, freely float in between these large polymers. Iron plays a special role in that it may participate in the polymerization or may just lie in between these polymers. We follow the enlargement of the first-coordination sphere with compression.

However, it is the collapse of the second coordination sphere that is responsible for accommodating the increase in pressure. For the first time, having sufficiently large simulation cells, we are able to monitor this collapse correctly. We find that the second coordination number of Si by O goes from about 24 at the top of the magma ocean to 40 at the base of the magma ocean.
We find the viscosity of pyrolite to be about one order of magnitude lower than that of molten basalt.

Finally, we give insights on the behavior of specific volatiles in the pyrolitic melt, with a special regard towards the transport and the loss of noble gases.

Probing the short- to medium range structures of simplified Ti-rich lunar glass using NMR spectroscopy: implication for lunar mantle dynamics

Elias EL GHAZAOUI[1]*, Seoul National University (egi340@snu.ac.kr)
Sung Keun LEE[2], Seoul National University

Abstract

Widening our understanding regarding the evolution of the lunar mantle and the origin of lunar glasses after the Theia Impact event is a challenging task. It remains a topic in lunar science that could be of great importance in comprehending the existence of a lunar dynamo and planetary evolution in general. The lunar mantle melts likely contain substantially more Ti compared to melts found on Earth. Therefore, one can ponder the question to what degree the evolution of the Moon's mantle is affected by this Ti-rich composition. As melt properties like viscosity and density are directly influenced by these compositional differences, studying, and understanding the atomic structure of lunar glasses is fundamental. Despite being a relatively less popular method of probing the structural data of glass materials, NMR spectroscopy has shown to be extremely insightful for certain simple glass compositions in the recent past. In this study, we report the short- to medium range atomic structures of a variety of simple and complex model lunar glasses using high resolution solid-state NMR spectroscopy, revealing the detailed impact of an addition of Ti on silicate melts. The novel structural results include the Ti-driven formation of Ti-O-Si, which tends to increase the bulk moduli of the lunar melts.

Sung Keun Lee[5], School of Earth and Environmental Sciences, Seoul National University, Seoul 08826, Korea

Abstract

Despite the implications for dense oxide melts in the Earth's and super-Earth's interiors, detailed structures of amorphous oxides at high pressure, particularly beyond Mbar pressure conditions, remain the challenging problems in the geosciences [1]. Structure of the simple oxides, such as B2O3 and GeO2, under Mbar compression can provide the insights into the geochemical behaviors of light- and heavy-elements in the magmatic melts in the planetary interiors. The inelastic X-ray scattering (IXS) of B2O3 glass up to ~2.2 Mbar reveals the formation of post-[4]B above ~1.4 Mbar, with the gradual coordination transformation from [4]B to [5]B over broad pressure ranges. Ab initio calculations suggest that the formation of [5]B partially localizes the boron electronic states, potentially due to the changes in the polarity of B—O bonds. The changes in the nature of electronic bonds upon the coordination evolution may affect the geochemical behavior of boron (i.e., isotope fractionation) in the oxide melts under multi-Mbar conditions, making the isotope signals of super-Earth's interiors to be largely different from those of Earth's [2]. The GeO2 glass provides an opportunity to explore the atomic and electronic structure of silicate melts under multi-Mbar, because pressure-induced phase transitions in germanium oxides occur at much lower pressures compared to silicates. The IXS of GeO2 glass up to ~1.5 Mbar reveals the formation of compressed oxygens, such as [4]O above ~55 GPa, giving rise to the pronounced electronic delocalization by the contributions from Ge d-orbitals. Other heavy-elements may also exhibit such contributions from d-orbitals, making their bonding environments distinct from the light-elements. The dispersion of electronic states around compressed oxygens may lead to enhanced conduction of electrons in deep mantle melts in super-Earth's interiors [3]. The bonding transitions in amorphous oxides revealed by the IXS shed light on the novel structural and electronic behavior of oxide melts in the interior of massive terrestrial planets.

[Invited] Planetary melts: constraining viscosity via the glass transition.

Donald B. Dingwell[1]*, LMU Munich (dingwell@lmu.de)

Abstract

The role of melts in the evolution and behavior of planetary systems (Earth, Moon, Mars, Venus) is undisputed. The behavior of magmatic and volcanic systems varies with melt chemistry and planetary conditions. In particular, the viscosity of planetary melts varies widely. Analysis of the glass transition provides a valuable window on the low temperature viscosities of these melts, defining their physical behavior both within planetary interiors and on planetary surfaces.

The advent of conjectures of major magmatism and volcanism on exoplanets has enhanced the appeal of understanding these materials under an even wider range of volcanic conditions. The future of their investigation will require concerted efforts, new infrastructure, and an expansion of the boundaries of chemistry and conditions anticipated from terrestrial planets of our solar system to the rapidly growing population of exoplanets.

Glass transition studies have for decades been an essential companion of high temperature viscometry studies of terrestrial melts. The essential link enabling their usefulness for constraining the temperature dependence of viscosity was clarified over 30 years ago. The most recent advances in its study have been provided by 1) a broadening of the target range of melt chemistry beyond terrestrial constraints, 2) a broadening of the range of the glass forming ability of "extreme" melt compositions using novel synthesis and quenching techniques, 3) new "flash" calorimetry methods for the determination of the glass transition of poor glass formers, 4) and a realisation that the variability of planetary surface conditions may place a significant role in volcanism on such planetary bodies and the resultant efficiency of degassing.

These aspects will be evaluated with a series of recent examples of experimental glass transition studies and estimates.

Speciation of carbon in silicate melts at high pressure up to 8 GPa

Eun Jeong KIM[1]*, Kongju National University (eunjkim@kongju.ac.kr)
Sung Keun Lee[2], Seoul National University

Abstract

Carbon is one of the most abundant volatiles in the magma. Understanding the speciation of carbon in carbon-bearing silicate melts helps us interpret the changes in the transport properties of carbon-bearing magma in the mantle. While the earlier studies have reported the solubility and carbon species in silicate melts at high pressure up to 4 GPa, experimental data has not been reported above 4 GPa. Here, we explore the carbon species in sodium silicate (Na2O-3SiO2, NS3) and sodium aluminosilicate (NaAlSi3O8, albite) glasses quenched from melts at high pressure up to 8 GPa using solid-state nuclear magnetic resonance (NMR). 13C NMR spectra of carbon-bearing NS3 show the presence of free carbonates, non-bridging carbonates, and bridging carbonates. The fraction of non-bridging and bridging carbonates increases with increasing pressure. With respect to the lower fraction of highly coordinated Si ([5,6]Si) in carbon-bearing silicate melts than in carbon-free melts in 29Si NMR spectra, the increase of bridging carbonates may indicate that the dissolution of carbon in silicate melt changes the silicate network structure and prohibits the densification of silicate melts by lowering the formation of highly coordinated silicon. 13C NMR spectra for carbon-bearing albite glasses show the presence of CO, CO2, free carbonates, and briding carbonates at 1.5 GPa. The fraction of bridging carbonates linked to Si and Al increases the most with increasing pressure. While the increase of bridging carbonates does not affect the peak width of [4]Al in 27Al NMR spectra, the peak intensity of [5,6]Al decreases with the presence of carbon. The 29Si NMR spectra show negligible changes with the presence of carbon in albite melts. The presence of carbon changes the Si environment in sodium silicate melts and Al environment in sodium aluminosilicate melts. With the presence of carbon in silicate melts, the fraction of highly coordinated network former decreases, which indicates that the melt structure is less densified. The lower density of carbon-bearing silicate melts can therefore be due to the carbon-related structural changes. The structural analysis of carbon in silicate melts at high pressure may make us to unravel a relationship between carbon-induced structural changes and related macroscopic properties.

The possible role of gold-rich colloids in the formation of high-grade supergene gold ores

Yafei WU[1]*, China University of Geosciences, Wuhan (wuyafei@cug.edu.cn)
Yage WU[2], China University of Geosciences, Wuhan

Abstract

Oxidative dissolution of auriferous sulfides such as pyrite and arsenopyrite within hydrothermal gold deposits under near-surface weathering conditions results in the release and redistribution of a large amount of gold and other related metals (e.g., As, Ag, Cu, Hg, Tl, etc.). The released gold can be subsequently re-enriched to form visible gold grains as well as micron-to-nanoscale gold particles within supergene iron oxides and oxyhydroxides such as hematite (α-Fe2O3) and goethite [α-FeO(OH)]. The supergene gold ores are generally high-grade (up to thousands of g/t) and easily processed, being one of the most important types of gold deposits in the world. However, the formation processes of abundant supergene gold grains largely remain unclear. It has been suggested that gold colloids play a critical role in the formation of supergene gold grains, but processes and mechanisms that control the formation of gold-rich iron oxides have not been fully understood.

Here we utilized scanning electron microscopy (SEM) and transmission electron microscopy (TEM) to decipher the formation processes of high-grade (200 g/t Au) oxidized auriferous pyrite-quartz veins from the Longtougou orogenic gold deposit in the West Qinling orogen, China. Detailed SEM observations show that hematite grains preserve the euhedral morphology of auriferous pyrite and contain abundant fine-grained goethite inclusions and local bright Ag-Cu-rich zonation. Irregular auriferous pyrite relicts are enclosed within hematite. The hematite is crosscut by slightly zoned goethite which contains fine-grained gold inclusions (<1 μm across). The zoned goethite is further overgrown by fibrous to acicular goethite that is intergrown with subrounded to irregular gold grains (5–100 μm across). The TEM results reveal that numerous irregular nanoparticles and nanoveinlets (<500 nm across) that are enriched in Au, Ag, As, Hg, and Bi occur adjacent to large gold grains within the fibrous to acicular goethite. The metal-rich nanoparticles are compositionally heterogeneous and contain spherical gold nanoparticles (5–20 nm across). The metal-rich nanoparticles are connected via veinlets that are depleted in Au and other metals relative to the nanoparticles.

Our results show that oxidation of auriferous pyrite during supergene weathering might proceed via three main stages: replacement of pyrite by aggregates of hematite and goethite with metal-rich zonation; replacement of these iron oxide aggregates by zoned goethite with fine-grained gold particles; formation of fibrous to acicular goethite and associated coarse-grained gold grains. The presence of connected Au, Ag, As, Hg, and Bi-rich nanoparticles and veinlets indicate that these metals released from auriferous pyrite might have formed polymetallic colloids due to the high degrees of supersaturation. These metal-rich colloids were then migrated and aggregated to form larger colloids. Spherical gold nanoparticles might be deposited from the metal-rich colloids,

which is consistent with the heterogeneous compositions of the metal-rich nanoparticles.

Variations of atomic structures and mechanical properties of natural opal-CT-based geopolymers with synthesis conditions

Hyo-Im KIM[1]*, Department of Geology and Research Institute of Molecular Alchemy, Gyeongsang National University (hyoim@gnu.ac.kr)
Min-Kyung Kim[2], Department of Geology, Gyeongsang National University
Sunhwa Bang[3], Research Institute of Molecular Alchemy, Gyeongsang National University

Abstract

In light of the global imperative for the reduction of carbon dioxide emissions, geopolymers have been considered environmentally sustainable alternatives to ordinary Portland cement, and have widespread applications in construction and building industries. Geopolymers are among the aluminosilicate amorphous materials, which lack long-range structural ordering. The disordered structures are attributed to the alkali-activation process of crystalline raw materials: particularly, the alkali activators such as waterglass and sodium or potassium hydroxide induce the depolymerization and dissolution of Si- and Al-tetrahedra, followed by the re-polymerization with amorphous nature. To date, the efforts have focused on synthesizing geopolymers utilizing solid wastes and industrial byproducts such as fly ash, steel-making slags, and red mud. The synthesis of waste products-based geopolymers, however, poses significant challenges, primarily due to the instability in the supply of raw materials. Therefore, the development of geopolymers based on the natural Earth materials should be necessary. We explored the utilization of the natural opal-CT as the precursor of the geopolymer. Natural mudstone used in this study has predominant opal-CT, obtained from the Miocene Pohang basin, in southeastern Korea. We synthesized the natural opal-CT based geopolymers with varying conditions, such as the fraction of natural opal-CT relative to the metakaolin (which is the source of alumina), the types of activators, the curing time, and the concentration of alkali activators. The mechanical durability of synthesized geopolymers has been obtained by measuring compressive strengths, and the morphology and atomic structures of those materials were explored by the mineralogical and thermal experiments (i.e., SEM, XRD, Raman, and DTA/TGA). These results are critical for fundamentally understanding the performance of natural opal-CT based geopolymers. This research can contribute to the development of sustainable construction materials using natural Earth materials. Additionally, it could open the way for utilizing in-situ materials on the Moon or Mars to build infrastructure during future planetary explorations.

Structure of silica glasses under ultrahigh pressure: ab-initio calculations of nuclear magnetic resonance properties

Jae-Hyeon PARQ[1]*, Seoul National University (parkq2@snu.ac.kr)
Yoo Soo Yi[2], Seoul National University
Sang-Mook Lee[3], Seoul National University
Sung Keun Lee[4], Seoul National University

Abstract

The densification of silica melts under extreme pressure offers useful opportunities to explain the seismic anomalies near the core-mantle boundary (CMB) partly due to the presence of dense silica-rich partial melts at approximately 130 GPa. While solid-state nuclear magnetic resonance (NMR) has resolved the detailed atomic structures of complex silicate melts and glasses under compression. the pressure condition for a direct high-resolution solid-state NMR experiment for compressed materials is limited to ~65 GPa (Li et al., J. Phys. Chem. Lett. 2003, 14, 2078). Alternatively, ab initio calculations of the NMR properties of silicate melts have revealed the nature of densification beyond 100 GPa (Lee et al., J. Am. Ceram. Soc. 2022, 105, 5151).

In this presentation, combined efforts using classical molecular dynamics (CMD) and ab initio calculations for structure relaxation and NMR parameter were carried out for silica glasses to investigate how their structural changes affect the nature of nuclear spin interactions beyond megabar pressures. The pressure-induced changes in geometric factors are consistent with those reported in previous studies. The average Si-O-Si angle is 149.3° at 0 GPa and it decreases with increasing pressure. The correlation between the Si-O bond length and the Si-O-Si bond angle is not clear at 1 atm, but the negative correlation is pronounced between ~20 and ~50 GPa. The Si and O coordination numbers increase with increasing pressure, leading to a nonlinear change in the isotropic chemical shielding (δcs), which is accompanied by an increase in the network distortion around O, parameterized with the quadrupolar coupling constant (Cq). The average 29Si δcs linearly increases with the increasing average Si coordination number. The average 17O δcs and Cq decrease with the increasing average oxygen coordination number. The average 17O δcs linearly decreases with increasing the Si-O bond length, and the 17O Cq of [2]O and [3]O tends to increase with the increasing Si-O-Si angle. These novel relationships between NMR properties and pressure-driven structural changes have potential for the development of new NMR protocols to broaden the application of high-pressure NMR experiments. The results constrain the element-specific densification pathways for multi-component magmatic melts at the CMB, which can provide crucial insights into the evolution of the silicate Earth.

Abstract

In a recent effort we have profoundly transformed the UMD package [1] into a highly efficient tool for analyzing molecular-dynamics simulations. The package is written in Python and c, it is parallelized on CPUs, and partly ported on GPUs. While all the scripts are run at the command line, a preliminary GUI version is in use as well.

We propose a simplified format to store the atomic trajectories and relevant thermodynamic information of the simulations, which is saved in UMD files, standing for Universal Molecular Dynamics. For the time being, it has interfaces/parsers with VASP, QBox, and LAMMPS.

The package allows the computation of a series of structural, transport and thermodynamic properties. Starting with the pair-distribution function it defines bond lengths, and builds an interatomic bonding matrix. Using this connectivity matrix, it employs graphs theory to construct the chemical speciation in the fluid. It identifies the coordination polyhedra up to any order, between any combination of atomic types; it can build and extract the polymerization in the fluid. Determining the lifetime of the chemical species allows running a full statistical analysis. Self-diffusion coefficients are obtained from the mean-square displacements; they can be obtained for either atoms or for chemical species. The implemented self-correlation analysis of the atomic velocities yields the diffusion coefficients and the vibrational spectrum. The self-correlation analysis applied on the shear stresses yields the viscosity. The package is available via its GitHub website at https://github.com/rcaracas/UMD_package address, under GNU-CPL v3 and CeCILL v2 licenses, mutually compatible.

Evolution of Li environment in partially molten magmas during fractional crystallization: A view from solid-state NMR spectroscopy

Seoyoung LEE[1]*, Seoul National University (2seo0@snu.ac.kr)
Sung Keun LEE[2], Seoul National University

Abstract

Lithium (Li) is among the critical elements with strong applications in the energy materials industry. As Li can often be enriched in fluid-bearing felsic melts, proper inference of efficient partitioning mechanisms of Li into silicate melts needs to be established. Geologically important partial melts during crystallization provide constraints to the formation/synthesis of technologically useful glass-ceramics. The atomic environments around Li in the silicate glasses depending on the composition and pressure conditions were previously explored using solid-state nuclear magnetic resonance (NMR) spectroscopy, which demonstrated Li's remarkable mobility in silicate glasses (Park and Lee, J. Am. Ceram. Soc. 99 3948, 2016; Kim et al., J. Phys. Chem. C 123 (43) 26608, 2019). However, the detailed Li environments in glasses in equilibrium with silicate minerals in the Earth's crust have not been explored. In this study, we report the first Li-6 NMR spectra for the Li-Na silicate glass-ceramics, revealing the evolution of the Li environment among the crystalline and silicate melts with varying crystallization paths. Particularly, the NMR spectra revealed the two distinct spectral components, corresponding to the crystalline components, exhibiting a narrow peak due to Li silicate and a much broader peak due to the non-crystalline Li-Na silicate ranging from 2 ppm to -1 ppm. The relative proportions of the two signals vary differently depending on the crystallization paths. The results also indicate that the Li-Na disorder in the melts influences the growth of Li-silicate crystals. This finding is expected to contribute to our understanding of Li behavior and its enrichment during melting and fractional crystallization, accounting for the potential formation of Li-resources within magma reservoirs.

Comparative study on phase transition of zeolite in subducting slabs by hydrous and anhydrous environments

HYUNSEUNG LEE[1]*, Pusan National University (hslee07@pusan.ac.kr)
Pyosang Kim[2], Chonnam National University
Soojin Lee[3], Pusan National University
Hyeonsu Kim[4], Chonnam National University
Huijeong Hwang[5], Gwangju Institute of Science and Technology
Donghoon Seoung[6], Chonnam National University
Yongmoon Lee[7], Pusan National University

Abstract

Zeolites are hydrous minerals commonly observed in the lowest metamorphism. Stilbite [(NaCa4)(Si27Al9)O72 · 28 H2O] and clinoptilolite [(Ca1.3, K1.7, Na0.8, Mg0.5)(Si30Al6)O72 · 20H2O] are the most common zeolite in the oceanic crust. These are characterized by a three-dimensional micro porous structure, can content water molecules and exchangeable cations.

Subduction zone is considered initial pathway to transport slab-composed minerals toward the deep interior. During zeolites transport into the Earth interior via subduction zones, they are predicted to engage in interactions with subducting materials. Previous studies investigating minerals in subducting slabs have focused on water contents, bulk modulus, density, structural stability, and dehydration under pressure and temperature of sub-arc depths (around 100 ~ 150 km). However, research remains insufficient the effect of presence or absence of subducting fluids surrounding hydrous minerals. This study focused to reveal the impact of water presence to stilbite and clinoptilolite during subduction.

We performed in-situ high-temperature and -pressure X-ray diffraction experiments to simulate the cold subduction zones conditions. Water and silicone oil were added with the sample as pressure transmitting mediums (PTM) to create hydrous and anhydrous environments. Synchrotron X-ray diffraction analysis confirmed changes in the mineral structure.

Under hydrous cold subduction conditions, stilbite breaks down to single layer smectite and quartz at 230 °C, 1.97 GPa (ca. 64 km) and clinoptilolite breaks down to 3 - 2 layer smectite and quartz at 300 °C, 2.20 GPa (ca. 70 km). Under anhydrous cold subduction conditions, there are no significant changes both stilbite and clinoptilolite.

Our study will provide evidence to understand the water transport mechanisms from the Earth's surface to its interior, contingent upon the hydrous and anhydrous conditions of the subducting crust. Moreover, it can shed new insights into depth-dependent density changes with relevant research results.

Mechanochemical amorphization of clay minerals: Understanding the role of low-crystalline fault gouge in slip behaviour

Hyun Na KIM[1]*, Department of Geoenvironmental Sciences, Kongju National University, Republic of Korea (hnkim@kongju.ac.kr)
Jin Woo Kim[2], Department of Geoenvironmental Sciences, Kongju National University, Republic of Korea
Bo Gyoeng PARK[3], Department of Geoenvironmental Sciences, Kongju National University, Republic of Korea
Byung-Dal So[4], Department of Geophysics, Kangwon National University, Republic of Korea
Chan-Hee Jang[5], Department of Geophysics, Kangwon National University, Republic of Korea

Abstract

In geoenvironments with mechanical friction, such as fault zones and subduction zones, mechanical deformation leads to the formation of ultrafine amorphous earth materials with physical and chemical properties that differ from those of bulk minerals. These mechanochemical changes can affect geological phenomena such as fault slip behavior. Given this importance, this study aims to investigate the changes in the inherent properties of clay minerals, including talc and montmorillonite, due to mechanical deformation-induced amorphization. We ground the talc powder by high-energy ball milling, which caused the gradual and significant amorphization. As amorphization by milling progresses, the intrinsic hydrophobicity of crystalline talc decreases, accompanied by an increase in adsorbed water. The adsorbed water in talc, which is rarely present in its crystalline form, can increase up to 11 wt% depending on the milling conditions and is linearly correlated with the specific surface area. Numerical simulations allow us to estimate the essential role of hydrous low-crystalline talc in fault slip behavior by contributing to thermal pressurization. For montmorillonite, a decrease in crystallinity leads to a reduction in its natural swelling capacity, with the swelling index of crystalline Na-montmorillonite decreasing dramatically from 35 ml/2g to 4 ml/2g upon amorphization. These results that amorphization causes changes in the hydration properties of clay minerals suggest that the properties of low crystalline clays in fault gouges differ from those of crystalline clays and may be a critical factor in determining fault slip behavior. Our results also highlight the need for a more systematic approach to studying the effects of mineral amorphization on crustal geological phenomena.

Byung-Dal So[5], Kangwon National University

Abstract

The explosiveness of volcanic eruption is dependent on the viscosity of magma and the amount of volatiles in the magma. During the upwelling of magma, the solubility of volatile species decreases with decreasing pressure, and the solubility drop causes bubbles to form in magma. The formation of bubbles affects the viscosity of magma due to the changes in volatile contents. The size and the distribution of bubbles in magma change the speed of magma upwelling. Therefore, it is essential to understand the bubble formation in magma and its effect on volcanic eruption.
Mt. Baekdu, located in the northernmost part of Korea, is believed to be an explosive volcano. The composition of the upper part of Mt. Baekdu is rhyolitic. The rhyolitic magma has a high viscosity and can dissolve >10 wt% of H2O at ~0.5 GPa, making the eruption of rhyolitic magma explosive. To better understand the latest eruption behavior of Mt. Baekdu, we used hydrous albite glasses as a model system of rhyolitic magma. The H2O bubble-bearing albite glass samples were synthesized using piston cylinders in Bayerisches Geoinstitut, University Bayreuth in Germany, and Institute for Planetary Materials, Okayama University in Japan. The samples were synthesized at 0.5 GPa at 1000-1200 ℃ for 1 hr with varying water contents from 6 to 14 wt%. As the water contents in bubble-bearing hydrous albite glasses differ from the input amount of water, the water content in synthesized albite glasses was measured by TGA. The viscosity of synthesized glass is estimated by the glass transition temperature and the calculated Qn species of albite glasses using Raman spectroscopy. The Raman spectra show a slight increase of Q0 and Q2 species with increasing water contents, but the estimated changes in the polymerization of glass are subtle. 2D image analysis using backscattered images in SEM and 3D analysis using an X-ray tomography are performed to measure the distribution of bubbles in the albite glasses. 3D analysis showed that large bubbles tend to connect more. The size of bubbles in albite glasses increases with increasing temperature and the amount of input water in the system. The information obtained and further studies with varying pressures will help us understand the changes in magma viscosity with the formation of bubbles.

Amphibole inclusions in emeralds

Stefanos Karampelas[1]*, Laboratoire Français de Gemmologie (LFG) (s.karampelas@lfg.paris)
Ugo HENNEBOIS[2], Laboratoire Français de Gemmologie (LFG)
Aurélien DELAUNAY[3], Laboratoire Français de Gemmologie (LFG)

Abstract

Emerald is the bluish green to green to yellowish green variety of beryl coloured by chromium and/or vanadium (iron may also contribute to the colour, but to a lesser extent); beryl coloured solely by iron is green beryl (and not emerald). Gem quality emeralds are frequently containing minerals inclusions. These inclusions can give valuable clues on their geological, and sometimes geographical origin. Gem quality emeralds are rare but can be grown under various geological environments. Amphibole crystals are observed in emeralds from different geological environments and countries such us from Austria, Russia, Zambia, and Zimbabwe. Several faceted emeralds from different countries with amphibole inclusions from LFG (Laboratoire Français de Gemmologie) reference collection are studied. In gemmology, only non- (or micro-) destructive methods can be used. Some amphibole inclusions are reaching the surface and are chemically analysed by EDS/SEM. However, in most cases amphibole inclusions are inside the sample. In these cases, micro-Raman spectroscopy is a useful method to analyse these inclusions. It has been found in the part that different amphiboles present different spectra; principally in the hydroxyl stretching vibrations region situated from 3400 to 3800 cm-1. Because of the chromium related luminescence of emeralds, it is better not using some laser excitation wavelengths (e.g. at 532 and 633 nm) so high luminescence in the Raman spectra over 3000 cm-1 is avoided. This is the first study of amphibole inclusions in emeralds from different countries by using chemical and spectroscopic means.

Geochemistry of blue fluorescence from golden amber in response to thermal maturity

Jing YU[1]*, Gemmological Institute China University of Geosciences (jingyu@cug.edu.cn)
Chaoyang Chen[2], Gemmological Institute China University of Geosciences
Chuting Zhang[3], Gemmological Institute China University of Geosciences
Yamei Wang[4], Gemmological Institute China University of Geosciences
Shukui Zhu[5], Gemmological Institute China University of Geosciences

Abstract

Amber, a fossilized resin originating from exudates of both angiosperms and gymnosperm trees. The fossilization of terpene resin is a complicated maturation process involving cross-linking of terpenoid components and loss of volatile components, spanning hundreds of millions of years. Extensive field observation commonly reveal amber in yellow, red or brown hues. The yellow variety displaying intense blue fluorescence are highly prized gemstones with significant commercial value. To maximize the utilization of amber resources, it becomes crucial to enhance the blue fluorescence effect in lower-quality amber. However, the exact mechanism responsible for the generation of blue fluorescence in amber remains elusive. Additionally, numerous studies have established a strong correlation between the fluorescence of sedimentary organic matter and the thermal maturity of their natural setting. With increasing thermal evolution, the degree of aromatization increases, first through the loss of functional groups and formation of aromatic rings, and subsequently the coalescence of single ring into polycyclic aromatic units or structural degradation from precursors. But how does amber's fluorescence respond to thermal maturity remains unknown.

Herein, five groups of golden amber with different brightness levels and varying hues of fluorescence color were collected for color measurement, excitation-emission matrix spectrum analysis, gas chromatography-mass spectrometric analysis and Rock-Eval analysis. The results revealed that compounds such as alkylbenzene, alkyl naphthalene, and aromatic terpenes contribute to the blue fluorescence. The intensity of fluorescence is determined by the concentration of alkyl benzene and alkyl naphthalene. The hue of fluorescence is governed by the specific category of these substances. Increased methyl groups in alkyl naphthalene induce a red shift in the emission spectrum, altering the fluorescence color towards blue- green. These fluorescent substances are byproducts of terpene resin decomposition and aromatization during the thermal alteration, indicating a correlation between fluorescence and thermal maturity (measured as equivalent Vitrinite Reflectance). This study thus revealed a strong correlation between amber fluorescence characteristics and low thermal maturity of sedimentary organic matter. Correlation models have been established for equivalent Vitrinite Reflectance versus intensity and equivalent Vitrinite Reflectance versus hue: equivalent Vitrinite Reflectance = 21111×fluorescence intensity -3659 and equivalent Vitrinite Reflectance = -254×hue value + 305, respectively. These relationships represent a promising method to assess thermal maturity in sedimentary organic matter during field investigation. However, further research is necessary to explore the

significance of other amber colors for higher thermal maturity.

Four thousand years of gem garnet trade in NW Africa

H. Albert Gilg[1]*, Technical University of Munich, Germany (agilg@tum.de)
Laure Dussubieux[2], Elemental Analysis Facility, Field Museum, Chicago
Joanna Then-Obłuska[3], Antiquity of Southeastern Europe Research Centre, University of Warsaw

Abstract

The chemical compositions of thirty-four red garnet beads from Lower Nubian sites dated between about 3200 BCE and 600 CE were characterized by Raman spectroscopy and laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS). Some LA-ICP-MS analyses yielded additional information on inclusions minerals and materials involved in polishing. All beads from the A-Group to the Meroitic period display a similar Ca-poor almandine composition (69-78% almandine, 15-22% pyrope, 2-6% grossular and andradite, 3-9% spessartine) with high Y (180 to 1205 ppm), moderately low Cr (13-70 ppm) and high Sc (119-213 ppm) contents that is distinct from other calcium-poor garnet types known in antiquity mostly sourced from Indian deposits. The compositions of the Nubian beads match with previous and new analyses of two alluvial garnet deposits in the Bayuda desert near the Forth Cataract of the Nile in Upper Nubia. Additional analyses of Predynastic and Middle Kingdom beads from neighboring Egypt indicate that red almandine garnets were traded for almost four millennia from the Bayuda desert to Lower Nubia and even beyond to Egypt. Northwestern Africa must be considered the cradle for the earliest and longest use of a gemstone harder than quartz.
The youngest, post-Meroitic bead shows unusual faceting, a diamond-tipped drill hole, excellent polish, distinct short- and long-prismatic inclusions and Ca- and Mn-poor pyrope composition. The features indicate that this bead from a Late Antiquity grave was not produced in Nubia but imported most probably from a South Asian site.

Gemological Characteristics and Heat Treatment of Trapiche-like Sapphires from Changle, Shangdong province, China

Xiaojing LAI[1]*, China University of Geosciences(Wuhan) (laixiaojing@cug.edu.cn)
Suqin XIA[2], China University of Geosciences(Wuhan)

Abstract

Sapphires from Changle county, Shandong province, China are famous for their high yield, large crystalline grains, complete crystal shapes, and diverse varieties. The studies on one of the special varieties trapiche-like sapphires from Shandong, however, are very limited. In this study, systematic research on Shandong trapiche-like sapphires were carried out, including gemological characteristics and heat treatment. When the sample was sliced perpendicular to the c axis, it shows distinctive hexagonal color zoning and trapiche-like phenomenon, that is, a blue-black hexagonal core and six silvery fibrous arms. The shining fibrous arms were mainly caused by thin-film inclusions and fine fissures parallel to their elongation direction and the dark core contains some dark iron oxides etc. as examined by microscope and Raman spectroscopy, The types of inclusions in the core, arms and sectors are different and summarized in this study. The chemical composition results indicate that the Shandong sapphires are of typical basaltic genesis. Trace element characteristics are easier to distinguish from other basaltic origin sapphires. In addition, the spectroscopic features of infrared and UV-VIS-NIR were also summarized.

Heat treatment study was also conducted in this study. The results of heat treatment experiments in air directly to a temperature of 1000~1600°C show that the heating can make the blue color lightened but with a gray hue. And at 1400~1600°C iron and titanium oxide inclusions can be dissolved, making the color more uniform. The trapiche-like pattern became blurry after the heat treatment. The identification of the heated sapphires can be characterized by internal and external characteristics as well as spectroscopic features. Heated sapphires are usually free from yellow goethite or reddish-brown (hematite) iron stains at the fissures. The edges of core and arms are blurry after the heat treatment. The OH-related vibrational absorption peaks are absent in the IR transmission spectrogram. In the reflection spectra, there are changes and displacements of the broad spectral bands between 600 and 700 cm-1. These can be the basis for the identification of heated trapiche-like sapphire from Changle, Shandong, China.

Spectroscopic Analysis of Defects in Photochromic Yellow Sapphire

Yunqi Yang[1]*, Gemmological Institute, China University of Geosciences (yangyunqi@cug.edu.cn)
Chaowen Wang[2], Gemmological Institute, China University of Geosciences
Chengsi Wang[3], Gemmological Institute, China University of Geosciences
Tian Shao[4], Gemmological Institute, China University of Geosciences
Andy Hsitien Shen[5], Gemmological Institute, China University of Geosciences

Abstract

Color holds considerable importance in the classification and valuation of gemstones. Yet, in recent years, the gemstone market has been troubled by many fancy sapphires, even those backed by authoritative certification, that have experienced varying degrees of fading or color change after a period of displaying or wearing. These sapphires, when exposed to sunlight or ultraviolet light, show reversible color alterations—a phenomenon that is ascribed to the photochromism of corundum. The photochromic effect in sapphires has captivated gemologists for many years. Previous studies indicates that this effect presents in a range of sapphires, including colorless, light blue, yellow, pink, and Padparadscha varieties, independance on their origins, natural or synthetic, and whether they have undergone heat treatment or irradiation. This photochromic phenomenon significantly impacts the grading and valuation of sapphires, but its underlying mechanism is still unclear.

A set of photochromic experiments has been conducted on sapphire specimens using a 254 nm shortwave UV light source and a D65 light source, which simulates sunlight, to generate different color states. The characteristic absorption, emission and excitation spectra have been analyzed, and a correlation has been observed between the color instability and fluorescence instability in yellow sapphires during the photochromism.

We hypothesize that the defect that releases orange fluorescence plays a crucial role in the photochromic effect of yellow sapphires. This is presumed to be associated with electron transfer between defects—specifically, Mg-related defects involving trapped holes and F-centers—during the photochromic process. Consequently, the face sample has been ground into a powder for the analysis of its EPR spectrum regarding the color instability of the yellow sapphire. Notable alterations were detected in the region at $g \approx 2.0$ before and after the color changes, which is indicative of the presence of trapped-hole and F-centers. Additionally, alterations in the fluorescence of Cr during the photochromic process have also been noted. The PL spectra of the sample pre- and post-color change have been tested, with observations showing that the pattern of orange fluorescence exhibited an inverse relationship to that of Cr fluorescence. This may be due to Cr combining with trapped-hole within the corundum structure. To verify that the process did not introduce new defect levels, the fluorescence lifetime of Cr has been measured. The results indicated that the fluorescence lifetime did not change, confirming that no new energy levels were

involved in the emission of Cr, except for the trapped-hole and F-centers during the photochromic process. Our findings indicate that the essence of the photochromic process of yellow sapphire is the electron transfer between trapped-hole and F-centers, which could also influence the electron transitions within impurity elements like Cr.

Annareta Touloumtzidou[7], PhD. Archaeologist, Independent researcher
Vasilios Melfos[8], Aristotle University of Thessaloniki: School of Geology
Nikolaos Kantiranis[9], Aristotle University of Thessaloniki: School of Geology

Abstract

Red coloured gems such as garnets, carnelians, sards, artificial glass etc. are quite often seen in GrecoRoman jewellery. In the present study 12 gems which were integral parts of various types of Roman jewellery from the collections of the Archaeological Museum of Thessaloniki (AMTh), Greece, were investigated. The studied artefacts originate from archaeological excavations in the city of Thessaloniki and from the former G. Papailiki's private collection. All jewellery are dated in Roman period (from 2nd century BC to 1st century CE). Most of the studied gems exhibit a brownish red to slightly purplish red hue and they appear in various shapes such as cabochons, intaglios, or engraved forms. All gems were investigated in the AMTh's archaeometry laboratory using strictly non-destructive methods such as a mobile Raman (GemmoRaman-532SG) and an Energy-Dispersive micro-Xray Fluorescence (micro-EDXRF) spectrometer. For the optical examination of the samples, a Zeiss Stemmi 508 microscope was used but as most of the samples are not particularly transparent and are set in jewels, the observation for inclusions was almost impossible. This is the first time these gems were studied with advanced techniques and most of them were either misidentified as sards and carnelians or their mineralogical variety was not identified at all. Mobile Raman spectroscopy defined 10 out of 12 gems as garnets and the remaining two samples as artificial glass beads. Micro-XRF analysis was applied to determine the chemical composition of the garnets and the major chemical elements of the artificial glass beads. Micro-Raman Garnets Evaluation Method (MIRAGEM) was also used to confirm the molar composition of the garnets. In most cases, the results of this method are in agreement with the XRF analysis. Most of the studied garnets are rich in Fe and Mg, therefore they mainly belong to the intermediate of pyrope – almandine series with a low amount of andradite and grossular (~12-20 %). Based on the existing bibliography, on the study of gems in antiquity, the garnets with the above chemical composition are mainly characterized as Rhodolites or as Type III garnets. Some samples correspond to the composition of almandine (over 70%) or in the composition pyrope (over 75%). The above garnet members can be found in Southeast Asia, such as Sri Lanka. Other important garnet deposits in antiquity are located in India, Czech Republic and East Africa. Further research is currently ongoing in order to determine the geographic origin of these garnets

and their trading networks in antiquity along with the identification of more gems from the collections of the AMTh.

Detecting epigenetic iron staining in ruby and sapphire by using Raman spectroscope

Wei ZHOU[1]*, SSEF Swiss Gemmological Institute (wei.zhou@ssef.ch)
Michael S Krzemnicki[2], SSEF Swiss Gemmological Institute
Pierre Lefèvre[3], SSEF Swiss Gemmological Institute

Abstract

Heat treatment of rubies and sapphires has a long history. It is an effective method of improving the appearance and color. In recent years, unlike conventional high-temperature heating that exceed 1200 °C, a low-temperature heating process for ruby and sapphire has been developed. According to experimental studies, the minimum temperature that can improve the appearance of gem quality corundum is low down to 600 °C. Comparing to traditional over 1200 °C “high” temperature, low temperature heating is not easy to be detected. The present of iron staining (mainly hematite and goethite) in the open fissures in ruby or sapphire is considered as a key argument of absence of heat treatment. Only around 300 °C, the gradual dehydration transformation of goethite into hematite would start to occur. To correctly and efficiently analyses epigenetic iron staining in ruby and sapphire has never been so important.

In this study we examined several gem quality samples with epigenetic iron staining in fissures. All the work has been done by Renishaw inVia spectrometer attached to a Leica DM2500 microscope. The analyses have been performed by an argon-ion laser (green, 514.5 nm) and a RL 405 laser (blue, 405nm) depending of the cases, with a spectral resolution of 1.5 cm–1. The results have been presented by using Renishaw Wire (version 3.3) software.

The very first problems encountered that the signal from host stone affect the spectra of the target mineral, particularly in ruby. To limited the influence of strong fluorescence, blue laser applied on these rubies and gave certain promising results with 10% intensity of the laser power. The green laser with an extra confocal setting has also performed well.

When study sapphire fissure, the less fluorescent trace elements (especially Cr) is allowing better data collections. However, to obtain a better signal-to-noise ratio, the intensity of laser needs to be handled with caution. High laser power applied on the iron staining might cause certain phase transformation and give questionable results. With green laser on sapphire sample, by using a 1% laser power, the goethite peaks are noticeable (247 cm-1, 296 cm-1,399 cm-1, 554 cm-1 and 574 cm-1 peaks). However, at the adjacent area, by raising up the laser power to 100%, only few scans, it starts to appear a “new” peak around 1327 cm-1, which indicating a beginning of an in-situ dehydration process.

To efficiently detect epigenetic iron staining by using Raman spectroscope, extra consideration of the experimental setup is needed. For minimizing the noisy signal from the host gemstone, different type of Raman laser or high confocality setup might offer a solution. The alternation process occurs on iron strain that triggered by Raman laser need to be avoid by using relatively low power setting.

A Correlation of Clay Minerals Distribution Map with Jasper Impurities Using Satellite Data in Garut, West Java, Indonesia

Kemala WIJAYANTI[1]*, Universitas Padjadjaran (kemalawijayanti@yahoo.com)

Abstract

Jasper is a type of gemstone that belongs to the cryptocrystalline form of Quartz. In Indonesia, Jasper comes in different colours, such as red, yellow, green, brown, and white. One of the famous types of Jasper in the Bungbulang Garut area is called Pancawarna, which means five colours. This type of Jasper is known for its combination of colours in one rock, which includes red, yellow, orange, green, brown, and white, sometimes forming a Pictured Jasper. Jasper is considered cryptocrystalline Quartz, which contains impurities from clay minerals. Creating a distribution map of clay minerals can help determine the impurities present in Jasper.

This study aims to analyse jasper samples from Garut, which combine red, orange, brown, and green colours. The study uses data from previous research, including XRF analysis, to determine the chemical composition of Jasper and SEM analysis to examine the nanotexture of the samples. The results indicate that Jasper is influenced by iron oxide and contains clay minerals such as illite and chlorite. Raster calculations were performed using data from ASTER, Sentinel, and Landsat maps to create a distribution map of clay minerals in the Garut region. This map provides an overview of the relationship between clay minerals and jasper colour. One of the advantages of using satellite data is that it is free and can be processed using the QGIS application. The study also compares the distribution of ferrous silicate, ferric oxide, kaolinite, chlorite, and illite to determine the composition of clay minerals that produce red to brown jasper colours.

According to the raster calculations based on ASTER data bands 1 to 9, ferrous silicate, ferric oxide, and illite distribution is reasonably high in the area where Jasper is found. Chlorite has a moderate value, while kaolinite has almost no effect. The results suggest that ferrous silicate and ferric oxide impurities mainly produce red to brown colours based on the colour of minerals, while illite affects the appearance of white. On the other hand, chlorite can have a moderate effect on the green Jasper. These findings support the results of previous research, which stated that the colour of Jasper in Bungbulang, Garut, is influenced by iron oxide, illite, and chlorite.

The study of external morphology and internal zonal structure of spinel law contact twinned natural macle diamond.

Ahmadjan ABDURIYIM[1]*, Tokyo Gem Science and GSTV Gemological Laboratory
(tgs@gemscience.tokyo)

Abstract

Spinel law contact twinned crystal of natural diamond rough called ‘Macle’ often show a flattened triangular morphology and it has been used to produce an un-cut rough diamond in its natural state and fashioned a brilliant cut jewelry for many centuries. This flattened shape has also been stressed in explaining by the preferential growth at re-entrant corners where two twin individuals contact mutually, the role of the re-entrant corner effect to the morphological change may depend strongly upon the supersaturation conditions. However, no detailed study has been carried out on the possibility of the preferential growth at the opposite side of re-entrant corner called ‘salient corner’ of macle diamond. The effect at ‘salient corner’ is revealed for the first time by previous and present study, and growth morphology appearing as external forms and internal zonal structures of spinel law contact twinned macle diamonds from South Africa were observed.

Based on the external morphology, the macle diamonds are divided into four groups (A, B, C and D) depending upon four types of re-entrant corners: I, II. III and IV which are based on the modification of their re-entrant corners by growth layers generated at the twin boundary. From estimating the degree of flatness of these twinned macle diamonds, the high flattened morphology is not only formed by the preferential growth at the re-entrant corners, but also the preferential growth at the salient corners.

To observe the internal structure, four types of twinned crystals were cut and polished perpendicular to a contact face of twinning. Zonal structure on the polished surfaces was observed by using a scanning electron microscope with cathodo-luminescence mode (SEM-CL), and the twin boundary was also checked by using an X-ray analytical microscope (XAM). By repeating the polishing and the SEL-CL and XAM observations, three-dimension of growth structure was visualized and the center of twinned macle crystals was decided.

The ratios of normal growth rate in the growth stage were estimated in detail by measuring the width along every direction of growth bands of above polished crystals. The measured ratios of normal growth rates among {111} faces at re-entrant and salient corners show predominant difference and change during the growth stage usually. It was confirmed that the morphological change and the flatness of macle diamonds were caused by the preferential growth at both re-entrant and salient corners. In additions, the change of supersaturation conditions was also estimated from the morphological change.

Enhanced Provenance Determination of Turquoise through Comparative Analysis of XRF and LA ICP MS Techniques Coupled with Machine Learning

Bahareh SHIRDAM[1]*, Gemmological Institute, China University of Geosciences (Wuhan) (shirdam@gmail.com)
Andy Hsitien Shen[2], Gemmological Institute, China University of Geosciences (Wuhan)
Dalal AL-Alimi[3], School of Computer Science, China University of Geosciences
Mingxing Yang[4], Gemmological Institute, China University of Geosciences (Wuhan)

Abstract

Investigating the geographical origins of turquoise is vital in archaeological and gemological fields. This research conducts a comparative study of two prominent analytical techniques, X-ray fluorescence (XRF) and Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA ICP MS), focusing on 120 blue turquoise samples from Neyshabur, Baghu, and Meiduk in Iran, collected directly from their deposit. Considering the restrictive use of LA ICP MS on some historical artifacts (including turquoise artefacts) by museums, the study emphasizes improving XRF's accuracy using various machine learning pipelines for pre-processing, training and testing, the data, including Linear Discriminant Analysis (LDA), Random Forest, Support Vector Machine (SVM), Principal Component Analysis (PCA), t-distributed Stochastic Neighbor Embedding (t-SNE) and Neural Networks, integrated with or without Quantile Transformer (QT) and Standard Scaler. Pipelines including Neural Networks and Random Forest frameworks elevated the XRF accuracy to 94.91% from 68.18% , while LA-ICP MS dataset achieved 93% of accuracy with t-SNE and 99.59% with Random Forest, Neural Networks. The study's approach to refining XRF analysis involved selection of elements with low correlation and noticeable variances in distribution origins, and data expansion, aiming to bridge the accuracy gap with LA-ICP MS. This research integrates geochemical methods with computational analytics, advancing the precision in identifying turquoise origins and facilitating future investigations in the fields of gemology and archaeology.

An “agate”-like mixed-habit diamond from Yuan River, Hunan, south-central China

Xinwei LIU[1]*, China university of geosciences(Wuhan) (azurelau@cug.edu.cn)
Tao CHEN[2], China university of geosciences(Wuhan)

Abstract

Cubic and octahedral mixed-habit diamonds with “agate”-like structure are rare. And the natural growth mechanism of the “agate”-like structure is rarely understudied. Here we present a diamond from Hunan Yuan River with mixed-habit and “agate”-like structure. This unusual diamond was studied by using EBSD, FTIR mapping, UV-Vis and photoluminescence spectroscopy and SEM-CL to analyze defect types, distribution, and texture. EBSD experiments confirmed that the “agate”-like diamond is a monocrystal structure, potentially grown by multicentered crystallization. The primary nitrogen defects are proved to be A and B centers, with no N3 centers but having notable nickel impurities. While hydrogen distribution uneven in the diamond. The content of hydrogen is more highly concentrated in the cuboid regions than those in the octahedral regions and is almost none in the center part. The inhomogenous distribution of hydrogen between the center and the peripheral areas indicates that the mixed-habit diamond growth is staged processes, might influenced by changing hydrogen levels in the growth environment. Moreover, carbon isotope analysis via NanoSIMS indicated that its δ13C values in the range of typical E-type diamonds. Some particular heavy δ13C values suggested a varying fluid source composition. Growth dynamics indicates that this monocrystal diamond initially grows slowly in low carbon supersaturation, exhibiting predominantly tangential growth of {111} facets. As carbon saturation increases, equal growth rates in <111> and <100> directions accelerating the rapid growth in mixed-habit section. Meanwhile excess carbon may combine with hydrogen to form C-H bonds, preferentially integrating at energetically favorable sites.

Gem Materials with Unusual Optical Properties

Andy H SHEN[1]*, China University of Geosciences (Wuhan) (shenxt@cug.edu.cn)

Abstract

Most single crystal gemstones can sometimes exhibit interesting optical properties. In the gemological literatures, many examples have been documented. Some of these phenomena are well understood now such as the iridescence in natural quartz are due to the very minute Brazilian twinning during the growth of the quartz crystal, while some are just observations such as the thermoluminescence observed in type IaB diamonds – in these cases, sometime we do not have any idea what has caused this. My research group has been focused on these subjects for years and we have observed unstable colors in the CVD diamonds due to the interplay of different color centers; pleochroism in sunstones due to the geometry and nature of the nanoparticles in the plagioclase feldspars; in addition, the perception of colors in diaspores under different lighting with different color temperatures, and so on. The purpose of this talk is to demonstrate the spread and diversity of these optical properties and to promote future collaborations and research efforts to solve these mysteries.

Analysis of the chemical composition of red gem garnets in ancient jewellery by Raman and hand-held X-ray fluorescence spectrometry for origin determination

H. Albert Gilg[1]*, Technical University of Munich, Germany (agilg@tum.de)
Dirk Müller[2], Department for Earth and Environmental Sciences, Ludwig-Maximilians-Universität München, Munich
Michelle Taube[3], Department of Research, Collections and Conservation, The National Museum of Denmark, Brede
Thorsten Allscher[4], Institute of Conservation, Bayerische Staatsbibliothek, Munich

Abstract

Silicate garnets were highly valued red transparent gemstones in Antiquity and medieval times, and remained popular during the Renaissance and Baroque period. Previous studies on the chemical compositions and inclusion characteristics of the gems reveal a great diversity of chemically distinct types of almandines, pyropes and grossulars with a narrow clustering of chemical compositions indicating that several specific deposits were exploited, in part during distinct periods. The mineralogical data allow a geological, and in some cases even a geographical, origin determination of the gemstones. Here we explore the potentials and limitations of portable Raman and energy-dispersive X-ray fluorescence spectrometry to determine the chemical composition of red garnets using a series of 26 reference materials characterized by electron microprobe and LA-ICP-MS analysis, as well as an application of calibrations on ancient gems. Previous attempts to use Raman spectrometry to determine the endmember compositions of garnets resulted in large uncertainties of more than 15 mol%. Our study shows that the spessartine content of almandine-rich garnets cannot be determined with certainty by Raman spectrometry due to the similarity of the Raman band positions of the two endmembers. In contrast, the calcium, magnesium, and in part chromium and titanium oxide contents of the aluminous garnets can be predicted by Raman spectrometry with a precision in the order of about 0.4 wt.%, if the spectrometer has sufficiently high spectral resolution.
Quantitative X-ray fluorescence analysis of single garnet crystals is hampered by diffraction, geometric and matrix effects, as well as mineral inclusions. At least two distinct acceleration voltage and filter settings are required to avoid diffraction peaks and allow detection of the lightest elements. Helium flushing, a vacuum setting or a graphene window on the detector are required to quantify the magnesium content in aluminous garnets. Our study shows that specific matrix calibrations are required for almandine-pyrope-spessartine, Cr-rich pyropes and calcic garnets. Major element oxides can thus be measured with a precision of better than 5% relative. The trace elements Sc, Ti, V, and Cr have a detection limit of about 100 ppm, while the detection limits of Zn, Ni, Zr, and Y are better than 30 ppm.

Raman spectrometry, XRF, garnet

Unraveling the role of impurities and thermal energy in sapphire structural relaxation: Insights from Raman spectroscopic analysis of heat-treated specimens

Seung Kwon LEE[1]*, WOOSHIN GEMOLOGICAL INSTITUTE OF KOREA and HANYANG UNIVERSITY (sklee1201@hanyang.ac.kr)
Dongwook SHIN[2], Hanyang University
Shoohack SHON[3], Hanyang University
Jungmin KIM[4], Hanyang University
Sungjae KIM[5], Hanyang University

Abstract

Various trace-element impurities (e.g., iron, titanium, chromium, or vanadium) and chemical reactions contribute to the coloration of natural corundum. These elements have a different atomic radius or charge compared to the aluminum ion. Depending on the degree of substitution, they may lead to localized structural relaxations. Throughout antiquity, corundum has undergone heat treatment for moderate color enhancement. However, contemporary heat-treatment techniques yield dramatic results, surpassing the subtle changes observed in historical practices. With the advancement of these treatments, it is becoming increasingly difficult to distinguish between natural and heat-treated sapphires.

This study has shown that changes in the crystallinity of sapphire or corundum correlate with the iron oxide content and the thermal energy applied, as determined using Raman spectroscopy. The Raman peak at around 417 wavenumber is always the strongest peak in natural sapphire. The full-widths at half-maximum (FWHM) of the 417 peak increase with the increasing iron oxide content due to the larger ionic size of iron compared to that of aluminum.

During the heat treatment of sapphire, impurities (mainly iron) within the sapphire host lattice absorb thermal energy. Consequently, impurity atoms experiencing the general heating treatment temperature could affect the local structure of the sapphire. We suggest that the local arrangement of atoms surrounding a substitutional Fe(III) ion in corundum is primarily governed by kinetics rather than thermodynamics during heat treatment, as the heat treatment process of the sapphire is relatively shorter than the creation process in nature.

We therefore find it reasonable to assume that the FWHM of the 417 peak increases with iron oxide content and the thermal energy applied. The Raman study on the structural relaxation induced by impurities might provide an opportunity to identify both natural and heat-treated sapphires.

Formation, identification and color grading of Nanhong agate from the Southwestern of China

Chaowen Wang[1]*, China University of Geosciences(Wuhan) (c.w.wang@cug.edu.cn)
Huimin Huang[2], China University of Geosciences(Wuhan)
Haotian Wang[3], Hubei Provincial Jewelry Quality Supervision and Inspection Center
Lingyue Yang[4], Chengdu Institute of Advanced Metallic Material Technology and Industry Co., Ltd.

Abstract

Nanhong agate is widely welcomed in China because of its bright red color. The pursuit of the red agate is the inheritance of Chinese red agate culture, which can be dated back to more than 3000 years ago. Field survey showed Nanhong agate geographically distributed in Yunnan and Sichuan Provinces, the Southwestern of China. Geologically, Nanhong agate can be either produced as fillers in cracks and pores of the Late Permian E'meishan basalts, or as pebbles in the Early Triassic conglomerates and mudstones. Petrographic analyses revealed the formation of agates could be linked to the alteration of basalts, especially in the process of transformation from pyroxene to chlorite. The formation of Nanhong agates could have experienced multi-stages, which was supported by the occurrence of multi-stage chlorites and different homogenization temperatures of fluid inclusions bearing in the coarse grained quartz. The Nanhong agate was characterized by diffusely distributed hematite and/or goethite, causing the red to reddish orange in color. These iron oxides occurred as aggregates showing dominantly spherical shapes and minor visible ellipsoid, hemisphere, radial and veil shape, with a size generally between 1.2 μm and 43.21 μm. Raman spectra, scanning electron microscopy, and high resolution transmission electron microscopy confirmed the present of hematite with single hematite particles smaller than 100 nm. Wide market survey of the selling Nanhong agates presented the quantified color parameters, including hue, saturation, and brightness, obeyed normal distribution in the Hue-Saturation-Brightness (HSB) color space. After standardization, the hue (H) of Nanhong agate was mainly distributed in a range between [3. 20°, 17. 52°] at a 95 % confidence level. The saturation (S) and brightness (B) were mainly within [63. 82 %, 92. 69 %] and [42. 97 %, 75.37 %], respectively. The Nanhong agate could be statistically classified as different grades by the Two Step Cluster analysis, which is objective compared to subjective visual evaluation. Factors causing the color difference of Nanhong agate were attributed to the color properties and distribution characteristics of hematite and goethite. The hue of Nanhong agate was dependent on the color of the impurity minerals, hematite or goethite. Saturation was affected by the area ratio of impurity minerals. As the area ratio of impurity minerals was both affected by the distribution density and the average particle size, the saturation of Nanhong agate was the largest when the average particle size was near 10 μm. No obvious correlation was observed between the brightness of Nanhong agates and their related properties and characteristics.

XRF and Photoluminescence combined as a tool in the determination of the origin of Colombian emeralds

JAVIER GARCIA TOLOZA[1]*, CDTECGemlab (ceo@gemlabcdtec.com)
Camilo Betancurt[2], Technological Development Centre Fort he Colombian Emerald
Holman Alvarado[3], Technological Development Centre Fort he Colombian Emerald
Carlo Cedeño[4], Technological Development Centre Fort he Colombian Emerald

Abstract

The origin becomes a determining factor in the value of gemstones. The reputation of a region for producing high-quality and highly valued gemstones in the market. For example, rubies from Mogok (Myanmar or Burma) and sapphires from Kashmir (India) are gems that, in addition to standing out for their high quality in terms of color, clarity, size, among other aspects, reach higher prices in the markets due to their specific origin.
In the gemological laboratory, the combination of techniques is essential to deepen the understanding of gemological materials. Photoluminescence is used for various purposes, with its utility highlighted in analyzing the crystalline structure of materials. A specific use is the identification and characterization of a band associated with the chromium element in emeralds, linked to their origin in previous research. Additionally, studies have been conducted to determine the origin of emeralds using chemical composition analysis techniques such as LA-ICP-MS and ED-XRF. Previous research has identified specific parameters, such as concentrations of Ga, Fe, Na, Mg, Cs, lithium, and potassium, that allow differentiation between Colombian emeralds and those from other regions.

Low iron concentrations, less than 3000 ppm, similar concentrations of chromium and vanadium with an average ratio of 1:1, and the location of bands related to chromium between 683.7nm for R1 and 680.6nm for R2 in photoluminescence are some aspects that can be correlated and are associated with Colombian emeralds. This combination of techniques enhances the robustness in determining origin and distinguishing between emeralds from different locations worldwide.

A Study of Turquoise Origins Based on Trace Elements and LDA Method: a Case Study of Liangzhu Culture-related Sites in China

YAN JIANG[1]*, Gemlogical Institute,China University of Geosciences,Wuhan
(Jiangyan@cug.edu.cn)
Mingxing Yang[2], Gemlogical Institute,China University of Geosciences,Wuhan

Abstract

Turquoise is a precious gemstone widely used in various civilizations around the world, and it has been used in China for 9,000 years. Turquoise inlays and turquoise beads were found in the Liangzhu Culture (B.C.3300-B.C.2300) in the Yangtze River Basin during the Neolithic period, and they were mostly used in necklaces or for the inlay of animal-face totems on the surfaces of jade artifacts, which proved that Turquoise is considered very precious at that time. Liangzhu culture is a representative archaeological culture of Chinese prehistory, which used a huge number and rich variety of jade artifacts, unique in Chinese prehistory, and was the highest peak of the development of Chinese prehistoric jade culture. The archaeological ruins of Liangzhu City which sited at the center of its cultural area was included in the UNESCO World Heritage List in 2019, and it not only provides reliable evidence of China's 5,000-year civilization, but is also a valuable world heritage site.

The source of turquoise used in the Liangzhu culture area remains unknown because of the lack of information on ancient local turquoise mines, and the evidence provided in this study contributes to the discussion of this issue. This research performed nondestructive gemmological physical and chemical analyses (FTIR, LA-ICP-MS, etc.) and microscopic observations on 40 excavated turquoise samples from six sites in the Liangzhu culture area, in order to study the selection, the processing, and the methods of application of turquoise materials at that time. Linear Discriminant Analysis (LDA) was applied to analyze the trace elements, and compare with the characteristics of Chinese turquoise origins of different genesis, different mining areas and mining zones, to determine the origin of turquoise excavated from Liangzhu culture-related sites. The study found that the turquoise artifacts in the Liangzhu culture area did not come from the nearby Anhui mining area of igneous nature, but from the farther E-Yu-Shaan Mining Area (located in the eastern part of the Qinling orogenic belt, named for the area spanning Hubei, Henan and Shaanxi provinces, the largest turquoise mining area in China) of sedimentary metamorphic nature, and the turquoise from the six sites may have come from three different mining zones. This study not only helps to reveal the source and trade network of turquoise during the Liangzhu culture period, but also deepens the understanding of exchanges and interactions between ancient cultures. Through trace element analysis, it is possible to trace the source of turquoise, and then explore the connection between Liangzhu culture and external cultures in terms of resource exchange and cultural dissemination. This research is of great significance to the understanding of socio-economic development, cultural exchanges and regional interactions in ancient China, providing new perspectives and evidence for historical research.

Synthesis of silica spheres with homogeneous size distribution by electrospray-assisted Stöber method for the fabrication of opal photonic crystals

JUNGMIN KIM[1]*, HANYANG UNIVERSITY (ohyes7017@hanyang.ac.kr)
SHOOHACK SHON[2], HANYANG UNIVERSITY
SUNGJAE KIM KIM[3], HANYANG UNIVERSITY
JAEHYEON EOM[4], SOLIVIS Inc. Hanam
SEUNGKWON LEE[5], HANYANG UNIVERSITY
DOOGWOOK SHIN[6], HANYANG UNIVERSITY

Abstract

SiO2 opal of higher quality is a self-assembled colloidal crystal, which consists of cubic dense packing(fcc) of silica nanospheres. Monodisperse and uniform sized spheres are major factor for obtaining opals with characteristic optical properties. The imperfect monodispersity and wide size distribution produce serious disorders and dislocations in opals.

The Stober process, commonly used to synthesize spherical silica particles by hydrolysis and condensation polymerization with the precursor of tetraethylorthosilicate(TEOS). However, agglomeration and wide size distribution in size obtained through the Stober process are major source of the defects of the opal photonic crystal.

In order to improve the monodispersity and uniformity in size distribution of the spheres, we present an effective method for synthesizing monodisperse silica nanosphere by electrospray-assisted Stober method. The electrospray technique was used to spray a dispersed aerosol of silica precursor (TEOS) into the reaction bath containing ethanol, water, and ammonia solution.

To find the best homogeneity in the size and low polydispersity of synthesized silica nanospheres, two methods of precursor incorporation into the reaction bath were compared: incorporation by drop-by-drop at a constant flow rate, and by continuous fine droplet flow using electrospray technique. Also, a surfactant (triton x100) was added while synthesizing the silica spheres to enhance stability of the silica dispersions and the monodispersity of the spheres. In addition, the concentration of the precursor was controlled to obtain a spherical diameter in the range of 200-350 nm to be able to produce a play-of-color of photonic crystal.

The results confirmed that the size and uniformity of the spheres were profoundly affected by the method of precursor incorporation. We achieved increased monodispersity and homogeneity of the nanospheres under all conditions when the electrospray-assisted method is employed. We obtained nanospheres with exceptionally high monodispersity in the size range from 192.5 nm to 370.5 nm, which can exhibit multicolor when arranged in a regular three-dimensional array.

ICE JADE FROM GUATEMALA

Tao CHEN[1]*, Gemology Institute, China university of Geosciences (chentao@cug.edu.cn)
Zhaoyin Huang[2], Gemologu, China university of Geosciences

Abstract

Ice jade is a kind of jadeite jade (also known as Fei Cui) which is translucent (semitransparent), and usually is expensive. A kind of nearly colorless ice jade from Guatemala newly appears in Chinese jewelry market. The ice jade is fine texture, often has white snowflakes impurities. Its glistening effect is difficult to be observed on the polished surface. In this paper, the mineral compositions, chemical composition and structural characteristics of the ice jade were studied by using Raman spectrometer, X-ray diffraction (XRD), electron probe micro-analysis (EPMA), scanning electron microscope (SEM), and cathodoluminescence (CL). The ice jade is mainly composed of jadeite pyroxene. Its impurity minerals include omphacite and albite. The seldom observed pale-green particles are composed of omphacite. The albite is clustered as white snowflake or disperses like crumbs in the jade. The chemical compositions of jadeite are usually pure. While the small or the edge of relatively large jadeite particles have a small amount of Ca and Mg because of isomorphic substitution. The omphacite pyroxene is lack of Fe, whose chemical composition is mainly composed of jadeite-diopside series. The jadeite exhibits micro-granular to fine-grained structure, often shows blue-violet and violet-red CL fluorescence. The origin of ice jade from Guatemala can be distinguished from its characteristic appearance, microstructure, impurity minerals, and chemical compositions.

Investigation of Traps in Electron-irradiated Sapphire: Insights from Thermoluminescence and Fluorescence Spectrum

Yuyang ZHANG[1]*, School of Earth Sciences (gembubble@cug.edu.cn)
Meihua Chen[2], /
Wensi Yang[3], /

Abstract

Sapphire is one of the most important gems. Meanwhile, renowned for its exceptional optical properties and chemical stability, sapphire is extensively employed in optical instruments, communication equipment, and various other fields. The color and other material performance of sapphire strongly depends on the type and concentration of internal defects. In this study, we investigated natural sapphire by measuring its thermoluminescence spectra after irradiation with high-energy electrons. The spectra were analyzed and fitted using the Computerized Glow Curve Deconvolution (CGCD) method. By employing this approach, we calculated the activation energy and kinetic order of various traps present in the sapphire samples. Additionally, we compared the three-dimensional fluorescence spectra of the sapphire samples before and after high-energy electron irradiation. By combining the results from thermoluminescence and fluorescence analysis, we found that the trap with a thermoluminescence peak around 450K is the main defect affecting the color, fluorescence, absorption spectrum, and other optical properties of the sample. It is related to Cr3+, with a trap depth of about 1.05eV. The method used in this study optimized the detection of low-concentration traps by combining high-energy irradiation with thermoluminescence and fluorescence spectroscopy, it offers a feasible method for the detection and attribution of low-concentration defects in mineral materials.

Effect of Fe2O3 Core/SiO2 Shell Nanoparticle Pigments Doping Ratio on the Color of Synthetic Precious Fire Opal

Bowen Li[1]*, China University of Geosciences Wuhan (libowen@cug.edu.cn)
Andy Hsitien Shen[2], China University of Geosciences,Wuhan

Abstract

Precious opal displays iridescent play-of-color due to the diffraction effects of visible light by the three-dimensional periodic ordering of uniformly sized silica nanoparticles. These properties make precious opal a valuable prototype for 3D photonic crystals. More and more researchers have attempted to synthesize precious opals not just for gemological applications but for potential applications in photonics, optoelectronics, and sensors.

Among the wide variety of opal types, precious fire opal has captured people due to its simultaneous display of play-of-color and red-orange-yellow body color. Previous studies believe that the body color of precious fire opal is caused by the dispersion of Fe2O3 nanoparticles. The body color would become darker when the concentration of Fe2O3 nanoparticles increases. In addition, the presence of Fe2O3 particles is equivalent to introducing defects in the opal structure. The increasing concentration of Fe2O3 nanoparticles will change the periodic dielectric structure of precious fire opal and ultimately affect the play-of-color. To study these phenomena quantitatively, synthesizing a series of fire opals with different Fe2O3 nanoparticle doping ratios is a good strategy.

Fe2O3 nanoparticle is one kind of widely used red inorganic pigment with strong tinting strength. However, only a few studies have been reported on synthetic opal with doped Fe2O3 nanoparticles, maybe due to the unstable properties of bare Fe2O3 nanoparticles. Bare Fe2O3 nanoparticles can easily agglomerate in their dispersed system. At high temperatures, bare Fe2O3 nanoparticles can be reduced to Fe3O4, which causes the color to turn dark red. Moreover, chemical pollution can result in the color fading of bare Fe2O3. These problems can be solved by coating Fe2O3 nanoparticle with a SiO2 shell. The SiO2 shell can prevent the aggregation of dispersed particles, adjust the distance between assembled particles, enhance the chemical stability of Fe2O3 core particles, and keep the color stability of synthetic precious fire opal.

In this research, we used Fe2O3 core/SiO2 shell (Fe2O3@SiO2) nanoparticles as red pigments and synthesized a series of opal films. First, the Fe2O3@SiO2 nanoparticles were prepared using a sol-gel process. Then, Fe2O3@SiO2 nanoparticles with different volume fractions were mixed in well-dispersed similar-sized SiO2 nanoparticle suspension. Finally, the opal films were synthesized using the vertical deposition self-assembly method. The nanostructure and color evolution of synthetic fire opal films with different Fe2O3@SiO2 nanoparticle doping ratios were studied and compared to the results of previous reports. It shows that the saturation and brightness of body color were enhanced than bare Fe2O3 particle doped opal. The doping ratio affected the structural color, and the effect reached its maximum when the volume fraction was nearly 50%. The present work would deepen our understanding of precious fire opal's color genesis and

improve synthetic techniques.

Anisotropic photoluminescence in ruby and chrysoberyl

Linling DONG[1]*, China University of Geosciences(Wuhan) (sarah1053839869@163.com)
Ren LU[2], China University of Geosciences(Wuhan)

Abstract

Raman and photoluminescence spectroscopy measurements were performed on ruby and chrysoberyl in different orientations. The polarized Raman spectroscopy was used to confirm the crystalline phase as well as the crystal orientation of the sample, and the photoluminescence properties of the materials for different crystal orientations were studied. In this study, typical gem materials - ruby (uniaxial crystal) and chrysoberyl (biaxial crystal) were used to study the anisotropy of photoluminescence, resulting in a clearer understanding of the structural information of gem materials, such as the local symmetry environment. The photoluminescence spectra of ruby and chrysoberyl were also functions of the observed polarization, which peak shape and relative intensity of R-Lines vary under the different orientations of electric field, magnetic field and crystallography. The photoluminescence spectra of ruby had anisotropy as it exhibited optical absorption anisotropy, could be characterized by the orientation of electric field and largely unaffected by the orientation of magnetic field; however, the Rm and Ri lines of chrysoberyl were not only affected by the orientation of electric field, but also by the orientation of magnetic field. Analysis and comparison photoluminescence spectra can reveal that lower symmetry and multi-site structure containing Cr–doped octahedra results in more pronounced anisotropy in spectra of chrysoberyl in various directions of the polarization than that in ruby.

Spectroscopic and DFT study of the orientational order of water molecule and its influence on the coloration of beryl

SUNGJAE KIM[1]*, Hanyang University (sjk310700@gmail.com)
SHOOHACK SHON[2], Hanyang University
JAEHYEON EOM[3], Solivis Inc. Hanam
JUNGMIN KIM[4], Hanyang University
SEUNGKWON LEE[5], Hanyang University
DONGWOOK SHIN[6], Hanyang University

Abstract

Beryl, Be3Al2(SiO3)6, is a natural gemstone with diverse colors. Small contents of chromophore elements like Fe, Cr, V, Cs, Mn and others are related to the colors of beryl. The colors can be altered by atmospheric heat treatments, which induces the valence change of chromophore elements. The studies on the coloration mechanisms have been of great interest with respect to how to improve or induce the color of beryl. By Fourier Transform Infrared Spectroscopy (FTIR), we investigated the correlation between short-range structural arrangement of impurities and their charge states to elucidate the mechanism for this color change.

The color change is largely related to the orientational order of water molecules residing in the beryl channel. The stable orientational states of water molecules are shown to be type I and type II, where the H-H vector is parallel and perpendicular to the c-axis respectively. In this work, a significant change in the FTIR spectra of beryl was observed only in green samples after exposure to reduction heat treatment. The significant decrease of the band at 3633 cm-1 may be related to the position of Na+ ion in the beryl channel along the c-axis, probably due to relocation of Na+ ions from position 2b to 2a. In order to explain these results theoretically, we examined the stability of water molecules under the coexistence of the substituted Fe and Na+ ions using the density functional theory(DFT) total energy calculations.

Firstly, the stable configuration of individual water molecule and Na+ ion is examined. It is found that water molecule is stable at 2a positions with type type I orientation but Na+ ion is stable at 2b positions. By examining the cohesive energy of Fe substituted structure, it is shown that Fe substitutes Al. Secondly, the interactions between water molecule, Na+ ion, and the substituted Fe are examined. Although the position of the Na+ ion is not affected by the existence of water molecule and substituted Fe, the orientation of the water molecule is changed from type I to type II due to the ionic field of Na+ ion. Furthermore, our preliminary results shows that the Fe2+ stabilizes the Na+ ion at 2a position in accordance with the rotation of water molecule into type I configuration.

Sergii Kurylo[8], Earth Science Institute of the Slovak Academy of Sciences

Abstract

REE bearing accessory minerals (monazite, xenotime, allanite and apatite) are some of the most widespread accessory phases in common magmatic and metamorphic rocks with granitic and metapelitic protoliths. In addition, monazite and xenotime are essential for petrochronology. Although these minerals commonly crystallise as primary magmatic or metamorphic accessory phases, younger postmagmatic or metamorphic hydrothermal fluids can cause their partial-to-complete transformation to low-grade neoblasts. The commonly observed breakdown of monazite includes a subsolidus retrograde corona around its partly dissolved core with distinctive concentric mineral zones of fluorapatite (often REE-rich), Th-silicate/oxide (huttonite, thorite, thorianite), and allanite-(Ce) to REE-rich epidote or clinozoisite. Occasionally, REE carbonates (bastnäsite- or synchysite-group) originated as later low-grade replacement products in these coronae. These microtextures are documented mostly in low- to medium-temperature metagranitoids with primary magmatic monazite-(Ce). However, it can also occur in metapelites if the high-temperature metamorphic monazite-(Ce) destabilises during post-peak metamorphic evolution.

Similar reaction coronae around xenotime-(Y) in granitoids and metapelites or the partial compositional alteration of xenotime-(Y) via dissolution–reprecipitation resulting in a texture characterised by thorite ($ThSiO_4$) and uraninite (UO_2) inclusions, are less frequent. The decomposition of xenotime-(Y) containing boron can results in a reaction corona of fluorapatite and Y-B-Be silicates, e.g., hellandite-(Y) and hingganite-(Y) mineral zones, involving HREE + Y, and also B and Be mobility.

Another example of REE-phosphate decomposition represents the replacement of primary magmatic monazite-(Ce) and xenotime-(Y) during post-magmatic alteration of the host rock by As-S-Sr-rich and high fO_2 fluids. This specific fluid composition led to the formation of a unique complex REE phosphate–arsenate (monazite-gasparite; xenotime-chernovite) solid solutions or to an extremely S,Sr-rich monazite-(Ce). This composition indicates a $(Ca,Sr)S(REE,Y)_{-1}P_{-1}$ substitution as a dominant mechanism of Sr and S entry into the monazite structure. Also, primary magmatic accessory fluorapatite and allanite-(Ce) can be affected by breakdown phenomena to producing a unique secondary assemblage of britholite group minerals as well as REE carbonates, monazite-(Ce), chlorite, epidote, and calcite in A-type granites. These textural and compositional

data indicate extensive replacement and breakdown of primary magmatic REE,Y-bearing phases by subsolidus H2O-, CO2- and F-rich fluids, deliberated during post-magmatic overprint of the host granite.
The investigation of REE-bearing accessory minerals and their stabilities suggests the formation of porous textures, significant dissolution, etching, and alteration dependent strongly on local mineral compositions, on P–T–X conditions as well as on the presence and character of pervasive low-T metamorphic or post-magmatic-hydrothermal fluids in granitic systems, so more complex and variegated breakdown products can originate in specific conditions.

Hyperspectral Imaging: An effective mineral mapping tool for apatite in the Upper Zone, northern limb, Bushveld Complex

Clement NDOU[1]*, Council For Geoscience (cndou@geoscience.org.za)

Abstract

The technological advances in efficient, rapid, and non-destructive hyperspectral core logging systems for systematic mineral mapping have led to the discovery and exploitation of new mineral deposits. Hyperspectral imaging in the long-wave infrared range has recently been used successfully to identify various phosphate bearing minerals (monazite, xenotime, and britholite), with limited work on apatite associated with mafic-ultramafic layered intrusions. In this study, we investigate the effectiveness of a hyperspectral imaging (HSI) system with long-wave infrared (LWIR) bandwidths to identify apatite in the Upper Zone of the northern limb of the Bushveld Complex. The accuracy of the HSI results was validated by mineralogical and geochemical data. The two apatite-enriched zones detected by HSI suggests a widespread development of apatite throughout the uppermost 600 m of the Upper Zone. The lower apatite-enriched zone is approximately 40 m thick, while the upper apatite-enriched zone is about 23 m thick. This is consistent with previous thickness determinations by traditional logging and analytical methods such as petrography and mineral chemistry using electron microprobe (Ashwal et al., 2005). Spectral mixing observed in the response of apatite is ascribed either to the common association of apatite and olivine in these rocks, or to differences between the spatial resolution of the hyperspectral image and the size of apatite grains. In our study, the visible-near infrared and the shortwave infrared (VNIR-SWIR) range had limited detection capabilities in mafic-ultramafic rocks dominated by silica, some silicates (nesosilicates such as olivine) and oxides, as they did not show prominent spectral features. The results showed the absence of fluorapatite diagnostic prominent VNIR features related to the LREE (Nd) while inconspicuous spectral features were detected in the SWIR range. Nonetheless, HSI in the LWIR range is effective in mapping apatite and should therefore be considered as an exploration tool. This research advances our knowledge of the reflectance spectroscopy of REE-bearing minerals, which makes it easier to detect, identify, and quantify REE-bearing silicate minerals using HSI.

Platinum-group minerals, an experimental overview

Anna VYMAZALOVA[1]*, Czech Geological Survey (anna.vymazalova@geology.cz)
Frantisek Laufek[2], Czech Geological Survey

Abstract

There are currently 166 platinum-group minerals (PGM) approved by the Commission on New Minerals, Nomenclature and Classification (CNMNC) of the International Mineralogical Association (IMA). Among 166 PGM there are: 79 palladium, 38 platinum, 23 rhodium, 15 iridium, 7 ruthenium and 4 osmium dominant minerals. The largest class of minerals are sulphides (38) followed by tellurides (23) and arsenides (22) reflecting the chalcophile character of platinum-group elements. There is also a significant class of alloys (20) consistent with the siderophile character of platinum-group elements. Our aim is an experimental assessment of platinum-group minerals, their revision in terms of chemical composition, physical properties, crystal structure investigation and thermal stability. We have experimentally focused on Pd-dominant PGM. A number of PGM display unique crystal structures like lukkulaisvaaraite $Pd_{14}Ag_2Te_9$ or thalhammerite $Pd_9Ag_2Bi_2S_4$. Such minerals with novel atomic ordering might be an inspiration for materials scientists and often show interesting structural properties. There is a significant group of PGM that also display desired properties (e.g. semiconductors or two-dimentional materials). Nevertheless there is still a significant group of minerals poorly characterized. The crystal structure of 33 Pd-dominant PGM is still not determined or solved and require further investigations.
The support from the Grant Agency of the Czech Republic (project No. 22-26485S) is greatly acknowledged.

Natural Radioactivity of the Mesozoic Granites in the Southern Part of the Korean Peninsula

Chaewon KIM[1]*, Chonnam National University (kimchaewon48@jnu.ac.kr)
Jieun Seo[2], Chonnam National University
Minju Kang[3], Chonnam National University
Eunsil Jang[4], Chonnam National University
Jaebong Park[5], Center for Asbestos and Environment, Chonnam National University
Yul Roh[6], Chonnam National University

Abstract

Naturally occurring radioactive materials (NORMs) refer to radioactive isotopes such as ^{238}U, ^{232}Th, ^{226}Ra, ^{222}Rn, and ^{40}K in geological media. The emission of radiation during their decay causes health risks in case of prolonged human exposure. Previous studies have shown the high concentrations of NORMs in Mesozoic felsic and plutonic rocks present in the southern part of the Korean peninsula. This research deals with the association of natural radioactivity and minerals in order to clarify the putative relationships between natural radioactivity and the mineralogical as well as the geochemical characteristics of the Mesozoic granites.

In this study, Mesozoic granites were collected from several regions of the southern Korean peninsula. Triassic granites were obtained from Hongseong and Yongyu-do. Jurassic granites were obtained from Daejeon and the northern part of Gyeonggi-do. Cretaceous granites were obtained from Chungcheongbuk -do and Jinan. Mineralogy of the granites was identified using XRD and PLM analyses. Gamma-ray spectroscopy analyses were conducted to identify radionuclides and to measure the energy. EPMA analyses were also used to analyze the distribution patterns of those NORMs in NORM-containing minerals.

The radioactivity of the Triassic granites ranges from 47.4 to 341.9 Bq/kg for ^{232}Th, from 17.1 to 248.7 Bq/kg for ^{226}Ra, and from 882.9 to 1961.5 for ^{40}K. The radioactivity of the Jurassic granites ranges from 16.64 to 145.10 Bq/kg for ^{232}Th, from 12.29 to 151.19 Bq/kg for ^{226}Ra, and from 175.02 to 1485.86 for ^{40}K. The radioactivity of the Cretaceous granites ranges from 46.1 to 185.2 Bq/kg for ^{232}Th, from 21.6 to 129.5 Bq/kg for ^{226}Ra, and from 881 to 1,572 Bq/kg for ^{40}K. XRD, PLM, and EPMA analyses revealed the mineralogy of the Mesozoic granites, with the high level of ^{232}Th and ^{226}Ra attributed to accessary minerals such as monazite, zircon, apatite, thorite, and sphene. Additionally, high activity concentration of K^{40} was related with K-containing minerals such as K-feldspar and micas.

Reaction Between Feldspar and Water Under the Mantle Transition Zone Conditions

Yeonhak JUNG[1]*, Yonsei University (muts0228@yonsei.ac.kr)

Stella Chariton[3], Center for Advanced Radiation Sources, University of Chicago, Argonne, IL, USA
Vitali Prakapenka[4], Center for Advanced Radiation Sources, University of Chicago, Argonne, IL, USA
Nico Giordano[5], Photon Sciences, Deutsches Elektronen Synchrotron, Hamburg, Germany
Hanns Peter Liermann[6], Photon Sciences, Deutsches Elektronen Synchrotron, Hamburg, Germany

Abstract

One significant mechanism for transporting water to the boundary between the Earth's lower mantle and its core involves the formation of stable, high-density hydrous minerals as a result of phase transitions by subduction process. Feldspar, a major mineral component of the crust, is known to transition into a hollandite-type structure under the mantle transition zone conditions, characterized by a tunnel structure. A key feature of the hollandite-type structure is its high affinity for large, low-valence cations such as potassium, which facilitates the transport of heat-producing radioactive isotopes like 40K to the lower mantle, thereby serving as a crucial factor in the thermal evolution of the deep Earth. In this study, we applied conditions of the transition zone, containing 2-3 wt% water, to feldspar composed of equal parts Na and K, to analyze the phase transition process of feldspar in the transition zone. Through synchrotron X-ray diffraction experiments employing diamond anvil cells and laser heating, we confirmed the formation of the hollandite-type structure under both hydrous and anhydrous conditions. The hollandite-type structure formed in the presence of water exhibited a unit cell volume increase of about 0.5% compared to that formed in the absence of water. Additionally, Rietveld analysis indicated that in the hollandite-type structure of feldspar, water and cations alternately occupy the structure's vacant cavities. Therefore, the transition of feldspar to the hollandite-type structure in a "water-rich" mantle transition zone environment suggests a novel mechanism for the co-transport of water and cations.

A high-precision measurement method for analyzing Sr, Nd and Sm isotope ratios in single-grain minerals

Guiqin WANG[1]*, Guangzhou Institute of Geochemistry, CAS (guiqinwang@gig.ac.cn)
Yuming Xu[2], Guangzhou Institute of Geochemistry, CAS

Abstract

High-precision measurements of Sr, Nd, and Sm isotopes in single-grain minerals are significant in geochemistry. It is also a challenge for analytical techniques. In this study, a single-column separation procedure was developed using TODGA-normal resin to purify Sr, Nd, and Sm from microgeological samples (∼3 mg). The total chemical procedural blank for Sr, Nd, and Sm is less than 80, 7, and 3 pg, respectively; the recoveries are all greater than 91%. Methods have also been developed for the static measurement of Sr, Nd, and Sm isotopes in small size samples using a TIMS with Faraday cups and 10^12 and 10^13 Ω amplifiers. The accuracy and precision of Sr, Nd, and Sm isotope ratios were analyzed using TIMS with three single-element calibration solutions, SRM 987 Sr, La Jolla Nd, and Alfa Aesar Sm, respectively. The results show that the repeatability of 87Sr/86Sr, 142Nd/144Nd, 143Nd/144Nd, 149Sm/152Sm and 150Sm/152Sm ratios at 30 ng each of Sr, Nd, and Sm is 0.710248 ± 11, 141 846 ± 25, 0.511852 ± 13, 0.516845 ± 17, and 0.275998 ± 9 (2 SD), respectively. Five geological rock reference materials and one meteorite sample were weighed at 3 mg and were used to validate the developed chemical procedure and TIMS measurement methods for Sr, Nd, and Sm. The results indicate that Sr, Nd, and Sm isotope ratios of all samples are consistent with the published data with a precision of 11–25 ppm (2 RSD). These methods are suitable for geochemistry studies for single-grain minerals and precious samples.

ASSESSMENT OF GOLD PROSPECTS AT EXPLORATION OBJECTS IN UZBEKISTAN

Vladimir Denevich TSOY[1]*, Institute of Mineral Resources (vtsoi@inbox.ru)
Sardor Savriddinovich Sayitov[2], Geologist

Abstract

In the process of geological exploration, it is important to promptly determine the prospects of deep horizons of objects and flanks. For this purpose, documentation of mine workings and well cores, testing with reference to sampling depths, spectral semi-quantitative and atomic absorption analyzes for gold and silver are carried out. Based on the results of the analyses, clarke concentrations for oreogenic elements are calculated, geochemical series are compiled for selected depth intervals, and the prospects of deep horizons are determined by comparing them with the stages of hypogene mineral formation. The results obtained are confirmed by mineralogical studies and the presence of typomorphic mineralization.

This technique was used at the Dzhasaul site, located in the Beltau mountains. Ore-bearing zones are confined to places of intense crushing and crumpling in the deposits of the Rokhat (O1-2rh) and Murun (upper subformation - O3) formations, located under the Mesozoic-Cenozoic cover with a thickness of 55-70 meters. The gold content in them is from 1.1 to 22.5 g/t, silver from 0.9 to 1225.0 g/t.

As a result of the study of ores, mineralized and ore-hosting rocks of the Dzhasaul site, selected from wells, depth gradations were identified.

1) 27-80 m (40 samples);
2) 80-130 m (78 samples);
3) 130-180 m (27 samples);
4) 180-230 m (24 samples);
5) 230-280 m (29 samples);
6) >280 m (6 samples).

The site has a very large thickness of Mesozoic-Cenozoic sediments. The Paleozoic basement begins in different wells at different depths. The closest bedrock exposure to the surface in the studied wells was 27 m.

Based on the results of spectral analysis for each depth gradation (sample), the average contents of ore elements were calculated. The obtained average contents of elements are normalized to their clarke abundances in the Earth's crust (according to Vinogradov, 1961). Geochemical series were compiled in descending order of clarke concentration (CC) values for each depth gradation.

An analysis of the abundance of elements by depth gradations and a comparison with a summary scheme of hypogene mineral formation in Uzbekistan was carried out.

In general, at the Dzhasaul site, ore-forming elements of the geochemical series are located in accordance with the stages of hypogene mineral formation, in places complicated by the manifestation of telescoping. The object is perspective at depth.

APOCARBONATE TYPE OF GOLD MINERALIZATION IN UZBEKISTAN, CONDITIONS OF FORMATION AND PREVALENCE

Bobir Farxadovich ISLAMOV[1]*, Ministry of Mining Industry and Geology of the Republic of Uzbekistan (idilniez@gmail.com)
Vladimir Denevich Tsoy[2], Institute of Mineral Resources
Shamsiddin Paxritdinovich Alimov[3], Uzbek geological exploration

Abstract

Currently, gold in carbonate rocks is known in the deposits of Uzbekistan: Rabinjan, Sintab, Bulutkan, Barkhanny, Northern Taushan, Akba, Akata, Shirotny, Almalyk ore district, etc. In Karamazar, gold-silver objects associated with silicified carbonate rocks located in in the form of lenses, fragments, tectonic packages, plates, blocks among volcanic rocks (Nadak, Charbi, Shkolnoye, Kyzyl-cheku, Aprelevka, Tulusai, Uchkyz, Chadak, etc.).

In the Central Kyzylkum Mountains, the main gold ore objects are located in formations containing carbonate rocks or silicification products of carbonate rocks (chert, quartzite, jasperoids). Thus, the Muruntau and Daugyztau deposits are located in the Kosmanachi formation, the former third Besapan subformation, Auminzatau in the Taskazgan formation and Kokpatas in the Kokpatas formation. At the deposits of Muruntau (in the M mine, quarry), Daugyztau (in the quarry), Bulutkan, Barkhanny, Sautbay, Turbay (in mine workings) silicified carbonate layers, lenses in terrigenous formations, which are often drawn as layered quartz veins, are installed (especially in Muruntau and Daugyztau). There are carbonate layers and lenses in the stratigraphic columns of the Kosmanachi strata, Tasqazgan and Kokpatas formations. In deposits where intensive hydrothermal development takes place, these carbonate layers and lenses are transformed into chert, quartzite, and jasperoids under the influence of essentially silicate solutions.

The presence of carbonate rocks in the Muruntau and Daugyztau ore zones is confirmed by the results of silicate analysis, recalculated to the mineral composition. Carbonates (dolomite, calcite, ankerite) occupy the third or fourth place in abundance after quartz, feldspar and hydromicas.

Layered quartz present in the Muruntau and Daugyztau deposits are apocarbonate formations. The gold content of the latter depends on the degree of silicification. Intensely silicified dolomites and limestones, as a rule, bear gold mineralization. Less silicified carbonate rocks, when their original composition is discernible, contain from zero to tenths of g/t gold. In addition to gold, these rocks contain scheelite, pyrite, arsenopyrite, stibnite and other minerals. At the Daugyztau deposit, carbonate layers, lenses transformed into silicified formations and jasperoids with gold and stibnite mineralization were identified. X-ray diffraction phase analysis revealed mainly the following vein minerals in the composition of apocarbonate formations: quartz, dolomite, sericite.

In the Kokpatas ore field in the early works of E.A. Markova, V.A. Horvat, S.Ya. Klempert, A.M. Gavrilov mention the presence of gold mineralization in carbonate rocks, in particular in the Dzhuskuduk formation. In the Kokpatas Formation, gold and tungsten mineralization is associated

with silicified carbonate layers and lenses among terrigenous rocks.

The presence of carbonate rocks in terrigenous formations is a necessary condition for the localization of gold mineralization, but not sufficient. In order for gold mineralization to form, an ore supply channel is needed, through which hydrothermal essentially aluminosilicate ore-bearing solutions penetrated into the carbonate-terrigenous rock. As a result of the interaction of the solution and the host rock, silicification of carbonate rocks occurs to a quartzite state, and at the same time, under conditions of neutralization of acidic solutions, gold precipitation occurs.

Abstract
Canfieldite is a mineral species recognized and described in 1893 by Samuel Lewis Penfield in honor of Frederick Alexander Canfield of Dover, New Jersey, USA. However, its crystal structure has not been yet precisely determined. This study employs X-ray single-crystal diffraction to determine the crystal structure of canfieldite from the Yukarang lead-silver mine in Tibet, China. The crystal structure of canfieldite is identified as an idealized Ag8SnS6, belonging to the orthorhombic crystal system with space group Pna21, a=15.3084(2) Å, b=7.5521(1) Å, c=10.7072(1) Å, V=1237.86(3) Å3Z =4. Refined indices for a total of 14,811 reflections (2,088 independent reflections) resulted in R1=0.0398and wR2 = 0.1023. The crystal structure exhibits a topology similar to artificially synthesized Ag8GeS6, with isolated SnS4 tetrahedra (average Sn-Sn bond length of 2.379 Å) arranged in a nearly equidistant manner (approximately 7.55 Å) in a three-dimensional framework. Two sulfur atoms (S5, S6) outside the SnS4 tetrahedra orderly occupy the spaces of an octahedron and a tetrahedron formed by six and four SnS4 tetrahedra, respectively, with average distances of S5-Sn and S6-Sn being 5.391 Å and 4.654 Å, respectively. Eight crystallographic sites within the SnS4 tetrahedra and spaces formed by S5 and S6 accommodate Ag atoms (S-Ag distances range from 2.16 to 2.67 Å) which exhibit instances of splitting with Ag-Ag distances ranging from 0.26 to 1.46 Å in multiple positions.

Minerals in Thin Section (MINTS) – An open-access interactive website for transmitted-light petrographic microscopy

Juergen REINHARDT[1]*, Department of Earth Sciences, University of the Western Cape, Bellville, 7535, South Africa (jreinhardt257@gmail.com)
Michael M. Raith[2], Institut für Geowissenschaften, Universität Bonn, 53115 Bonn, Germany
Tanja Reinhardt[3], Science and Technology Education Centre, University of KwaZulu-Natal, Durban, 4041, South Africa

Abstract

Polarized-light microscopy remains an indispensable, low-cost tool for the mineralogical analysis of geological samples, and in many instances presents the critical step before taking mineral and rock analysis to the next level such as electron microbe, XRF, ICP-MS analysis. Petrographic microscopy not only reveals the precise mineralogical composition of rocks, but also critical information on textural relationships between its minerals, including crystallization features, reaction textures, and deformation structures. The rise of online teaching and learning resources has seen various websites being developed that use colour photomicrographs, either arranged systematically or by putting emphasis on petrographic analysis of specific rock types. In some instances, the websites focus on historical collections of rock samples.

The open-access MINTS website combines all the advantages of the web-based approach, in particular large storage space and easy accessibility, with the flexibility to modify the database at any time, to upgrade, add and delete as desired. While the previously published online book 'Guide to Thin Section Microscopy' by Raith, Raase & Reinhardt (2012) focuses on the methodical-practical approach to thin section microscopy, the new website is essentially a systematic optical-mineralogical database, sorted by minerals and mineral groups, in combination with thin sections image series.

MINTS involves the following elements:
• A mineral index (A-Z) with links to data pages and thin section image sets;
• A graphical presentation of crystallographic-morphological properties combined with optical indicatrix geometry;
• A graphical overview of refractive index range in combination with a crystal-plate thickness versus birefringence plot using a modified interference colour chart (Sørensen, 2013);
• A condensed, but sufficiently comprehensive listing of optical and morphological mineral properties;
• An extensive archive of photomicrographs involving multiple image sets for each mineral species. These image sets include plane-polarized-light and crossed-polarizers modes showing critical grain sections and orientations as well as lambda-plate overlays.

The website in its present stage comprises close to 140 minerals and mineral groups. The nature of

the project is such that it is never a “closed book” as long as we continue to extend the mineral and data coverage and the photographic documentation. The website is presently hosted by the University of the Western Cape: https://mints/uwc.ac.za/mints.home.php

Semi-quantitative analysis of minerals in manganese nodule from the Magellan seamount cluster in Western Pacific Ocean

Jeongmin KONG[1]*, Pusan National University (wjdals3659@pusan.ac.kr)
Soojin LEE[2], Pusan National University
Hyunseung LEE[3], Pusan National University
Yongmoon LEE[4], Pusan National University

Abstract

Manganese nodules formed in the deep sea are composed of minerals bound to various metals in iron-manganese oxides containing elements such as Co, Ni, Cu, Li, Mo, Zr, and rare earth metals regarding as valuable future resources. The Magellan Seamounts, the study area, is a collection of undersea mountains in the high seas of the Western Pacific where a large amount of manganese nodules are distributed. The purpose of this study is to understand the relationship between the enrichment of metal resources within manganese nodules and the distribution of minerals. As a first step, we aim to understand the qualitative and quantitative distribution of minerals forming nodules within the Magellan Seamounts.

Manganese nodules collected from the tabletop of the Magellan Seamounts (KC-8, KC-2, OSM-XX) in the western Pacific were provided by the KIOST(Korea Institute of Ocean Science and Technology). In order to understand in detail the qualitative and quantitative differences in the minerals of manganese nodules according to the seamounts, samples were segmented into 3 to 5 areas from the center to the rim of the nodules. Each sample was subjected to phase identification analysis through X-ray diffraction measurement and semi-quantitative analysis was performed on manganese minerals through peak area calculation. In all three seamounts, Vernadite ((Mn4+,Fe3+,Ca,Na)(O,OH)2·nH2O) was dominantly distributed at over 95%, and Todorokite ((Na,Ca,K,Ba,Sr)1-x(Mn,Mg,Al)6O12·3-4H2O) and Buserite (Na4Mn14O27·21H2O) were confirmed to be less than 5%.

Relationship between distributions of the extra-framework species and adsorption capacity for CO2 gas on synthetic mordenite.

Soojin LEE[1]*, Pusan National University (mark85@pusan.ac.kr)
Yongmoon LEE[2], Pusan National University
Hyunseung LEE[3], Pusan National University
Donghoon SEOUNG[4], Chonnam National University
Huijeong HWANG[5], Gwangju Institute of Science and Technology
Hyeonsu KIM[6], Chonnam National University
Pyosang KIM[7], Chonnam National University

Abstract

Synthetic mordenite, one of the siliceous zeolites, is widely used as a molecular sieve, adsorbent, and catalyst. To improve these performances, it is essential to understand the ion-exchange properties and cation exchange sites of the zeolite. In this study, we observed the structural changes in fully Cs-, Sr-, Cd-, and Pb-exchanged mordenite using synchrotron X-ray powder diffraction under ambient conditions. Structure analysis by the Rietveld method revealed that Cs+ ions are mainly located near the 8MRb due to their low electronegativity and hydration energy. However, Na+ ions are found at the center of the 8MRc and in the 12MRc because they are less affected by these effects. On the other hand, divalent cations such as Sr2+ and Cd2+ ions, with higher hydration energies than that of monovalent cations, are present as hydrated ions at the center of the 12MRc. In the case of Pb2+ ions, with higher electronegativity than framework atoms (Si and Al), exhibit a strong affinity for the electron cloud of framework oxygen atoms, thus positioning close to the wall of the 12MRc. Thermogravimetric analysis showed that, except for Pb-MOR, divalent cation exchanges generally contain more water molecules per unit cell than monovalent cation exchanges, by their higher hydration energies. The differences in the positions of the extra-framework cations were considered due to the electrostatic and hydration effects. The CO2 gas adsorption capacities were compared based on the type and site of exchangeable cations. The results indicate that an increase in CO2 capacity was correlated with the number of cations capable of effectively interacting with CO2.

Infrared behavior of phlogopite from some magnesian skarns in the Banatitic Magmatic and Metallogenetic Belt from Romania

Cristina SAVA GHINET[1]*, Geological Institute of Romania (ghinet.cristina@yahoo.com)
Stefan Marincea[2], Geological Institute of Romania
Delia Georgeta Dumitras[3], Geological Institute of Romania
Aurora Maruta Iancu[4], Geological Institute of Romania

Abstract

The occurrences of phlogopite from the thermo-metamorphic areas of the Banatitic Magmatic and Metallogenetic Belt (Romania) are ascribed to Upper Cretaceous magnesian skarns (Ocna de Fier, Cacova Ierii, Maşca Băişoara, Băiţa Bihor, Pietroasa and Budureasa). The common mineral association includes, besides phlogopite, spinel, forsterite, humite-group minerals (generally clinohumite and chondrodite, but also norbergite), and diopside. They are locally overlapped by magnesian retromorphic zones of pseudoskarn type, composed of serpentine, brucite, calcite, dolomite, clinochlore, and pyroaurite.

The infrared absorption spectra on representative phlogopite samples were recorded in the frequency range between 250 and 4000 cm-1, using both FT-IR and IR devices. The main absorption bands could be ascribed to the following spectral domains: (1) 3800 – 2500 cm-1, which hosts the fundamental stretching modes of the OH groups in the structure. The study of this region can be quite difficult in the case of the strongly hydrated samples or in the case of strongly hydrated phlogopite – serpentine mixtures (e.g., in samples from Ocna de Fier). Depending on the chemical composition, the frequencies of the OH group in the structural Mg3OH units occur in the spectral range between 3692 and 3716 cm-1. The presence of the trivalent cations (Fe3+, Al3+) in one of the three octahedral positions around the hydroxyl group leads to the splitting of the OH stretching band visible in some samples (Pietroasa, Budureasa, and Ocna de Fier). The 3620 cm-1 band can be associated with Mg2+Al3+ coordinating pair, the band at ~3600 cm-1 with Fe2+Al3+ coordinating pair, while 3550 cm-1 with the Fe2+Fe3+ coordinating pair, in good agreement with the chemical composition determined by EMPA; (2) the 1800 – 1400 cm-1 spectral range hosts the bendings of H-OH bonds within the H2O-absorbed molecules in KBr or in the intra-layer water. It is almost impossible to have an unequivocal assignment of the water nature. (3) 1200 – 700 cm-1 characterizes the internal vibrations of the Si(Al, Fe3+)O4 tetrahedrons in the phlogopite structure. A first broad band with an apex at 985 – 1010 cm-1 is due Si-O-Si vibrations of Si2O5 groups. The intensity of the band around the value of 770 cm-1 is clearly visible in the samples with a high content of annite and can ascribed to vibrations of both (Al, Fe3+)-O-Si and Fe3+-O-AlIV type. The splitting or shift to lower frequencies of the bands from 820 to 730 cm-1 is remarkable in the case of samples with higher content of tetrahedral Fe3+, in which Fe3+-Si stretching bands shift to lower frequencies; (4) 700 – 250 cm-1 is the spectral region given by metal – O stretching bands composed with bands materializing O-H vibrations, difficult to be assigned. These bands are visible in the 590 – 615 cm-1 spectral range. Even if the Ca-O

vibrations are expected to materialize through bands located at higher frequencies, they are kept in the far infrared domain, below 250 cm-1.

Abstract

Spodumene, known for its important role as Li source, occurs as the main mineral species in the pegmatite bodies from Conţu (Lotru Mountains, Romania), of albite-spodumene type. The occurrence is located on the homonym valley, at N 45°33'39" – E 23°52'19". The main associated minerals are albite, microcline, quartz, and muscovite, with an important number of accessories (e.g., beryl, purpurite - heterosite, amblygonite - montebrasite, fluorapatite, triphylite - lithiophylite, maricite, gatehouseite, monazite, schorl, spessartine, cassiterite, columbite - tantalite, uraninite). The average chemical composition, obtained based on 21 electron-microprobe point analyses, with Li deduced for stoichiometry, is (in wt.% oxides): SiO2 = 64.47, Al2O3 = 28.00, Fe2O3 = 0.59, Li2O = 8.05, Total =101.11. The chemical-structural formula, calculated based on 6 oxygen atoms p.f.u., is: Li0.995(Al0.995Fe3+0.013)(Si1.981Al0.019)O6. The mineral can be satisfactorily refined as monoclinic, space group C2/c (with R = 0.0244), and have as cell parameters: a = 9.4670(4) Å, b = 8.3967(3) Å, c = 5.2198(3) Å, β = 110.15(4)°. As expected, the SiO4 tetrahedron is far to describe a punctual Td symmetry. The Si-O distances obtained by refinement are Si-O1 = 1.640(1) Å, Si-O2 = 1.586(1) Å, Si-O3 = 1.621(1) Å, Si-O4 = 1.629(1) Å. All the bands that can be assigned to Si-O-Si vibrations in the FTIR spectrum seems triple degenerate (antisymmetric stretchings at 1163, 1085, 1072 cm-1, symmetric stretchings at 919, 860 and 797 cm-1, in-plane bendings at 695, 641 and 593 cm-1) corresponding to the three dispersed Si-O values given before, whereas O-Si-O are simple degenerate, reflecting the presence of a sole tetrahedron in the chain repeat unit (antisymmetric stretching at 919 cm-1, symmetric stretching at 779 cm-1, in-plane bending at 518 cm-1, out-of-plane bending at 450 cm-1). In the Raman spectrum the trend remains the same: the Si-O-Si antisymmetric stretching bands were recorded at 1092, 1050 and 1017 cm-1, the symmetric stretching at 841, 793 and 706 cm-1 whereas the in-plane bending is materialized by bands at 596 and 523 cm-1, and the out-of-plane bending by a band at ~481 cm-1. The out-of-plane O-Si-O bending was recorded at 446 cm-1. Bands expressing lattice vibrations (principally Al-O and Li-O) were recorded at 396, 357, 299, 249, 114 and 78 cm-1.

TOURMALINE AS AN INDICATOR MINERAL FOR BASE METAL AND ASSOCIATED MINERALIZATION IN SUPRACRUSTAL ROCKS OF NORTH SINGHBHUM MOBILE BELT

MANSI JAIN[1]*, GEOLOGICAL SURVEY OF INDIA (mansi.jain@gsi.gov.in)
MANSI JAIN[2], GEOLOGICAL SURVEY OF INDIA

Abstract

The emplacement of quartz tourmaline veins along the contact of Chhotanagpur Gneissic Complex and Singhbhum Supracrustal Rocks of North Singhbhum Mobile Belt and in the proximity of South Purulia Shear Zone holds importance from base metal mineralization point of view. They are mainly exposed along the regional foliation in and around Mudidih-Kashidih-Magatdih-Laka area, Purulia District, West Bengal. These quartz veins are milky white and contain profuse amount of black tourmaline crystals with no preferred orientation. Since tourmaline is a chemically stable mineral over large temperature and pressure range, it can be used as a geological indicator because it is highly resistant to modification even during high-grade metamorphism and alteration. Emphasis has been given on geological setting of quartz tourmaline veins, petrography of tourmalines and its mineral chemistry to understand its role in mineralization. Occurrence of quartz tourmaline veins at the regional scale along the shear zone indicates high temperature hydrothermal activity involving boron enrichment. These boron bearing magmatic hydrothermal fluids must have circulated through the entire shear corridor which possibly serves as a structurally favorable domain and suitable conduit for the mineralization. Microscopically, tourmaline is coarse grained and occurs in both elongated and equant variety. Both varieties of tourmaline are zoned; from core to rim the color varies from blue-green to light brown. It is intensely pleochroic and fractured. Quartz grains are present as inclusion within the tourmaline grains. The tourmaline of the present area belongs to the Alkali group. The majority of tourmalines are categorized as dravitic sub-group and only a few are schorlitic. The findings of the present study was correlated with a recent well-known study in the Jervois mineral field and Bonya Hills, Aileron Province by MV McGloin, A Weisheit, RB Trumbull and R Maas, 2019 which stated a close spatial association between epigenetic tourmaline-bearing rocks, felsic igneous rocks and tungsten-copper mineralization, suggesting a genetic link. In their case study, tourmaline in pegmatites and quartz veins is associated with epigenetic tungsten and copper mineralization in the Bonya Hills area. It was noted in the study that analyzed tourmaline has schorl–dravite composition regardless of the associated mineralization, which is similar to the findings of the present study. Moreover, the chemical analytical data of the present study area reveals significant values of copper: 1083 ppm & 1099 ppm; lead: 1001 ppm and REE: 1177 ppm, 1391 ppm & highly anomalous value of 20,930 ppm. These values have been obtained from cherty quartzite and tuffaceous rocks, exposed in the vicinity of quartz tourmaline veins. Thus tourmaline mineral chemistry of the present study area attests to the favourability of basemetal mineralization in the terrain.

Structure vs. FT-IR and Raman behavior of wollastonite-2M ("parawollastonite") from Cerboaia Valley, Măgureaua Vaţei (Metaliferi Massif, Apuseni Mountains, Romania)

Delia Georgeta DUMITRAS[1]*, Geological Institute of Romania (d_deliaro@yahoo.com)
Stefan MARINCEA[2], Geological Institute of Romania
Cristina SAVA GHINET[3], Geological Institute of Romania
Aurora Maruta IANCU[4], Geological Institute of Romania
Fabrice DAL BO[5], Geological Institute of Romania
Frédéric HATERT[6], Geological Institute of Romania

Abstract

The gehlenite-bearing, high-temperature skarn from Măgureaua Vaţei occur at the contact of a shallow-level pluton of Upper Cretaceous age, with monzodiorite to quartz-monzodiorite differentiates, with Tithonic - Kimmeridgian reef limestones. The preserved peak metamorphic assemblage includes gehlenite, wollastonite-2M, monticellite, Ti-poor calcic garnet, perovskite, and Ca-Tschermak diopside. Wollastonite-2M is the main component of the outer skarn zone. The mineral occurs as almost monomineralic aggregates of long-prismatic or acicular crystals of 1 to 10 cm in length. A cathodoluminescence zoning of some individual crystals could be observed, but no solid evidence of correlation with the chemical zoning of the mineral was found. Wollastonite from Măgureaua Vaţei exhibit only relatively small deviations from the ideal composition: the substitutions for Ca in the six-fold coordinated sites are minor, with Mn < 0.004 apfu, Fe2+ < 0.107 apfu (generally much lower) and Mg < 0.043 apfu (on the basis of 18 oxygen atoms). The average composition, based on 102 EMP point analyzes is: (K0.002Na0.004Ca5.959Mn0.004Mg0.026Fe2+0.018)(Si5.984Ti0.003Al0.011)O18. The mineral can be satisfactorily refined as monoclinic, space group P21/c (with R = 0.0387), and have as cell parameters: a = 7.0684(3) Å, b = 7.3228(3) Å, c = 15.4206(7) Å, β = 95.34°. All the bands that can be assigned to (SiO4)4- vibrations in the FTIR spectrum are triple degenerate, reflecting the number of three tetrahedrons in the chain repeat unit. Bands assumable to Si-O-Si antisymmetric stretching were recorded at 1085, 1060, and 1018 cm-1, and to the Si-O-Si symmetric stretching at 681, 645 and 565 cm-1. Three other bands recorded at 967, 926 and 902 cm-1 are apparently due to O-Si-O antisymmetric and symmetric stretching, whereas bands at lower frequencies (509, 472 and 453 cm-1) express Si-O-Si bending vibrations and the latter could be reasonably assigned to Ca-O lattice vibrations. The intensities of the bands expressing the stretching vibrations of wollastonite-2M from Măgureaua Vaţei are higher than those of the homologue bands recorded from wollastonite-3T from Băiţa Bihor (Bihor Mountains, Romania), which express a superior structural ordering. In the Raman spectrum, the Si-O-Si antisymmetric stretching seems double degenerate (bands at 1057 and 1042 cm-1) as well as the symmetric stretching (688 and 637 cm-1). The Si-O-Si bending was recorded at 585 cm-1, whereas the bands at frequencies below 450 cm-1 are certainly due to lattice (Ca-O) vibrations.

Mineralogical variations of shallow manganese nodules in the East Siberian Sea with respect to water depth

Hyo-Jin KOO[1]*, Future Earth Research Institute, Pusan National University, Korea (ghj6011@nate.com)
Hyen-Goo Cho[2], Department of Geology , Gyeongsnag National University, Korea
Hyo-Im Kim[3], Department of Geology , Gyeongsnag National University, Korea
Sangmi Lee[4], Department of Geology , Gyeongsnag National University, Korea
Hanjin Choe[5], Department of Geological Sciences, Pusan National University, Korea

Abstract

The formation mechanism of Mn nodules is broadly categorized into hydrogenesis and diagenesis, and this difference can be controlled by the redox conditions of the formation environment. Mineralogical investigation of Mn nodules can serve as a valuable tool for acquiring geological insights into their formation. The structures of Mn oxide minerals can be classified into two main types: layer structure (phyllomanganate) and tunnel structure (tectomanganate). Reprensentatve tectomangante mineral include todorokite, and phyllomanganate minerals include birnessite, buserite, and vernadite. In general, hydrogenetic nodules form through the precipitation of metals from seawater or freshwater with a relatively high redox potential. These predominantly comprise layered vernadite characterized by high Fe content and Fe-hydroxide with very low crystallinity such as δ-FeOOH (i.e., feroxyhyte). Conversely, diagenetic nodules arise from the precipitation of metals from pore water within the sediment, and they can be categorized based on their formation within oxic or suboxic diagenesis, determined by the fluctuation of the oxic/suboxic redox front in the sediment. Suboxic diagenetic nodules have abundant of phyllomanganate minerals, while oxic diagnetic nodules are commonly characterized by todorokite. On the other hands, Mn nodules can be classified into deep-sea Mn nodules and shallow-water Mn nodules based on the water depth of the sea area where they are distributed. Shallow-water Mn nodules are generally understood to originate from diagenetic processes, although their specific mineral composition remains unclear at present. In this study, we present the findings of a mineralogical analysis conducted on Mn nodules collected from the shelf-slope region of the East Siberian Sea as part of the Arctic expeditions carried out with the R/V Araon. The Mn nodules in the East Siberian Sea are distributed across the continental shelf and slope, spanning water depths ranging from 73 to 240 m. Previous investigations have noted substantial variations in the morphological characteristics of these nodules corresponding to different water depths. These morphological differences, linked to water depth, suggest potential changes in the nodule formation environment. This phenomenon can be further validated by examining the mineralogical features constituting the manganese nodules. Consequently, the mineralogical study of Mn nodules in the East Siberian Sea could serves as a robust platform for elucidating the mineral composition of shallow-sea manganese nodules and comprehending the distinctions in the formation of Mn oxide minerals based on varying water depths.

Occurrence of Perovskite-magnetite hosted REE mineralization in Jashora Ultramafic Alkaline Complex, West Karbi Hills, Assam, India.

TAPAN PATOWARY[1]*, Geological Survey of India (tapan.patowary@gsi.gov.in)
Hrushikesh H[2], Geological Survey of India
Nikunja Bihari Singha[3], Geological Survey of India

Abstract

The Jashora ultramafic alkaline complex (JUAC) of Cretaceous Period located in the northern fringe of the West Karbi Hills occurs as intrusive into the metasedimentary sequence of Shillong Group and the Pan-African granitoids. It is an elliptical shaped body spreading over an area of about 3.2 sq. km. The intrusive complex comprises wide variety of rocks identified as pyroxenite, perovskite-magnetite, olivine gabbro, nepheline syenite, phonolite, ijolite and fenite. Petrographic studies and modal analysis of perovskite-magnetite reveal that the rock is constituted by 65-70% of magnetite and 35-30% of perovskite. Perovskite occurs as euhedral to subhedral phases. It appears pale brown granules set in a matrix of magnetite occurring as opaque and fills the interstitial spaces of the rock. EPMA and SEM-EDX analyses of perovskite-magnetite show that the rock is composed of magnetite and perovskite with accessory phases like monazite, ilmenite and pyrochlore. Systematic surface and subsurface sampling have been conducted in the rocks and regolith developed over rocks of JUAC to assess REE potentiality. It has been observed that the mineralization in the complex is attributed to the perovskite-magnetite rock which occurs as rich fragments within the regolith developed over the pyroxenite (0.3-1.3 m) and as lenses or discrete layers (0.1-0.3 m) within pyroxenite. Studies of 650 nos. of drill core samples of perovskite-magnetite bearing pyroxenite have indicated dissemination of perovskite-magnetite within pyroxenite upto the depth of 130 m and yielded ∑REE value up to 12278 ppm (ave. ∑REE 2038 ppm). The regolith rich in fragments of perovskite-magnetite has yielded ∑REE values 4348-20142 ppm and (ave. ∑REE 9190 ppm), Nb values 975-3132 ppm (ave. 1404 ppm) and Vanadium 1377-2466 ppm (ave.1772 ppm). Mineralized zone chemistry suggests Fe2O3, TiO2 and CaO together constitute 96% of total bulk composition corroborating the unique mineralogy magnetite + perovskite. The correlation bivariant diagrams suggest anomalous REE concentration is contributed by perovskite or the Ti rich exsolution phases in the magnetite which is also contributing Ti, Nb and V.

Mineral chemistry and trace element variations in index minerals around pyrophyllite deposit in the Mailar village, Lalitpur district, Uttar Pradesh.

MADHUMITA BANERJEE[1]*, Geological Survey of India (madhumita.banerjee@gsi.gov.in)
Surabhi Srivastava[2], Geological Survey of India
Siladitya Sengupta[3], Geological Survey of India

Abstract

Detailed mineral chemistry of the alteration minerals have provided valuable inputs to establish the porphyry related hydrothermal character of the altered granitoids associated with the pyrophyllite deposit in the Mailar village, Lalitpur district, Uttar Pradesh situated in the southern part of Bundelkhand Craton. Variation in the alteration mineralogy and trace element composition in index minerals from different hydrothermal alteration zones- argillic, phyllic, potassic and propylitic have been studied in the present work. The chlorite chemistry from the potassic alteration zone shows that the formation of chlorite was started towards the end of potassic alteration stage and continued progressively in the course of propylitic alteration. The composition of the chlorite within the potassic zone is characterized by relatively higher Fe/(Fe + Mg) ratios (0.57 to 0.66) and AlIV content (2.2 to 2.4) than the other alteration zones. The chlorites from phyllic and potassic alteration zone fall in ripidolite, brunsvigite field, whereas chlorites from argillic, propylitic alteration zone fall in pychnochlorite and diabanite field. Empirical chlorite thermometer after Jowett, E. C, 1991 shows the total temperature ranges from 250°C to 334°C. The highest temperature (298°C- 334°C) is associated with potassic and phyllic alteration zone whereas lower temperature (250°C -298°C) is confined to the argillic and propylitic alteration zone.

Magnetite trace element chemistry carried out from the selective magnetite grains separated from samples collected systematically across the pyrophyllite deposit using LA-ICPMS technique shows elevated values of Ti, V, Co, Ni, Cu, in magnetites from pyrophyllite and associated sericitic alteration zone. The magnetites from the altered granitoids have Ti content, less than 0.1 wt% which correspond to hydrothermal origin of the magnetites. The discrimination diagrams using V, Ti, Fe relationships show that the magnetites plot in the hydrothermal field and the overlapping area between igneous and hydrothermal field. Potassic zone magnetites show high Zn and Ga concentration indicating high temperature hydrothermal character. Sn vrs. Ga discrimination diagram, after Nadoll et al., 2014 shows the magnetite grains plot broadly between the hydrothermal and porphyry related magnetite field. Overall chemistry of major and trace elements, mineral chemistry of alteration minerals, point towards a porphyry type hydrothermal regime experienced by the granitoids of the Mailar area.

A Comparison Study of Quantitative analysis and Morphology of Microlites in the Obsidians Using Electron Probe Micro Analysis

JIN MI-EUN[1]*, HANARO Utilization Division, Korea Atomic Energy Research Institute (jin4860228@gmail.com)
Jwa Yong-Joo[2], Department of Geology, Gyeongsang National University
Sun Gwang-Min[3], HANARO Utilization Division, Korea Atomic Energy Research Institute
Hwang Ga-hyun[4], National Research Institute of Cultural Heritage

Abstract

Obsidian is one of glassy volcanic rocks formed by the rapid cooling of silica-rich rhyolite or decite magma. Within the obsidian, there are numerous microlites, which are crystals usually having a size of about 1 μm. These microlites could be distinguished based on their morphology and composition depending on the composition of magma and tectonic setting. We conducted investigated morphological characteristics and chemical compositions of the microlites included in the obsidians from the Baekdusan in North Korean side and in the obsidians from the Kyushu and Hokkaido in Japan. The morphology of the microlites from the Baekdusan obsidians can be divided into three groups among which trichite-acicular and trichite-asteroidal types are predominant. On the other hand the microlites from the Kyushu and Hokkaido Obsidians show various morphological features such as acicular, margarite, lath, and asteroidal types. Silicate microlites from the Baekdusan obsidians are mostly of Ca-pyroxene compositions (hedenbergite to augite), whereas those from the Kyushu obsidians are mostly of biotite (annite) with small amount of clinopyroxene (ferrosilite). It is well understood that the microlites from the Baekdusan obsidians are different from those from the Kyushu obsidians in terms of the morphology, mineral content and mineral composition. Therefore, results of this study would be a useful discriminator to divide the obsidian provenances.

Mineralogical studies of iron ore deposits of Sonhari member of Eocene age, Laki Formation, Sindh, Pakistan

Muhammad Hassan Hassan AGHEEM[1]*, University of Sindh, Jamshoro
(mhagheem@usindh.edu.pk)
Ghulam Mustafa Thebo[2], University of SIndh, Jamshoro
Akhtar Hussain Markhand[3], University of SIndh, Jamshoro
Aijaz Ali Halipoto[4], University of SIndh, Jamshoro

Abstract

Like a few other countries, Pakistan is also bestowed with a variety of mineral commodities including all types of industrial minerals including various ore minerals and a variety of gemstones. Some of these have been discovered before the partition while majority of minerals is also discovered after 1947. Pakistan is not only famous because of diversity of mineral resources but currently is one of the best example of continent to continent collision. Because of this collision, uplifting of Himalayas and finally the rapid denudation; a variety of mineral commodities of secondary origin has been formed in different regions of the country. Along with other mineral resources, Pakistan is also rich in iron deposits. These iron ore deposits are of diverse origin starting from igneous magnetites to sedimentary hematite types. Like, other provinces of Pakistan, the Sindh province is also bestowed with both metallic and non-metallic industrial minerals along with great potential of oil and gas production.

In this regard, a research work was carried out on iron ore deposits and associated clay beds in two sections of Sonhari member of Early Eocene Laki Formation in district Thatta, Sindh, Pakistan where some iron deposits are reported. The major objective of this study was to properly characterize the iron-bearing and other associated minerals and to establish the possible genetic relationship, if any. During the field work, it was noted that the iron ores were alternative with a variety of clay minerals. The laminations and beds are variable both in size and shape and ranging from a few centimeters to as thick as 4-5 feet. The representative samples were collected and then were analyzed on D8 Advance Spectrometer for XRD analysis for proper mineral characterization along with the EDS to know about the chemistry. The XRD analysis indicates that a variety of other minerals is also associated with the iron-bearing minerals. The qualitative and quantitative XRD analysis show that the hematite, goethite, and maghemite are the major iron phases present in various proportions in the analyzed samples while a significant proportion of other minerals in the form quartz and clays is also present. Among the three identified iron-bearing minerals, the hematite is common with higher percentage while the maghemite is present in only four samples and goethite in eight samples. The XRD analysis of alternative clay beds shows the presence of kaolinite, faujsite, calcite, illite, magnetite, maghemite, clinochlore, vermiculite, dickite, and boehmite. In addition, two titanium bearing minerals in the form of titanite and anatase are also identified. The evaporates are in the form gypsum and halite. The EDS analysis also confirms the presence of above minerals identified through XRD.

On the basis of such mineral assemblage, it can be concluded that the source of sediments was

mixed and the sediments were deposited in fluvial to deltaic environments; during the major phase of transgression and regression which occurred during the Late Paleocene and Early Eocene time.

The component analysis and U-Pb dating of cassiterite using LA-(MC)ICP-MS

YounJoong JEONG[1]*, Korea Basic Science Institute (hero0123@kbsi.re.kr)
Sookju Kim[2], Korea Basic Science Institute
Hyojin Kim[3], Kongju University
Giun Han[4], Korea Basic Science Institute
Yeoungmin Kim[5], Korea Basic Science Institute

Abstract

Cassiterite is a significant ore mineral of tin, and research utilizing LA-(MC)ICP-MS for component analysis and U-Pb dating of cassiterite provides valuable insights into geological processes in the fields of mineralogy and geology. This study focuses on analyzing the composition and age dating of cassiterite, a tin-bearing mineral found in the Sangdong and Wangpiri regions of the Korean Peninsula, aiming to understand the characteristics of ore deposits and their geological implications. Cassiterite is commonly associated with metal ore veins, playing a crucial role in both industry and contributing to our understanding of ore formation and vein genesis processes. The LA-(MC)ICP-MS equipment used for this study is installed at the Korea Basic Science Institute. The laser ablation utilized Teledyne's Excite Pharos femtosecond laser ablation. Component analysis was conducted using an Agilent 7900 ICP-MS, while U-Pb analysis was performed using a Nu Plasma II MC-ICP-MS. The component analysis by LA-ICP-MS measured the content of major and trace elements, particularly focusing on the tin content (Sn) and trace elements such as Ti, Na, and K, to discuss the ore-forming environment. Additionally, mapping analysis of ore minerals will help elucidate the distribution patterns of trace elements and reveal the chemical characteristics of the ore veins. Moreover, U-Pb dating of cassiterite using LA-MC-ICPMS yielded results similar to those obtained by ID-TIMS, analyzing ore minerals from the same mounts for consistency. The obtained age measurements for ore minerals in the Sangdong and Wangpiri regions can be used to determine the timing of ore vein formation. These component analysis and age dating results offer crucial information for understanding the formation and evolution of ore minerals. Particularly, by elucidating the timing of ore formation in geological time, it enhances our geological understanding and can be instrumental in resource exploration and geological modeling.

Production of Montmorillonite Nanosheets using high-energy ball milling: A Study on Milling Methods and Solvent Effects

Bo Gyeong PARK[1]*, Department of Geoenvironmental Sciences, Kongju National University, Republic of Korea (pbk0150@smail.kongju.ac.kr)
Mi Rae Kim[2], Department of Geoenvironmental Sciences, Kongju National University, Republic of Korea
Hyun Na Kim[3], Department of Geoenvironmental Sciences, Kongju National University, Republic of Korea

Abstract

Montmorillonite, a 2:1 phyllosilicate clay mineral with high CEC capacity, swelling index and large specific surface area, has wide applications in various industrial fields such as construction and waste management. In particular, montmorillonite nanosheets can improve the mechanical properties of nanocomposite polymers, and thus the demand for montmorillonite nanosheets in the industry is increasing. Montmorillonite nanosheets are primarily produced by exfoliation using ultrasound or mechanical milling. While milling is cost-effective, it raises concerns about sample reaggregation and potential collapse of the crystalline structure. This research investigated methods to produce montmorillonite nanosheets by milling that preserve its unique crystalline structure.

The experiment was conducted using both dry and wet milling methods with a high energy ball mill. For wet milling, distilled water and ethanol were used as solvents. Milling was performed at 1500 rpm for durations of 1 and 2 hours. In order to understand the effects of milling method and solvent type on particle size, crystallinity and structural changes, analyses including X-ray diffraction (XRD), scanning electron microscopy (SEM), BET specific surface area analysis, laser diffraction particle size analysis (PSA) and Al-27 NMR were performed. Results showed that dry milling significantly increased montmorillonite specific surface area, but almost completely collapsed crystal structure. SEM images also revealed granular morphologies and the unique layered structure of montmorillonite rarely appeared. Wet milling with distilled water preserves the crystal structure but results in a slight increase in specific surface area, indicating poor particle size reduction, which is also supported by PSA and SEM results. Wet milling with ethanol reduces the particle size from ~10 μm to ~3 μm, and the crystal structure is also preserved according to XRD and Al NMR analyses. SEM images clearly showed the particle shapes of the nanosheets formed by exfoliating montmorillonite layers.

This study suggests that wet milling using ethanol as a solvent has the potential to produce montmorillonite nanoparticles without collapsing the crystal structure, and that the choice of milling method and solvent can control the desired particle size and shape of montmorillonite. Our results could be useful in preparing montmorillonite samples for various industrial applications.

State of the art of global geochemical mapping in Mozambique

Vicente Albino MANJATE[1]*, National Institute of Mines (sovimanjate@gmail.com)

Abstract

Environmental and natural resource managers throughout the world urgently need the global geochemical database. The Commission on GLOBAL GEOCHEMICAL BASELINES established an international network of applied geochemists throughout the world to implement harmonized sample collection, preparation, quality control, and analysis protocols for geochemical mapping programs. We aim to provide the actual development of global geochemical mapping in Mozambique. Mozambique has a surface of approximately 800 000 km2 and is situated in southern Africa with border extremities varying between 10°30' and 26°52'S and 40°50' and 30°13'E. Mozambique is partially (~50%) covered by geochemical mapping programs. These geochemical programs focus on mineral resource exploration and cover a prospect scale of 2-3 samples/10 km2 sampling densities. In 2021, Mozambique joined the initiative of the Commission on GLOBAL GEOCHEMICAL BASELINES and started the soil sampling in a 160x160km grid for the whole country. This work follows the standard methods established in the International Union of Geological Sciences manual and is aligned with the Global Geochemical Reference Network. In this network, Mozambique consists of 51 grid cells of 160x160 km with 132 observation points (Fig. 1). According to the global geochemical reference network, each cell consists of five random observation points. Up to 2023, the sampling program covered almost 90% of the predefined 132 observation points collecting 117 soil samples. The next challenge is to sign an agreement with an international partner for chemical analyses.

[Keynote] International Union of Geological Sciences Manual of Standard Methods for Establishing the Global Geochemical Reference Network

ALECOS DEMETRIADES[1]*, IUGS Commission on Global Geochemical Baselines
(alecos.demetriades@gmail.com)

Abstract

The International Union of Geological Sciences (IUGS) is the organisation responsible for studying geological problems, especially those of worldwide significance. It supports and facilitates international and interdisciplinary cooperation in the Earth sciences. IUGS gives special consideration to (i) international standards; (ii) geoscience education; (iii) geoscience information, and (iv) environmental management and hazards. It does this work through its Commissions, Task Groups and Initiatives. International standards are set up by the IUGS Commissions. Under this premise, the Commission on Global Geochemical Baselines has compiled the "International Union of Geological Sciences Manual of Standard Methods for Establishing the Global Geochemical Reference Network" [1]. It presents, for the first time, a comprehensive overview of the standardised geochemical methods and procedures that should be used across the Earth's land surface to map the distribution of chemical elements in various sample types. As the randomised sampling scheme will cover the whole globe, according to the 7356 Global Terrestrial Network (GTN) grid cells of 160x160 km, the procedure must be consistent for all sample types and, therefore, is standardised to be applicable in all morphoclimatic environments. The Manual of Standard Methods describes in detail all the necessary methods that should be used from planning the sampling campaign, through the sampling of rock, residual soil (A and C horizon), humus, stream water, active stream sediment, overbank sediment (top and bottom) and floodplain sediment (top and bottom); sample preparation; development of project reference materials; analytical methods; quality control and assurance procedures for the production of harmonised data sets; data levelling of existing regional geochemical data sets in relation to the established Global Terrestrial Network datum for each element (or variable); data conditioning for the production of seamless geochemical maps; data management and map plotting and, finally, project management. Applying these standardised methods allows the production of internally consistent quality-controlled data sets for each sampling medium for multipurpose use. Any applied geochemist carrying out a geochemical mapping project at any scale and purpose should find a wealth of useful information within the pages of this Manual.

The Manual of Standard Methods is freely available from the following hyperlink: https://www.globalgeochemicalbaselines.eu/content/174/iugs-manual-of-standard-methods-for-establishing-the-global-geochemical-reference-network-/. Apart from the pdf file of the Manual, there are available the following: (i) Supplementary Material for a few Chapters, (ii) the Microsoft Word and PowerPoint files, and (iii) the original figures of all Chapters. This material is useful for all professionals in applied geochemistry.

Why stop at the regolith? Plants as an active geochemical mapping sampling media

David Cohen[1]*, Australian Geosci. Council / UNSW (d.cohen@unsw.edu.au)
Joseph Schifano[2], University of New South Wales
Neil Rutherford[3], University of New South Wales

Abstract

When undertaking geochemical mapping at various scales, we are confronted by a large array of potential sampling media, sample spacing and locations, sample processing and analysis strategies, and statistical and data visualisation approaches. The combinations of choices within this array will influence the types and scales of objects and processes that can be detected or characterised by geochemical mapping programs. Plants and related biological materials have received less attention compared with other potential media in geochemical sampling and mapping at various scales.

By sampling large volumes of soil and groundwaters via their root systems, the metal content of plants may present a more representative and spatially coherent geochemical fingerprint of a given location than regolith materials. While regolith materials are typically more consistently available than plants, particularly at sampling scales less than 1 km, the dependence of biogeochemical mapping patterns on species and organs mirrors the dependence of regolith mapping patterns on the origin and subsequent geochemical evolution of the available regolith materials. Controls that plants may exert on the selective uptake of metals will affect their capacity to reflect variations in the chemistry of the substrate. In contrast if the regolith is transported or elements have been leached, a lack of geochemical relationship between the regolith and underlying geology or land use may be present.

Regional studies in various terranes demonstrate the capacity of plants to respond to changes in underlying geology and regolith, and even more strongly to highly atypical geochemical entities such as zones of mineralisation or of contamination. In the Cobar Region of New South Wales, cypress pines display changes in background concentrations of a range of elements (such as As, Ba and Mn) to variations in lithology, as well as strong multi-element responses over a wide range of mineral deposit types (especially Ag, Au, Pb, W and Ni). Similarly, the needles of brutia pines display marked variations in their geochemistry in traverses across the various lithologies of the Troodos Ophiolite and surrounding marine carbonate units, with a dramatic increase in Re contents in the vicinity of Cyprus-style Cu deposits. Adjusting for variations in metal uptake between different plant genera, a number of elements displayed similar spatial patterns in a regional geochemical survey of the New England Region of NSW, in which both stream sediments and leaves or needles of the nearest adjacent tree species were sampled. Further examples are drawn from surveys in Canada and elsewhere in Australia.

The Geochemical Mapping of Ireland: Geological Survey Ireland's Tellus Programme - results, challenges, and outcomes.

Ray Scanlon[1]*, Geological Survey Ireland (ray.scanlon@gsi.ie)
Victoria Lowe[2], Aurum Exploration Limited
Jim Hodgson[3], Geological Survey Ireland
Koen Verbruggen[4], Geological Survey Ireland

Abstract

Since 2011, The Tellus Programme of the Geological Survey of Ireland has sampled soils, stream-sediments, and stream-waters across the island of Ireland. This geochemistry programme has been coupled with a low-flying multi-physics geophysical campaign. Beginning as an EU funded natural extension to the Tellus Project of Northern Ireland, itself based on the BGS GBASE programme. Following IUGS global baseline protocols and design, the geochemical soil sampling programme is scheduled to be complete by mid-2024 with the collection of the final soil sample by July 2024. A sampling density one sample per 4km2 is allowing unprecedented insight into the national baseline geochemistry in applications like mineral exploration, agricultural productivity, soil Carbon stocks. Challenges associated with decade long sampling and analytical programmes, constrained by outsourcing of sampling, sample preparation and analysis via national and EU procurement rules will also be outlined. Mid term reviews of the Programme led to the focus on soil sampling along with product development and close partnerships with other government agencies and central departments. Partnerships with other government science agencies has led to applied products derived from data analytics or sample archive reanalysis to answer specific societal needs. Current governmental policy focus on Critical Raw materials and Soil Monitoring Laws have placed the Programme in an ideal space to provide unparalleled evidence-based policy support across the whole of government.

Geochemical Map of Latin America and the Caribbean. Methods for implementation

Maria João Farinha Batista[1]*, LNEG (mjoao.batista@lneg.pt)
Andrea Turel[2], SEGEMAR
Iván Martin[3], IGME
João Larizzatti[4], Serviço Geológico do Brasil
Gloria Prieto[5], CGGB-IUGS
Geochemical Group ASGMI[6], ASGMI

Abstract

The Geochemistry Experts Group of the Ibero-American Association of Geological Services is a group of experts who exchange knowledge on exploration geochemistry and geochemical mapping as a result of the experience of each Geological Service. Currently, the group of experts has started to test the methodology for collecting information for the Geochemical Map of Latin America. The continental data unit used is the Global Terrestrial Network (GTN), following the recommendations for International Geochemical Mapping, but instead of 160x160 km, it will have a 40x40 km cell. The geochemical data will be collected in each cell, and an average value (median or geometric mean) will be determined.

The medium used to harmonize the information will be stream sediments, as most Geological Surveys use and have archives of stream sediment geochemistry data from previous exploration projects. The geological and mineral resource information of the 40x40 km cell will also be part of the attribute table that will make up the database. The criterion for leveling data between contiguous stream sediment analytical datasets will be the greatest similarity in chemical analysis methods, sampling density and stream order. The continental geological map used to prepare the metallogenic map of Latin America and the Caribbean will also be utilized for the geochemical map of Latin America and the Caribbean. This map will include as many chemical elements as possible on a continental scale.

Soil geochemical mapping of the Aotearoa New Zealand convergent margin

Mark Rattenbury[1]*, GNS Science, New Zealand (m.rattenbury@gns.cri.nz)
A P Martin[2], Earth Systems
Regine Morgenstern[3], GNS Science, New Zealand
Karyne Rogers[4], GNS Science, New Zealand
Rose Turnbull[5], GNS Science, New Zealand

Abstract

Over the last decade, seven systematic soil geochemistry baseline surveys have been undertaken in Aotearoa New Zealand at a variety of scales, from cities and regions to the national scale. These surveys have been conducted using similar sampling and processing methodologies and the same analytical laboratory using common standards. Samples were acquired at 2-20/30 cm below surface (A-depth) for most surveys, while O-depth (0-2 cm) and B-depth (50-70 cm) samples were also collected in many surveys. ICP-MS analyses of 65 elements were acquired for all surveys with additional element analyses and C, N isotope measurements undertaken for some surveys. The results for all surveys have been presented as maps for each element utilising symbolised points and colour-ramped interpolated grids.

City-based surveys were the 2017 Dunedin urban survey involving 83 sites across a 1 km sampling grid with a further 30 sites from school grounds, the 2023 Auckland urban survey involving 112 sites across a 4 km grid and the 2024 Wellington survey involving 151 sites at variable spacing. The regional surveys undertaken were the 2015 southern South Island survey involving 360 sites spaced across an 8 km grid, the 2017 Buller-east Nelson-Marlborough survey involving 446 sites across an 8 km grid with 2 km sample spacing over mineral belts and the 2017 Otago survey involving 463 sites across an 8 km grid with 4 km and 2 km sample spacing over mineral belts. The 2023 national survey utilised samples from a single depth, generally corresponding to the A-depth, from 833 sites at variable spacing. The samples included in the national survey were selected from multiple baseline and other surveys collected earlier and reanalysed collectively.

The soil geochemistry results for all surveys show a strong correlation with underlying mapped geology, particularly outside of built-up areas. In the South Island, basement terrane geology appears to strongly influence soil geochemistry. Within cities and some agricultural areas, some elements such as Pb, Mn and P are elevated compared to natural background levels and are linked to anthropogenic influences such as pollutants and fertilisers.

Aotearoa New Zealand median values for Ag, As, Hg, Li, Mo, Nb, Se and Zn are more than double aqua regia partial digest element concentrations from Australia and median Pr, Te and Zr values are less than half of the Australian median values. Differences could be due to cooler, damper, more maritime conditions in Aotearoa New Zealand as well as denser vegetation, younger soils and a shorter-span geological history dominated by convergent margin and volcanic arc activity compared to Australia's predominantly continental and considerably older craton geology.

Addressing the problem of microplastic contamination in soil: Challenges during separation and recovery of natural and anthropogenic organic polymers.

Ariadne ARGYRAKI[1]*, IUGS Commission on Global Geochemical Baselines (argyraki@geol.uoa.gr)
Stefania Koutsourea[2], National and Kapodistrian University of Athens
Andreas Gondikas[3], National and Kapodistrian University of Athens
Karin Mattsson[4], University of Gothenburg
Artemis Kontomichalou[5], National and Kapodistrian University of Athens
Alexandros Liakopoulos[6], Hellenic Survey of Geology & Mineral Exploration

Abstract

Considering the estimated maximum 300k Tn of microplastics (MPs) released yearly in the EU and the scarcity of systematic surveys for MPs, monitoring and managing their potential risks poses notable challenges to researchers and governments worldwide. Primarily owing to their small size and complex composition, the lack of standardization on methodologies for sampling & analysis, reporting units, and QA/QC procedures, present significant challenges for synthesizing research findings, interpreting data, and drawing meaningful conclusions. Furthermore, up to now the focus of research has been mostly on developing methods to estimate the amount and type of MPs in the marine environment. Standardized protocols for the recovery and characterization of MPs in soils are still under investigation, although it has been established that they are characterized by elevated adsorption capacity as the result of their large specific surface area; thus, they adsorb typical soil contaminants such as metals and metalloids, promoting their dispersion in the environment.

In this study, soil samples were selected from the systematic soil dataset of the Attica region in Greece, taken at depths of 0-20 cm and 20-40 cm. Spiking experiments were conducted using a composite mixture of soil collected at natural forest sites and blank samples spiked with cryomilled polymers. Various techniques and reagents were tested to enhance recovery and facilitate characterization. Different reagents were compared regarding their effectiveness on the degradation of organic particles, including Strand solution (0.67 mol/L NaClO, 0.45 mol/L KOH), KOH (2.6%), H2O2 (30%), and one using porcine pancreatic enzymes. Mineral particle removal involved density separation with supersaturated NaCl and ZnCl2 solutions, followed by filtration to retain MPs. Modifications were made in the choice of reagents for repeated experiments. A multi-method approach for identifying and characterizing MPs included analysis with an optical microscope, FTIR, and Raman spectroscopy for evaluating the MP recoveries based on different treatments. All pre-treatment methods effectively removed organic matter, and both saline solutions extracted lighter plastic particles such as polyethylene (PE) and polypropylene (PP). Despite their higher density, PVC and tire particles were able to float in both density separation methods. However, the KOH and Strand solutions were unable to decompose organic aggregates.

Gavine Kavindikiza[4], Geological Survey of Namibia
Ulf Kasuto[5], Geological Survey of Namibia
Benyamen Ndiili[6], Geological Survey of Namibia

Abstract

The contents and spatial distributions of copper, iron and arsenic in 192 soil samples from the selected study area in the Otjozondjupa region, Namibia, were investigated and the findings are presented. The soil samples analysed for this study were collected as part of the ongoing countrywide Regional Geochemical Sampling Programme (RGSP) in Namibia. The RGSP is carried out based on individual 1:250,000 scale index map, measuring 208 km x 110 km (approximately 23,000 km2). Each 1:250,000 index map is further divided into 1:50,000 scale index maps measuring 26 km x 28 km (approximately 720 km2), such that there are thirty-two (32) 1:50,000 scale index maps in one (1) 250K index map. The study area covers four (4) 1:50,000 scale maps of the Okahandja 2116 (1:250,000) index map. The four 50K index maps are identified as 2117DA, 2117DB, 2117DC and 2117DD and are collectively noted as 2117 DA-DD for the purpose of this study. The RGSP employs an established, systematic sampling protocol that involves the collection of composite soil samples at a density of 1 sample/10 km2. A composite sample from a minimum of five holes was collected and screened onsite to recover a coarse fraction (< 2 mm) sample and fine fraction (<180 microns) sample. Only the fine fraction samples were selected for this study and the samples were processed and analysed at the Geological Survey of Namibia (GSN) laboratories. An aliquot of each 180 µm fine fraction was milled into fine powder of < 64 µm and analysed using the handheld Niton Energy Dispersive X-Ray Fluorescence Spectrometer (ED-XRF). The QAQC protocol utilised for this study includes insertion of International Certified Reference Materials (CRM), inhouse secondary standards and duplicates into batches of samples at every 20th interval. From the analysed soil samples, Cu ranges between 5.57 and 94.73 ppm, Fe values ranges from the lowest of 14 494.15 ppm to the highest of 50 033.80 ppm, and As ranges between 1.34 ppm to 5.21 ppm, respectively. Cu and Fe distribution appears to be lithological and structurally (Dome and Basin) controlled. Cu values are consistent with crustal and world soil values determined by Salminen (2005) and Adriano (2005), while Fe values are lower than average crustal concentration determined by Williamson (1998). The As distribution does not appear to follow geological controls or structural orientation, as both low and high concentrations are observed across all major geologic units. Areas with high As concentration are observed near settlements/homesteads, croplands, roads/tracks, fence boundaries, as well as in old workings. This indicates that As distribution in the study area is a factor of anthropogenic influence. Therefore, to comprehensively understand the spatial

distribution of Cu, Fe and As, more related elements should be investigated.

Geochemical Mapping in Sweden – establishing baselines at national to local scales

Anna LADENBERGER[1]*, Geological Survey of Sweden (anna.ladenberger@sgu.se)
George Morris[2], Geological Survey of Sweden
Patrick Casey[3], Geological Survey of Sweden
Merita Murtola[4], Geological Survey of Sweden
Mattias Sörengård[5], Geological Survey of Sweden

Abstract

Geochemical mapping is an established method for studying the spatial distribution of chemical elements in different sample media, e.g. rock, sediment, soil, water and plants, and to document variation in chemical compositions within a given area. Apart from the sample type, the scale which determines the grid plays an important role in planning geochemical surveys. There have been many discussions whether low-density sampling is suitable for baseline studies while high-density sampling in mineral exploration and environmental monitoring is a preferred approach., High-density sampling (100 to 1000 samples/km2) is however very expensive when covering large regions therefore many geological surveys worldwide started applying lower sampling densities in order to deliver country wide datasets within a reasonable time frame and cost.

At the Geological Survey of Sweden regional geochemical mapping using till has been carried out for more than 40 years. Since 1995, SGU has been working towards producing a uniform till database covering the whole of Sweden. After the last ice sheet melted, about 10 000 years ago, large parts of the bedrock in Fennoscandia were covered by several generations of glacial deposits with till as most important. Till provides a good proxy for the bedrock composition with glacial transport of only 5 – 15 km from source at most locations.

Modern chemical analyses of till samples are available from more than 40 000 sites. The currently used analytical methods are nitric acid digestion and aqua regia digestion followed by ICP-MS analysis. More than 60 elements can be obtained with the in-house developed method at the SGU laboratory.

The till sampling has been carried out at three major scales: national, regional and local. Regional geochemical mapping provides data with a sample density of ~1 per 7 km2. In parallel, focused studies with higher sampling density were carried out in forest fire areas, at historical mining sites and in urban environments with sampling density up to 10 samples per 1 km2. In 2014, the countrywide Geochemical Atlas of Sweden was published with a sample density of 1 sample per 150 km2. All data is publicly available and can be seen online via SGUs Mapviewer. Modern geochemical mapping relies on building databases and providing digital data services to the society.

The results of geochemical mapping allow understanding of natural processes operating at the continental to regional scale, such as weathering, climate, glaciations, tectonic evolution, but also to understand the consequences of modifications of the natural environments, which are no longer pristine and undergo changes caused by human activities. Geochemical data can be used in

various applications: mineral exploration, environmental monitoring, medical and forensic sciences, agriculture, forestry, land use planning, and in policy making.

PLANAGEO-Methodology to conduct a geochemical survey for mineral exploration in SW Angola

Maria João Farinha Batista[1]*, LNEG (mjoao.batista@lneg.pt)
Cátia Prazeres[2], LNEG
Iván Martin[3], IGME
Enrique Merino[4], IGME
José Feliciano Rodrigues[5], LNEG
Iván Cuervo[6], IMPULSO ANGOLA
José Manuel[7], IGEO ANGOLA
Daniel De Oliveira[8], LNEG
José Luís Lobon[9], IGME

Abstract

A 7-year project (Plano Nacional de Geologia, PLANAGEO) was conducted in SW Angola, which involved geological mapping at 1:250.000 and 1:100.000 scales, airborne geophysics (magnetics, radiometrics), geochemistry at 1:250.000 scale and investigation on the potential for metallic and non-metallic minerals. The selection of regional potential areas for metallic mineral exploration was backed by the analysis of previous exploration reports, the Mineral Catalogue of Angola, other publications, as well as unpublished theses, that were compiled to create a comprehensive mineral database. The selected targets were: i) rare earth elements (REE) located in the southwestern end of the alkaline-carbonatitic structures related to the Volcanic Belt of Angola, namely Serra da Neve greenfield area, Tchivira-Bonga and Catanda brownfields; ii) the brownfield areas of the Archean terrains and granitic intrusions containing Au-Fe in Jamba-Cassinga-Tchamutete, Chipindo and Cuima-Samboto regions; iii) Cr-Ni and Cu and Nb-Ta-Li-Be in the ultramafic intrusions of Chibia-Humpata region and the granitic rocks and the Giraúl pegmatites, respectively, in the Namibe region. Planning the field campaign was a challenging task due to the diverse terrains in an area over 476,000 km2, ranging from desert areas near the coast to the Angolan Plateau. The time for the field work was very tight and it was divided into two campaigns during the dry seasons. The implemented sampling plan needed to consider the sampling sites within a reasonable distance to the rarely available roads and the tracks covered during the geological mapping. The morphoclimatic conditions guided the field program, e.g.in certain areas, such as, the Plateau during the rainy season where the poor drainage led to flooding and saturation of the land. As a result, sampling stream sediments often becomes impractical because it was difficult to define water flow lines and understand the origin of any anomalies. Sampling in non-perennial streams near the desert should not occur in watercourses with sediment that is markedly lighter than the surrounding rock due to the action of aeolian transport and deposition of desert sand. Instead, it is chosen watercourses sediment that reflects the decomposition of the rock. Clearly the usual criteria of low stream order is not applicable in this case, but rather the colour of the sediment should be considered. This is because even the first-order watercourses on the desert border can contain desert sands. Soil sampling in the desert

boundary is frequently impossible because it is almost absent. Regions such as the Serra da Neve alkaline complex rocks were used to represent the distribution of chemical elements, and in the surrounding area of the complex, stream sediments were considered the best option.
Under these circumstances and considering the wide area where the target raw materials occurred, it was decided to collect different sampling media according to the region and type of existing surface material to highlight the geochemical signal and ensure a clear contrast between background and anomalous values of chemical elements. In summary, multimedia sampling was more efficient but, interpretation needs to be somewhat cautious.

A COMPREHENSIVE REVIEW OF ABANDONED MINING WASTE FACILITIES TO ASSESS THE REPRESENTATIVENESS OF THEIR SAMPLING

Paula ADANEZ-SANJUAN[1]*, Geological Survey of Spain (IGME-CSIC) (p.adanez@igme.es)
Julio C. Arranz-González[2], Geological Survey of Spain
Adrián J. Rosario-Beltré[3], Geological Survey of Spain
Marcelo F. Ortega[4], ETSI Minas y Energía (UPM)
Francisco Javier Fernández-Naranjo[5], Geological Survey of Spain
Virginia Rodríguez-Gómez[6], Geological Survey of Spain

Abstract

The investigation of mining waste facilities intended for use as secondary resources is gaining importance in recent years and tailings dams are especially relevant because of their greater recovery potential. These deposits are quite heterogenic due to the grain selection from the discharge point and secondary weathering processes. Thus, the representativeness of the surface samples with respect to the waste mass will highly depend on the degree to which all processes have occurred.

A review was performed on published reports providing data measured in abandoned sulphide flotation facilities that were obtained from boreholes. In total, 36 reports were published between 2000 and 2021, corresponding to different facilities. All continents are covered, with 6 sites in North America, 3 in South America, 7 in Asia, 12 in Europe, 7 in Africa and 1 in Oceania. The studied mining waste facilities provide information on total elemental contents (ICP-OES, ICP-MS, XRF) of at least Fe and S, Cu, Zn and Pb and some include information on other elements.

This study aims to make a preliminary global comparison of the significant differences or similarities between the elemental contents of samples taken from the surface and at depth. For this purpose, the samples were classified as P1 (the most superficial samples taken from each borehole) and P2 (the rest of the samples taken at depth). To draw more reliable conclusions at a global level, two other factors, climate and main commodity exploited, were considered as having the greatest influence on the variability of elemental contents in the facilities studied. So, a variable was developed according to aridity. Hence, the location of each facility was classified as hyperarid, arid, semiarid, dry-subhumid or humid. With the classification according to the main commodity mined, 11 classes were generated (Au, Cu, Cu-Zn, F-W-Cu, Ni-Cu, Ni-Cu-PGM, Pb-Ag, Pb-Zn, Pb-Zn-Ag, Pb-Zn-Cu, Pb-Zn-Cu and Sn-W).

The graphical and statistical study of the depth variation according to aridity classes and main commodity produced interesting results regarding the practicality of sampling. In the specific case of Cu and Zn, it can be stated that in most installations the depth-related differences are not significant, and if they are, these elements are more abundant at depth, regardless of the ore. In terms of climate, it is found that in arid and hyperarid areas, there is a very significant enrichment in the surface samples, which is explained by the effect of dissolution and capillarity. In the case of Pb, this phenomenon does not occur, due to its lower mobility. In this case, the largest

differences occur in the Pb-Ag ores that are more enriched in the surface samples, which does not seem to be related to climate.
This study evaluates patterns of behaviour at a global scale in abandoned mining waste facilities and its application can be extrapolated to the sampling method. In particular, conclusions are drawn on surface samples and their representativeness in relation to the entire mining facility and the content of certain elements contained in the wastes.

Cadmium content in soils of the Upper Silesia Region – an analysis based on geochemical mapping in Poland

Irena Agnieszka WYSOCKA[1]*, Polish Geological Institute National Research Institute (irena.wysocka@pgi.gov.pl)
Agnieszka Konon[2], Polish Geological Institute National Research Institute
Angelika Szczypczyk[3], Polish Geological Institute National Research Institute
Paulina Kostrz-Sikora[4], Polish Geological Institute National Research Institute

Abstract

A detailed geochemical mapping project for the Upper Silesia Region (scale 1:25,000) has been conducted at the Polish Geological Institute since 1996. One of the main goals of this long-term assignment is to investigate the industry impact on soil condition and assessment of the degree of soils contamination with heavy metals. For many years the most important sectors in the Polish part of the Upper Silesian Coal Basin have been coal mining and iron metallurgy, as well as zinc metallurgy (operating mainly in the past). Nowadays this area shows a diverse relief, locally highly altered as a result of industrial activity. There are many landfills of slag and mining waste near historical and present-day metal smelters.

Within the framework of the detailed geochemical mapping project, 21 map sheets were developed and released in the form of separate atlases until 2021. Here we present the outcome for cadmium contamination in soils of the most recent map sheets (~20% of the whole investigated area). The selected area covers 329 km2 with sampling density of 16 samples/km2. As the studied area covers different land usage including grasslands (~5%) and croplands (~29%) we look at the obtained data in the context of the risk assessment based on the cadmium threshold value 1 mg/kg. In total 5241 topsoil samples were collected and analyzed by ICP-OES after aqua regia digestion.

Cadmium is one of the most toxic elements within the heavy metals group that are considered as a major threat to human health when their concentrations exceed a certain threshold. However, at the EU level there is no common agreement on cadmium threshold values in soil for the definition of risk. According to the analysis based on LUCAS topsoil database about 14% of the soil samples in Poland are above 1 mg/kg, that is generally considered limit for the risk assessment. In absolute numbers Poland has 236 out of 1648 soil samples with Cd higher than 1 mg/kg and according to the publication by Ballabio et al. (2024). In this work we focus on data for cadmium in soils located in the region strongly affected by industrial activity at the aim to provide a detailed assessment in term of land use, regional Cd content and risk of high Cd. We compare our results to (1) the outcome of the analysis based on LUCAS data and (2) the Cd limit values used by the Polish law for the ground classification (Regulation of the Minister of the Environment on the method of conducting the assessment of land surface contamination. Journal of Laws 2016, item 1395).

Ballabio, C., Jones, A., & Panagos, P. (2024). Cadmium in topsoils of the European Union - An

analysis based on LUCAS topsoil database. Science of the Total Environment, 912, 168710.

Determination of Rare Earth Element Baselines in the Brunei Darussalam Soils.

Haezan JANGARUN[1]*, Universiti Brunei Darussalam (Hznjgrn@gmail.com)
Elena Ifandi[2], Universiti Brunei Darussalam
Khairunnisa Nazirah Karim[3], Universiti Brunei Darussalam
Basilios Tsikouras[4], Universiti Brunei Darussalam

Abstract

The notable recent surge in soil research reflects the increasing awareness of its fundamental significance. In Brunei Darussalam, limited research has been conducted on the mineralogical and geochemical characteristics of the soil, even though healthy soil is essential for agricultural activities and sustainable food production. This project aims to determine the geochemical baselines and threshold values of rare earth elements (REEs). Topsoil (0-20 cm depth) and subsoil (50-70 cm depth) samples were collected with the aid of a 10 x 10 km grid and subsequently analysed using INAA and ICP-MS to determine the distributions, possible sources of any soil-related pollution and sinks of the REEs. Statistical analysis and geochemical heatmaps were used to determine the threshold values and the distribution of the REEs. Certain geochemical anomalies or elevated baseline values are spatially associated with agricultural and industrial activities and landfill areas. Potential reasons for the elevated REEs values include the excessive use of fertilisers, herbicides, pesticides, and animal food additives. In addition, REEs may originate from utilising or dumping numerous technological items such as automotive catalytic converters, fibre optics, superconductors, and electronic devices. The REEs usually accumulate in an area because they are trapped by different mechanisms. Clay and organic matter are often associated with the adsorption of REEs in the soil, leading to elevated values in the area. The REEs are bound onto the surface of clay minerals and organic matter via ion exchange and surface complexion. The cation exchange capacity (CEC) in clay and organic matter favours the REEs adsorption to their surface. This study provides REEs geochemical baselines on both topsoil and subsoil of Brunei Darussalam, which aims to aid policymakers in developing sustainable land use practices.

Challenges and Opportunities in Compiling a Complete Africa Geochemical Database for Medical Geology Applications

Theophilus Clavell DAVIES[1]*, Mangosuthu University of Technology
(daviestheophilus2025@yahoo.com)

Abstract

ABSTRACT

The significance of a complete, high quality Africa Geochemical Database (AGD) for addressing the range of Earth and environmental science issues (e.g., mineral exploration, resource evaluation, agriculture, land use planning, processes of crustal evolution, and modelling of environmental systems) cannot be over-emphasised; because, for such applications to be made in a robust fashion, we need to understand how the Region's unique and complex geochemical landscape was carved out in the first place. The distinctive nature of Earth processes such as intense tropical weathering, leaching, erosion, podzolization and gleying, as well as later imprints of urbanisation and industrialisation, have engendered the mobilisation and clear redistribution of all but the most refractory elements. As a consequence, it is not uncommon to find large tracts of the Continent's surface environment containing anomalous trace element contents or deficiencies in essential micro-nutrient elements. Through water and food crops, extremes in trace element variation in soils are transmitted into the food chain, with often undesirable consequences for human and animal health. It is thus considered that one of the most important applications of an AGD would be in understanding the hydrological, chemical and biological processes that determine the behaviour of nutritional and toxic elements in the surface environment, in relation to how they may affect the health of man and animals (Medical Geology). This is so, because most of the population still live close to the land, and depend on it for their daily sustenance.

Important scientific problems that have confronted the construction of an AGD include: defining and understanding "regional background", and the evolution of appropriate sampling and analytical protocols that would take into account the Regions' unique and complex element distribution patterns. These problems are apparently intractable, but are not unsolvable.

Other challenges include longstanding operational and logistical problems that have impeded previous (largely uncoordinated) efforts at an AGD compilation such as the limited availability of state-of-the art analytical instrumentation and requisite laboratory infrastructure. An even more important limitation has been the dearth of a sufficient number of highly skilled analytical geochemists and other technical personnel located at appropriate regional centres, who are able to install, operate, trouble-shoot and maintain modern analytical equipment. These problems are compounded by the lack, up to now, of adequate international funding to undertake such a high precision and systematic mapping exercise.

In this presentation, recommendations are put forward for carrying out a successful and complete compilation of a high quality AGD that would be invaluable for studies in Medical Geology, as well as in an array of other multipurpose, multi-national environmental applications; and proposed measures given for counteracting potential limitations in its development.

Overview of geochemical mapping in the Geological Surveys of Ibero-America.

Iván MARTÍN-MÉNDEZ[1]*, IGME-CSIC (i.martin@igme.es)
Maria Joao Batista[2], LNEG
Gloria Prieto[3], The Commission on Global Geochemical Baselines (CGGB), IUGS
Andrea Turel[4], SEGEMAR
Geochemical Expert Group ASGMI[5], ASGMI

Abstract

In recent years, the Geological Surveys of Ibero-America have collaborated through the Association of Iberoamerican Geological and Mining Surveys (ASGMI) experts group to exchange information about the status of the different geological and mining activities in the region and to share experiences in geosciences programs in each country. The Geochemistry Expert Group (GEGOQ-ASGMI) has proposed the development of a manual of geochemical methodologies (Batista et al. 2023) employed by as its main ASGMI member countries that could be used for other countries to promote their knowledge of geochemistry and its applications.

The preparation of this manual has allowed us to understand the status of geochemical work in each country. While most of the Geological Surveys have systematically generated geochemical information for their projects and programs, the methodologies employed to generate this information have been diverse and have not corresponded to homogeneous standards. Most of the countries of the GEG have only partially mapped their territory geochemically, with varying sampling densities. Spain and Portugal are the only countries to have achieved complete coverage of their territory. Honduras, Ecuador, and Argentina and Brasil have covered 30 to 40% of their territory. Colombia has covered 95%, while Cuba and Peru have covered 77%. Most countries have achieved regional coverage with different objectives, using distinct sampling media and diverse analytical techniques to obtain data. However, this has not yet allowed us to create a geochemical map of the entire region

The exchange of information has corroborated the need to work jointly among the ASGMI member countries to have more harmonized information at the continent level.

USE OF NATIONAL SCALE GEOCHEMICAL DATA FOR THE DEVELOPMENT OF A GEOSTATISTICAL METHODOLOGY FOR INTERACTION ANALYSIS OF VARIABLES AT DIFFERENT SCALES

Paula ADANEZ-SANJUAN[1]*, Geological Survey of Spain (IGME-CSIC) (p.adanez@igme.es)
Juan Antonio Luque-Espinar[2], CN-Instituto Geologico y Minero de España (CSIC)
Eulogio Pardo-Egúzquiza[3], Instituto de Geociencias

Abstract

The development of this work is based on the data of potentially toxic elements (As, Sb and Pb), as well as total organic carbon from the Geochemical Atlas of Spain, provided by the Geological Survey of Spain, and of water points from wells for consumption, piezometers and springs, provided by the Ministry of Environment. This work therefore exemplifies the importance and options provided by the availability of data for studies with different objectives. In this case, the aim is to study the interaction of these elements in topsoil in relation to lithology and groundwater, by considering different scales of variability at a national level.

Kriging and its multivariate version, cokriging, have been used as geostatistical tools to develop the necessary probabilistic framework for the decomposition of spatial variability into scales of variation. Experimental variograms have been estimated and modelled using the linear co-regionalisation model. Finally, the different scales of variability related to the ranges observed in the experimental variograms have been estimated. The ranges established for the optimised models were 5 km, 35 km and 135 km. Factor cokriging was also used to determine the correlation between different variables and to separately map the structures in the fitted variogram models. In general, the shorter range detects local anomalies of both natural and anthropogenic origin, the middle range reflects larger anomalies as well as the natural geochemical background, while the long range is related to the geochemical background and is also able to reflect faults and other tectonic features. Finally, a contingency analysis has been performed to verify the spatial relationship between pairs of variables.

Among the results obtained, it can be highlighted the relationship between high values in water bodies and anomalies detected in the short range in the case of Sb, As, especially in large river basins, although sectors with a high influence of geochemical background are also identified. Areas with low background values in soil and high values in groundwater bodies are interpreted as influenced by industrial activities. The contingency tables show a high degree of affinity of the three elements, as well as with TOC, in groundwater and in soil at all scales, being the higher the range the higher the affinity.

Using factorial cokriging, the relationship between elements in soil and groundwater is better explained, confirming the association of elements in soil and groundwater with the influence of the scales of variation. This method enhances more traditional approaches to environmental studies and the methodology is exportable to other areas. This work therefore exemplifies the importance and options provided by the availability of geochemical data for a wide range of

studies with different objectives.

Nonlinear nature-based localization criteria for the resource potential assessment and interpretation of the anomalous structural-geochemical fields

Igor SPIRIDONOV[1]*, FSBI IMGRE (imgre@imgre.ru)
Sergey Grigorov[2], FSBI IMGRE
Viktor Tatarinov[3], FSBI IMGRE

Abstract

Traditional approaches to prediction, exploration, and assession of hydrothermal, metasomatic and magmatic mineral deposits using geochemical data and based upon the assumed history of the linear (historical) evolution of mineral matter and energy, have exhausted their potential and mismatch the efficiency level required.

The parent processes of geochemical halos, by definition, are nonlinear and follow the fundamental law of self-organization in an open dissipative system. During the course of its evolution, the primary planetary geochemical field forms structural-geochemical ensembles where the constant form associates with an infinite variety of content provided by the periodic system of chemical elements.

The structural ordering is conditioned by a combination of the four key types of geochemical zoning, i.e., synchronous, lateral, centrifugal and centripetal in the context of fractal fragmentation that controls the taxa hierarchy within the system.

The nonlinear nature of the halo and ore formation requires a fundamentally different approach to the analysis of prospecting information, determination of the boundary criteria of the mineralized objects in question and evaluation of the geochemical field's anomalousness grade.

Using real case histories we present the structure of a system of geochemical fields that displays a discontinuous-continuous series: ore body – ore zone – ore field – ore cluster – ore region – mineragenic region.

The target localization criteria at different exploration / prospecting stages are developed, as for mineral resources, as well as for ore reserves.

The geochemical anomaly ranking criteria by their prospectiveness, the rules for the ore showing's sorting out, and criteria for assession the completeness of knowledge on the mineralized objects, including assessment of blind mineralization, are developed.

THE RESOURCE POTENTIAL ASSESSMENT OF SOLID MINERALS BASED ON THE RESULTS OF MULTI-PURPOSE GEOCHEMICAL MAPPING OF THE TERRITORY OF RUSSIA

Viktor KILIPKO[1]*, FSBI IMGRE (kilipko@rambler.ru)
Igor Spiridonov[2], FSBI IMGRE
Yuriy Sharoiko[3], FSBI IMGRE

Abstract

In order to increase the reliability of prediction, identification and estimation of mineralized objects thus creating a prospecting reserve on the Russian territory, IMGRE carries out the overview, regional and medium-scale geochemical surveys. The regional and medium-scale projects prevail here, and their key result is the creation of the geochemical bases of the so-called State Geological Maps, scale 1:1M, employing the multi-purpose geochemical mapping technology. In turn, such maps serve as the update sources for the summary prognostic geochemical map, scale 1:2,5M.

During 2023, this map was updated using data from the multipurpose geochemical mapping projects performed at 1:1M and 1:200k scale. In total, geochemical data on 52 1:1M mapsheets were used to update the prognostic geochemical map covering the territory of the Russian Federation.

The updated prognostic geochemical map displays the anomalous geochemical patterns correlated to the mineralized objects in the rank of ore district and cluster combined into geochemical zones, which mineragenic specialization by the major groups of minerals (precious, non-ferrous, ferrous, etc.) and relative prospectivity grade (high, medium, unclear and low) is specified.

A cadastre accompanies the map that lists the characteristics of anomalous geochemical fields and confirms the assessments made.

The results of the analysis of the updated prognostic geochemical map of Russia at a scale of 1:2,5M confirm the thesis that regional-scale geochemical exploration is an effective tool identifying mineralized objects, what supports the following conclusions:

1. The 1:2,5M geochemical map of Russia in GIS format makes the fundamental basis for justifying exploration directions. Its updated version identifies anomalous geochemical patterns on the territory of the Russian Federation which delimit territories for future geological, geophysical and geochemical studies of various scale and extent.
2. The main task of geochemical research aimed at increasing the information content of the 1:2,5M prognostic geochemical map of Russia is its updating with actual geochemical data.

Continental-scale distribution of niobium and tantalum in catchment sediments throughout China: Prospecting implications from the China geochemical Baselines project

Hanliang Liu[1]*, Institute of Geophysical and Geochemical Exploration, Chinese Academy of Geological Sciences (liuhanliang912@163.com)
Xueqiu WANG[2], Institute of Geophysical and Geochemical Exploration, Chinese Academy of Geological Sciences
Bimin ZHANG[3], Institute of Geophysical and Geochemical Exploration, Chinese Academy of Geological Sciences

Abstract

Niobium (Nb) and tantalum (Ta), which are chemical twins with very similar geochemical properties, are critical mineral resources for emerging global industries. Owing to increasing demands, understanding their concentrations and distributions in the pedosphere is essential for assessing potential Nb and Ta resources in China. To address this, we used geochemical data obtained from the China Geochemical Baselines (CGB) project, which began in 2008 and has since then yielded continental-scale datasets. With a density of approximately-one sampling site per 3,000 km2, the CGB project involved catchment sediments from two horizons at each site: a top sample collected at a depth of 0–25 cm and a deep sample collected at a depth greater than 100 cm. In total, 3,394 samples each of top and deep catchment sediments were collected, and Nb and Ta concentrations were measured using inductively coupled plasma mass spectrometry under strict quality control conditions. The Nb concentrations in the top and deep sediment samples varied in the ranges 0.04–89.86 ppm with a median value of 12.71 ppm and 1.20–104.12 ppm with a median value of 12.41 ppm, respectively. Further, the Ta concentrations in the top samples ranged from 0.01 to 26.41 ppm with a median of 0.97 ppm, while those in the deep samples ranged from 0.14 to 26.41 ppm with a median of 0.96 ppm. Furthermore, both the top and deep samples had similar 2.5th, 25th, 50th, 75th, and 97.5th percentile Nb and Ta contents, indicating that Nb and Ta in the catchment sediments underwent similar and consistent formation processes. Our results also

indicated that the
concentrations of both elements varied widely across regions, and their distributions in the catchment sediments
throughout China were predominantly governed by the parent rock, particularly granites and alkaline rocks.
Mineralization and sedimentation properties also played roles at a regional scale. Overall, the spatial distributions
of Nb and Ta in the top and deep catchment sediments were relatively consistent, with concentrations being
higher in southeastern China and lower in northwestern China. Twelve large-scale geochemical Nb-Ta belts were
delineated based on continuous anomalous point distributions wherein many well known Nb-Ta deposits are
already located. These nationwide Nb and Ta concentrations and distributions provide foundational large-scale
data for further exploration and geological studies.

K isotope separation based on liquid solution centrifugation and its application to cation exchange experiments between birnessite and aqueous solution

Jiayang CHEN[1]*, Nanjing University (840513732@qq.com)
Weiqiang Li[2], Nanjing University
Huan Liu[3], Nanjing University

Abstract

Enriched isotope tracers play a crucial role in various geochemical, biological and environmental research endeavors, however, isotope tracers are generally expensive and difficult to produce. Recently, liquid solution centrifugation was emerged as an efficient method for isotope separation. We generated millimole-level 39K enriched (δ41K < -8‰) and 41K enriched (δ41K > 8‰) KCl solutions through ultra-centrifugation. Using the produced stable K isotope tracers, we investigated the exchange and fractionation of K isotopes between aqueous solutions and K-bearing birnessite. The results reveal that the cation exchange between K in birnessite and aqueous K are very fast, and efficient exchange of K between the two phases can be achieved within 1 hour. The K isotope results align well with the model for first-order rate reactions. A fractionation facotr (Δ41Ksolid-aq) of -0.11 ± 0.02 ‰ was derived after two systems, progressing from opposite directions, achieved equilibrium. Our results also indicate an obvious influence on the exchange rate caused by the particle size of birnessite. Our study highlights the promising potential of the solution centrifugation method in isotopic exchange experiments, offering a viable alternative to traditional isotope spikes for measuring isotope fractionation and tracing kinetic processes. The measured Δ41K fractionation between birnessite and solution indicates insignificant fractionation between natural Fe-Mn oxides and their surrounding solutions. The efficient exchange of K between the solution and birnessite suggests that the K in natural Fe-Mn oxides is likely to be labile and sensitive to the surrounding solutions.

Comprehensive assessment of Cu, Mo, Pb, and Zn isotopes in contaminated groundwater, surface water, and soil in Erdenet city, Mongolia

Dukmin KIM[1]*, Sangji University (kdukmin8@sangji.ac.kr)
Bayartungalag Batsaikhan[2], Institute of Geography and Geoecology
Dae-Gyu Im[3], Korea University
Hyeon-Soo Seo[4], Korea University

Telmen Turmunkh[6], Institute of Geography and Geoecology
Erdenetsetseg Tsogtbayar[7], Institute of Geography and Geoecology
Seong-Taek Yun[8], Korea University

Abstract

Major mining cities worldwide have been developed near places enriched with ore deposits. These cities, however, have also suffered from contamination of soil and water. Erdenet, the second largest city in Mongolia, has a world-class Cu-Mo mine, and surface water, groundwater, and soil have been contaminated by Cu, Mo, As, and SO42-. Surface water, groundwater, soil, and ore samples were analyzed for δ65Cu, δ2HH2O-δ18OH2O, δ98Mo, 208Pb/206Pb, δ34SSO4-δ18OSO4, and δ66Zn.

Cu and Mo contents were particularly high in the S-T1 soil sample, which was collected as surface dust, possibly originating from a tailings dump. δ65Cu, δ66Zn and 208Pb/206Pb in soil approached those of S-T1 with increasing Cu, Zn, and Pb content, suggesting that wind-blown tailings were the dominant soil contamination source. Also, Cu, Mo, Pb, and Zn isotopic ratios and Zn/Cd ratios revealed that the eastern part of the residential area was influenced by the tailings.

δ65Cu and δ98Mo in surface water and groundwater in the area in front of the tailings dam and near the open pit were higher than those in S-T1 and ore minerals, respectively. This indicated that oxidative dissolution increased δ65Cu and subsequent adsorption and/or precipitation (e.g., wulfenite) increased δ98Mo. Groundwater wells near the heap leaching area also exhibited higher δ65Cu and δ98Mo than those of soil in the waste rock area, suggesting contamination from heap leaching activity. In contrast, another well in the heap leaching area had distinguished δ65Cu, δ98Mo, δ2H, and δ18O, which suggested the other Mo and water source from the east. Downstream of a coal ash pond used in a power plant, stream water exhibited increased Mo concentrations and distinctly low δ98Mo, which increased after the junction with seepages from the tailings dump, suggesting the mixture of Mo contamination and adsorption of Mo in the stream. In the advanced argillic alteration zone in the northwest, groundwater had low pH and δ34SSO4 and high Zn and SO42- concentrations and δ66Zn, indicating alteration characteristics. δ34SSO4, δ65Cu, and δ98Mo of groundwater and surface water in the residential area were similar to those of groundwater in the alteration zone, indicating the influence of contamination by the alteration zone.

Overall, contamination sources and geochemical reactions in the region could be comprehensively

described using various isotopes. Use of δ65Cu, δ2HH2O-δ18OH2O, δ98Mo, 208Pb/206Pb, δ34SSO4-δ18OSO4, and δ66Zn could track diverse sources of water and soil contamination. Also, the geochemical reactions were indicated by specialized isotopic ratios. Particularly, oxidative dissolution, sulfate reduction, and adsorption could be effectively revealed by δ65Cu, δ65Cu-δ34SSO4-δ18OSO4, and δ66Zn-δ98Mo, respectively.

The Cenozoic Seawater Conundrum: New constraints from Mg isotopes

Zhongya HU[1]*, Tongji Univeristy (zhongyahu@tongji.edu.cn)
Weiqiang Li[2], Nanjing Univerisity
Shouye Yang[3], Tongji Univeristy
Zhiguang Xia[4], Nanjing Univerisity
Chuan Liu[5], Nanjing Univerisity

Abstract

The Mg/Ca ratio of seawater increased from ~1.5 to its present value of 5.4 over the Neogene, indicating a fundamental imbalance in the Mg–Ca cycle during the late Cenozoic. The imbalance in Mg–Ca cycles since the late Cenozoic, however, is contrasted by an arguable constancy in the Mg isotope compositions of seawater (δ26Mgsw) reconstructed from several low-resolution carbonate records. Addressing such Cenozoic Seawater Conundrum requires reliable seawater Mg isotopic records. The Xisha Islands in the South China Sea host large Cenozoic dolostone sequences that record seawater chemistry over the past 23 Myr. This study reports the Mg isotopic and trace elemental compositions of island dolostones in the well-studied Xike-1 drill core from the Xisha Islands. Petrographic, C–O–Sr isotopic, and paleomagnetic data from the drill core samples collectively support a “fluid-buffered”, syn-depositional origin for the dolostones. The dolostones from the Xike-1 core have a narrow range of δ26Mg (-2.83‰ ± 0.12‰), confirming that δ26Mgsw have been stable around the modern value (-0.83‰) since the late Cenozoic. This record provides a new opportunity to better understand the Mg–Ca cycle during the late Cenozoic. To better constrain the δ26Mg value of silicate weathering flux, we present mineralogical, elemental, and Mg isotopic compositions of terrigenous siliciclastic sediments in the Changjiang (Yangtze River) estuary and the adjacent continental shelf of the East China Sea. δ26Mg values of the clay-sized sediments vary from -0.15‰ to 0.00‰ and lack of the correlation with the proportion of different clay minerals. An isotopic mass balance calculation indicates that the δ26Mg value of silicate weathering flux on a continental scale is ca. -0.60‰ to -0.40‰. With these up-to date flux and isotope fractionation data, we ran numerical models of global seawater Mg-Ca contents and δ26Mgsw. The results show that the contrast between the constancy of δ26Mgsw values and the dramatic increase in seawater Mg/Ca ratios cannot be explained by a single mechanism (i.e., a decrease in the rate of phyllosilicate formation on the seafloor alone). Instead, processes involving different Mg fluxes need to be coupled to explain the observed trends in Mg content and isotopic compositions of Cenozoic seawater. The solution to the Cenozoic Seawater Conundrum includes simultaneous decreases in the rates of both clay formation and dolomitization on the seafloor, or an increase in the rate of both continental weathering together with decreased seafloor clay formation. Our study underlines the sensitivity of the Mg cycle to the interactions between climate, continental weathering, and seafloor processes during the late Cenozoic.

Experimental determination of kinetic isotope fractionation during chemical diffusion of alkaline and alkaline-earth elements in aqueous solution

Weiqiang LI[1]*, Nanjing University (liweiqiang@nju.edu.cn)
Zhihan Ji[2], Nanjing University
Xianglong Luo[3], Nanjing University
Yuqi Li[4], Nanjing University

Abstract

We developed a “diffusion-cell” method to determine diffusion-driven kinetic isotope fractionation factors of seven metal cations in aqueous solutions. This method utilizes a Rayleigh process to magnify the isotopic effect associated with diffusion and enables continuous determination of the isotopic evolution of fluids during the Rayleigh fractionation, thus it provides superior efficiency and precision compared with other methods for experimental determination of diffusion-driven isotope fractionation in aqueous solutions. Using the “diffusion-cell” method, we measured the kinetic isotope fractionation factors (α) for seven alkaline and alkaline earth elements (Li, K, Rb, Mg, Ca, Sr, Ba) in aqueous solutions at 25ºC, and calculated the index of mass dependence of isotope fractionation during diffusion (β) for these elements. The obtained isotope fractionation factors are, α7/6Li = 0.996139α41/39K = 0.998572α87/85Rb = 0.999333α26/24Mg = 0.999877α44/42Ca = 0.999704α88/86Sr = 0.999781α138/135Ba = 0.999716. The β factors show a strong dependence on the charge of the cation and the ion-water bond length for the aquo ions of the metals, suggesting that the isotope effect of diffusion of cations in aqueous solutions is fundamentally controlled by the strength of cation-water interaction, with more prominent kinetic isotope fractionation occurring for the case of weaker cation-water interactions. Therefore, heavy elements can still exhibit large diffusion-driven isotope fractionation in supergene environments, this is opposite to equilibrium isotope fractionation which decreases in magnitude dramatically for heavy elements. Therefore, attention to diffusion is needed particularly for stable isotope studies of heavy elements.

Stable chromium isotope fractionation during the alteration of abyssal peridotite: Implications for marine chromium isotope mass balance

LiJuan Li Xu[1]*, China University of Geosciences (Beijing) (xulj@cugb.edu.cn)
Yang Chun Liu[2], China University of Geosciences (Beijing)
Hai Bo Ma[3], China University of Geosciences (Beijing)
Sheng Ao Liu[4], China University of Geosciences (Beijing)

Xiang Li Wang[6], Institute of Geology and Geophysics, Chinese Academy of Sciences
Ning Shu Li[7], Peking University

Abstract

The stable chromium isotope system has been widely used as a redox proxy to reconstruct the oxygenation history of ocean atmosphere systems. However, the Cr isotope mass balance in modern oceans (i.e., inputs and outputs) remains poorly constrained. To investigate the influence of seawater-peridotite reaction on the global marine Cr isotope mass balance, we report high-precision Cr isotope data (d53Cr) on a series of fresh and altered abyssal peridotites from the Gakkel Ridge and the Southwest Indian Ridge (SWIR). The least altered peridotites give a d53Cr value of –0.08 ± 0.06‰ (2SD, n = 4) for the oceanic mantle which is consistent with the established d53Cr of the Bulk Silicate Earth. Compared to fresh peridotites, a subset of altered peridotites exhibit a loss of isotopically light Cr with relatively positive d53Cr values (up to 0.04‰). These altered peridotites are characterized by significant Cr loss and likely have been subject to serpentinization. By contrast, seafloor weathering has limited influence on the Cr concentrations and isotopic compositions of the altered peridotites. Monte Carlo (MC) simulations of marine alteration suggest a net Cr flux into seawater from altered abyssal peridotites of ~3.5 × 108 mol/yr, which is on the same order of magnitude as the riverine input flux of 108–109 mol/yr. Furthermore, the MC results suggest that the peridotite-sourced net Cr flux has a negative d53Cr signature (−0.33 ± 0.21‰, 2SD). Thus, seawater-peridotite interactions must be considered when evaluating the modern oceanic Cr isotope mass balance.

Applying standard addition to measure antimony isotopes in low-Sb samples using HG-MC-ICP-MS

Jian-Ming ZHU[1]*, State Key Laboratory of Geological Processes and Mineral Resources,China University of Geosciences (Beijing) (jmzhu@cugb.edu.cn)
Honggang Zhu[2], State Key Laboratory of Geological Processes and Mineral Resources,China University of Geosciences (Beijing)
Decan Tan[3], State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences
Zhuo Lu[4], State Key Laboratory of Geological Processes and Mineral Resources,China University of Geosciences (Beijing)
Hongfei Liao[5], State Key Laboratory of Geological Processes and Mineral Resources,China University of Geosciences (Beijing)

Abstract

The standard addition (SA) method has been successfully employed in measuring metal stable isotopes in recent years. Here, using hydride generation (HG)-multicollector inductively coupled plasma mass spectrometry (MC-ICP-MS, Nu Plasma II and Neptune Plus), we evaluated the method's robustness through achieving the high-precision data of the δ123/121Sb(antimony) values (relative to NIST 3102a) in samples with more complex matrices and low-Sb concentrations. By using element doping (113/111cadmium) coupled with sample-standard bracketing (SSB), the Sb isotope ratios of numeral geological and environmental reference materials (GRMs/ERMs) were reported, and selected GRMs agreed well with previously published values. Then, five of which with low-Sb concentrations were chosen to conduct the SA. According to the isotope binary mixing and error propagation model, the analytical precision (2 standard deviation: 2SD) is a function of only sample fraction(fspl). The ideal mixing range for calculating δ123/121SbNIST 3102a ratios of low-Sb samples using the SA method is suggested as fspl = 0.4 – 0.6, and better precision can be achieved with ≤ 0.09‰ (2SD) during this range. The δ123/121Sb ratio calculated for basalt BCR-2 (Sb = 0.30 μg/g) was 0.28 ± 0.09‰, confirming that the accurate and precise Sb isotopes can be measured for samples with as low as 5 ng Sb and the uncertainty is adequate to distinguish the natural variation of Sb isotopes with the total range of ~1.93‰ that found so far. Validating the measurement of Sb isotope composition in low-Sb samples with complex matrices by SA will expand the application of Sb isotopes in environmental, agricultural, life and Earth/Planetary sciences.

Lithium rich salt lakes in small-scale basin on the Qinghai Tibet Plateau——Tracing by lithium isotope

Maoyong HE[1]*, State Key Laboratory of Loess and Quaternary Geology, Institute of Earth Environment, Chinese Academy of Sciences (hemy@ieecas.cn)
Zhengyan Li[2], Taiyuan university of technology
Yulong Li[3], Qinghai Institute of Salt Lakes, Chinese academy of Sciences
Binkai Li[4], Qinghai Institute of Salt Lakes, Chinese academy of Sciences

Abstract

Lithium-rich salt lakes have attracted much attention as important lithium resources. The source and enrichment mechanisms of lithium in salt lakes are fundamental to uncovering the genesis of brine-type lithium deposits. However, the origin of lithium in salt lakes has been controversial, especially for the holistic study on the source-transport-storage of lithium rich salt lakes, there is still a lack of research at present. The lithium isotope, which serve as discerning geochemical tracers, can facilitate the monitoring of geological processes and sources. Among the numerous lithium rich salt lakes on the Qinghai Tibet Plateau, small-scale salt lakes have become an important part of salt lake research due to their unique geological background and short transportation distance. We investigated the hydrochemistry, Li isotope characteristics of surface brine and recharge river samples collected from the Lakko Co and Kushui lake on the Qinghai-Tibet Plateau in China, and further analyze the sources and transport process of lithium elements in lithium rich salt lakes. The results indicate that the main material sources of the two lithium rich salt lakes are basically related to rock weathering, deep crustal water rock interaction, and hot springs. However, due to the different geological backgrounds of the two lakes, the contribution of these factors also varies. The transportation process is characterized by the precipitation of secondary mineral, resulting in an increase of δ^7Li. Meanwhile, source-transport-aggregation models for both lakes have been established, this investigation of the lake contributes to a more comprehensive understanding of the origins and mechanisms involved in the transportation and storage of lithium in lithium-rich salt lakes.

Liu Jingao[8], China University of Geosciences, Beijing, China

Abstract

Continental composition shift from mafic to felsic in the late Archean was widely proposed to have induced the Great Oxidation Event (GOE). Here, using iron isotopes of 3.0-2.5 Ga crustal rocks, we show that anoxic weathering of Archean continents caused the rise of continental oxidation and signifcantly contributed to the GOE. S-type potassic granites show statistically heavier Fe isotope compositions compared to I-type potassic granites and tonalite-trondhjemite-granodiorites (TTG), indicating anoxic chemical weathering recorded in their sedimentary precursors. Because during anoxic weathering processes, soluble Fe2+ with light isotopes was finally transported into the ocean and insoluble Fe3+ with heavy isotopes retained in the regoliths. Notably, younger (2.5 Ga) S-type potassic granites have higher δ56Fe and K2O/Na2O ratios than the older (3.0 Ga) ones, suggesting that prolonged anoxic weathering led to Fe3+ accumulated in the sediments towards the end of Archean. Taking the global Archean granitoids into account, a statistic result shows a growing S-type potassic granites from 3.5 Ga to 2.5 Ga. Acorrdingly, more volcanic oxidized gas equilibrated with S-type potassic granitic magma would be released, accelerating atmospheric oxygen increase and subsequently contributing to the GOE. Besides, in the process of the anoxic continental weathering, large amounts of Fe2+ were released into the ocean over a billion years from 3.5 Ga to 2.5 Ga, providing abundant iron for massive banded iron formations (BIF) during the GOE. Therefore, anoxic weathering of Archean continents was a key contributor to oxidation accumulation of continental crust, the GOE and the large-scaled BIF formation.

Abstract

Climate-induced meltwater discharge from high-latitude glaciers comprises of an important component of the global water and nutrient budgets. How the fluxes of glacier meltwater vary in space and time in response to climate change is the frontier in marine sciences, yet also remains a matter of intense debate. In this study, we present dissolved Ba and δ138Ba from three fjords (Disko, Arfersiorfik, Qasigiannguit) in Disko Bay, West Greenland to investigate the magnitude of meltwater release and the subsequent nutrient discharge within these fjord systems. Preliminary data show contrasting results regarding the biogeochemistry of Ba and Ba isotopes at different fjords. The Ba concentrations ([Ba]) at the Arfersiorfik fjord (up to 400 nmol/kg) are drastically higher compared to those from the Disko fjord (50-60 nmol/kg), with the former corresponding to a much higher fresh water flux. Correspondingly, surface water δ138Ba at the Arfersiorfik fjord approaches near crustal values. At the Arfersiorfik fjord, strong binary correlations between [Ba] and salinity, and between δ138Ba and 1/[Ba] are observed. These correlations suggest conservative, binary mixing of meltwater vs. seawater endmembers, contrary to previous observations that reported nonconservative behavior of Ba and δ138Ba at continental margins. Conversely, no significant correlation is observed at either Disko or Qasigiannguit fjord. Our study suggests that contrasting lithologies and the magnitude of meltwater fluxes along West Greenland post the dominant control at land-to-sea Ba discharge, and that Ba and δ138Ba could reliably trace hydrodynamic mixing processes in West Greenland fjords.

Abstract

Heavy metal pollutants cause serious threats to animal and human health, and have been widely concerned. The primary work of heavy metal pollutants control is to determine the source of pollution. With the rapid development of Multi-Collector Inductively-Coupled-Plasma Mass Spectrometry (MC-ICP-MS), the isotopic compositions of metals can be accurately measured, and thus makes it possible to use metal isotopes to metal pollution sources in the environment. In terrestrial and marine environments, manganese oxides exist widely and have high reactivity towards heavy metals through adsorption processes. This will cause isotopic fractionation, and hinder the application of metal stable isotope in the environment. But the underlying mechanisms are not clear yet. In this study, the isotope fractionation behavior and mechanism of Cd during adsorption on layered manganese oxides were elucidated. Results show that Cd adsorbed on triclinic birnessite reaches isotope equilibrium within 72 h, and the light Cd isotope is preferentially enriched on the mineral surfaces, which belongs to the equilibrium fractionation model. The theoretical isotopic fractionations ($\Delta^{114/110}Cd_{solid\text{-}solution}$) during Cd^{2+} adsorption onto triclinic birnessite and hexagonal birnessite are -1.54 ± 0.11‰ and -0.96 ± 0.06‰, respectively. EXAFS and DFT analysis show that Cd forms triple-corner-sharing complexes at vacant sites and double-corner sharing complexes at the edge sites. Based on the relative proportions of Cd^{2+} binding on vacancies and edge sites of hexagonal birnessite determined by surface complexation modeling, the Cd isotope fractionations on edge sites and vacancy sites are calculated to be -1.54 ± 0.11‰ and -0.68 ± 0.15‰, respectively.

Abstract

Molybdenum (Mo) concentrations and isotope ratios can serve as indicators for past occurrences of methane seepage/ sulfidic events at the sediment-water interface in marine realms. These events may often be episodic in nature and may be traced through geological history from high-resolution studies of sediment cores. Methane seep regions are typically characterized by episodic flux enhancement leading to hydrogen sulfidic enrichment at the sediment-water interface. The recent discovery of extensive occurrences of active methane seep sites in the Krishna-Godavari basin has opened up the opportunity to investigate such episodic methane/ H2S enrichment events. Here we present a high-resolution Mo concentration, Mo isotope ratio (d98Mo), pyrite-sulfur isotope ratio (d34SFeS2), and Ba concentration measurements in a core from the KG- basin seep site. Sediment sampling was carried out on board ORV Sindhu Sadhana (SSD-045) at a water depth of 1760 meters. The pyrite-S contents range from 0.13 to 2.54 wt%. The Mo concentrations and d98Mo ratios vary from 1 to 17.4 ppm, and +0.3 to 2.37‰ respectively. Throughout the core several Mo concentration peaks (Mo concentrations > crustal average of ~2 ppm) are observed which may be attributed to focussed precipitation of MoS42- (Thiomolybdate). The Mo concentration peaks are closely associated with the low d34S values (-18 to -38 ‰) suggesting sulfidization at the sediment-water interface. The whole sediment d98Mo values range from typical seawater value (~2.3‰) to as low as 0.1‰ suggesting variable contributions of iron minerals, siliciclastic and organic matter. The consistent presence of barium fronts (high Ba/Al compared to non-cold seep cores) on the other hand suggests a recent drawdown and methane flux and drop in the depth sulfate–methane transition zone (SMTZ). Our results are tell-tale signatures of remarkable variation past methane flux and accompanied sediment biogeochemistry. A detailed Mo-speciation work is being carried out to deconvolute the deposition versus diagenetic overprinting of Mo isotope signature

Equilibrium metal isotopic fractionations at the calcite-water interface

SANGBO SON[1]*, Kangwon National University (s3247@kangwon.ac.kr)
Weiqiang Li[2], Nanjing University
Kideok Kwon[3], Kangwon National University

Abstract

The non-traditional metal isotope composition of natural calcite has emerged as a potential indicator to infer insights into the Earth's paleo-geochemical history. A key observation from experiments is that the isotopic fractionation factors of metals between calcite and aqueous solution depend on the crystal growth rate. As the growth rate increases, the isotope fractionation factor increases for some metals, but it decreases for some metals. However, underlying mechanisms of the growth rate-dependent isotopic variations have not been established yet. In this presentation, we demonstrate that equilibrium isotopic fractionation at the calcite-water interface, which has been neglected so far, can play an important role in the isotopic variation during crystal growth. For some divalent metal isotopes (Ni, Mg, Zn, Ca, Sr, Ba), we calculated their reduced partition function ratios [= (10^3)lnβ] of the calcite-water interface and of bulk calcite using density functional theory calculations. The calculated metal (10^3)lnβ values at the interface are distinctively greater or smaller than in the bulk lattice, depending on the metal element. Comparison of these values with the observed isotopic variations indicates that the isotopic composition shifts from the bulk composition toward the interface composition at faster growth rates. We shall discuss the roles of equilibrium isotopic fractionation at calcite-water interface in the isotopic variations during mineral crystallization.

Zinc isotope fractionation during wastewater treatments

Jeonghun KIM[1]*, Department of Earth and Environmental System Sciences, Pukyong National University (hyun6569@naver.com)
Jong-Sik Ryu[2], Department of Earth and Environmental System Sciences, Pukyong National University
Kongtae Ra[3], Marine Environmental Research Center, Korea Institute of Ocean Science and Technology (KIOST), Busan, Korea

Abstract

Environmental pollution is a significant issue in modern urban areas, in which zinc (Zn) can accumulate in plants, animals, and humans within the ecosystem, leading to severe health issues. In recent, Zn isotopes have been used to trace the origin of contamination sources and understand the behaviors in the aquatic environment, although Zn isotopes could be fractionated during wastewater treatment with either inorganic or organic reactions. Here we collected dissolved and particulate samples during three different treatments, and measured their Zn isotopes in order to examine how and to what extent they may be fractionated.

Measured δ66ZnJMC values in particulate (PM) and dissolved (DM) samples range from 0.00 to +0.29 ‰ and –0.05 to +0.47‰, respectively. Furthermore, the differences in δ66ZnJMC values between PM and DM samples (Δ66ZnPM-DM) during wastewater treatments indicate that abiotic process can fractionate Zn isotopes up to –0.32‰, while biotic process up to +0.33‰, respectively. This result suggests that abiotic and biotic processes favors light and heavy Zn isotopes, respectively, although the magnitude of Zn isotope fractionation is similar. Although the magnitudes of Zn isotope fractionation by abiotic and biotic processes is a slightly less than those in previous experimental studies, the direction of Zn isotope fractionation is consistent with them. However, the difference in Zn isotopes between the influent and effluent is only –0.04‰ because the combination of abiotic and biotic processes during wastewater treatments with three different methods hinder the effect of Zn isotope fractionation.

Influence of estuaries on chromium isotope ratio and geochemical behavior: A study in two rivers, Kochi, Japan

Akane ITO[1]*, Kyushu University (aito@mine.kyushu-u.ac.jp)
Kazuto ISAMOTO[2], Kwansei Gakuin University
Masaharu TANIMIZU[3], Kwansei Gakuin University

Abstract

Chromium (Cr), a redox-sensitive element, has two stable oxidation states, Cr(Ⅵ) and Cr(Ⅲ), with Cr(Ⅵ) being more soluble than Cr(Ⅲ) under oxidative conditions. The Cr isotope system ($^{53}Cr/^{52}Cr$, hereafter $\delta^{53}Cr$) is a promising redox proxy due to the highly variable isotope fractionation in the surface environment, mainly resulting from the conversion between Cr(Ⅲ) and Cr(Ⅵ). Recently, $\delta^{53}Cr$ values recorded in marine sediments have attracted researchers to reconstruct ancient atmosphere-ocean redox conditions. Such an application is only possible if some variables can be constrained, such as Cr flux and $\delta^{53}Cr$ of the global river input, isotopic fractionation factors during the removal process. Rivers are important sources of dissolved chromium to the ocean. However, the effects of the estuarine mixing zone on changes in Cr flux, redox speciation and $\delta^{53}Cr$ in rivers are not well understood (Mallick et al., 2022). To better understand estuarine Cr isotopic and geochemical behavior, this study investigated Cr concentration, speciation, and isotopic ratios along salinity gradients in two rivers in Kochi Prefecture, Japan.

The Kuma and Sakura Rivers flow through serpentinite and limestone area, respectively, and finally flow into the Pacific Ocean. River water and riverbed sediment porewater samples were collected from each river in the winter and summer of 2023. The concentrations of major anions and cations were measured by IC, and trace element and Cr speciation were determined by ICP-MS and HPLC-ICP-MS, respectively. The total Cr isotope ratios of river water samples were analyzed by double-spike TIMS after pre-concentration of Cr by Fe(Ⅱ) coprecipitation using 0.5 to 2 L river water samples, followed by 3-step column separation.

In both rivers, Cr(Ⅵ) was dominant, with a decreasing concentration downstream, and the $\delta^{53}Cr$ values increased until salinity reached 10 PSU and then decreased downstream. The logarithm of total Cr and $\delta^{53}Cr$ were negatively correlated at low salinity. This suggests that Cr(Ⅵ) may have been partially reduced to Cr(Ⅲ) and removed from river water. For the estuarine mixing zone of the Sakura River, a simple mixing model between river and seawater end members roughly explained the trend of $\delta^{53}Cr$ along the salinity, suggesting that conservative mixing may control Cr concentration and isotopic variations. In contrast, downstream of the Kuma River showed a slight increase in total Cr and a significant decrease in the $\delta^{53}Cr$ values. This may be due to the inflow from porewater, supported by the fact that porewater contains higher Cr concentration than river water and $\delta^{53}Cr$ values of sediment porewater reported so far are relatively lower than those of river water. Alternatively, dilution by river water with unidentified low Cr concentrations could

be responsible. These results suggest that most dissolved Cr has been removed and redox induced isotope fractionation has occurred before the estuary. In the estuarine mixing zone, the main mechanism controlling Cr isotopic ratios may be conservative mixing with seawater, although release of Cr from benthic sources may also have some effect.

Geochemistry of shale, quartzite and carbonaceous shale of the Cumbum Formation of Kadapa Basin: Implications for provenance, weathering and tectonic setting

Raghunath MISHRA[1]*, Geological Survey of India (raghunath.mishra@gsi.gov.in)

Abstract

Representative fresh bed rock samples were collected from shale and quartzite lithounit for whole rock analysis to decipher their provenance, paleo-weathering conditions and tectonic setting. The shales have high Al2O3, Fe2O3, K2O, TiO2,Ga, La, Nb, Rb, Sc, Sr, Th and Y content more than the quartzites, whereas, quartzites are higher in SiO2, Cu, Hf and Zr than the shales. The shale samples plot on the two triangular diagrams in the relatively more weathered region and also in the A–CN–K diagram above the granodiorite and shale suggesting a source which had suffered relatively a high degree of chemical weathering. Al2O3 is positively co-related with other elements as well as the abundance of Ba, Ce, Th, Rb, Zn and Zr suggest that these elements are primarily controlled by the dominant clay minerals. From the Fe2O3/K2O versus SiO2/Al2O3 plot the studied samples classify as shales and out of four quartzite samples, one sample falls in the sub-arkose field and the rest three falls in Fe-sand field. For the quarzitic samples, La/Sc, Th/Sc, La/Co and Th/Co values are more similar to values for sediments derived from felsic source rocks than to those for mafic source rocks, thus suggesting felsic source rock. Th/U ratios in the quartzites range from 0.83 to 1.45 indicating the quartzites neither suffered intense weathering nor intense recycling. Th/Sc ratio is used to know the composition of the source rocks. When Th/Sc is plotted on the diagram of Zr/Sc–Th/Sc, the recycled source rocks for the all quartzite samples from the study area are further supported by their high Zr/Sc ratio. Out of four samples two samples are enriched in zircon due to sedimentary sorting and recycling and the rest two samples fall in between andesitic to felsic magmatism field. On a chondrite-normalised diagram, the studied shales display slightly enriched LREE patterns (average LaN/SmN = 5.27), small negative Eu (average Eu/ Eu* = 0.69) and fairly flat HREE patterns (average GdN/YbN = 0.13) except for Yb which are characteristic of sediments derived from upper continental crust. The chondrite-normalized REE patterns for the studied quartzitesare characterized by high light REE/heavy REE (LREE/HREE) ratio (6.79-15.52), flat HREE pattern except Yb and pronounced negative Eu anomaly.LREEs are fractionated, (La/Sm)n = 4.98 and the HREE patterns are almost flat, (Gd/Yb)n = 0.15. This chondrite-normalized pattern is typical of sediments and sedimentary rocks enriched in light REE (LREE), flat heavy REE (HREE) and negative Eu anomaly. The ratio of log K2O/Al2O3 vs log MgO/Al2O3 was used to demarcate the marine and non-marine clay and it shows that studied samples fall in the marine part. Tectonic discrimination diagrams revealed that the carbonaceous shales are mostly of quartzose sedimentary provenance, suggesting that they were derived from a cratonic interior or recycled orogen. The ternary diagram of V-Ni- Th*10 indicate that the studied carbonaceous shales are derived from felsic source rocks. V/(V + Ni) ratios of carbonaceous shale suggest that the carbonaceous shales were deposited in a marine

environment with euxinic conditions.

Anthropogenic Activities Have Accelerated the Global Sulphur Cycle

Haoyang NIE[1]*, Nanjing University (niehy@smail.nju.edu.cn)
Shilei LI[2], Nanjing University
Yang CHEN[3], Nanjing University

Abstract

The oxidation weathering process of sulfides is increasingly recognized as a significant negative feedback mechanism in the carbon cycle, potentially playing a crucial role in stabilizing the global climate during the Cenozoic era. Recent findings indicate that the carbon flux coupled with sulfide oxidation weathering may be considerably underestimated, and precise calculations of its actual flux are still lacking. It is widely acknowledged that sulfur sources in rivers primarily include sulfides, evaporites, and human activities. The dissolution of evaporites is generally believed to have a neutral impact on the carbon cycle and remains stable over a specific period. We focus on human activities in this work partly because they can interfere with the signal of sulfide oxidation weathering entering the ocean and partly due to the complex impact of this process on the carbon cycle. To accurately estimate the flux of sulfide oxidation weathering, it is necessary to exclude the influence of human activities.

We have identified that human activities predominately affect the global sulfur cycle in two ways: first, by entering rivers through direct emissions and second, by notably increasing the release of sulfur element through glacier activity influenced by climate change. Spatially, these two processes collectively accelerate the sulfur cycle in rivers both downstream and upstream. Our research involved gathering data on sulfate concentrations in major rivers globally, supplemented by new test results. Overall, there is a discernible upward trend in sulfate concentrations. Endmember decomposition analysis highlights anthropogenic activities as key sulfur sources, primarily driven by the combustion of fossil fuels. Additionally, we observed significant growth in sulfate concentrations in some high-latitude basins, attributed mainly to changes in glacier activity in these regions.

Our study offers new insights into the influence of human factors on weathering processes. While Human activities can markedly accelerate river acidification, they also have potential to reverse this trend. For instance, the sulfate concentration in the Yangtze River has decreased in recent years, largely due to stricter environmental regulations. Considering this, alongside the environmental protection commitments of nations worldwide, we have formulated informed predictions regarding the future sulfur cycle in rivers, which may serve as valuable references for shaping relevant policies moving forward.

Heavy metal migration and Lithium isotope fractionation under extreme weathering of basalt on tropical Hainan Island, China

Weihua WU[1]*, Nanjing University (wuwh@nju.edu.cn)

Abstract

Basalt contains a higher concentration of heavy metals that are harmful to the environment. As basalt weathers into soil, heavy metals can easily enter the environment and cause environmental risks. This weathering process can be traced by lithium isotope. However, the relations among intensity of the chemical weathering, migration of heavy metals, and fractionation of Li isotopes remain unclear. We conducted systematic examinations of a basalt weathering profile on the tropical Hainan Island in China. The primary minerals in the fresh basaltic bedrock include olivine, plagioclase, pyroxene, and quartz. In the semi-weathered basalt zone, primary minerals remain but peaks are diminished, and a few kaolinite peaks emerge. In the saprolite layer and above, the peaks of olivine, plagioclase and pyroxene diminish markedly or disappear while secondary minerals such as kaolinite and Al-Fe (hydro)oxides (gibbsite, goethite, hematite, magnetite, and ilmenite) are observed. Both the saprolite and laterite layers exhibit chemical index of alteration (CIA) values >99, meanwhile mass transfer coefficients of Ca, Mg, Na, and K close to −1, indicating the characteristics of extreme weathering. Among the major elements, there is a significant decrease in alkalis/alkaline earths and Si from the fresh bedrock to the topsoil, whereas Fe, Al, and Ti increase. The heavy metals except Co increase from bottom to top with Pb showing the largest increase (six-fold). Fe and heavy metals Cr, V, Co, and Cu have the highest contents at the depth of 210 cm, showing the crucial role played by Fe-(hydro)oxides. From bottom to top there are increasing and decreasing trends in Li content (from 3.6 mg/kg to 15.7 mg/kg) and Li isotopic ratio (from +2.8‰ to −2.4‰), respectively.

There are strongly negative correlations between mass transfer coefficient of Al (an index for weathering intensity to replace CIA under extreme weathering conditions) and Li isotopic ratio (R2 = 0.91), enrichment factors of Ni, Cd, Cu, Co, and Cr (R2 is from 0.31 to 0.93). During the initial-intermediate weathering stage, clay minerals such as kaolinite that are prone to adsorb lighter 6Li and heavy metals are rapidly formed, leading to decrease of Li isotopic ratio and accumulation of heavy metals in the weathering products. As weathering proceeds, these clay minerals are further converted to Al-Fe-Ti (hydro)oxides, and the adsorbed heavy metals become desorbed and leached into the local environment. This process may be a distinct characteristic of extreme basalt weathering and warrants more attention in the investigation of environmental risks associated with heavy metals in tropical basaltic regions.

Regional Geochemical Survey of the Rooikraaldam Area, Eastern Bushveld Complex, South Africa.

Mehdi BENSID[1]*, Council for Geoscience (bmehdi@geoscience.org.za)
Abdul Kenan[2], Council for Geoscience

Abstract

As part of the South African national regional geochemical programme, the Council for Geoscience carried out a geochemical regional survey in the Roikraaldam area which is part of the Eastern Bushveld Complex within the North West Province, South Africa. The primary objective of this survey is to generate a geochemical data layer of the present erosional surface which will serve a wide range of industries including mineral exploration, environmental management, agriculture, construction, etc.

Soil samples were collected in the Rooikraaldam area at a density of one sample per km2 and analysed using simultaneous quantitative X-ray fluorescence spectrometry (SXRF). Two types of single-element geochemical maps, namely bubble plots and contour maps, were generated. The bubble plots display five interval classes that were generated using the Jenks Natural Classification system combined with the knowledge of the average abundance of each element in the soils. Conversely, the contour maps display ten interval classes and were produced. The primary objective of the bubble plots is to delineate anomalous areas that may be prospective for mineral exploration, whereas the contour maps are designed to demarcate the different geological units within the study area.

To facilitate the interpretation of the geochemical data and the generation of multi-element maps, a Pearson's Correlation Matrix was compiled. Additionally, a Principal Component Analysis (PCA) was conducted. These statistical techniques aided in the identification of element associations that were used to compile the multi-element maps represented mainly by Weighted Sum maps.

The geochemical interpretation revealed that the most prominent mineral targets correspond to V-Fe-Mg-Cu anomalies, which are particularly associated with the magnetites of the Upper Zone of the Rustenburg Layered Suite. Additionally, the Principal Component Analysis yielded Ni-Cu-Sr-Co targets that may be indicative of Ni-Cu-PGE sulfide deposits in the southeastern portion of the mapped area. Furthermore, two distinct Pd-Pt anomalies, identified through the Pearson's correlation matrix, warrant further investigation as they could represent potential mineralization zones. Within the felsic rock units, several Nb-Rb-Y-W targets were delineated, potentially signifying the presence of Nb, rare earth elements (REE), and U mineralization in the study area.

The study delineated several mineral target zones that should be further verified and followed up in addition to delineating areas of potential environmental risk.

Isotopic Behavior and Distribution of Bromine and Chlorine in Evaporites: Insights from the Salina Formation in the Michigan Basin

Yon-Gyung RYUH[1]*, University of Waterloo (yryuh@uwaterloo.ca)
Randy L STOTLER[2], University of Waterloo
Shaun K FRAPE[3], University of Waterloo

Abstract

Processes controlling the isotopic range of δ81Br values in natural waters and evaporite deposits are not well understood due to limited available data. While previous studies have explored δ81Br in natural water samples, recent research on evaporite deposits has not yielded clear answers regarding bromine isotopic systematics and distribution. For a better understanding of the isotopic system, it is essential to comprehend the δ81Br values of evaporites, which serve as one of the primary reservoirs of bromine. This study aims to address this gap by investigating the δ81Br of evaporites within the Salina Formation in the Michigan Basin, where a diverse range of evaporites is present in a sedimentary rock sequence.

Our objective is to characterize the distribution of Br isotopes within the sedimentary rock sequence to comprehend the influence of geological and geochemical processes on isotope compositions. To achieve this, the δ81Br and δ37Cl of Salina Formation cores were analyzed and compared with data from previous studies, including isotopic, litho- and fluid geochemistry, as well as features such as color, textures, and facies that provide insights into depositional environments and diagenetic processes.

The δ81Br values range from -1.78 to +1.40‰ (SMOB), while δ37Cl range from -1.81 to +1.04‰ (SMOC). Although no significant correlation between δ81Br and δ37Cl is evident, it seems that depositional environments and secondary processes (e.g., hydrothermal alteration) may influence isotope compositions. Most halite samples exhibit positive δ81Br, while carbonate tends to exhibit negative δ81Br. Samples with hydrothermal alteration features show a more varied range of δ81Br values.

In conclusion, this study provides valuable insights into the isotopic behavior of bromine within the sedimentary basin, contributing to a better understanding of the processes that further fractionate δ81Br. Such knowledge is crucial for utilizing δ81Br as an environmental tracer in various applications.

Geochemistry, mineralogy, and origin of Late Cretaceous ironstone deposits, Northern Oman Mountains

Salah Al-Khirbash[1]*, Sultan Qaboos University (khirbash@squ.edu.om)
Ahmed Hassan Ahmed[2], King Abdulaziz University
Khadija Semhi[3], Independent consultant, 4, Rue de Marlenheim Strasbourg France

Abstract

Seven ironstone occurrences (Fe-1 to Fe-7) are geochemically and mineralogically investigated in the Northern Oman Mountains to constrain their origin and economic importance. These ironstone deposits were formed on the top of the lateritic soil of both peridotites and layered gabbros of the Semail ophiolite complex of the early Cretaceous time. The studied ironstones vary in thickness from a few meters up to 13 m. and vary in textures from well-rounded to ellipsoidal-like oolitic and pisolitic types to mainly laminated massive texture types. The mineral composition of these ironstones is hematite, magnetite, and goethite (Ni- and Al-rich) as the main iron minerals, in addition to clays (kaolinite), calcite, dolomite, gypsum, and birnessite, and inherited chromite and chamosite. Ilmenite and apatite are also recorded in some localities. Hematite is replacing magnetite and chromite along cleavage planes and grain boundaries. Chromite occurs as massive or fractured grains filled with secondary hematite and magnetite. Chlorite and clays are concentrated mainly within the nuclei of ooids and the matrix. Pentlandite and Co-rich pentlandite appear as blebs within magnetite matrix. Calcite is found as fracture filling cross-cut other mineral phases. Iron content (as Fe2O3) forms the majority of the bulk-rock constituents of ironstones; it ranges from 31.14 to 83wt.%. SiO2 (2.23-14.14 wt.%) and Al2O3 (1.38-15.5 wt.%) form significant components of the ironstones. The summation of these three oxides forms the major components of the studied ironstone deposits. MgO (0.27-4.94 wt.%) and CaO (0.13-30.31 wt.%) are relatively low compared with Fe2O3, SiO2, and Al2O3. Nickle (as NiO) and chromium (as Cr2O3) form substantial components (mostly > 2 wt.%) in the studied ironstones. Other detectable minor elements include Sc, V, Co, Cu, Zn, and Sr.

Compositional variations and elemental relationships showed that the studied ironstones mostly fall within the shallow water environment and in the detrital compositional field. In addition, the paleosol mineralogy, their oolitic texture, and bulk-rock REE patterns suggest that the Oman ironstone deposits most probably formed in a shallow-water environment with substantial inputs from detrital sources, which is similar to many other ironstone deposits described in the literature. The high NiO and Cr2O3 contents in the studied ironstones support the derivation of Fe2O3 from the peridotites and layered gabbros parent rocks by in-situ leaching from the Fe-rich minerals such as olivine, pyroxenes, amphiboles, and chromite, which are all major components in the protolith bedrocks.

Geochemical preservation of Mid-Ordovician carbonates in the Taebaeksan Basin: Insights from strontium isotope analysis

Joonseok LIM[1]*, School of Earth and Environmental Sciences, Seoul National University (joonseok98@snu.ac.kr)
Jena Jeong[2], School of Earth and Environmental Sciences, Seoul National University
Sunhwa Bang[3], Research Institute of Molecular Alchemy, Gyeongsang National University
Seung-Gu Lee[4], Geology Division, Korea Institute of Geoscience and Mineral Resources
Youngsook Huh[5], School of Earth and Environmental Sciences, Seoul National University

Abstract

Isotope data from past sedimentary rocks are considered useful for interpreting paleoclimatic and paleoceanographic conditions. The Joseon Supergroup, consisting of marine-deposited sedimentary strata spanning the Cambrian-Ordovician period, forms part of the Taebaeksan Basin in the central-eastern part of the Korean Peninsula. However, the basin is known for its hydrothermal ore deposits due to Mesozoic intrusions. Given that hydrothermal alteration during the late diagenesis stage can critically affect the chemical properties of the rock, its influence must be excluded before interpreting the isotope data. This study aims to assess the geochemical preservation of carbonates in the Jigunsan and Duwibong formations, the two uppermost strata of the Joseon Supergroup in the Seokgaejae section, by comparing their 87Sr/86Sr ratios with those of contemporary global seawater.

Concentrations of major and trace elements, including calcium (Ca) and strontium (Sr), were analyzed using an Agilent 8900 QQQ ICP-MS at Seoul National University while the 87Sr/86Sr ratios of the samples were measured using Nu plasma 3 MC-ICP-MS at Seoul National University or Neptune Plus MC-ICP-MS at Korea Institute of Geoscience and Mineral Resources. Prior to isotope analysis, a column separation method was applied to the dissolved carbonate to remove rubidium (Rb) and Ca, which could potentially affect the accuracy and precision of the 87Sr/86Sr measurement. The analyzed samples generally exhibited higher 87Sr/86Sr ratios compared to the contemporaneous global seawater value. While more radiogenic 87Sr/86Sr ratios in carbonates can originate from hydrothermal fluids with granitic signatures, a corresponding decline in Sr concentrations in the samples would be expected during the water-rock interaction. Nevertheless, the Sr/Ca ratio of the samples ranged between 1.1 and 1.3 mmol/mol, with no observed trend of decreasing Sr concentrations. Therefore, it is reasonable to consider that the 87Sr/86Sr values of the samples represent their initial values, despite differing from those of the global seawater.

Simultaneous measurement of 147Sm/144Nd and 143Nd/144Nd ratios in natural geological samples by MC-ICP-MS after one stage chemical purification using TODGA resin

Zhuyin Chu[1], Institute of Geology and Geophysics, Chinese Academy of Sciences
Yueheng YANG[2]*, Institute of Geology and Geophysics, Chinese Academy of Sciences
(yangyueheng@mail.iggcas.ac.cn)

Abstract

The classic 147Sm-143Nd isotopic system has been extensively used as a powerful tracer or chronometer since the 1970s. Isotope dilution (ID) mass spectrometry, without doubt, is a well-known technique for its excellent precision and accuracy when properly used. Isotope dilution thermal ionization mass spectrometry (ID-TIMS) is still regarded as a benchmark technique for Sm-Nd measurement, despite its tedious, time-consuming and restrictive or extensive source filament and loading preparation procedure. Recently, isotope dilution multiple collector inductively coupled plasmas mass spectrometer (ID-MC-ICP-MS) has become a competitive technique for Sm-Nd analysis with high sample throughput and comparable precision to classical ID-TIMS. In this contribution, we demonstrate the capability of the simultaneous measurement of 147Sm/144Nd and 143Nd/144Nd ratios, in natural geological samples by MC-ICP-MS, after one stage chemical purification using TODGA resin, which can be a potential alternative to isotope dilution method. After sample digestion, one-step chemical isolation of Sm and Nd with almost 100% recovery from sample matrix elements, was accomplished by employing TODGA extraction chromatography resin. Then, simultaneous determination of 147Sm/144Nd and 143Nd/144Nd ratios, was conducted in single analytical session using MC-ICP-MS. The present analytical protocol relies on mathematic correction of isobaric interferences, thus alleviates the separation of Nd and Sm from each other, and usage of enriched tracer. The feasibility of the present protocol was investigated by duplicates analyses of international certified reference materials (CRMs), which encompassed wide range of chemical composition, and found to be nearly on the similar precision, as those obtained data using isotope dilution method, but at a fraction of the cost and time consumption, both chemical preparation and mass spectrometric measurement.

Submarine groundwater discharge in coastal zones of a mountainous island: the evidence of trace elements and uranium isotopes

Ruo-Mei WANG[1]*, Institute of Earth Sciences, Academia Sinica, Taiwan (rmwang4112@gmail.com)
Chen-Feng You[2], Department of Earth Sciences, National Cheng Kung University, Taiwan
Chen-Tung Arthur Chen[3], Department of Oceanography, National Sun Yat-Sen University, Taiwan
Tsung-Ren Peng[4], Department of Soil and Environmental Sciences, National Chung Hsing University, Taiwan

Abstract

Growing evidence indicates that the flux of terrestrial materials to the ocean through submarine groundwater discharge (SGD) plays a significant role in the hydrological cycle, marine chemistry, and coastal ecosystem. However, the impact of SGD on elemental cycles and chemical budgets in the ocean remains debated. To trace SGD and understand its effects on elemental and isotopic variations in the coastal ocean, we analyzed major and trace metals, as well as uranium (U) and strontium (Sr) isotopes, in pore water, freshwater, and seawater samples collected from the coast region of southwestern Taiwan.

Our results indicate that dissolved U is removed in pore water at middle to high salinity levels and covaries with elevated barium (Ba) contents, which are likely due to Ba desorption triggered by changes in ionic strength and redox conditions at the freshwater-saltwater mixing zone. Compared to seawater, lower U concentrations (average 7.31 nM) and higher U isotopic ratios (average 1.178) are observed in the pore waters, suggesting a terrestrial origin and indicating the presence of fresh SGD in our study area. This finding is further supported by the low salinity observed in the pore waters and the distribution of trace elements, as well as the relationship between (234U/238U) and Sr isotopes, which indicates the source of fresh SGD and the mixing between groundwater and seawater. The results presented here demonstrate the potential of U isotopes as tracers for SGD and water mass mixing in the coastal areas. Moreover, our findings highlight the influential role of SGD in the variations of oceanic trace elements and uranium isotopes.

Data recovery of incomplete rare earth element data sets

David M ERNST[1]*, Critical Metals for Enabling Technologies - CritMET, Constructor University, Germany (dernst@constructor.university)
Malte Mues[2], Department of Computer Science, TU Dortmund University, Dortmund, Germany
Michael Bau[3], Critical Metals for Enabling Technologies - CritMET, School of Science, Constructor University, Bremen, Germany

Abstract

Rare earth elements (REEs) are a group of elements with similar physical properties and coherent geochemical behaviour. As a result, REEs are widely used as proxies for many geochemical sources and processes. Availability of analytical data on REEs increased significantly in the 1960s with the advent of neutron activation analysis (NAA) and later of isotope dilution techniques (ID). However, due to the limitations of these methods, concentration data cannot be determined for all of the REEs. In the case of ID, praseodymium (Pr), terbium (Tb), holmium (Ho) and thulium (Tm) are typically missing due to their monoisotopic nature. In NAA data sets, praseodymium, dysprosium (Dy), holmium, and erbium (Er) are usually missing, and many data sets are even more incomplete. However, since the interpretation of REE data is primarily based on distribution patterns in normalised graphs, missing REEs can alter the appearance of the REE patterns and, hence, the interpretation. In the 1970s, inductively coupled plasma atomic emission spectroscopy (ICP-AES) became capable of measuring all 14 naturally occurring REEs. However, although incomplete, published ID and NAA data are generally of superior quality. Unfortunately, samples from these older publications are often not available anymore for re-measurement, sampling locations may no longer be accessible, or the samples may represent past states of the sampled ecosystem (e.g., soil or water samples). It is, therefore, of great scientific interest to extract as much information as possible from such old yet high-quality datasets. We present our recent results on the determination of missing REE data from incomplete datasets based on regression analysis via REE shape coefficients [1]. Our approach provides accurate and precise REE data (<10% relative deviation) well within the common analytical uncertainties of modern analytic approaches, for example, routine ICP-MS measurements. The accuracy and precision were determined via a method verification dataset consisting of >13,000 individual samples. The data recovery can be easily applied to REE datasets with missing data for some REEs, which need not be exactly the same as those missing in ID and NAA datasets. The re-modelled REE data can be used to interpret the overall pattern and to quantitatively determine anomalies, one of the most important tools in REE research. Another application for high-precision REE data is the determination of partition coefficients, for example, between minerals and melt.

Formation of H2 by serpentinization of (ultra)mafic rocks

Sookyung KIM[1]*, Division of Earth Environmental System, Pusan National University
(sukyoung0421@naver.com)
Yoojin Cheon[2], Division of Environmental System, Pusan National University
Hoon Young Jeong[3], Pusan National University

Abstract

Hydrogen can be produced via serpentinization of (ultra)mafic rocks. The extent and kinetics of H2 generation were assessed for a range of (ultra)mafic rocks, which included two peridotite, one serpentinite, one pyroxenite, two gabbro, and four basalt. Prior to serpentinization, their major elemental composition, mineralogical composition and Fe speciation were characterized by using X-ray fluorescence, X-ray diffraction, scanning electron microscopy-energy dispersive spectroscopy, and Mössbauer spectroscopy. Subsequently, a series of kinetic experiments were conducted to monitor H2 production under the ambient condition. A peridotite from Horoman River, Japan (PR-HR), with olivine being the major Fe(II)-bearing mineral, showed hydrogen production on an order of magnitude greater than the other one from Jackson County, USA (PR-JS). The lower H2 production of the latter may have resulted from its higher amount of talc which would passivate the reactivity of Fe(II)-bearing minerals (e.g., olivine). A serpentinite from Yellow Dog Plains, USA (SP-YD), which was mainly composed of serpentine with a minor fraction of magnetite, produced H2 a half as much as PR-JS. In this case, Fe(II)-bearing serpentine largely accounted for H2 generation. A pyroxenite from Harcourt Township, Canada (PY-HC), with ~90% of Fe(II) present in pyroxene, showed only one tenth of the H2 production by PR-HR despite its greater Fe(II) amount. This suggest the lower reactivity of pyroxene-bound Fe(II) than olivine-bound Fe(II). In case of gabbro, one from Duluth, USA (GB-DL) showed a greater H2 production than Funehiki-machi, Japan (GB-FH) due to the presence of Fe(II)-bearing olivine in the former. All basaltic rocks but the one from Sinsanri, Korea (BS-SS) showed lower H2 production than peridotite and gabbro. Due to the greater Al2O3 amounts, serpentinization of basalt is known to make Fe(II) incorporated into nonreactive, secondary phases (e.g., chlorite). Nevertheless, a relatively higher amount of Fe(II)-bearing olivine in BS-SS would lead to its greater H2 production. Upon the completion of kinetic study, we will characterize the solid products and analyze the solution chemistry to better asses the effect of Fe oxidation state and its distribution amount constituent minerals on H2 production during serpentinization.

The Biogeochemical Cycle of Rhenium in the Yangtze River Basin and Perturbations by Human Activities

Ye Wang[1], MOE Key Laboratory of Surficial Geochemistry, Nanjing University
Yang CHEN[2]*, Nanjing University (chenyang@nju.edu.cn)
Shilei Li[3], MOE Key Laboratory of Surficial Geochemistry, Nanjing University
Pengxiao Xu[4], School of Earth and Atmospheric Sciences, Georgia Institute of Technology
Haoxian Wang[5], MOE Key Laboratory of Surficial Geochemistry, Nanjing University
Jun Chen[6], School of Earth Sciences and Engineering, Nanjing University

Abstract

Rhenium, which is primarily found in sedimentary organic matter, is commonly used to estimate the rate of petrogenic organic carbon (POC) weathering. Accurately understanding the cycle of rhenium on Earth's surface is crucial for using dissolved rhenium (Re) in rivers as a marker for POC weathering. However, human activities, particularly those related to mining, industry, and chemicals, which frequently use Re, can impact the usefulness of this marker. This study collected water samples from the Yangtze River and industrial wastewater from 2018 to 2019 to analyze Re and major ion concentrations, with the aim of examining the primary sources and anthropogenic effects on riverine dissolved Re flux. The concentration of dissolved Re in the Yangtze River ranged from 67.7 to 167.6 pmol/L, significantly higher than the global average of 2.3 pmol/L, and the calculated Re flux was 16.98 tons per year. Assuming that all denudation materials in the Yangtze River basin are weathered, the calculated upper limit of Re flux provided by natural weathering processes is approximately 1.48 t/yr, accounting for only 8% of the total measured Re flux. Thus, it is estimated that human activities contributed at least 92% of the dissolved Re flux in the Yangtze Basin. Analysis of wastewater from factories closely related to Re use in the Yangtze River basin showed little influence on the dissolved Re flux. Therefore, other human activities along the Yangtze River, such as mining or coal utilization, may contribute a significant amount of Re. With human activities being the primary driver of the riverine dissolved Re flux in the Yangtze River, the annual Re flux may have increased from 9.44 t/yr to 16.98 t/yr from 2007 to 2019. The findings of this study suggest that human activities can rapidly and significantly impact the geological elemental cycle of Re over decadal timescales.

Geochemical significance of Eu Isotope Ratio in Carbonate rocks

Seung-gu LEE[1]*, KIGAM (sgl@kigam.re.kr)

Abstract

Chondrite-normalized REE pattern based on the concentration in various kinds of the geological rocks have provided a lots of information for understanding the evolution history of Earth system including mantle and crust. Particularly, Eu anomaly in the chondrite-normalized REE pattern produced by feldspar crystallization during magma differentiation provides us a valuable information to understand the evolution history of igneous rocks. Eu has only two stable isotopes (151-Eu and 153-Eu). Lee and Tanaka (2019, 2021a) developed a method that Eu isotope ratio can determine precisely by MC-ICP-MS using Sm internal standard (combined standard-sample bracketing and internal normalization, C-SSBIN). Lee et al. (2023) also reported that Eu isotope ratio in igneous rocks has a relatively systematic relationship with the variation of the magnitude of Eu anomaly suggesting that Eu isotope fractionation in igneous rocks may occurred during magma evolution process. Ismail et al. (1998) showed that isotope effects in Eu2+/ Eu3+ exchange reaction can occur in aqueous solutions during cation exchange chromatography and also found that the heavier 153-Eu isotope is preferentially fractionated in Eu2+ solution phase which forms part of the Eu2+/Eu3+ electron exchange system. It means that Eu isotope fractionation occurred in carbonate rock, which is a product of climate change in a low-temperature environment. Therefore, Eu isotope ratio in the carbonate rocks including geochemical reference materials of the Geological Survey of Japan was measured using MC-ICP-MS to check whether Eu isotope fractionation in carbonate rocks occurred. In this conference, I will discuss a geochemical implication of Eu isotope fractionation in carbonate rocks.

Abstract

The regional geochemical survey of the Mahd adh Dhahab quadrangle, utilizing stream sediments, aims to augment the Geochemical Atlas of the Kingdom of Saudi Arabia. The primary purpose of this geochemical survey is to systematically sample stream sediments at a density of one sample per 25 km^2, determine the concentrations of elements, and present the spatial variations of the elements as geochemical maps of various styles. The stream-sediment samples were meticulously collected from 699 sites across Proterozoic supracrustal/plutonic basement terrain, as well as Tertiary volcanic and sedimentary facies. Subsequent multi-elements analysis, employing ICP-OES and AAS techniques following HF/HClO4/HCl/HNO3 digestion, were performed on the -2 mm/+0.177 mm fraction of the sediments. The resultant analytical dataset facilitated the production of diverse geochemical maps, crucial for delineating targets for mineral exploration. Thorough scrutiny of individual element distributions and associations revealed 38 multi-element targets potentially conducive to sulfides, precious metals, and rare earth elements mineralization. These encompass 16 Priority 1 anomalies, 10 Priority 2 anomalies, and 12 Priority 3 anomalies, classified based on the consistency of their elemental associations.

The Priority 1 and 2 targets, all associated with Proterozoic supracrustal/plutonic terrain, feature anomalies suggestive of precious metal/sulfide and high-temperature vein mineralization. Priority 3 targets exhibit a spectrum of element associations, including some indicative of precious metal/sulfide mineralization and others of barium and Fe-Ti mineralization.

Beyond assessing the mineral potential of the Mahd adh Dhahab quadrangle, the program has significantly enriched a comprehensive geochemical database suitable for environmental monitoring, geological mapping, and land-use planning. The analytical data underpinning this report are archived within the National Geological Database (NGD), accessible via official request to the Saudi Geological Survey management (visit https://sgs.gov.sa/en).

Geochemical features of intrusion related gold deposits (IRGD) in the Yana-Kolyma Gold Belt (Northeast Asia)

Anna Igorevna NESMEYANOVA[1]*, Russian Mineral Resourse Institute – VIMS (nesmeyanova_a@vims-geo.ru)
Evgeniy Gennadievich Eremenko[2], Russian Mineral Resourse Institute – VIMS
Pavel Igorevich Chernov[3], Russian Mineral Resourse Institute – VIMS

Abstract

The studied deposits lie within deformed lower greenschist-facies rocks of the eastern part of the Yana-Kolyma Gold Belt (Inyaly-Debin basin). The deposits are genetically related to Cretaceous felsic stocks of intermediate oxidation state. The intrusion-hosted gold deposits most commonly are of stockwork type. Gold may also be concentrated more distally (1–2 km) with respect to the intrusions, where deposits are of auriferous, sheeted quartz vein/veinlet type.

The geochemical studies incorporated a variety of analytical techniques (fire assay, AAC, ICP-MS) and sample media (residual soil and bedrocks). Surficial geochemical criteria include anomalies of Au, As, Bi, Te, Ag, W, Mo, Co, Ni, Pb, Cu. The structure of the geochemical field play major role in the secondary halos of Au, As, Bi, W. Anomalies of these elements are spatially related to the central zones of deposits and inherit the chemical composition of auriferous ores. Aureoles of Sb, Pb, Zn, Cu, Mo surround anomalies of the central zone. Secondary halos of Co, Ni, Ti, V are characterized by limited development, and they are widely extended around anomalies of Au, As, Bi, W. The general pattern of the geochemical field is determined by the obvious concentric zonality in the distribution of elements.

The distributions of elements in samples of bedrock suggest the existence of the aureoles of Au, As, Bi, W, Ag, Sb, Cu, Mo. The Au, As, Bi geochemical association is the strongest and is associated with ore bodies at the present level of erosion.

Assessing fluoride occurrence in groundwater and related factors in the Eumseong Basin area

Jong Hyun OH[1]*, University of Science and Technology (ohjong2009@naver.com)

Hyo-Sik Seo[3], University of Science and Technology
Sung Won Kim[4], Korea Institute of Geoscience and Mineral Resources

Abstract

If water with high fluoride is consumed for a long period of time, there is a risk of causing problems with bones or teeth. In groundwater, fluoride usually originates from minerals in rocks, and the longer the reaction period, the higher the concentration. In this study, we aim to understand the distribution characteristics of fluoride concentration in groundwater in relation to other elements and stable isotopes of oxygen and hydrogen, and to investigate the origin of fluoride and factors that may affect fluoride concentration. The study area is the Eumseong Basin and nearby areas, where large-scale faults and various lithologies appear. A total of 146 groundwater samples and 14 rock samples were collected at the site. Groundwater samples were subjected to on-site water quality measurements, chemical analysis, and isotope analysis, and rock samples were subjected to microscopic observation and chemical analysis. Considering that Ca2+, Na+, and HCO3- account for most of the dissolved ions, it is considered that the hydrochemical properties of groundwater in the study area are generally controlled by water-rock reaction. In the case of F- concentration, it appears to have a positive correlation with Na+ and HCO3- concentration and a negative correlation with NO3- concentration. Therefore, F in groundwater in the study area appears to originate from minerals in rocks. Groundwater samples with high F- concentration have depleted δ18O and δD values, which is presumed to be because the groundwater was recharged from high-altitude area and reacted with surrounding rocks for a long time through longer flow paths. Some chemical characteristics of groundwater vary depending on the bedrock lithology. Typically, groundwater in granite and metamorphic rock areas tends to have a higher F- concentration than groundwater in sedimentary rock areas. Few other fluorine-containing minerals were observed in granite and metamorphic rock samples, but biotite was observed well in most samples. Biotite is one of the representative mineral that efficiently dissolves F when reacting with groundwater. Therefore, it seems likely that most of the F in groundwater in the study area originated from reaction with biotite. Fault zone also appears to be a factor that can affect the F- concentration of groundwater, because in groundwater groups with high F- concentration, F- concentration tends to decrease as the distance from the fault zone increases. One of the reasons for these results is the possibility that some fault zones act as groundwater flow paths, causing deep groundwater to flow upward and mix with shallow groundwater. Precipitation of fluorite or calcite is also likely to have an effect on the F- concentration in groundwater. Although the upper limit of F- concentration in groundwater in the study area is partially influenced by precipitation of fluorite, calcite generally precipitates before

fluorite. So it seems likely that the precipitation of fluorite will be slowed down, and F-concentration will continue to increase. This work was supported by the Basic Research Project (24-3121) of the Korea Institute of Geoscience and Mineral Resources (KIGAM), Republic of Korea.

Byung Yong Yu[7], Korea Institute of Science and Technology

Abstract

The application of cosmogenic nuclides (in-situ 10Be and 26Al) in surface exposure dating has provided valuable chronological constraints for understanding changes in Antarctic terrestrial glaciers. Building on previous data related to Marine Isotope Stage (MIS) 5 simple exposure ages of Campbell Glacier moraines, we conducted further analysis on the palaeo-subglaciated bedrock. This analysis revealed simple exposure ages during MIS 3 (49.8~35.3 ka), confirming continuous glacial lowering throughout the late Quaternary, including the Last Glacial Period (MIS 4~2). Notably, our findings indicate that the Local Last Glacial Maximum (LLGM) occurred at an elevation of 150~90 masl during MIS 4, rather than MIS 2.

The new and recalculated dataset for the Campbell Glacier stands out compared to other outlet glaciers flowing into Terra Nova Bay. It suggests that Mt. Melbourne's volcanic activity may have directly influenced the glacier through glaciovolcanic processes during the late Quaternary, challenging the notion of a general influence from climate and oceanic factors. Further investigations into palaeo-glaciovolcanic interactions on the East Antarctic Ice Sheet (EAIS) could provide more robust insights. Such studies hold the potential to refine models predicting future accelerated glacial melt and sea level rise, particularly concerning the numerous volcanoes beneath the West Antarctic Ice Sheet (WAIS).

Abstract

During the Last Glacial Maximum (LGM), a marine-based ice-sheet occupied the Ross Sea Embayment. The LGM grounding line position in the western Ross Sea is suggested by the presence of a grounding zone wedge (GZW) north of Coulman Island, but radiocarbon dates on biogenic carbonates support more limited LGM ice extent. We used acoustic sub-bottom profile data from the Northern Drygalski Trough in the westernmost Ross Sea, palaeoenvironmental proxy analyses on marine sediment cores, and radiocarbon dating on biogenic carbonates to reconstruct changes in depositional environment since the LGM. We show that the maximum extent of LGM grounded ice in the western Ross Sea was smaller in its extent than previously thought, and an open marine condition was present on the outer continental shelf during the LGM. The large GZW north of Coulman Island probably formed during larger ice sheet advances prior to the LGM because older sediments are preserved on and south of the GZW. Periods of glacial advance during the LGM are interrupted by establishment of open marine condition in the Northern Drygalski Trough, concurrent with Antarctic Isotope Maximum 2 warming event at ~24ka. The onset of deglaciation in the Northern Drygalski Trough started as early as ~19.5 ka in response to rising atmospheric and oceanic temperatures. Our results imply that marine-based ice sheet was highly sensitive to environmental forcing, even during the peak glacial period.

Abstract

The West Antarctic Ice Sheet (WAIS) presently holds enough ice to raise global sea level by 4.3m if completely melted. Despite previous land and ship-based drilling on and along the Antarctic margin, unequivocal evidence of major WAIS retreat or collapse in times of past warmth has remained elusive. Yet such data are vital to inform numerical models aimed at quantifying predictions of future sea level rise.

Sensitivity of the West Antarctic Ice Sheet to a Warming of 2°C (SWAIS 2C) is supported by the International Continental Drilling Program and aims to constrain past and current drivers of WAIS dynamics and identify temperature thresholds and ice sheet tipping points.A primary goal is to acquire records of WAIS extent during late Quaternary “super-interglacials”, which were characterised by warmer than present conditions. Researchers, engineers, and logistics providers representing ten nations have established a partnership to achieve this goal. Our team of geologists, glaciologists, oceanographers, geophysicists, microbiologists, climate and ice sheet modelers, and engineers will recover and examine Neogene and Quaternary geological records from the West Antarctic interior adjacent to the Kamb Ice Stream and at Crary Ice Rise.

Scientific and technological advances developed through SWAIS 2C will enable us to test whether WAIS collapsed during past intervals of warmth. Connection to similar research efforts in Greenland offers an opportunity to examine bi-polar response to past climate change and determine the sensitivity of WAIS and GIS to a +2°C global warming threshold. Together our communities can identify when, where, and by how much Earth’s most vulnerable ice sheets melted in the past and drove sea level change across the planet.

Abstract

Biological processes have changed atmospheric composition on tectonic- and orbital-time scale via biological pump. Surface biological processes changed in both high latitudes during global climatic cooling events (Northern Hemisphere Glaciation at 2.73 Ma and Mid-Pleistocene Transition; MPT during 1.25 – 0.7 Ma). However, little is known about the feedback of changed surface biological processes on the earth climate event. Here we provide sedimentary evidence from the Antarctic Zone for a biotic shift from diatom- to coccolithophore-dominant surface production during the MPT from cores RS15-GC107 and RS15-LC108 in the Ross Sea continental rise. We found increased CaCO3 (calcareous nannofossils – coccolithophores) along with decreased biogenic opal in core RS15-GC107 during the MPT. In addition, CaCO3 concentration of <20 μm fraction, indicative of coccolithophore production, showed significant amount of CaCO3 was produced by coccolithophores. As coccolithophores produce dimethylsulfoniopropionate (DMSP) 10–100 times more than diatoms and DMSP is linked to enhanced cloud formation, we suggest that cloud formation in the Antarctic zone increased during the MPT, resulting in increased albedo in the Antarctic Zone and increased snowfall in the Antarctic. These findings suggest that climate-driven biological processes can influence back the climate changes. Further investigation and atmosphere-ocean-cryosphere modelling simulations are required in the future.

Sun-Yong Ha[7], Korea Polar Research Institute

Abstract

Dinoflagellate cysts are known to be valuable tracers to infer paleoceanographic parameters such as sea-surface temperature, salinity, nutrients and sea-ice cover. However, this potential has yet remained largely uncovered, particularly in Antarctic proximal regions of the Southern Ocean. Sixteen surface sediment samples were collected from the Ross Sea, Antarctica during R/V ARAON expeditions and investigated to determine the distribution, abundance and species composition of resting stages of dinoflagellates (dinoflagellate cysts). This study is the first to document the distribution of the dinoflagellate cysts in the area. The data presented here reveal a clear longitudinal trend in species diversity, concentration and taxa dominance. Results indicate dinoflagellate cyst concentrations vary between 46 cysts/g and 145,159 cysts/g. A total of 11 dinoflagellate cyst taxa were identified. The assemblages were dominated by Polarella glacialis, Selenopemphix sp.1, Nucicla umbiliphora and Islandinium minutum. Accompanying taxa included Cryodinium meridianum, Gymnodinium microreticulatum and Impagidinium pallidum. A particular note is for the cysts of P. glacialis, which show a restricted distribution along the western Ross Sea coastal areas. This result tentatively suggests a potential use of dinoflagellate cysts as tracers of past oceanographic conditions, particularly Antarctic proximal regions of the Southern Ocean. Our study also highlights the importance of further investigation to identify the main environmental drivers of the dinoflagellate cyst distribution patterns, several regional and in situ environmental parameters.

Abstract

Understanding the behavior of ice sheets in the geological past is crucial for assessing the cryosphere's role in the climate system and for predicting the rate and extent of sea level rise in future warming scenarios. While both geological data and ice sheet models suggest that marine-based sectors of the East Antarctic Ice Sheet experienced instability during Pliocene and late-Pleistocene warm intervals, the dynamics of the East Antarctic Ice Sheet remain highly uncertain. Here, we present evidence from marine sedimentological and geochemical records indicating ice margin retreat near the Ross Sea during warm late Pleistocene interglacial periods. The most notable changes in sediment provenance, reflecting the retreat of the WAIS and EAIS, occurred during marine isotope stages (MIS) 9, 11, 17, and 31. During these stages, Antarctic air temperatures were at least two degrees Celsius warmer than pre-industrial levels for 2,500 years or more (MIS 9 and 11), and marked the end of the Mid-Pleistocene Transition (MIS 17). MIS 31 is recognized as one of the "superinterglacials" in the Northern Hemisphere and around Antarctica, characterized by elevated temperatures and potential instabilities in the Antarctic ice sheet. Consequently, our study reveals a strong connection between prolonged Antarctic warmth and ice loss from the Ross Ice Shelf and the Western Ross Sea, offering continuous data for the last 1.3 million years that support the contribution of interglacial intervals to sea level rise.

Enhanced terrestrial methane cycle during the early Eocene hyperthermals

Zuoling CHEN[1]*, Institute of Geology and Geophysics, CAS (chenzl@mail.iggcas.ac.cn)
Peizong Lü[2], College of Geosciences, China University of Petroleum (Beijing)

Abstract

The early Eocene was characterized by a series of transient global warming events (hyperthermals), including the Paleocene-Eocene Thermal Maximum (PETM), ETM2/H1, H2, I1, and I2 (Nicolo et al., 2007; Zachos et al., 2010). These events can provide insights into the biogeochemical response to extreme climate states. Increased terrestrial methane (CH4) cycling has been evidenced during the PETM (~56 Ma) (Pancost et al., 2007; Inglis et al., 2021); however, whether other subsequent smaller-magnitude hyperthermals share common terrestrial CH4 feedback remains unknown due to the lack of sedimentary records. Here we report new biomarker data from a wetland deposit sequence in the Fushun Basin which records four early Eocene hyperthermals to examine CH4 cycling response to different levels of elevated warming. Increased 3β-methylhopane index and highly negative $\delta^{13}C$ values of hopanes (<-45‰), synchronous with carbon isotope excursions, indicating vigorous wetland CH4 cycling during all hyperthermals. These results suggest that the wetland CH4 emissions acted as a common positive feedback mechanism for all hyperthermals, sustaining elevated temperature levels and producing prolonged carbon isotope excursions. Our data also suggest that the methane-climate feedback scaled with warming levels, with warmer climatic modes invigorating more intense CH4 cycle and thus greater methane fluxes.

Lithium isotope evidence for enhanced weathering during the Middle Ordovician

Jena JEONG[1]*, Seoul National University (jenajeong@snu.ac.kr)
David Wilson[2], University College London
Sunhwa Bang[3], Gyeongsang National University
Youngsook Huh[4], Seoul National University

Abstract

The Ordovician period is known for substantial environmental changes within the Paleozoic era, marked by rapid temperature fluctuations from an early warm climate to a later ice age. Furthermore, beginning in the Middle Ordovician, the continental weathering environment experienced significant changes, coinciding with increased tectonic activity and active volcanism. Lithium isotopes have been widely used as a silicate weathering proxy due to the higher concentration of lithium in silicate minerals compared to carbonate minerals. Therefore, lithium isotopic composition of past seawater can help interpret paleoclimate and paleoenvironmental conditions.

The objective of this study is to interpret environmental changes during the Middle Ordovician period by analyzing lithium isotopes in Darriwilian carbonate rocks from the Taebaeksan Basin in South Korea. These samples are shallow platform carbonate rocks, within which the Middle Darriwilian Carbon Isotope Excursion (MDICE) has been documented. Major element concentrations were analyzed by Agilent 8900 ICP-QQQ at Seoul National University, and lithium isotopic compositions were analyzed using Nu Plasma 3 MC-ICPMS at Seoul National University and University College London. The lithium isotopic ratios of standard reference materials (NASS-7 = 31.1 ± 0.4 ‰, L-SVEC = 0.3 ± 0.5 ‰) agree well with published values.

The data reveal a significant decrease of 10‰ in lithium isotopic ratios from the Middle to Late Darriwilian. A dynamic (non-steady state) model is applied to investigate the causes of the negative lithium isotope excursion over a relatively short period (1 Ma). This study provides additional evidence for increased weathering during the Middle Ordovician.

Depositional records by the active glacier in the northern Drygalski Basin in the Ross Sea since the Last Glacial Maximum

Sangbeom HA[1]*, Korea Polar Research Institute (sb_ha@kopri.re.kr)
Jae Il Lee[2], Korea Polar Research Institute
Kyu-Cheul Yoo[3], Korea Polar Research Institute
Young_Suk Bak[4], Jeonbuk National University
Boo-Keun Khim[5], Pusan National University

Abstract

The Drygalski Basin, which is the deepest basin in the Ross Sea, was generated by the advanced ice sheet during the glacial periods. The advanced ice sheet eroded the continental shelf sediments and formed large-scale lineations. During the deglaciation, the retreating ice sheet transported sediments to develop grounding zone wedge on the continental shelf. After the retreat of the ice sheet, the northern Drygalski Basin became the sub-ice shelf environment. The sediments were mainly supplied to the deepest basin from the grounding line or shallow banks by the debris flow originated by the instability of deposited sediments and/or breakup of ice sheet. Four gravity cores were obtained (DG12-GC03A, DG12-GC03B, RS15-LC100, and RS19-GC02B) at the three sites (DG12-03, RS15-100, RS19-02) from the northern part of the Drygalski Ice Tongue. Sediment properties, geochemical proxies, carbon isotopic values of organic matter, clay mineral composition were analyzed with AMS 14C dating from bulk organic matter. Based on the core descriptions, X-radiograph, and grain size distribution, the core sediments were classified: muddy diamicton, bioturbated mud, massive mud, sandy mud, laminated mud, laminated muddy sand, muddy sand, and scattered mud chunks. Diamicton was deposited proximal to the grounding line during the deglaciation. Several erosional boundary and upward fining facies might form by the debris flow from the grounding line under the sub-ice shelf condition. The previous studies reported that the readvance of the ice sheet during the deglaciation at the Drygalski Basin, based on the sea floor features like recessional moraines or grounding zone wedge. In this study, the sedimentological properties, geochemical proxies, and diatom assemblages indicate that the debris flow was originated by the readvance of the ice sheet during the mid-Holocene at the north of the Drygaslki Ice Tongue. After the retreat of the ice shelf, biogenic materials increase from the surface water under the seasonal open marine condition. The glaciomarine depositional process on the northern Drygalski Basin were closely linked with the ice sheet dynamics and ice shelf activity.

Tsuyoshi Watanabe[6], Department of Natural History Sciences, Hokkaido University

Abstract

Temperature of the ocean is one of the major parameters to understand the climate changes. Minor and trace elements measured in the aragonitic coral skeleton can be used as environmental proxies. Here, we present analyses of Li/Ca, Li/Mg, B/Ca, Na/Ca, Mg/Ca, Sr/Ca, and U/Ca ratios in one slab of scleractinian corals, Porites lobata collected alive in 2008 from Koshiki Island (Japan). These corals have the particularity to experience a large sea surface temperature (SST) seasonality, with winter SST of a about 15°C up to 28°C in summer. This kind of seasonality is quite exceptionnal for tropical corals, and it offers the opporunity to test the temperature proxies on a large range of temperature.

About 250 samples were micromilled with a spatial resolution of 300 µm. Solution ICP-MS measurements were carried out on an Agilent ICPMS. The isotopes of 7Li, 11B, 23Na, 24Mg, 43Ca, 44Ca, 88Sr and 238U were measured after dissolution with ultraclean nitric acid. Possible contamination was checked by the determination of Al and Mn contents. The standard JCp-1 was analysed every 5 samples to ensure the stability and the accuracy of the measurements.

The X-ray photography of the sample highlighted 4 growth stops during 7 years sampled in this study. These stops are likely linked to the low seawater temperature of winters. The annual extension rate is between 6.8 and 10.4 mm. The Li/Ca, B/Ca, Sr/Ca and U/Ca ratios show well defined seasonal cycles. From these cycles, it was possible to develop some age models. Three age models were tested: fortnightly, monthly and in depth. Whatever the age model used, all these ratios are negatively correlated with temperature. The relation between B/Ca and temperature is in agreement with previous studies (e.g. Hart and Cohen, 1996; Montagna et al, 2007). Uranium to calcium and Sr/Ca ratios are positively correlated with a correlation coefficient R2 close to 0.9. This correlation is in agreement with the data of Min et al. (1995) and Cardinal et al. (2001). The geochemical signals were examined in more details to highlight their potential use as environmental proxies, including those analysed across the growth stops to provide more insights into a potential “cold bleaching” response.

Biologically mediated trace element mobilization and isotope fractionation: Are certain redox-sensitive trace elements bio-proxies rather than redox-proxies?

Dennis Kraemer[1]*, Federal Institute for Geosciences and Natural Resources (BGR) - Germany (dennis.kraemer@bgr.de)
Timmu Kreitsmann[2], University of Tartu, Estonia
Robert Frei[3], University of Copenhagen, Denmark

Abstract

Microbes, plants and other organisms actively shape the Earth's surface by a variety of processes. Current research suggests that they have a significant impact on the mobility of trace elements and there is growing evidence that they may have done so since the dawn of life. The secretion of extracellular compounds that bind strongly to iron and other micronutrients are evolutionary traits that may, besides acquiring bio-essential trace metals, also have helped mitigating the toxicity of certain heavy metals. An example of such compounds are siderophores which are produced by many different plants, microbes and fungi and which are ubiquitous in many parts of the pedo- and hydrosphere, with concentrations up to the millimolar range, for example in the rhizosphere. Besides iron, they increase the (bio)availability of different highly-charged cations in the natural environment. The hydroxamate siderophore desferrioxamine B (DFO-B), for example, promotes the mobilization of certain trace elements that hydrolyze easily, and hence were traditionally considered 'immobile' during water-rock interaction. The impact of natural organic ligands on redox-sensitive elements may thus be largely underestimated. Siderophores are omnipresent today and chemically similar compounds may have been present since the advent of life on Earth. In paleoclimate studies, a range of redox-sensitive trace elements (e.g., Ce, Cr, Mo, V, U) are commonly used as geochemical proxies (e.g., Ce anomalies, Th/U ratios, stable isotopes of Cr, Mo, U) for reconstructing atmospheric oxygen levels through time. In the past decade we thoroughly investigated the effect of siderophores on the mobilization of rare earth elements (REE), Cr isotopes, Th and U (isotopes) from natural rocks under anoxic, hypoxic and oxic conditions. Siderophores have the potential to significantly promote the (oxidative) fractionation of redox-sensitive elements even under hypoxic and anoxic conditions. We show that experimental water–rock interaction in the presence of siderophores even under strictly anoxic conditions produces positive Ce anomalies – a geochemical signal that is usually attributed to the presence of atmospheric oxygen. Siderophores also affect the Th/U ratio, as U is preferentially mobilized over Th during WRI in the presence of siderophores. However, our recent investigations revealed that this siderophore-promoted mobilization is not accompanied by significant U stable isotope fractionation. Likewise, siderophores mobilize Cr from igneous rocks and chromite ores, but do not induce a significant stable isotope fractionation. In summary, the oxygen-independent mobilization and fractionation of some redox-sensitive trace metals during geo–bio interaction may thus hold the potential to use certain trace elements as a bio-proxy in

addition to or rather than as a redox-proxy. While the interaction of trace elements with biogenic ligands will further complicate the use of geochemical redox-proxies, our results open an exciting venue for future studies and potential applications, including the field of astrobiology.

Giant discoveries for magnetofossils from Cretaceous and Quaternary marine sediments

Courtney WAGNER[1]*, Kent State University (courtneywagner.geo@gmail.com)
Nitin Kadam[2], National Museum of Natural History, Smithsonian Institution
Ioan Lascu[3], National Museum of Natural History, Smithsonian Institution

Abstract

Here we report recent magnetofossil discoveries and highlight advantages of using magnetofossils as paleoenvironmental proxies. Conventional magnetofossils are the magnetic mineral remains of redox and nutrient-sensitive iron-biomineralizing organisms called magnetotactic bacteria. Magnetotactic bacteria are prolific microorganisms that live near the oxic-anoxic interface within a variety of modern aquatic environments (e.g., oceans, lakes, hot springs, and more). Conventional magnetofossils are nanometer-sized (20-150 nm) and have magnetite or greigite compositions. These biominerals may be consumed by other organisms, dissolved into the water column, or preserved in the geologic record. Conventional magnetofossils are abundant within sediments spanning the Late Cretaceous (~85 Ma) to present, although metagenomic studies suggest that the genes responsible for iron-biomineralization by magnetotactic bacteria may have originated during the Archean (~3.3 Ga). Giant magnetofossils are the micrometer-sized (>1 μm) remains of, as yet, unidentified organisms. Giant magnetofossils have only been identified within global records of the upper Paleocene and Eocene (~56-40 Ma), leading to the interpretation that they are linked to environmental conditions exacerbated by large-scale climatic events.

We report two new records of conventional and giant magnetofossils, from Cretaceous (~97 Ma) and Quaternary (~30-1.8 ka) marine sediments. Together, these reports 1) highlight that giant magnetofossils are more widely distributed in the geologic record than we thought, 2) showcase the oldest robust record of both conventional and giant magnetofossils, and 3) provide clues toward understanding the ecological thresholds and sensitivities of the iron biomineralizing organisms responsible for producing magnetofossils. The widespread distribution of magnetofossils both in the modern and the geologic record suggests that these organisms have played an important role in iron cycling and regulating environmental pressures throughout Earth's history. This information, combined with the cost-effective, straightforward, non-invasive magnetic detection of magnetofossils, underscores their usefulness as environmental proxies.

Geochemical evidence for an increased primary productivity during the Bölling-Alleröd interstadial period compared to Holocene along the south-western continental margin of India

Busnur Rachotappa Manjunaha[1]*, Mangalore University (omsrbmanju@gmail.com)

Abstract

The south-western continental margin of India (SWCMI) is one of high primary productivity (PP) regions in the Northern Indian Ocean (NIO) owing to the dominance south-west monsoon winds (S-W MW) during the summer monsoon, followed by north-east winds during the winter monsoon. The decreased PP during the glacial conditions attributed to the weakened S-W MW, however, this study shows that the S-W MW seems to have been increased during the interstadial conditions, particularly during the Bølling–Allerød (B-A) period than the Holocene. Geochemistry of a radiocarbon dated sediment core from SWCMI at 1400 m depth around 13o N latitude indicates that the PP indicator elements, such as Zn and Ni show contrasting behaviour from late-Glacial to the Holocene period. The Al-normalized Zn and Ni data of the core studied show an inverse trend particularly during the B-A period and to some extend during the mid –Holocene. Further, Al-normalized Zn ratios to Al-normalized Ni ratios are nearly two-fold higher during the B-A, than the entire core, particularly the Holocene section. This suggests that the diatom productivity was much higher during the B-A period relative to the Holocene time span. This finding is in agreement with the increased rainfall inferred from speleothems over the terrestrial regions of the Indian sub-continent, and decreased salinity, enhanced PP and increased denitrification rate noticed in the continental marine realm surrounding the India during the B-A period. Although many trace elements required for primary productivity, the biochemical/metabolic reactions of a cell and uptake of carbon by the phytoplankton, the most preferred trace element is Zn rather than Ni. Henceforth, Zn and Ni in marine sediments, particularly in the pristine continental margin can be used as proxies to delineate paleo-primary productivity variations. The utility of the trace elements suggested here is in agreement with the similar trace elemental isotopic investigation made by the GEOTRACES group in the productive upwelling regions.

A new method for quantifying astronomical forcing in paleoclimate proxies by evaluating spectral power distribution

Cheng PENG[1]*, China University of Geosciences (Beijing) (pengc@cugb.edu.cn)
Changchun ZOU[2], China University of Geosciences (Beijing)

Abstract

The quantification of astronomical forcing in paleoclimate proxies is the basis for many studies on important issues in the field of geosciences (e.g., astronomical timescale, astronomically forced climate, sea/lake level fluctuation and ancient solar system behavior). However, how to accurately identify astronomical cycle signals in paleoclimate proxies in the absence of absolute age constraints is still the focus of debate. Here, we propose a new quantification method of astronomical forcing in paleoclimate proxies based on multiple features of power ratio. This method uses power ratio accumulation value to quantify the relationship between the power spectrum of proxies and target curve of astronomical solution under the constraint of astronomical cycle length ratio. The synthetic series containing astronomical cycles and noise signals are used to validate the effectiveness of this new method. The new method is successfully applied to three types of paleoclimate proxies from different periods, namely Late Paleogene color data in South Atlantic, Late Cretaceous thorium content logs in Songliao Basin and Late Triassic depth-rank series in Newark Basin. These paleoclimate proxies belong to core measurement data, downhole geophysical log data and rank data, respectively. The analysis results provide new evidence related to astronomical cycles from the perspective of power ratio to support the previous cyclostratigraphic interpretations. This study will contribute to the decryption of paleoclimate information from proxies worldwide and promote the development of cyclostratigraphy. Acknowledgment: We acknowledge the financial support of National Natural Science Foundation of China (No. 42002029).

Land Snail Shell Morphology Records Multiple Orbital Cycles of the Asian Monsoon

RUI Bao[1]*, Nanjing Normal University (baorui@njnu.edu.cn)
HUA SHEN[2], Nanjing University
XUEFEN SHENG[3], Nanjing University
MIN WU[4], Nanjing University

Abstract

Both loess proxies in northern China and speleothem δ18O in southern China are purported to be capable of recording changes in the Asian summer monsoon (ASM) on the orbital scale. However, their understandings regarding the evolution cycle and forcing mechanism of ASM are inconsistent and remain controversial. These disputes may arise from the uncertainty and complexity of the climatic significance of previous physical-chemistry proxies, such as those influenced by pedogenesis processes and sedimentation rates in the case of loess proxies. These necessitate the development of a new proxy, particularly the biogenic proxy, which offers the advantage of greater sensitivity and direct responsiveness to climate change. Here, we selected the morphology of land snail shells as a proxy to evaluate its potential for reflecting climate change and further recoding the variations in ASM. To this end, we investigate the morphology variations in fossil Cathaica orithyia shell from the Chinese Loess Plateau over the past ~470 ka and compare them with current ASM records. Our findings indicate that the aperture morphology, which plays a crucial role in regulating the shell's anti-drought ability, exhibits a distinct precession (23-kyr) cycle similar to that of Chinese speleothem δ18O, as well as potential obliquity (41-kyr) and eccentricity cycles. These results validate the use of shell morphology as a reliable proxy for reflecting climatic aridity or humidity, which may be influenced by multiple climate factors. Additionally, this proxy suggests that the ASM variations are forced by multiple orbital periods with the precession predominates.

Evolution of sea surface temperature in the North Pacific over the past 10 million years

Kyung Eun Lee[1]*, Korea Maritime and Ocean University (kyung@kmou.ac.kr)
Tae Wook Ko[2], Korea Maritime and Ocean University

Abstract

Various past temperature proxy records indicate long-term cooling of Earth's climate during the past 10 million years. Yet, the existing records lack the temporal resolution needed to identify climate dynamics. Here, we present a new, extremely highly resolved (1 to 3 kyr), continuous alkenone temperature record spanning the past 10 million years, from the middle latitude northwestern Pacific margin, to understand temperature response to climate forcing. Comparisons between changes in temperature, sea level (e.g., polar ice sheet volume) and astronomical cycles reveal that the two completely different climate records of temperature and sea level have very similar periodicities over the past 10 million years, and changes in periodicity of temperature and ice sheet volume were generally modulated by those of eccentricity and obliquity over the past 10 million years. However, the intensity of temperature and ice sheet volume changes varied over the entire time period. The intensity increased toward the present during the northern hemisphere glaciation. These indicate that climate responses to astronomical forcing varied over the time period. We compared our temperature record with those from the subarctic and western and eastern equatorial Pacific oceans, anticipating being able to reconstruct the evolution/variability of the subpolar front and North Pacific subtropical gyre during the northern hemisphere glaciation.

The effect of barrier layer's evolution in the western Pacific warm pool on the deglaciation

Shuai ZHANG[1]*, Hohai University (zhangshuai5@126.com)
Zhoufei Yu[2], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Fengming Chang[3], Institute of Oceanology, Chinese Academy of Sciences
Tiegang Li[4], Key Laboratory of Marine Sedimentology and Environmental Geology, First Institute of Oceanography

Abstract

The role of the El Niño-Southern Oscillation (ENSO) in modulating global climatic changes is critical, while the role of the barrier layer (BL, a salinity stratification above the thermocline) in forming this phenomenon, which could reduce subsurface entrainment cooling into the mixed layer and impede the energy transmission downward and finally determine the ENSO state, is not clearly discussed, and prior BL changes are weakly restricted by marine archives. Here, we used the Ontong-Java Plateau sediment core KX97322-4 (00º01.73'S, 159º14.66'E, water depth 2362 m) to reconstruct previous changes in the BL. Based on the minor difference in calcification depth between two surface species of planktonic foraminifera (Globigerinoides ruber and Trilobatus sacculifer), we used stable isotopes of oxygen and Mg/Ca ratio analyses to document temperature and salinity variation (considering the linear correlation between the sea water δ18O and salinity, it is represented by residual δ18Osw) of surface water in the centre of western Pacific warm pool over the last 140 kyr. The comparison of vertical temperature and salinity change amplitudes suggests that the BL was strengthened during the last two deglacial, and a larger scope of BL was developed during the Termination II, which would intensify the warming in MIS5e compared to MIS1. This is compatible with the maritime continent's increasing precipitation and open ocean of the warm pool's decreased rainfall. In the modern short-term climate state, increased rainfall in the warm pool during the deglaciation period may have produced in higher vertical salt stratification in the surface water, resulting in BL thicknessening. While our results shown that on long time scale, the BL is determined by the lateral hyperhaline intrusion. It might provide positive feedbacks to the La Niña-like condition that existed during the deglaciation and amplified the ENSO's global impact. Earlier in the Holocene, the BL is thinner and associated with an El Niño-like condition. Moreover, 169 δ18Osw measurements gathered throughout the whole western Pacific suggest that rainfall in the western section of the warm pool rose while rainfall in the eastern part of the warm pool declined. This rain band's westward migration may have contributed to the BL's thinning. Our data give fresh light on the dynamics of ENSO-like events during the deglaciation.

Beatriz Teixeira [4], Universidade Federal Fluminense
Ana Paula LINHARES[5], Museu Paraense Emílio Goeldi

Abstract

Sedimentary carbonate outcrops in NW Brazil represent the exposed portion of the entire carbonate succession of the western equatorial Atlantic coast. Most of the Neogene succession of this carbonate-siliciclastic platform consists of the late early to late middle Miocene Pirabas Formation. During the Neogene high-energy coastal storms and hurricanes, developed as a consequence of trade wind anomalies, impacted the shallow-water marine heterozoan assemblage deposits of the Pirabas Formation in NW Brazil. A chaotic superposition of benthic infauna and epifauna, and of demersal and pelagic species in the same section was analyzed using petrography, micro- and micropaleontology diversity and abundance, taphonomy, geochemistry (XRF and XRD), high-resolution microCT imaging, and 3D reconstructions of heterozoan fossil assemblage to understand the sedimentary and paleoenvironmental processes. The equatorial carbonate platform of Brazil reveals a high-energy setting and evidence for multiple tropical storms during the Miocene. This high-energy wave environment caused severe damage to the shallow-water heterozoan assemblages at the seafloor in the inner to middle marine platform, resulting in the chaotic faunal arrangements observed, including a mixture of elements from different paleoenvironments. The resilience and turnover of successive carbonate heterozoan layers took place after each storm episode. The combination of storm removing of fine-grained particles and the diagenetic dissolution of hard shells was favorable for the development of high porosity and permeability of the carbonate.

Characteristics of late Pleistocene TEX86-based temperatures in the northern Okinawa Trough

Tae Wook KO[1]*, Korea Maritime and Ocean University (ted09@g.kmou.ac.kr)
Kyung Eun LEE[2], Korea Maritime and Ocean University
Masanobu Yamamoto[3], Hokkaido University

Abstract

This study reconstructed seawater temperature using the TEX86 proxy from marine sediments of U1429 (31°37.04' N, 128°59.85' E, water depth 732 m) in the northern Okinawa Trough. Continuous TEX86 temperatures were reconstructed with a 2 kyr resolution over the past 400,000 years. TEX86 temperatures varied in the range of 17-26 °C during 400,000 years, clearly presenting glacial-interglacial cycles. The result of spectral analysis of TEX86 temperature showed a strong 100 kyr cycle. The TEX86 temperatures during the last three interglacial periods (MIS 5, 7, and 9) are in the range of 24-26 °C, which is broadly similar to that of the mid-to late Holocene. The temperatures for glacial periods were between 17 and 19 °C. During the transition period of glacial termination, the temperature rapidly increased by nearly 6 °C. During the transition period of glacial inception, the temperature of TEX86 decreased by 3 °C. Reconstructed U1429 TEX86 temperatures were compared with other proxy temperatures (planktonic foraminiferal Mg/Ca ratio and alkenone) reconstructed in previous studies on U1429. The TEX86 temperatures were always lower than foraminiferal Mg/Ca-based temperatures over the entire period. Meanwhile, they were either similar to or lower than alkenone temperatures over the entire period. In particular, during the glacial termination periods, the TEX86 temperatures were characterized by low temperatures compared to alkenone temperatures. One possible reason for these differences is likely to be caused by differences in the seasonality and production depth of each temperature proxy and the resulting differences in sensitivity to climate forcing.

Abstract

Marine calcifiers are the most important components of the marine ecosystem that grow in the Tropical Oceans. They are widely known as the best marine archives to provide high-resolution records of ocean atmospheric variability on sub seasonal to daily scale resolution spanning up to a few hundred years. However, the atmospheric CO2 rise during the post-industrial era has resulted in a decrease of ~0.1 unit in surface ocean pH, a process commonly known as Ocean Acidification (OA), which has highly threatened the growth and existence of these marine calcifiers. Lakshadweep Islands located in the north Indian Ocean harbor various types of such marine calcifiers and various workers have recently studied them for paleoclimatic/paleo-environmental reconstruction. In the present study, we highlight the isotopic (δ18O, δ13C) and microstructure records of a giant clam shell (Tridacna maxima) collected from the Lakshadweep Archipelago, India. Our records show relatively slow growth rate during 2010 caused by exceptionally warm sea surface temperature. The results reveal that even short high-temperature events can significantly perturb the biology of giant clams and require long recovery phases. These results are particularly significant for conservation efforts of some of the most endangered marine calcifiers growing in regions in with on-going global warming trends.

Cretaceous alkenones from Southern high latitudes: potential for paleoceanographic proixies

Takashi HASEGAWA[1]*, Kanazawa University (jh7ujr@staff.kanazawa-u.ac.jp)

Abstract

Mid-Cretaceous was characterized by high sea levels, elevated average temperatures, and increased carbon dioxide concentrations, resulting in an exceptionally warm climate. Around 94 Ma, a significant perturbation event in carbon cycling (OAE2) occurred, accompanied by a pronounced excursion of carbon isotope values (d13C) observed worldwide. Previous study has detected ethyl alkenone with 40 carbon atoms (C40:2 Et) from IODP Site U1516, located on the southern margin of the proto-Indian Ocean, and applied its d13C values for international correlation. Additionally, C40:3 ethyl alkenone was also identified, leading to proposals for paleotemperature estimates using the ratio of C40:2 Et to C40:2 Et + C40:3 Et. However, GCMS analysis consistently revealed spectral overlap between C40:3 Et and C40:2 Et-derived spectra in the mass spectrum at m/z 572.5. Some results clearly indicated the presence of an isomer peak distinct from the main peak (all trans) of C40:2 Et, occurring at the same retention time as C40:3 Et.

On the other hand, high S/N analysis with GCMS (SIM mode) enables detection of alkenones with extremely low concentration. This technique provided unique alkenone data from Southern high latitude sites including new finding of Santonian C37-40 alkenones and C41:2 Me from OAE2 interval which is the third report from world marine sediments. Isomers of C37:2 Me, C38:2 Et and C39:2 Me are firstly found from Cretaceous sediments.

In this presentation, I summarize current findings then potential of Cretaceous alkenones for understanding paleoceanography, especially how to address paleotemperature variations under the influence of the isomers will be discussed.

Abstract

The geochemical composition of the aragonite skeleton of cold-water corals (CWC) can provide unique information on the physico-chemical changes and dynamics of water masses at intermediate depths at high temporal resolution (e.g. sub-decadal). Previous studies have shown that variations in seawater temperature, water ventilation age, and water mass provenance can be inferred from measurements of skeletal Li/Mg ratios, paired U/Th and 14C, and neodymium isotopes, respectively. In particular, the solitary azooxanthellate scleractinian coral species Desmophyllum dianthus is particularly valuable due to its widespread distribution, century long lifespan, and stratified skeletal growth, which facilitates the use of geochemical tracers at sub-decadal intervals.

Here, we investigated several Desmophyllum dianthus samples retrieved in 2012 from the Northern Iceland Basin at depths of 570-700 m during the ICE-CTD R/V Thalassa expedition, using the Remotely Operated Vehicle Victor 6000 operated by IFREMER. Sub-samples of the coral skeletons collected along the growth axis were analysed for Li/Mg, stable isotopes (d11B, d18O, d13C), U/Th, 14C and Nd isotopes, with the aim to reconstruct the physico-chemical changes of the North Atlantic intermediate water masses (Iceland-Scotland Overflow Water, Sub-Arctic Intermediate Water and Western North Atlantic Central Water), and quantify how their contributions have varied over the past few decades. The Li/Mg ratios revealed sub-decadal temperature records that vary between ~2 to ~6 °C, which is closely related to changes in Nd-isotopic compositions. These results can be explained by decadal fluctuations in the North Atlantic Oscillation and East Atlantic atmospheric patterns, with those atmospheric drivers causing strengthening or weakening of the Atlantic Subpolar Gyre, leading to changes in the amount of

warmer Subtropical Gyre-sourced water or colder SPG-sourced water. Additionally, the prevalence of ISOW is shown to have roughly halved over the past ~70 years, suggesting an increase in northward transport of warm subtropical waters over recent decades, which may have contributed to recent warming in the Arctic region, as well as substantial multi-decadal weakening of Nordic Sea overflow currents.

Quantitative constraints on the environmental conditions of bauxite formation since Mesozoic

Xiujuan BAO[1]*, Institude of Geology and Geophysics, Chinese Academy of Sciences (xbao@mail.iggcas.ac.cn)

Abstract

The bauxite is a critical paleoclimatic proxy, and it is also the main material for refining aluminum. Therefore, it is of great scientific, economic and strategic significance to study the mineralization of bauxites. The formation of bauxites is largely affected by intense chemical weathering, closely related to temperature, precipitation and vegetation cover. In paleoclimatic studies, bauxites are used to qualitatively indicate warm, humid and vegetated environmental conditions, but how bauxites in the deep time were quantitatively related to temperature and precipitation has not been established, which limits the paleoenvironmental indication of bauxites and the metallogenic prediction. Here, we combine geological records with climate simulations to establish the quantitative relationships of bauxites with temperature and precipitation since the Mesozoic era. The Earth system model CESM1.2.2 and the vegetation model BIOME4 were combined to simulate the climate and vegetation distribution. Then the environmental information of the paleo-locations of bauxites is extracted, and the quantitative relationships between bauxites, and temperature, precipitation and vegetation are established. We show that bauxites formed with an annual mean temperature of 24.8 °C and precipitation of 1097 mm y-1 after 250 Ma. The climatic variations of bauxites are due to land distribution, climate states, and vegetation coverage. Our research results provide a new understanding of the mineralization of bauxites, and also offer a reference for the exploration of bauxites.

Pliocene palaeoceanographic changes reconstructed by biomarker analysis of sediments from the Gulf of Alaska of the northeastern North Pacific

Kotaro HOSHI[1]*, Division of Natural History Sciences, Graduate School of Science, Hokkaido University (souryuu1223@eis.hokudai.ac.jp)
Akemi FUKUMURA[2], Division of Natural History Sciences, Graduate School of Science, Hokkaido University
Ken SAWADA[3], Department of Earth and Planetary Sciences, Faculty of Science, Hokkaido University

Abstract

The past 5 million years from the Pliocene to Pleistocene started off with a warm climate represented by the Pliocene climatic optimum (PCO; ca. 4.4~4.0 Ma) alongside with the partial closure of the Central American Seaway (CAS), gradually altering the boundary conditions of Pacific Ocean. Global climate faced a significant cooling after the onset of Northern Hemisphere Glaciation (NHG; ca. 3.2 Ma~) until modern day. At the Gulf of Alaska (GOA), the development of Alaskan alpine glaciers started after 4.2 Ma, which enhanced sedimentation at the GOA. In the present day, enhanced nutrient input via glacial meltwater as well as coastal upwelling during the spring and summer results in algal blooms composed mainly of diatoms. In the present study, we analyzed biomarkers in sediment core samples from the GOA to reconstruct the variations in paleoenvironments and primary productions in the sea surface layers since the early Pliocene (ca. 5.3 Ma) in the northeastern N Pacific.

We used the sediment cores recovered at the distal Surveyor Fan in the GOA (Site U1417; 56° 57.5'N, 147°6.5'W) by Integrated Ocean Drilling Program (IODP) Expedition 341. Freeze-dried sediments were extracted by solvents and then separated into fractions by silica-gel column These fractions were analyzed by GC-MS and GC-FID.

We identified various algal biomarkers including long-chain alkenones (haptophyte), long-chain alkyl diols (diatom and eustigmatophyte), C25 highly branched isoprenoids (HBI) alkane (diatom), and steroids such as dinosterol (dinoflagellate), brassicasterol (haptophyte and diatom), ostreasterol (diatom), and occelasterol (diatom). Sea surface and subsurface temperatures estimated by alkenone unsaturation indices (UK37 and UK’37) and long-chain diol index (LDI) varied with global cooling since the late Miocene as previously reported foraminiferal δ18O records, and also showed remarkable increase/decrease during the warming/cooling events such as the PCO and NHG, respectively. Upwelling intensity estimated by diol index shows major spikes corresponding to the climatic events. Concentrations and mass accumulation rates (MARs) of the algal biomarkers show that marine paleoproduction frequently varied over the past 5 Ma. Diatom production generally increased towards the Pleistocene, matching the global cooling trend.

Benjamin SRAIN[5], Centro Interdisciplinario para la Investigación Acuícola (INCAR), Chile
Victor ACUÑA[6], Centro de Investigación Oceanográfica COPAS-Coastal, Chile

Abstract

The Baker-Martínez fjord system is an estuarine system located between the Northern Patagonian and the Southern Patagonian icefields. It connects the Andes Mountains to the east with the Pacific Ocean to the west and receives freshwater and sediment from four glacier-fed rivers and from the Jorge Montt Glacier.

In this study, we use a sediment core recovered from the Martínez Channel (47.81°S, 74.06°W; water depth 400 m) to investigate land-ocean interactions in Patagonia during the past 500 years. The core chronology, which is based on a combination of radionuclides and radiocarbon ages obtained on plant remains and carbonate shell fragments, shows a continuous record starting in 1520 -185+155 CE (Common Era). Sea surface temperature (SST) reconstructions based on the TEX86 paleothermometer reveal that SST was low (8 – 10 °C) between 1600 and 1900 CE, in line with offshore records from the entire western coast of Patagonia.

These results point to an equatorward shift of the Southern Westerlies coeval with the observed lower SSTs. All terrestrial input indicators (δ13Corg, sterols, n-alkanes, BIT) provide evidence for an increased detrital supply during the same period, and, grain-size measurements on the detrital fraction show the presence of particles >150 μm. Together, organic biomarkers and grain-size can be interpreted as precipitation-favored mass removal sediments from the steep slopes surrounding the basin, between 1550 and 1870 CE. Two coarse-grained maxima in 1600 – 1650 CE and 1840 – 1870 CE coincide with the lowest sea temperatures (8 – 9 °C), the most depleted δ13Corg values (-26 to -27‰) and a high BIT index (0.44).

Our results from this multi-proxy high-resolution record show that the pre-1900 CE SST decrease previously observed along the Patagonia coast also reached inland regions, and that the concomitant changes in climate affected river discharge and/or sediment mass removals, as a result of enhanced precipitation.

Radiolarian Events and Palaeoceanography of Core ABP-06, Station-I (Section 6), Central Indian Ocean.

ABHISHEK KOHLI[1]*, DEPARTMENT OF GEOLOGY, KUMAUN UNIVERSITY, NAINITAL (kohliabhishek96@gmail.com)
GIRISH KUMAR SHARMA[2], 2Department of Geology, University of Delhi, Delhi-110007

Abstract

The study area, Akademic Boris Petrov (ABP) -06, Station I, Section 6 lies between Latitude $11^0$44.004'S and Longitude $76^0$3.311'E in Central Indian Ocean. 198 cm long having 51 Samples from ABP-06 #I, 5, 400-404 depth 5236 to ABP-06 #I, 6 596-598 depth from 5237.98 m were taken to carry out the study. The Section is composed of radiolarian ooze and dark brown fine grained clayey material having disturbed and loose sediments.

The sediment was first disaggregated in dilute hydrogen peroxide (H2O2) for 2 hours, followed by heating to just below the boiling point. One tea spoonful of Calgon (R) was added to further disaggregate the samples and complete the treatment. The sample was then sieved through a 63µm mesh stainless sieve. After final wet sieving the residual material was dried and used for the preparation of slides.

40 radiolarian taxa were identified and presented in the temporal distribution of these taxa. On the basis of first and last common occurrences and abundance of radiolaria, one radiolarian Zones i.e. *Anthocyrtidium angulare* Zone has been established. The base of the *Anthocyrtidium angulare* is defined on the morpho typic last appearance of *Pterocanium prismatium* and it coincides with the upper limit of the *Pterocanium prismatium* zone. However, the base of this zone could not be marked due to the absence of *Pterocanium prismatium*. This zone is equivalent to NR5.Two Events are marked in this zone viz., - Bm *Lamprocyrtis nigriniae* and -Tm *Lamprocyrtis neoheteroporous*. The radiolarian assemblage consists of Tropical, Subtropical, Northern Indian Ocean Group, Bimodal Group and Temperate latitudes Group. This region is fed by the Antarctic bottom water currents evident by the presence of sub-Antarctic species.

Morphological Variations On The Growth Of Quaternary Saturnalids Radiolaria In The Antarctic Ocean

Girish Kumar SHARMA[1]*, university of delhi, delhi (gksharma61@yahoo.com)

Abstract

This work presents the morphological variations in the growth and evolution of Saturnalid radiolaria in the Antarctic region and compared with other world oceans. The area is located on a large sediment drift at the base of the Southern slope of the Kerguelen plateau at 59°35.71'S and 85°57.60' E. The 284 samples were collected at a water depth of 4082.5m and length of the core is 214.05 m. The sample was first disaggregated in dilute hydrogen peroxide followed by heating and then add Calgon for further treatment. The wet sample was sieved through 63um sieve. The strewn and picked slides was prepared by using Canada balsam as a mounting medium.

Significant, well-preserved and diversified taxa of Saturnalids viz.,*Saturnalis* and *Saturnulus* were recovered from twenty-three sections (1H to 24H) from Site 745B Leg 119 of Southern Ocean Region

The morphometric analysis includes thickness, shape of the connecting ring and size of polar spines of Saturnalids was carried out and 8 new taxa of *Saturnalis* and 15 *Saturnulus* were identified respectively. The single shelled *Saturnalis* nspp present in the early late Miocene of Tau zone and evolved into two shells of *Saturnulus* nspp in the Late Miocene and became extinct in the late Chi zone of Middle Pleistocene. It is interpreted that there is a progressive evolution in the sizes of shell of *Saturnalis* circularis and *Saturnulus* nspp whereas *Saturnalis* nspp showed retrogressive evolution in the growth of shell. Around 1.5 My.,the Antarctic Ocean was rich in silica and have favorable environment for the growth of the siliceous skeleton which results in the increase of the size and thickness of the shell.

Millennial scale variability of Indian Winter Monsoon during mid-late Holocene and its links to Solar Changes: New Evidence from Coastal sediments from Sri Lanka

Hewa Marambage Kusala Madhushani Madhushani PREMARATNE[1]*, IOW
(kusala.premaratne@io-warnemuende.de)
Rohana Chandrajith[2], Department of Geology, Faculty of Science, University of Peradeniya, Peradeniya, 20400, Sri Lanka.

Abstract

Solar forcing is a broadly expressed prospect of earth´s climate history. Monsoonal response to Sun´s energy output is evident in many paleo-monsoon records at a range of time scales. Considering the Indian monsoon domain, the response of winter monsoon to solar forcing is not well understood though summer monsoon show asynchronous variations with solar activity throughout the Holocene. This study aims to explore the variability of Indian Winter Monsoon and possible links to solar activity during Holocene. Here we present mid to late Holocene Indian Winter Monsoon record in an AMS 14C dated sediment core from Pottuvil Lagoon. Paleo-monsoon reconstruction was based on geochemistry of trace elements and Rare Earth Elements (REE) of coastal sediments from south-eastern Sri Lanka. A 5.1m core was logged for concentrations of K, Rb, Mg, Al, Ti and REE at a 5cm interval using ICP-MS. The extracted monsoon signal was compared with Holocene records of solar proxies (14C and 10Be nuclide production rates). Results revealed a distinct variability of Indian Winter Monsoon during mid-late Holocene with three phases of intense monsoon activity at 2553-2984 yrs BP, 3899-5021 yrs BP, and at 5244-5507 yrs BP intervals. Further, spectral analysis on elemental proxies showed an occurrence of dominant 1 kyr and 1.6 kyr periodic bands in Lomb Scargle spectra. The millennial scale pacing detected in Pottuvil monsoon record show a close coherence with variations of 14C and 10Be nuclide production rates, implying a possible link to solar forcing. Notably, 1000-year millennial-band is consistent with Eddy solar cycle. The geochemical approach executed in this study provides new perception on millennial scale variability of Indian winter monsoon and ´Sun-monsoon´ climate connection.

Reconstructing Temperature Changes in the Upper Ocean of the Central South China Sea Since the Industrial Revolution Using Cold-water Corals

Xinru HUI[1]*, State Key Laboratory of Marine Geology, Tongji University (306900680@qq.com)
Xiaoli ZHOU[2], State Key Laboratory of Marine Geology, Tongji University
Peijun QIAO[3], State Key Laboratory of Marine Geology, Tongji University
Xiangtong HUANG[4], State Key Laboratory of Marine Geology, Tongji University
Xiaoying JIANG[5], State Key Laboratory of Marine Geology, Tongji University

Abstract

Since the Industrial Revolution, the continuous increase in atmospheric carbon dioxide concentration has led to global warming. Ice core and observational data, however, indicate that "global warming hiatus" happened in the mid-20th century and the early 21st century. This phenomenon is explained partly by changes in ocean heat storage. The deep ocean is a vast heat reservoir, thus changes in deep ocean heat content may result in short-term decreases in atmospheric temperature. Therefore, understanding the mechanisms of deep ocean heat storage and their historical changes is of great practical significance for predicting future climate change and mitigating global warming.

Cold-water corals, due to their wide distribution, slow growth rates, and unique structure, can record various environmental changes over their lifespans. This study aims at reconstructing seawater temperature changes in the upper ocean of the South China Sea since the Industrial Revolution using cold-water corals collected from water depths between 300 and 2000 meters in the central South China Sea. The growth rates and lifespans of corals were obtained by radiocarbon dating. It is estimated that the radial growth rates range from several micrometers to tens of micrometers per year, yielding lifespans ranging from several decades to several centuries. By analyzing the carbon and oxygen isotopic compositions at the radial direction of the sectioned calcium carbonate skeletons, changes in seawater temperature during coral growth were determined. The results show that samples from shallower depths exhibited larger temperature variations. Additionally, by analyzing the elemental composition of the calcium carbonate skeleton, seawater temperature was reconstructed by applying the modern seawater Mg/Ca-temperature calibration. The results show that Mg/Ca generally decreases from the center to the edge consistently in different radial directions on the long term, while displaying short-term periodic fluctuations for corals from different water depths. According to the modern calibration of Mg/Ca and temperature data, the positive correlation between the two suggests that temperature in the upper and intermediate seawater of the South China Sea may have been decreasing in the past decades to hundreds of years. Nevertheless, other factors such as vital effects also have to be considered while reconstructing temperature from Mg/Ca records. The results of this study have the potential to provide new evidence for understanding the relationship between ocean heat storage and atmospheric carbon dioxide concentration, as well as the "global warming hiatus" event.

Late Cretaceous high-resolution sea and lake-level reconstructions based on sedimentary noise modeling: water circulation and orbital forcing

Kaixuan JI[1]*, Peking University (jikaixuan_cug@163.com)
Mingsong Li[2], Peking University
Fanhao Gong[3], Shenyang Geological Survey Center, China Geological Survey
Dejun Zhang[4], Shenyang Geological Survey Center, China Geological Survey

Abstract

Research on water dynamics within greenhouse settings is drawing more interest due to its significance in understanding the connection between orbital forces and the mutual evolution of organisms and their environments. A major challenge lies in deciphering the fluctuation of water levels in the world's oceans and continents under conditions absent of ice and identifying what primarily influences sea level shifts. Conventional methods such as sequence stratigraphy and sedimentology have only offered limited and imprecise data, which restricts a thorough analysis of ancient water circulation patterns. Thus, the precise measurement of changes in sea and lake levels becomes crucial for the exploration of the Earth's historical hydrology. This study introduces the use of sophisticated sedimentary noise models (DYNOT and ρ1) derived from astrochronology and time-series analysis to map out fine-scale changes in water levels across different landscapes: the continental Songliao Basin in Northeast China, the Basque-Cantabric Basin off the coast of Spain, and the Espírito Santo Basin in the western South Atlantic, spanning the Maastrichtian Stage to the Cretaceous-Paleogene (K-Pg) boundary. Through sedimentary facies analysis and paleosol studies, this research uncovers periodic shifts in sea and lake levels every 1.2 million and 2.4 million years, displaying a contrasting pattern of rises and falls. These findings suggest that sea level variations could be related to the fluctuating volumes of continental waters, shedding light on the intricate relationship between land and ocean water circulations.

Catastrophic Flooding during Late Holocene in Northern Bihar Plains, India: A Geo-archaeological Perspective

SHANKER SHARMA[1]*, ARCHAEOLOGICAL SURVEY OF INDIA
(shanker.sharma74@yahoo.co.in)

Abstract

Generally we consider that the growth and downfall of several civilizations have been directly or indirectly related to changes in climatic conditions. The Northern Bihar plain was one of the areas which were affected from short term adverse environmental conditions during the late Holocene time (circa 1400 BP) causing catastrophic flooding. Probably, this occurred because of unprecedented amount of glacial melt on the Himalayas and lake outbursts due to changes in temperature. Some reconstructed palaeoclimatic data also suggests that at the same time there were some environmental backdrop that ascended due to changes in climatic conditions. The data over reconstructions of past climate have also revealed that large-scale changes in temperature and rainfall patterns have occurred throughout the geological history over almost all time scales ranging from decades to centuries to millennia and spatial scales from small regions to almost the entire globe.

Archaeological sequences are often found buried under thick fluvial sediments. The sediments found during excavations in the study region have revealed an identical physical context including floodplain deposits of silt and clay and marked by prominent discontinuities in the human settlements at all the sites. Several episodes of fieldwork by the author has demonstrated that abandonment of the region was probably a result of catastrophic flooding in the low lying area of northern India and southern Nepal. The archaeological evidence is supported by some contemporary historical texts and travelogue accounts. The present perception has been conceptualized through various scientific investigations using DEM model, absolute dating method, palaeobotanical remains, sedimentological analysis and archaeological evidences. Indeed the paper is a geo-archaeological perspective which provides an insight into the past climatic conditions of the region and its impact on life during that time span.

Spatial and Temporal Distribution of Typhoons during the Joseon Dynasty (1392 – 1910)

Jin Gu KANG[1]*, Department of Sustainable Environment, Catholic Kwandong University (kang99104@cku.ac.kr)
Kwang Hee CHOI[2], Department of Geography Education, Catholic Kwandong University

Abstract

Sea surface temperatures are increasing due to global warming, leading to more intense tropical cyclones such as typhoons. Veritable Records of the Joseon Dynasty, a historical document from AD 1392 to 1910, is an important source of information on typhoon occurrences in South Korea, especially considering the relatively short period of modern typhoon observations. This study aimed to analyze the spatiotemporal distribution of typhoons in the Korean Peninsula during the last half millennium, using the Veritable Records of the Joseon Dynasty. The study extracted past typhoon records from the documents and determined their occurrence time and affected spatial area. A GIS program was used to convert each record into a point datum, and the paths of past typhoons were calculated by combining the points with similar dates. The analysis identified 580 records related to strong winds, with 97 classified as past typhoons occurring between July and September, accompanied by precipitation. The study found that typhoons during the Joseon Dynasty were mainly distributed in the southern and eastern coastal regions of the Korean Peninsula, similar to the current spatial pattern of typhoons affecting Korea. The southern region, including Goseong, Sacheon, and Suncheon, was the area most affected by typhoons. Nearly half of the typhoon records were concentrated in the 17th century, related to the Little Ice Age in East Asia. The path of typhoons during the Joseon Dynasty was similar to today's, from west to northeast or south to north. The study is significant in estimating the characteristics of typhoons by examining their spatiotemporal distribution in the past and representing the paths of typhoons and affected areas geographically. However, there is a possibility of duplicate or erroneous records and intentional omissions of records unfavorable to the ruling class of the time, as the study relied on documentary records as a source of research data.

Terrestrial n-alkane and alkenones flux and its relationship with climate and paleoceanogrphy of the low-latitude Indian Ocean during the Quaternary

Sangmin HYUN[1]*, Korea Institute of Ocean Science and Technology (smhyun@kiost.ac.kr)
Jeongwon Kang[2], Korea Institute of Ocean Science and Technology
Hiroyuki Takata[3], Pusan National University

Abstract

We investigated Quaternary two biomarkers of alkenones an terrestrial organic compounds, n-alkane, in core GPC 1803 from the eastern equatorial Indian Ocean since ~740 ka to examine the relationship between alkenones-n-alkane influx and climate-paleoceanographic variations. The oxygen isotope result shows cyclic glacial-inter glacial variation, it reachs marine isotope stage(MIS) 18. As the oxygen, the total alkenones concentration shows cyclic variation with increase during glacial periods except for MIS18. Also, the total sum of terrestrial n-alkanes (nC25~nC35) high during glacial periods except for MIS2. Given them that terrestrial n-alkanes influx controlled by relative strong wind strength during glacial periods, both biomarkers of alkenoens and n-alkenes are characterized by high concentration of total alkenones and high concentration of total n-alkanes during glacial periods, implying strong relationship between climate and in situ paleoceanography. This implying increase of paleo productivity during glacial periods. Alkenone-based SST(Sea Surface Temperature) shows high amplitude variations throughout, ranged about 27oC to 29oC. However, the alkenones-based SST does not follow glacial-inter glacial patterns, high temperature in inter glacial and low temperature in glacial periods. In this study, C37:4, C37:3, C37:2 were detected, the C37:3 compounds are generally less than 5%, and C37:2 % is much higher than 85%. Therefore, calculated alkenoen-based SST may be over estimated, hard to interpretation. We will conduct additional alkenones analysis and will compared with previously published paper in this study.

The Strontium and Neodymium isotopic signatures of the Zambezi River Basin in Southern Africa: From source to sink.

Sonwabile Kidwel RASMENI[1]*, University of South Africa (65104129@mylife.unisa.ac.za)
Lindani Ncube[2], University of South Africa
Elna Van Niekerk[3], University of South Africa
Baojin Zhao[4], University of South Africa
Junsheng Nie[5], Lanzhou University
Jing Yang[6], Lanzhou University

Abstract

The isotopic signatures of radiogenic strontium (Sr) and neodymium (Nd) are commonly employed to trace the movement of sediment particles in rivers and reconstruct alterations in tectonics and climate during particle formation. These signatures are widely acknowledged as dependable indicators of sediment provenance due to their minimal isotopic fractionation during chemical weathering. Since the Cretaceous period, the Zambezi River has been transporting and depositing substantial detritus particles, causing natural fluctuations in river flow, erosion, and sedimentation before reaching the Indian Ocean. A comprehensive understanding of sediment transportation pathways from initial source regions to the ocean is crucial for discerning the origin of these detrital particles.

This study represents the inaugural in-depth analysis of the Zambezi River's provenance, utilizing Sr-Nd data from various segments of the main river and some major tributaries. Results reveal that the isotopic signatures of river sediments closely align with the underlying geology of distinct river sections, implying a significant influence of local geology on sediment origin. Consequently, sediments carried by upper Zambezi River sections draining interior continents predominantly accumulate in on-land sedimentary basins rather than marginal seas. This underscores the limitation of using sediments from marginal seas to infer mountain uplift and exhumation history in the hinterland, as these materials originate from three distinct Zambezi River sections exhibiting diverse precipitation patterns, geology, and geomorphology.

Therefore, it is recommended to consider the isotopic provenance of riverine sediments instead of solely relying on marine sediments deposited off marginal seas as proxies for river sediment. This approach enhances the accuracy of interpreting erosion history associated with mountain uplift and exhumation in the Zambezi River region.

Calcareous Nannofossil and Paleoclimatic Evolution Across the Eocene–Oligocene Transition at IODP Site U1509, Tasman Sea, Southwest Pacific Ocean

Abstract

Around 34 Ma, the Earth's climate shifted from a Warmhouse to a Coolhouse state marked by a rapid temperature drop and the formation of permanent ice-sheets on Antarctica. This transition, known as the Eocene-Oligocene transition (EOT), stands as one of the most important climate event in the Cenozoic. During this time, significant changes and turnovers in marine fauna and flora occurred and primarily related to major modification in ocean thermal and trophic structure.

In order to assess how climate changes across the EOT impacted the surface-ocean conditions, we generated a high-resolution calcareous nannofossil and geochemical datasets (δ18O, δ13C and % CaCO3) over a ~5 Myr stratigraphic interval from IODP Site U1509 (Tasman Sea, southwest Pacific Ocean). Site U1509, located between the Southern Ocean (high-latitudes) and the Equator (low-latitudes), represents an ideal case study to reconstruct the paleoclimatic evolution of the Southwest Pacific Ocean and to understand the impact of high latitude cryosphere changes on lower latitude calcareous nannoplankton communities.

At this site, major trends and shifts in the calcareous nannofossil assemblage indicate four distinct phases characterized by a temperature decrease and variations in paleocurrents: (a) late Eocene warm-oligotrophic phase, (b) precursor diversity-decrease phase, (c) early Oligocene cold-eutrophic phase and (d) steady-state cosmopolitan phase. Overall, these phases point to a decline in warm-oligotrophic taxa and to an increase in opportunistic genera better adapted to cooler and more eutrophic conditions. The shift in the assemblage composition was likely driven by sea-surface water cooling and eutrophication, resulted by the northward transport of cooler and nutrient-rich waters from the circum-Antarctic area caused by the inception of a proto-Antarctic Circumpolar Current (ACC).

The most significant change, documented by the marked and permanent loss of the late Eocene

warm-oligotrophic community, occurred during the precursor diversity-decrease phase, a transitional time window of ~550 kyrs, characterized by relatively high bulk δ18O and % CaCO3 values, and followed by a phase of maximum glacial expansion (Earliest Oligocene Glacial Maximum, EOGM) and eutrophication.
To conclude, data from the Tasman Sea provide further support to the idea that e modifications and invigoration of Southern Ocean circulation profoundly influenced and shaped also middle latitude regions.

Paleoceanographic changes in the Western Equatorial Pacific Ocean since the latest Miocene: Insights from Planktic Foraminiferal Census Data

Ayushi RAM[1]*, Indian Institute of Technology Kharagpur (ayushiram.richi@gmail.com)
Anil Kumar Gupta[2], Indian Institute of Technology Kharagpur

Abstract

Understanding the dynamics of air-sea interactions in the tropical Pacific holds significance in unraveling climate variability. A focal point of our study lies in assessing the mixed layer thickness in the Western Equatorial Pacific (WEP), as it offers an opportunity to understand strength of the Walker circulation and the resulting strength of air-sea interactions, both of which play pivotal roles in recent high-frequency tropical climate variability. To investigate this dynamics, we chose Ocean Drilling Program (ODP) Site 803D (2°25.98'N, 160°32.46'E) located within the core region of WEP to analyze planktic foraminifera relative abundance to investigate the evolution of the oceanographic system in this area since the latest Miocene (~ 6 Ma). Fluctuations in the relative abundance of thermocline dwelling species (TDS) serve as qualitative indicators of changes in the depth of thermocline. During the early Pliocene (~ 5.5 to 4.7 Ma), a moderate decrease in the relative abundance of TDS, coupled with an increase in mixed layer species (MLS) suggest a simultaneous deepening of the thermocline and thickening of the mixed layer, which is attributed to the prevailing warmth during this time. A significant shift in the relative abundance of TDS occurred from 3.5 to 2.7 Ma, with their relative abundance increasing from approximately 55% to 70%. During this time, the Indonesian Throughflow was restricted, which led to the buildup of more southern-sourced water, including the cold and nutrient-rich Subantarctic Mode Water (SAMW) and Antarctic Intermediate Water (AAIW). This event is followed by a gradual decline of TDS to ~50% from ~70% alongside an increase in MLS relative abundance at around 2.7 Ma. This indicates a deepening of the thermocline and a thickening of the mixed layer, signifying the development of Western Pacific Warm Pool to its current state. Notably, *Neogloboquadrina* spp. exhibited a remarkable increase during ~ 2.2 to 1.7 Ma and 1.0 to 0.3 Ma, indicating enhanced productivity in the WEP. Despite the minor fluctuations in Sea Surface Temperature (SST) in the Western Pacific region, our planktic foraminiferal abundance data suggest greater variability indicating that the distribution and ecology of planktic foraminifera were influenced not only by SST but also by productivity, nutrient input, and the provinciality of planktic foraminifera. This might be related to the development of the Equatorial Undercurrent and Countercurrent systems owing to the gradual emergence of the Indonesian archipelago.

The evolution of Southern Benguela Upwelling System and its impact on southwest African climate during the Late Miocene

RUDRA NARAYAN MOHANTY[1]*, Indian Institute of Technology Kharagpur (rudranarayanmohanty000@gmail.com)
ANIL KUMAR GUPTA[2], Indian Institute of Technology Kharagpur

Abstract

The Benguela Upwelling System (BUS) is marked by intense upwelling making it one of the most productive regions among the Eastern Boundary Upwelling Systems (EBUS). In this study, new planktic foraminiferal relative abundance data from ODP Site 1087 (31°27.9137'S, 15°18.6541'E), situated in the Southern Benguela Upwelling System (SBUS), is employed to comprehend the upwelling dynamics of the BUS and its impact on the continental climate of southwest Africa during the Late Miocene. During the early Late Miocene interval of weak upwelling, there was a notable high relative abundance of tropical Indian Ocean species, possibly indicating a probable connection between the Indian Ocean and the Southeast Atlantic Ocean. Our planktic foraminifera relative abundance data suggest that the BUS perhaps initiated between ~ 10 - 9 Ma, with intensified upwelling occurred only after ~ 8 Ma. Our results corroborate earlier observations on the initiation of BUS. Between ~ 8 and 5 Ma, the Late Miocene Biogenic Bloom period witnessed a high relative abundance of upwelling indicator species, signifying the presence of intense upwelling and increased productivity in the SBUS. Over this period, the warm water species gradually decreased, whereas the cold water species increased. The growth of Antarctic ice sheets and subsequent strengthening of southeast trade winds likely played a crucial role in fueling the Benguela Coastal Current and establishing the upwelling-dominated regime in the SE Atlantic Ocean. Interestingly, the timing of the development of the upwelling in the SBUS at ~ 10 Ma, aligns with the shift in vegetation type in southwest Africa. The cooling effect of the upwelling process and subsequent reduced moisture supply to the adjacent land would have profoundly contributed to the aridification in southwest Africa, leading to the transition from tropical to arid vegetation.

Grain size distribution in the Northwest Pacific deep-sea sediments: implication for rare earth elements and Yttrium enrichment

EUIJONG LEE[1]*, Department of Environment and Energy, Jeonbuk National University (euijong98@gmail.com)
KISEONG HYEONG[2], Ocean Georesources Research Department, Korea Institute of Ocean Science & Technology
INAH SEO[3], Department of Earth and Environmental Sciences, Jeonbuk National University

Abstract

Rare earth elements and yttrium (REY) are metallic elements with unique chemical and optical properties which allows their applications across various industries. The global supply is heavily reliant on ion-adsorption deposits primarily located in southern China, with increasing demand due to energy transition trends. Recently, there has been growing interest in REY-rich muds in deep sea as a potential alternative resource, as reports indicate comparable REY concentrations in the Pacific Ocean to those found in terrestrial deposits. Notably, extremely REY-rich mud (>5000 ppm) was reported in Japanese Exclusive Economic Zone (EEZ) near Minamitorishima Island, only at certain stratigraphic levels in specific locations. Such heterogeneity in REY distribution calls for a thorough investigation into its genetic origin and the relevant paleoceanographic factors involving reliable age models for conducting a comprehensive resources assessment and evaluation.

We conducted grain-size analysis on surface sediments from 7 cores in the Northwest Pacific to examine the correlation between grain size distributions (GSD) and REY concentrations. There is a positive relationship between the proportion of coarse-grained (greater than 55 micrometers) sediments and the maximum REY contents at the individual sites, with exceptions observed below ~700 ppm. This suggests that in the regions with high REY concentrations, mineral phases constituting the coarse fraction, presumably including biogenic apatite, serve as the primary host of REY, thereby inducing their regional enrichment. However, below a certain concentration threshold, factors unrelated to GSD seem to exert a greater influence on REY enrichment.

In addition, we employed down-core end-member mixing analysis (EMMA) on the sediment core (WP21GPC04; 20.7657° N, 152.5923° E), which contains an extremely REY-rich mud layer, to isolate the modes identified in GSD spectrum. In most samples, the GSD shows a trimodal distribution, and the peak height of the coarsest component is associated with the REY concentration. However, the position of each peak's mode is not consistent with regard to sampling depth, requiring the integration of 8 end-members to effectively explain GSD variance with R-squared value of 0.68. Such depth-wise variance in the average grain size of each mode indicates temporal changes in the environmental factors, which necessitates further specification of each end-member through optical microscope analyses.

Abstract

Submarine landslides are capable of generating tsunami that threaten coastal communities, infrastructure and global economies. The eastern coast of the Korean Peninsula is also not safe from such geohazard. The Ulleung Basin is the source to more than 100 submarine landslides that occurred in the last 300 kyrs with source areas that may attain 165 km2 and up to 24 km3 in volume. A series of stages characterizes the occurrence of submarine landslides: pre-failure, failure and post-failure; each of which presents distinct hazards. For the pre-failure stage, we assessed the potential occurrence of excess pore pressure based on average sediment compressibility and porosity profiles and 2D basin analysis models. Both analyses point to little overpressure in sediments of the Ulleung Basin. Only the upper range of potential compressibility, or sudden deposition of MTDs in the basin center could reduce the effective stress by ~30 %. For the failure stage, we carried out a regional susceptibility mapping using normalized parameters. We found that the slopes of the basin are quite safe under static conditions and most areas show factors of safety of 3 and above. A pseudo-static analysis (calibrated with dynamic parameters) indicates that maximum potential earthquake loading could involve failure of sectors of the basin's western slope, where gradients exceed 20º and faults provide the most intense ground shaking. Although not analyzed in detail, the depth to the base of the gas hydrate stability zone also seems to play a role in occurrence of slope failures. To characterize post-failure evolution, we set up a series of numerical models to reproduce the main features of a 23,5 +-8.3 km3 debris flow with a runout of 152 km using Herschel-Bulkley rheology in the depth averaged code MassMov2D. The latter was modified to account for buoyancy, remoulding and drag forces. We found no value that actually allows to accurately reproduce the pattern of sediment distribution

within the debris flow, likely indicating the turbiditic nature for the deposit most distal part. The models with the highest yield strengths display limited runout distance, while those with the lowest yield strength lead to large lateral spread and fail to reproduce the pattern of thickness distribution. The simulations imply, however, that significant wetting (i.e., a gradual reduction of yield strength) of the materials involved in the debris flow must occur as deformation proceeds. The yield strength also controls initial velocity history of the failed mass. Coupling the landslide dynamics to a NLSW tsunami model (GeoClaw) shows that the landslide is clearly subcritical and produces trains of 2 km long waves. Instantaneous onset of the landslide compared to more gradual release produced slightly larger waves and more energy focused towards the Korean coast. Bathymetric features such as the Hupo Bank focus tsunami energy. Resulting tsunami waves are up to 0.6 m in 50 mwd considering gradual landslide release and up to 0.8 m considering instantaneous landslide release. These should be translated to runups of a few meters at the coast.

Generation and propagation characteristics of submarine-landslide tsunami

Ao SHEN[1]*, China University of Geosciences, 388 Lumo Road, Hongshan District, Wuhan (cugshen@cug.edu.cn)
Qiliang Sun[2], China University of Geosciences, 388 Lumo Road, Hongshan District, Wuhan

Abstract

Tsunamis generated by submarine slope failures have the potential to cause devastating consequences. Quantifying the potential tsunami impact caused by landslides is particularly crucial for geohazard assessment. Separating tsunami wave signals from other influencing factors (e.g., wave refraction and reflection) would be greatly helpful for understanding wave propagation characteristics and improve the accuracy of tsunami prediction. This paper numerically investigated the processes of landslide deformation, tsunami generation and propagation in the Xisha Islands, South China Sea (SCS), and evaluated the impacts of resonance, wave refraction and reflection on the time series characteristics of tsunami waves, and quantified them during wave propagation. The tsunami waves generated by submarine landslides have strong dispersion, which is different from those generated by earthquake. They are mainly concentrated around the Xisha Islands, with the maximum wave height of ~10 m. The landslide process has an obvious influence on the initial tsunami wave. The waves usually have a chirp change in frequency. By decomposing and analyzing the time series of tsunami wave, the wave signals can be reconstructed by two components, characteristic components 1 (CC1) and 2 (CC2). The former (CC1) is characterized by small-amplitude, high-frequency, short-period waves; the latter is characterized by high-amplitude, low-frequency, long-period waves. CC1 represents the normal tsunami wave without influencing by other factors; CC2 represents the tsunami wave influenced by resonance, wave refraction and reflection. This study suggests that morphology could greatly influence the propagation of submarine landslide-generated tsunami. It also indicates that tsunamis generated by submarine slope failure are a significant geohazard to the islands of SCS and should be considered during the assessment of SCS geohazard. The results would improve the understanding of the processes and characteristics of submarine landslide-related tsunami generation, and also improve the hazard assessment in coastal areas.

Factors controlling carbonate slope failures: Insight from stratigraphic forward modelling

Jianliang LIU[1]*, China University of Petroleum (East China) (liujianliang@upc.edu.cn)
Keyu LIU[2], China University of Petroleum (East China)

Abstract

A carbonate slope links platform and basin-floor regions holding crucial information on the carbonate source-sink system of a vast ocean. There is a generally poor understanding of the entire process of carbonate slope deposition, failure, and subsequent transportation and re-deposition etc. due to the lack of field observation and adequate numerical modelling algorithms. Based on a comprehensive literature review on carbonate slope failures, a three-segment carbonate slope depositional model was conceptualized and simulated using a stratigraphic forward modelling (SFM) program. The model is capable of simulating carbonate slope failures in a) subaerial, b) shallow marine, and c) deep marine settings concurrently. The SFM program was employed to simulate the evolution of carbonate slope and the occurrence and distribution of mass transport deposits (MTDs) in a deeply buried upper Ediacaran carbonate succession in the central Sichuan Basin, China. The simulation results show that MTDs were mainly developed at the toe-of-slopes and in the center of the Ediacaran trough, offering a new potential play for future hydrocarbon exploration in the area. Several key factors controlling carbonate slope failures, including carbonate lithologies, carbonate growth rates, and frequencies and amplitudes of sea-level fluctuations, were quantitatively evaluated in both time and space domains. Simulations have confirmed that carbonate lithologies can notably affect the frequency and magnitude of slope failures and the development of MTDs, indicating that the higher the proportions of coarser and cemented sediments, the less frequent slope failures and the less the volume of the MTDs would be. The frequency of slope failures and the volume of the MTDs would increase with carbonate growth rates. Slope failures are more likely to be triggered by high-frequency sea-level fluctuations than by low-frequency sea-level changes. For a given sea-level change frequency, the magnitude of a single slope failure event and the total volume of associated MTDs are more likely to be more significant under a greenhouse climate, with a relatively smaller amplitude of sea-level changes, than under an icehouse climate.

Analysing submarine landslide distribution along the Calabrian continental margins, insights from high-resolution morpho-bathymetric data.

Marco BIANCHINI[1]*, Institute of Oceanography and Applied Geophysics (mbianchini@ogs.it)
Silvia Ceramicola[2], Institute of Oceanography and Applied Geophysics
Daniele Casalbore[3], Sapienza, University of Rome
Francesco Latino Chiocci[4], Sapienza, University of Rome

Abstract

Submarine landslides are common geological features occurring on the seafloor and at the same time difficult to characterize, but very important for the assessment of geohazards for a given area.

The geodynamic evolution of the Mediterranean region caused steep continental margins, canyon formation, seismicity, high uplift, and sedimentation rate that played an important role as preconditioning and triggering factors for landslide occurrence. This has led the southern Italy continental margins to be among the most landslide-prone regions of the Mediterranean Sea.
Our work consists in the inventory, mapping, morphometric parametrization, and statistical analyses of about 2000 morphological features related to mass wasting processes occurring in continental slope of the active Calabrian arc (uplift rate up to 1 mm/y). Namely the analysis was performed in two areas, in back arc (Tyrrhenian) and forearc (Ionian) settings, driven by the subduction and roll-back of the Ionian plate under the Calabrian Arc. The research is part of Ph.D. programme in the framework of a PNRR national project “Geoscience IR” and will make use of an extensive high-resolution morphological dataset acquired during the Magic project.
Due to the difficulties in carrying out direct in-situ observations and geotechnical parameterization of landslides in the submarine realm, the morphometric analysis seems to be a useful tool that allow us to analyse the amount of submarine landslide, and therefore, balancing the lack of information using a statistical analysis on the control factors.
For the reason we make use of the extensive high-resolution MaGIC bathymetric dataset (about 15.000 km2) to analyse landslide morphologies (aspect, ratio, length. volumes...) to assess existing relations between landslide occurrence, their shape, and spatial distributions. To do this we will make use of several thematic maps derived by the bathymetry (contour, shaded relief slope, roughness, gradient ...).
The overall aim is to use bathymetric derived information to gain better understanding of the triggers and driving mechanisms causing a slope to fail and recognise spatial correlations between submarine landslide occurrence and other geological factors, as well as being able quantify landslide occurrence. Gaining a better understanding of failure dynamics will allow us to develop an increasingly accurate hazard estimates of the seabed.

Multistage submarine landslides and their effects on widespread seeps, shallow gas and gas hydrate occurrences

Xiujuan WANG[1]*, Ocean University of China (wangxiujuan@ouc.edu.cn)

Abstract

Multistage mass transport deposits (MTDs) or submarine landslides have been delineated using three dimensional (3D) seismic data in the sedimentary basins of the world oceans, especially in the deep-water basins. Moreover, widely distributed gas hydrate, shallow gas and numerous paleo-seeps or active seeps are also found from 3D seismic data, in situ detection and multibeam data. Gas hydrates been confirmed by logging-while-drilling and coring with different morphologies and even coexistence with free gas in some areas. Gas hydrates are found below or within MTDs above the base of gas hydrate stability zone (BGHSZ) showing layered or mounded-like structures which is controlled by the internal structure of MTD and the fluid flow. Mostly seeps and the high concentrated gas hydrate are found in the sand-rich reservoir above the shallow gas trapped zones, where the faults and gas chimneys zones root from basement uplift. More than 200 chimney-like and mounded-like structures are identified above MTD near the BGHSZ from 3D seismic data in the Qiongdongnan basins, South China Sea. The thrust faults and fractures are found within the MTD using the geophysical attributes which provide pathways for fluid flow migrations. Detailed studies show that the fluids migrated from the structural faults and the tensile faults directly above the basement uplift which contribute to the accumulated shallow gas, seeps and gas hydrate. However, we found that the long-distance fluid migration along sand-rich below MTD provides the main gas resource for the gas trapped below MTD. We quantitatively reveal that a similar vertical distribution of gas hydrate saturation can be formed around the open faults above the base of hydrate stability zone and the thermogenic gas migration along faults contribute to enrichment of gas hydrate. The integrated studies provide a better understanding how the fluids can pass through the MTD and form seeps, shallow gas and the concentrated gas hydrate.

Cesare Angeli[4], Dipartimento di Fisica e Astronomia "A. Righi" - Università di Bologna, Italy
Martina Zanetti[5], Dipartimento di Fisica e Astronomia "A. Righi" - Università di Bologna, Italy
Alberto Armigliato[6], Dipartimento di Fisica e Astronomia "A. Righi" - Università di Bologna, Italy

Abstract

The Ionian Calabrian Margin (ICM, located in south Italy) is deeply incised by submarine canyons and failure scars, testifying an intense mass movement activity, enhanced by the steep slopes and the continuous sediment supply from the dryland, favoured by the rapid uplift (1 mm/a) the margin is undergoing since 1 Ma.

High-resolution bathymetry and 2D seismic surveys acquired by OGS revealed in detail the morphology and the acoustic facies of multiple failure events that occurred along the steep slopes (from 110 to over 1500 m depth, around 9° average incline) of the ICM and only 5 km away from the coast. The analysis and interpretation of geophysical data allowed to reconstruct the failure dynamics, defining in particular three landslide geometries, with their volumes and run out. These pieces of information have been used to simulate failure scenarios and the potential ensuing tsunamis, together with the quantification of the possible effects of the latter on the coastline in terms of maximum tsunami amplitude, inundation depth and penetration distance.

The whole phenomenon is evaluated by means of numerical techniques, developed by the University of Bologna research team: the landslide dynamics is simulated through a numerical code able to reproduce the time evolution of the landslide shape and motion, factors that deeply influence the tsunamigenesis; the generated wave propagation is mimicked by a shallow-water equations solver, able to quantify the impact of the sea level perturbation on the coast.

The simulations produce maximum wave amplitudes of more than 2 m that, though not catastrophic, are certainly able to produce damage to boats and coastal infrastructure. Land flooding is limited, due to the steep slopes characterizing the coasts, but the riverbeds act as preferential direction for onshore penetration of the tsunamis, that can climb inland for hundreds of meters far from the coast. Coastal shelf-indenting canyons located south of the modelled failures and only some hundreds of meters away from the coast also play an important role in the coastal expression of the tsunami. Moreover, these scenarios have been taken as the basis for a sensitivity analysis that explored the influence of landslide parameters on the generation of the tsunami, bringing new light to the hazard analyses of this portion of ICM.

(Withdrawn) Causes of Mass Transport Complexes (MTCs): Implications for the Guyana Basin

Deron Saul[1]*, Heriot-Watt University (dos2@hw.ac.uk)
Uisdean Nicholson[2], Heriot-Watt University

Abstract

The Guyana Basin, a large sedimentary basin situated off the north-eastern coast of South America holds a repository of stratigraphic data that provides insights into the causes and consequences of submarine landslides. The upper Cenozoic stratigraphic record of the Guyana Basin is dominated by mass transport deposits (MTDs). In this study we seek to understand their distribution in time and space, ultimately to understand their preconditioning and triggering mechanisms and to better mitigate the risks to people and submarine and coastal infrastructures.

Numerous moderate to giant (10^2 to 10^3 km3) MTDs were mapped using 2D seismic lines across the Guyana Basin. They often consist of stacked geometries with individual MTDs which eroded into older deposits forming mass transport complexes (MTCs). In some cases, the MTDs were larger than the 8100 BP Storegga Slide.

The persistent failure of the continental slope of the Guyana Basin is likely related to significant increases in sedimentation rates that began in the Tertiary. This was likely associated with tectonic uplift and paleoclimatic conditions which promoted significant erosion and sediment routing to the basin since that time. Because of the increase in sediment accumulation rates, overpressure generated by disequilibrium compaction since the Miocene may have been the preconditioning mechanism. The triggering mechanisms are likely related to seismicity at the Caribbean and South American Plate Boundary, particularly since the Pliocene.

There was a gentler and extended slope during the Miocene in the southwestern Guyana Basin while there was a steeper slope and more occurrences of frequent MTDs in the southeastern Guyana Basin. However, the modern southwestern slope is steeper, and dominated by MTDs, more than anywhere else in the basin. Thus, this active area of persistent failures which is closer to the ongoing collision between the Caribbean and South American Plate may be more prone to submarine landslides. This may have implications for damages to subsea infrastructure and tsunami hazards for Guyana's coast. The modern continental shelf is most extensive in the southeastern Guyana basin and contains fewer MTDs, indicating more stability and the potential for less frequent but larger submarine landslides in this region.

Ground subsidence studies of Mumbai city, India using InSAR

Santhosh Kumar SAKTHIVEL[1]*, CSIR-National Institute of Oceanography
(san.santhos@gmail.com)
Mani Murali R[2], CSIR-National Institute of Oceanography
Deepika Dwivedi[3], CSIR-National Institute of Oceanography

Abstract

Coastal subsidence or uplift is a predominant problem in many coastal cities that are least explored and requires significant attention to know the status of the cities. The sinking land and rising sea levels make the deformation situation alarming. The coastal cities of India experience a rise in sea level, but the effect on the subsidence rate of these cities is still unknown. The coastal megacities of India hold high socio-economic importance as most of them are highly populated and have substantial economic returns to the country. This study explored the subsidence rate of Mumbai city, which is the financial capital of India and is under serious threat due to many coastal disasters. The Mumbai's line of sight (LOS) deformation rate was derived from January 2018 to November 2023 using C-band Sentinel 1 on-demand interferometric synthetic aperture radar (InSAR) data. A time series analysis using Mintpy revealed high subsidence in some regions of Mumbai, such as the Deonar dumping area, Wadala, and the railway track behind the IMC-limited land Sangam Nagar. Overall, the subsidence values in these areas vary between -5 and -2.5 cm from 2018 to 2023. The elements contributing to this deformation revealed changes in land use and land cover (LULC) pattern. Increased urbanization with groundwater exploitation makes the regions subside at a higher rate than expected. These areas also fall into established high flood-prone parts of the city. The predicted inundation regions due to the rising sea level are also closer to these places, showing high subsidence rates. The combined effect of land sinking, groundwater running down, increased urbanization in flood-risk areas, and rising sea level pose a serious threat that needs to be addressed and monitored. Land subsidence and its consequences should be considered for effective coastal planning and management.

Tapping into Potential: Unveiling Geological Dynamics and Geohazard Risks in the Potiguar Basin, Brazil

Yasmym Consthance SILVA[1]*, Federal University of Rio Grande do Norte (yasmym.silva.701@ufrn.edu.br)
Helenice VITAL[2], Federal University of Rio Grande do Norte, Postgraduate Program in Geodynamics and Geophysics (PPGG), Brazil

Abstract

The Potiguar Basin, situated in the Brazilian Equatorial Margin, represents an exploratory frontier situated within a complex geological framework. Studies have demonstrated its significance as a crucial reservoir of valuable hydrocarbon reserves, making it a promising area for exploration and potential oil and gas discoveries. Additionally, the Potiguar Basin stands out by possessing one of the largest offshore wind potentials in the region, further enhancing its significance in both the energy and exploration sectors.

Despite the substantial potential inherent in this basin, it remains relatively unexplored and poorly understood, particularly concerning its seabed and subsurface. Recognizing this challenge, the aim of this study is to comprehensively map the seafloor in the slope between the cities of Caiçara do Norte and Guamaré, encompassing depths ranging from 100 to 2000 meters. The data was collected within the scope of the SeabedMap project during the month of June 2022 aboard the Hydro-oceanographic vessel Cruzeiro do Sul, in a partnership between Brazilian educational institutions, the Brazilian Navy and the Brazilian Geological Service. Data from multibeam bathymetry (MBES), high-resolution seismic (CHIRP), measurements of speed of sound along the water column (XBT) were acquired.

In addition to being imaged for the first time with multibeam bathymetry, the results revealed several features, predominantly canyons, on the studied slope. Despite the Potiguar Basin being on a passive margin, the identified canyons exhibit steeper, shorter, and more closely spaced characteristics compared to others in its vicinity, introducing a unique geological dimension to its dynamics. This comprehensive mapping not only enhances our understanding of geological processes but also aids in identifying potential geohazards, such as submarine landslides, with significant implications for seabed stability.

The presence and characteristics of these canyons on the slope offer valuable insights into past or potential submarine landslide activity, contributing to a broader understanding of the geological dynamics and risk factors associated with the Potiguar Basin. This comprehensive approach is pivotal not only for advancing energy exploration but also for safeguarding environmental sustainability in offshore operations. Furthermore, these initiatives in the Potiguar Basin, including mapping the continental slope, align not only with the objectives of SDG 14 - Life Below Water, but also of SDGs 4 – Quality Education, 5 – Gender Equality, and 13 – Climate Action. These efforts also resonate with the goals of the Decade of the Ocean, focusing on enhancing scientific capacity, deepening understanding of ocean interactions, and promoting the utilization of ocean

knowledge for sustainable development. This integrated approach contributes to a more informed and responsible management of marine environments and resources.

Abstract

A large proportion of the world's megacities rely on groundwater resources stored in underlying coastal aquifers. These systems are often geologically heterogeneous and contain both natural and human-engineered structures, for example, in land reclamation areas that make subsurface hydraulic properties unpredictable and challenging to investigate. The interactions of submarine groundwater discharge (SGD) and seawater intrusion (SWI) exert a major control on the onshore-offshore fluxes of organic carbon and nutrients. Characterizing groundwater dynamics in coastal aquifers is fundamental for understanding both processes and their interaction, yet investigating these systems has remained understudied to date due to a scarcity of observational data. Exploring the various spatiotemporal scales of drivers that limit, or enable SGD and SWI especially in land reclamation areas is a knowledge gap in coastal groundwater research. We aim to bridge this gap through a case study along the South Flank of the Yangtze Delta in the Nanhui artificially restored wetland and tidal flat system of the greater Shanghai coastal region. We integrate ground penetrating radar (GPR), drone remote sensing, and borehole groundwater sampling collected over three field campaigns to draw inferences on how the groundwater system is responding to a recent large-scale ecological restoration project. We find that although the land surface (i.e., vegetation cover) changed considerably over a six-month period during restoration activities (November, 2022 – May, 2023), subsurface structures imaged by the GPR show little change over tidal and seasonal cycles. On the other hand, a sharp change in groundwater salinity, pH, and Fe concentrations at a narrow zone near the high-tide line is observed. A localized Fe-enriched signal in the groundwater dissipates and deepens from November, 2022 (beginning of the restoration) to May, 2023 (end of the restoration) that likely reflects a change in the redox conditions within the sampling site. This change in Fe concentrations within the liquid phase is corroborated by a strong and persistent reflector in the GPR data that is more sensitive to Fe in the solid phase. The coincidence in variations between groundwater Fe concentrations and GPR signals suggest a strong interaction between the groundwater and surrounding reclaimed material at the study site. Our study thus offers a unique "before" and "after" view into the response/recovery mechanisms of this complex engineered coastal system.

Analysis of major Shoreline changes along southern Karnataka coast,India for Five Decades.

Gayathri Nivedha Nivedha R[1]*, Masters student, NITK (gayathrinivedha05@gmail.com)
Ramesh H [2], Professor,NITK

Abstract

Coastal erosion is a natural phenomenon affecting a large number of coastal areas. The coastal zone is an area with immense geological, geomorphological and ecological interest. Monitoring and mitigation of shoreline erosion along populated coastal areas is an important task and remains a difficult goal to achieve.

The coast of Karnataka state extends from Talapadi in south to Sadashivgad in north covering a distance of about 280 km. In this study, an attempt has been made to investigate the shoreline transformation along the Karnataka coast. Fair weather satellite images of CORONA (1965), LANDSAT from 1975 to 2016 with an interval of ten years were used to delineate the shoreline.

The main purpose of the work is to provide a systematic historical information on shoreline change along Karnataka coast using multi resolution satellite data (Landsat (MSS, TM & ETM+) and Geographic Information System (GIS) for past 50 years period i.e. from 1965 to 2016. The six historical shorelines (1965, 1975, 1985, 1995, 2006 and 2016) were used in GIS for computing the shoreline change rate along the coast.

The analysis revealed that about 70% of the coastline was either stable or accreting in nature, whereas remaining 30% region was experiencing varying magnitude of erosion. The change rate was classified in three categories indicating the accretion, low erosion and high erosion locations. The erosion and accretion pattern observed along the coast is influenced mainly by the coastal process and riverine inputs. Area of study is mainly considered to be a part of tourist economy and 75% of the regions occupation is based on the coastal belts of southern Karnataka, India.

Erosion was found in isolated pockets throughout the coast. The variation in river mouth morphology was quite significant. The present study demonstrates that combined use of satellite imagery and statistical method such as weighted linear regression can be a reliable method for shoreline change analysis.

Monitoring time-series surface deformation of coastal port area in Busan with space-based radar interferometry

Seongcheon PARK[1]*, Pusan National University (parksc@pusan.ac.kr)
Sanghoon HONG[2], Pusan National University
Jeyun LEE[3], Pusan National University

Abstract

Coastal areas that are adjacent to the sea have been developed continuously because of its advantage of resource transport and accessibility. These regions are suitable for the construction of social infrastructure such as ports, airports and urban areas. Thus reclamation projects have been conducted to expand the coastal areas. Because, however, coastal reclaimed land is vulnerable to several natural hazards like sea levels rise, land subsidence, and soil erosion, it is necessary to monitor continuously for geohazards prevention. For monitoring coastal reclaimed land, Global Navigation Satellite System (GNSS) and traditional leveling surveys are widely used. Although its high accuracy of monitoring displacement, these have limitations in terms of spatial resolution and high cost over large areas. To overcome these limitations, remotely sensed Synthetic Aperture Radar (SAR) dataset from space have been utilized in volcanoes, earthquakes, and land subsidence. The SAR satellite is a useful tool that can acquire high spatial resolution data at a relatively low cost for extensive areas in all-weather conditions by transmitting microwaves to the surface.

In this study, we apply differential interferometric synthetic aperture radar (DInSAR) to observe surface displacements on the new port that is coastal reclaimed land in Busan, South Korea. The DInSAR technique calculates the phase difference between two SAR images acquired at different times and obtains surface displacements by removing the topographic phase using known topographic information from an existed Digital Elevation Model (DEM). We utilize three datasets comprising COSMO-SkyMed X-band data acquired from 2016 to 2019 and Sentinel-1 C-band ascending and descending orbit data from 2016 to 2021. The Small BAseline Subset (SBAS) technique, which is one of fascinated time-series DInSAR analysis method, was used to observe time-series surface deformation occurring in coastal reclaimed land. The results show significant land subsidence in the eastern part of the new port. The subsidence rate in vertical direction at randomly selected point A was approximately –1.55 cm/year and –1.90 cm/year from Sentinel-1 ascending and descending orbits data, respectively, and –2.80 cm/year from COSMO-SkyMed data. In contrast, we also observe slight ground uplift phenomenon in the western part of the new port. The ground uplift rate in vertical direction at randomly selected point B from Sentinel-1 ascending and descending orbits was approximately 0.08 cm/year and 0.20 cm/year, respectively, and COSMO-SkyMed is showing a uplift rate of about 0.28 cm/year. The ground uplift behavior occurred along the region that underwent mountain excavation for development, and it is inferred to be an isostatic rebound resulting from the compensation in regions where the loss of mass

occurred. To verify surface deformation observed by radar interferometry, we compared with bouguer anomaly data caused by changes in density beneath the surface using satellite gravity observations. Our results suggest that the SBAS technique is efficient method for monitoring time-series surface displacements in coastal reclaimed land, representing the necessity for continuous monitoring of coastal reclaimed land using space-borne synthetic aperture radar.

Earth observation on Asian Mega-deltas environment risk under climate changes and mitigation strategy for sustainable development

Ping YIN[1]*, Qingdao Institute of Marine Geology,China Geological Survey
(yinping@mail.cgs.gov.cn)
Jingpeng LIU[2], Qingdao Institute of Marine Geology,China Geological Survey

Abstract

Delta and estuary are the link between the land and the sea, the early settlements for our ancestors and still embrace most of the megacities today. Delta and estuary also provide important ecosystem combining the terrestrial and marine eco-functions, they are the most dynamic interaction of biosphere-hydrosphere-pedosphere. Delta and estuary locate on low-land region along the world-wide coast and are exposed to threats from both land and sea, such as the catastrophic flooding, storm surges, tsunamis as well as the long term impact of global warming and sea level rise. Land uses through history and urbanization have greatly changed the feature of global deltas and estuaries and lead to reduction of these important ecosystems. Coastal erosion, land subsidence, pollution and wetland degradation in the delta and estuary areas are global challenges which need more earth observation (EO) data to support the stakeholder decision-making via local, regional and global scales for sustainable and resilient coastal social-ecological system. Varieties of remote sensing sensors and spatial resolution of data and their availability make it possible to monitor deltas and estuaries and to understand their evolution processes under natural and anthropogenic impacts with unprecedented spatial and thematic detail information, to better understand the pressures of deltas and estuaries and to provide global reliable information in order to improve sustainability and resilience of social-ecological system in global deltas and estuaries.

Integrated Earth Observation on ecosystem and environment changes were applied on the Asian Mega-deltas and estuaries, including the Yellow River Delta, the Yangtze River Delta, the Red River Delta and the Indus River Delta, varying from different climate zone, development stages and geological conditions. These mega-deltas have experienced dramatic changes under the impacts of global climate changes and anthropogenic impacts in the past century, consequently, these environmental risk are influencing the safety of cities which embanked on the deltas, as well as the economy developments. Geo-information based geo-hazards modeling and future tendency were studied to provide functional delta management strategies for adaptation to climate change, smart spatial planning for risk mitigation.

Construction of hydrogeological database of coastal reclaimed land considering underground development in industrial area

Juhee KIM[1]*, Korea University (juhee97218@korea.ac.kr)
Soonjae LEE[2], Korea University

Abstract

The development of underground in coastal reclaimed lands typically involves deep excavation resulting groundwater leakage. Various hydrogeological information is required to manage the risk related to groundwater. We constructed a hydrogeological database for coastal reclaimed land considering underground development. The study area is a coastal reclaimed land undergoing industrial area development. The geological and hydrogeological data were collected from open-source database and previous subsurface investigations. For the construction of geological model, stratigraphy modeling was conducted using 590 boreholes, digital elevation model (DEM), and the cross-sections. Regression analysis have been used to determine the distribution of geological material. The groundwater system was defined by the hydrogeological model using MODFLOW simulation. A hydrogeological model was constructed based on the geological model and groundwater model for the watershed. The hydrogeological database constructed using ArcGIS (Esri) and Arc Hydro Ground Water (AQUAVEO) could compile and visualize the multiple dimensional geological and hydrogeological information, such as borehole, cross-section, strata, aquifer, water level and groundwater flow. The integrated hydrogeological model could be compiled into the database along with the input data for preprocessing, such as boundary conditions and hydrogeological properties. Considering the underground development, this hydrogeological information could be used to assess vulnerability of underground development. The database can suggest the distribution of hydraulic head at specific development depths and excavation depth limits for the determination of optimal development depth. The hydrogeological database could serve as a useful tool for planning and implementing underground development projects in specialized environments like coastal reclaimed areas.

Geochemical and mineralogical characteristics of beach sediments along the Bay of Bengal coast, Bangladesh

H. M. Zakir HOSSAIN[1]*, Jashore University of Science and Technology (zakirgsd@yahoo.com)

Abstract

The geochemical composition of sediments from Cox's Bazar and Kuakata Beach sites along the Bay of Bengal coasts, Bangladesh, has been carried out to determine provenance, maturity, and weathering conditions. The mineralogical composition reflects abundant quartz, followed by feldspar and lithic fragments, inferring a quartzose recycled provenance. All samples contained a significant portion of zircon, rutile, magnetite, apatite, epidote, and monazite. The Cox's Bazar Beach sands contained high SiO2 (84-90 wt.%) and low Al2O3 (4.4-6.4 wt.%), while the Kuakata Beach sands have low SiO2 (63-79 wt.%) and high Al2O3 (9.0-11.3 wt.%). Concentrations of the investigated sediments show similar dispersal patterns with high enrichment of Th and SiO2 compared to the UCC. Lead, Rb, Y, Ga, Sr, and Fe contents of the Kuakata Beach sediments are slightly elevated than UCC, and the remaining elements for both sites are strongly depleted, suggesting the destruction of feldspar in the fluvial transportation pathways. The beach sediments of both locations are classified as subarkose and litharenite and compositionally low mature to immature. Chondrite-normalized REE patterns for the beach sandy sediments show high enrichment of LREE and flat HREE (LaN/YbN, 7.6-9.4 and 5.5-8.8, respectively) coupled with marked Eu anomalies (Eu/Eu*, 0.5-0.7 and 0.5-0.8, respectively), indicating felsic source composition. Discriminant function diagrams, elemental ratios, and REE parameters suggest that both beach sediments originated from felsic rocks, with compositions similar to the average rhyolite, granodiorite, granite, and UCC. The ICV, CIA, and PIA proxies, Rb/Sr, and K2O/Rb ratio values show low to moderate chemical weathering intensity in the source. This result suggests that the strength of Himalayan monsoon climates might control the intensity of the chemical weathering patterns in the sediments.

Investigation of coastal dynamics in the Nakdong Estuary using sediment core biogeochemistry

YUNJI KIM[1]*, Korea Institute of Ocean Science & Technology (helena4818@kiost.ac.kr)
JEONGWON KANG[2], Korea Institute of Ocean Science & Technology
JOOBONG JEONG[3], Korea Institute of Ocean Science & Technology

Abstract

For the last century, the Nakdong Estuary has been undergone continuous physicochemical environmental changes including modification of river discharge, tidal prism, salinity, and nutrient ratio (Si:N:P) by various human activities (e.g. damming, reclamation, dredging), which has changed vegetation, phytoplankton community structure, and other related ecological parameters. For example, changes in river discharge and nutrient ratio (Si:N:P) would have modified primary productivity and phytoplankton community structure (i.e. diatom dominance), and enhanced harmful algal blooms in the estuary and adjacent coastal area. These environmental changes could be well recorded in sediments as various biogeochemical parameters including TOC (total organic carbon), TN (total nitrogen), carbon and nitrogen stable isotope (δ13C and δ15N), biogenic silica (BSi). Therefore, this study aims to investigate the influence of human activities on the Nakdong Estuary by reconstruction of spatial and temporal variation of sediment characteristics and productivity using biogeochemical parameters of sediment cores. We plan to investigate the changes in river discharge (TOC/TN ratio, δ13C), primary productivity (TOC), diatom productivity (BSi), phytoplankton community structure (BSi/TOC ratio), and other related biogeochemical environment by human activities during the last century, using the various biogeochemical parameters of sediment cores collected at back-barrier tidal flat of the major barrier islands in the Nakdong Estuary, Korea.

Lithofacies, Petrographic, SEM-EDX, and Isotope Analyses of Emergent Late Holocene Beachrocks as Sea-Level Indicators along the Negros Trench Forearc, Philippines

Lyndon Jr Nawanao[1]*, Geomorphology and Active Tectonics Research Laboratory, National Institute of Geological Sciences, College of Science, University of the Philippines Diliman, Quezon City, Philippines (lpnawanao@up.edu.ph)
Noelynna Ramos[2], Geomorphology and Active Tectonics Research Laboratory, National Institute of Geological Sciences, College of Science, University of the Philippines Diliman, Quezon City, Philippines
Robelyn Mangahas[3], Geomorphology and Active Tectonics Research Laboratory, National Institute of Geological Sciences, College of Science, University of the Philippines Diliman, Quezon City, Philippines; Department of Science and Technology-Philippine Institute of Volcanology and Seismology, Diliman, Quezon City, Philippines

Abstract

Beachrocks have been widely used as markers of past relative sea-level (RSL) changes. However, a major challenge of beachrocks is constraining their indicative meaning. Different approaches have been proposed to address this uncertainty, from bedding architecture to cement characteristics. Along the forearc of Negros Trench in the Philippines, two parallel, discontinuous northeast-trending strips (BRS1 and BRS2) of emergent beachrocks occur along the coast of southwest Panay Island. In this study, we integrate lithofacies, petrographic, scanning electron microscopy with energy dispersive X-ray spectroscopy (SEM-EDX), and cement oxygen–carbon isotope analyses to better constrain the paleoenvironment of the latest beachrock formation and their indicative meaning. Nine facies were mapped from BRS1 and BRS2, with the topmost units composed of poorly sorted, subrounded coarse sand-to-cobble composed of volcanic lithic fragments with seaward-dipping foreset cross-stratifications. Petrographic analyses of 14 samples collected on the topmost facies in both strips all showed partial to complete isopachous cementation, but the cement type and phases vary laterally, including rims of acicular microcrystalline calcite, acicular aragonite, and micrite envelope. SEM-EDX analysis of cements also revealed a relative abundance of Na, Mg, and Sr of marine affinity compared to Mn and Fe which are of meteoric association. Relatively higher δ13C (-1.15 to +0.55 ‰PDB) and δ18O (-7.57 to +0.15 ‰PDB) also indicate a marine origin, as exemplified by Z values ranging from 123.81 to 127.58. Consistent with lithofacies and isotope analyses, both beachrock strips indicate the latest formation occurring in the subtidal upper shoreface before emergence. This constrained paleoenvironment posits an indicative meaning having an upper (U) and lower (L) limit of mean lower low water (MLLW; -0.61 m amsl) and wave base (-8.91 m amsl), respectively, as well as a reference water level (RWL) of -4.76 m. A maximum RSL of 7.60 m was constrained for BRS1, while 6.43 m for BRS2. Bulk radiocarbon dates of beachrock cement indicate that the BRS1 formed until 5855–4508 cal BP, whereas BRS2 formed until 3128–1825 cal BP. These two beachrock strips imply at least two abrupt RSL fall events after their formation. The absence of

Late Holocene highstands in glacial isostatic adjustment (GIA) RSL models and the anomalously higher maximum RSL elevations of these beachrocks suggest local uplift along the forearc. This study emphasizes the significance of integrating these analyses to establish the indicative meaning of beachrocks.

Characteristics of surface topography and sedimentation before and after typhoons Kompasu and Soulik in the Gochang Donghori intertidal flat, Korea

Woo Hun RYANG[1]*, Jeonbuk National University (ryang@jbnu.ac.kr)
Sol Ip Kang[2], Jeonbuk National University

Abstract

In the macro-tide intertidal flat of the Korean western coast, this study has investigated typhoon effects on the variation of topography, surface sediment texture, sedimentary properties, and sedimentary environment, which appeared before and after the typhoons Kompasu in 2010 and Soulik in 2018, respectively. Along the southwestern coasts and across midlands of the Korean Peninsula, the typhoons Kompasu and Soulik moved from 1 to 2 September 2010 and from 23 to 24 August 2018, respectively. Topography and surface sediments before and after the typhoons were measured and sampled along the survey line in the Gochang Donghori intertidal flat. The intertidal area was divided into the upper tidal zone, middle tidal zone, and lower tidal zone based on mean high water level, mean sea level, and mean low water level. Surface sediments of the intertidal flat consist mainly of very fine to medium sands, and the ratio of fine sand is the largest both before and after the typhoons. Surface sediments after both typhoons became finer in mean grain size showing well sorting rather than those before the typhoon. It is interpretative of the strong wave effect, caused by typhoons. The surface sediment texture of the middle tidal zone shows rare variations and band-shaped deposits appeared in some lower tidal zone intervals.

Abstract

Selection of a candidate site for a submarine space platform is very important in terms of the stability of the structure and the geographical efficiency of users, and there are factors to be considered such as seafloor topographic information and sediment environment characteristics. In this study, factors for evaluating the ground stability of the candidate site were identified and topographic geological information was analyzed through marine physical exploration (bathymetry, side scan sonar) and sediment investigation methods.

As a result of geophysical exploration, the water depth ranges up to 54.7m and increases from the coastline to the open sea (southeast direction). The average slope is 5.5°, and the water depth changes rapidly below 10m, and the seafloor is mainly covered with exposed rock and conglomerate sediments. Due to the distribution of rock mass, the local slope increases and reaches up to 60°. It is a landform with two waterways formed on the sea floor, and ships frequently move through the waterways. At a depth of about 10m to 20m, the seafloor is curved and sandy and coarse-grained sediments are distributed. The proportion of rock mass has decreased compared to the previous depth zone, making it a relatively stable environment, and the distribution of ripples on the sea floor suggests that it is an environment dominated by wave energy. Above approximately 20m, the water depth increases gently toward the open sea, and the seafloor is flat with sandy or sandy-sized sediments distributed. As a result of analysis of surface sediments, sand was dominant in water depths of 10 m or less, showing sandy and silty sand sedimentary characteristics, and as water depth increased, silt and clay were distributed. The sediment content was 0.00~0.86% gravel, 0.00~99.19% sand, 0.00~47.01% silt, and 0.00~100.00% clay, with almost no gravel appearing. The average particle size is –0.05∼6.14Φ, which corresponds to very coarse sand to medium silt. The classification degree was found to be 0.54 to 2.40, which was found to be a spatially diverse energy environment ranging from moderately well sorted to poorly sorted. As a result of analyzing the spatial distribution factors of seafloor stability, the slope of the seafloor and the boundaries of sediment distribution according to water depth were identified. It is believed that this can be used as basic data for an undersea space platform. In addition, future research will contribute to improving the stability and efficiency of candidate site selection by applying a Benthic terrain modeler based on the results of

this analysis.

Spatio-temporal distribution and migration patterns of microplastics on tourist beaches: A case study in the Beidaihe District, North China

Yutao ZUO[1]*, 488568703@qq.com (488568703@qq.com)
Yawen Ge[2], geyawen@hebtu.edu.cn

Abstract

Coastal zones are generally acknowledged to be significant reservoirs of microplastics, posing substantial threats to coastal ecosystems, and human health. However, the extent to which marine-land interaction and human activities impact the occurrence and migration of microplastics on popular tourist beaches remains unclear. We conducted a comprehensive investigation into the spatial and temporal distribution of microplastics on tourist beaches in northern China. The study focused on the disparities in microplastic abundance between beach sediments and seawater, and migration patterns of microplastics within intertidal zones.Additionally, comparisons were made between microplastic levels on tourist beaches versus natural beaches, along with variations across different years. The findings revealed that the mean microplastic abundance in beach sediments was 2,212.0±895.2 items/kg while it was 30,670.8±15,094.9 items/m3 in seawater at Beidaihe coastal zone. The most common shape observed for microplastics was fibers, followed by films and fragments. Transparent, blue, green and black colors prevail among the microplastics found with cellulose and PET being the most common components. Microplastic abundances decreased from high tide zone to low tide zone, and the abundance in seawater was positively correlated with the high tide zone and negatively correlated with the low tide zone, suggesting that microplastics mainly originated from nearshore transport and were significantly influenced by wave sorting. This also resulted in higher microplastic abundance with more complex compositions found at high tide zones thereby posing greater ecological risks. Compared to wave influence, the impact of human activities such as tourism, aquaculture, and fishing on microplastic abundance was relatively limited. There were no significant differences observed in the abundance and composition characteristics of microplastics between tourist beaches and natural beaches, potentially attributed to the wave disturbance. Watershed precipitation and human activity intensity emerged as primary factors contributing to substantial annual variations in microplastic abundance and characteristic compositions.

The Neogene delta-front wave-built sand bodies and their petrophysical characteristics in the Enping Sag of the Pearl River Mouth Basin.

YA XUE[1]*, China University of Petroleum (East China) (1587837149@qq.com)
GUANMIN WANG[2], China University of Petroleum (East China)

Abstract

Enping Sag is situated within the western sector of the Zhujiangkou Basin, part of the Pearl River Mouth Basin. During the Neogene period, specifically the deposition phases of the Hanjiang Formation and Zhujiang Formation, Enping Sag witnessed the development of a series of elongated or tabular wave-generated sand bodies along the deltaic front. These formations exhibit rapid variations in both thickness and connectivity, thereby complicating the comprehension of sedimentary dynamics and reservoir properties. This ambiguity significantly hampers the exploration and exploitation endeavors targeting the Neogene deltaic-front sand bodies in the region.This study, grounded on meticulous interpretation of 3D seismic data, endeavors to elucidate the spatial distribution attributes of deltaic-front sand bodies via attribute extraction and fusion techniques. Furthermore, through detailed scrutiny and analysis of core samples, the deltaic-front sand bodies are classified into two microfacies types: wave-generated sand bars and tabular sands. These microfacies are further delineated into secondary categories including nearshore-frontshore, backshore, and mixed shoal microfacies.Employing a suite of analytical methods encompassing thin-section examination, grain size analysis, and well log interpretation, it is ascertained that medium to fine sand grains, particularly within well-sorted nearshore-frontshore sands, exhibit heightened porosity and permeability, indicative of preferential reservoir facies. The favorable depositional milieu, coupled with attenuated compaction and cementation processes, emerge as principal controlling factors facilitating the genesis of high-quality reservoirs in this setting.

Global lacustrine ecosystems are experiencing a variety of anthropogenic stressors. One such stressor is urban development and contaminant inputs through hydrological connections, leading to water quality degradation. Paleolimnology is a useful approach for assessing changes in water quality of urban shallow lakes. We investigated three urban/suburban lakes in and around the city of Glasgow, Central Scotland to assess environmental change in response to historical anthropogenic stressors. Diatom microfossils, supplemented with plant and insect macrofossils, and geochemical elements, were analyzed in a dated sediment core from each lake to determine chemical and ecological changes over the last 150 years. Ordination techniques were used to explore the shifts in the diatom assemblages. The study found that two of the lakes in more heavily industrialized urban catchments experienced eutrophication in recent decades. The third lake had been managed by private landowners but now is under protection as a nature reserve and did not show a clear sign of eutrophication. Our data suggest that local land-use history and degree of connectivity are important considerations in assessing the onset, degree and nature of environmental change and can result in lakes with varying types of anthropogenic stressors and variable impacts, even within the same small geographical region. This variation needs to be taken into account when designing lake-specific eutrophication management strategies. The potential of paleolimnology for better understanding the impacts of industrialization on urban waterbodies is highlighted.

Variations in paleovegetation and paleoclimate recorded by plant terpenoids in the sediments from Lake Suwa (central Japan) from the last glacial period to Holocene

Ryosuke FUKUCHI[1]*, Hokkaido Universitry (fukuchirs@eis.hokudai.ac.jp)
Nozomi HATANO[2], Natural Environment Division, Nagano Environmental Conservation Research Institute
Ken SAWADA[3], Department of Earth and Planetary Sciences, Faculty of Science, Hokkaido University

Abstract

Sediments collected from and around lake frequently record the change of various depositional environments such as floodplain and wetland depending on scaling of the lake water areas. Such various and unsteady sediments are important sources to interpret paleoclimatic and paleoenvironmental changes. However, there have been few reports for paleoenvironmental and paleoclimatic reconstructions with the glacial-interglacial time scale in Japanese inland areas, especially mountain areas. Lake Suwa (Nagano Prefecture, central Japan) located in mountain area, has changed its water areas, and the sediment core collected from the shore has various sedimentary facies. The authors have mainly reported the paleoenvironmental changes associated with the scaling of the water area by biomarker analysis of the sediment core (Fukuchi et al., 2023). In this presentation, we will focus paleovegetational reconstructions using plant terpenoids in the sediment core from Lake Suwa, especially the changes with the glacial-interglacial climate changes, comparing with previous pollen research.

In our study, we used a sediment core (ST2020) collected from the shore of Lake Suwa. The ages were determined by AMS 14C dating, and the lowermost horizon was estimated to be about 27 cal kyrs BP. The sediments (1-2 cm thick) were extracted by solvents and then separated into fractions by silicagel column. The apolar and polar fractions were analyzed by GC-MS. Sedimentary facies evaluated by sedimentary investigation indicated that the depositional environments changed from meandering fluvial, lacustrine, and delta in the ST2020 (Hatano et al., 2023).

In the ST2020 sediment core samples, gymnosperm-derived diterpenoids (DTs) and angiosperm-derived triterpenoids (TTs) were mainly identified. We established the ratios of sugiol/ΣDTs, totarol/ΣDTs and dehydroabietic acid (DAA)/ΣDTs as vegetation proxies. Considering the DTs such as totarol and sugiol are mainly derived from the Cupressaceae, the sugiol/ΣDTs and totarol/ΣDTs indicate the contributions of the Cupressaceae to the total gymnosperm vegetations. Although the DAA is thought to be widely distributed among various gymnosperm, the DAA/ΣDTs indicates mainly the Pinaceae contribution in the core. This is because the pollen records in the sediments from Lake Suwa suggested that Pinaceae was dominant in coniferous vegetation (Anma et al., 1990). The DAA/ΣDTs were higher in the glacial period, but the totarol/ΣDTs and sugiol/ΣDTs were higher in the deglacial stage. These results suggest that the

vegetation around Lake Suwa converted from subalpine coniferous forest to temperate coniferous forest with deglacial warming. Noticeably, Pinaceae vegetation in DT indicators rapidly decreased but Cupressaceae vegetation indicators showed increasing spikes during the cooling events such as Heinrich Event 1 and 9.3 ka event. Thus, the coniferous vegetation in the mountain areas around Lake Suwa might vary affected by global climatic events, although the detailed mechanism(s) for the linkages need to be examined.

Paleo-oceanographic reconstruction using geochemical and mineralogical proxies from sediment core off Lakshadweep Islands, Arabian Sea

SAINABA N N.K[1]*, GEOLOGICAL SURVEY OF INDIA (sainus@gmail.com)
REMYA C[2], GEOLOGICAL SURVEY OF INDIA
SELVASUNDARAM S[3], GEOLOGICAL SURVEY OF INDIA
PRIYA T N[4], GEOLOGICAL SURVEY OF INDIA
BHUSHAN R[5], PHYSICAL RESEARCH LABORATORY

Abstract

The gravity core of 4.6 m recovered at a depth of 4492m from the Arabian Sea off Lakshadweep Islands was studied to reconstruct/unravel the paleoceanography/ paleoclimatology through detailed and integrated multiproxy analysis of isotopic, geochemical, sedimentological, and micro-paleontological studies. The dominant sediment size of the core sample is mainly silt with subordinate clay and sand. Around 40 kyrs data could be traced through AMS dating. This data was compared with oxygen isotope data for fixing Marine Isotope Stages (MIS) boundaries. MIS-1 represents Holocene and MIS-2 is the Last Glacial Maximum (LGM) and MIS-3 warmer period between 24 and 60 ka. High values for the CaCO3 were observed during LGM with a gradually declining trend during the early Holocene and subsequently marginal increase during the late Holocene. Two conspicuous peaks of OC during ~12 ka years BP at 9 to 10 cm bsf and 24 to 25 cm bsf have been observed. This peak corresponding to the LGM period, however, resulted due to high productivity and better OC preservation because of strong NE monsoonal winds that enhanced nutrient levels in the photic zone. In MIS-3, the negative and positive per mil values of δ18O at various levels down the core. In the alternating warmer episodes of MIS-3, the clay content decreases with a corresponding increase in coarse silt. The higher ratios of Si/Al and low TOC at this climatic event indicate the increased influx of silt-sized terrigenous sediments to the basin. The incidence of more quartz grains in the sediments at these levels also supports this. Ten species of Planktonic foraminifera are most abundantly present in this core, among which *Pulleniatina obliquiloculata*, *Globorotalia menardii*, *Neogloboquadrina dutertrei*, *Globigerinoides conglobatus*, *Globorotalia tumida* reflects tropical warm water climate. The sedimentation rate is calculated in comparison with AMS age data as 0.016 cm/yr (0.16 mm/yr). Within a time span of 39960 years, 4.6 m thick sediments were deposited and Marine Isotopic Stage up to MIS-3 could be traced. In the top 118 cm of the sediment column covering late phases of MIS –3, LGM (MIS-2), and Holocene (MIS-1), the sedimentation rate is comparatively low in the order of 0.005 cm/yr to 0.001 cm/yr. From 118 cm bsf to 350 cm bsf, the sedimentation rate is higher in the order of 0.049 cm/yr, which may be due to the high intensity of monsoon or prominent warmer climatic conditions at the mid of MIS-3. It implies that, there is a decreasing trend in sedimentation rate from MIS-3 to LGM followed by Holocene.

Hydroclimatic Variability during the 4.2 ka Event: Insights from a High-Resolution Diatom Record in Korea

Ara CHO[1]*, Korea Institute of Geoscience and Mineral Resources (joara5813@kigam.re.kr)

Abstract

Understanding the East Asian monsoon holds significant importance within the realm of climate change, given its far-reaching impacts on society, culture, and the environment. While previous research has generally depicted the 4.2 ka event as a widespread abrupt cooling episode in the Northern Hemisphere, its hydroclimatic effects have displayed regional variations. Currently, the weather dynamics on Jeju Island diverge notably from those on the mainland, with precipitation levels showing altitude-dependent variability. Our study, which draws upon diatom assemblage data collected from Sara-oreum and Muljangori wetland, volcanic cones located on Jeju Island in South Korea, highlights the prevalence of tychoplanktonic species during this period. Through meticulous monthly analysis, we found that during the 4.2 ka event, tychoplanktonic species like *Aulacosiera alpigena* were notably abundant in July, whereas a similar species, *Aulacoseira nygaardii*, reached peak abundance at Muljangori wetland. These observations suggest a humid climate prevailing during this timeframe. Moreover, the abundance of tychoplanktonic species such as *Aulacosiera alpigena* correlates with the westerly effect index during the Holocene. Although precipitation patterns between Sara-oreum and Muljangori wetland exhibit notable similarities, the results from Sara-oreum appear to be more influenced by the westerly jet due to its higher altitude. The reinforcement and southward shift of the westerly jet might have prolonged the rainy season over Jeju Island and central China.

Abstract

A ten-day geophysical survey was conducted in the largest saline lake, Lake Van (<450 m in depth) by a Turkiye-KIGAM joint research team. The study area is located in the eastern part of Turkiye near the borders to Syria and Iraq. The main purpose of the survey was to search and identify any earthquake-induced change in the lake floor sediments, which were possibly resulted from the 2011 Van earthquake (up to 7.2 in magnitude). More than 650 line-km-long records of a chirp-type acoustic profiler were achieved along previous survey tracks made before the 2011 earthquake. Six cored samples were also recovered in the eastern part of the lake floor using a handheld gravity corer. Several signatures in the acoustic images indicating syn- or post-earthquake deformation, movement or redeposition of the lake floor sediments could be recognized along with subaqueous slope failures and shallow gas anomalies. In some records new acoustic turbid zones were found, which were invisible in the previous survey records acquired before the 2011 Van earthquake and possibly be formed during the period of ground movement. This study shows a good example of repetitive surveys applicable to investigate and monitor subaqueous hazardous elements and their characteristics in earthquake-prone areas.

Late Holocene hydroclimate changes in Tsushima Island, Japan

Jaesoo LIM[1]*, Korea Institute of Geoscience and Mineral Resources (limjs@kigam.re.kr)
Kota KATSUKI[2], Shimane University

Abstract

To predict future water availability in a small island in response to anticipating global warming, it is essential to understand past behavior of hydrological changes in terms of its frequency and controlling factors. Based on the geochemical analyses (carbon isotope, C/N ratios), we investigated past hydroclimate variability using coastal sediments in Tsushima Island where freshwater input has been constrained by limited catchment area, suggesting high sensitivity to small precipitation. The time series of C/N ratios in a bay clearly indicate decreasing trend during the last 3000 years, suggesting decrease in the influence of terrestrial plant. And this can be supported by increasing trend in the time series of the δ13CTOC values. This long-term trend is superimposed by low-amplitude fluctuations at multi-decadal to millennial variability. Significant peaks are found at 700 and 2000 cal yr BP, and troughs are found at 400 and 1700, and 2700 cal yr BP, suggesting remarkable shifts in the hydroclimate change over study area. To test more high-frequency variability in the time series of the C/N ratios, we subtracted its long-term trend described by three-order polynomial (dashed line) and their detrended values were achieved. Using this detrended C/N ratios, spectral analysis was performed. The result reveals prominent three periodicities (1300, 645, and 134 years), indicating significant centennial to millennial fluctuation in hydroclimate changes in the island.

Abstract

Recently extreme climate events have been increasing due to global warming, accordingly the importance of research on the climate event is increasing and such information is considered very important to prepare for future climate prediction. To trace past extreme climate changes, paleo-hydrological fluctuations were reconstructed using 10 m-long sedimentary cores (20CR-02) from Yongho paleo-lake located in Changnyeong area, south korea. Radiocarbon dating was performed using plant fragments in the lake sediments. Particle size analysis and XRF core scanning were performed to determine the physical and chemical characteristics of the sediment layers. Radiocarbon dating results indicate modern age at about 1.5 m and 4500 cal yr BP at about 8.5 m in depth, suggesting that the paleolake sediments were deposited over the past 4500. The time series of the median grain size and elemental ratios (e.g., Zr/Ti and Zr/Rb ratios) showed similar variability. For example, the Zr/Ti ratios significantly increased at 800, 1200, 2000, 2400, 4400, 5000 cal yr BP, suggesting increased heavy rainfall events. Dry periods based on the Zr/Ti and Zr/Rb ratios were found at 1000, 1600, 3000-3800 cal yr BP. These multi-centennial hydroclimate fluctuations in the study area seem to have been influenced by regional summer monsoon changes coupled to sea surface temperature in Western Pacific.

Abstract

Understanding the determinants of extreme hydrological climate change is critical to mitigating the impacts of floods and droughts causing by global warming. Historical records can provide useful parallels to the past, but continuity must be tested and gaps filled based on data from reliable long-term climate records. This study delves into reconstructing the intensity of summertime extreme rainfall during the middle to late Holocene period by analyzing median grain size, strontium/titanium (Sr/Ti), and zircon/titanium (Zr/Ti) ratios of sediments from the Gaho Paleolake core in the southern Korean Peninsula. Centennial-scale variations, evidenced by concurrent decreases or increases in grain size, Sr/Ti, and Zr/Ti ratios in lake sediments, exhibit strong correlations with historical droughts or floods, such as the megadrought period (AD 1593–1698), and fluctuations in sea surface temperature in the western North Pacific region. Notably, pronounced declines in grain size and Zr/Ti ratios around AD 900–1000 and 1300–1400, as observed in the lake sediment records, suggest a direct association between extreme drought events and the downfall of ancient civilizations—namely, the Unified Silla and Goryeo kingdoms on the Korean Peninsula. This research underscores the Sr/Ti and Zr/Ti variations in Gaho Paleolake sediments as proxies for historical flooding and drought events, aiding in bridging gaps within incomplete historical records. Furthermore, also provides a deeper understanding of how historical disasters

Sedimentary diatom records and climate and environment changes of Yazihai Lake, Ningwu County, Shanxi Province before and after the 4.2 ka event

Huiyuan JIA[1]*, Hebei Normal University (1300987550@qq.com)
Yawen Ge[2], Hebei Normal University

Abstract

The 4.2 ka event was an important extreme climate event in the mid-late Holocene, which had a significant impact on environmental changes in different regions of the world. However, there were still limited studies on the response of alpine lake ecosystems to 4.2 ka event in the East Asian monsoon region, which limited the understanding of the relationship between Holocene extreme climatic events and lake environmental evolution. In this project, the Yazihai Lake, an alpine, enclosed freshwater lake in Ningwu County, Shanxi Province, North China, was selected as the research target, and YZH-2022-B core with a length of 1.91m was obtained. A high-resolution sedimentary dating model was established by using AMS 14C and 210Pb/137Cs technique. Using environmental proxies such as diatoms, geochemical elements and grain size in sediments, the aim was to reconstruct the succession of diatom community and the environmental changes of lake before and after the 4.2 ka event. The results showed that during 4,490-3,190 cal yr BP, the dominant diatom genera of the Yazihai Lake mainly included Anomoeoneis, Amphora, Aulacoseira, Gomphonema, Fragilaria, Navicula, Neidium, etc. The succession of diatom community was obvious in different stages. On the basis of clarifying the changes of diatom composition and combining the methods of transformation function, this study quantitatively reconstructed the changes of lake water level and lake temperature before and after the 4.2 ka event, providing more accurate evidence for revealing the evolution of mountain lake ecosystems, and more clearly defining the characteristics and potential mechanisms of the sensitive response of lakes in the East Asian monsoon region to the 4.2 ka event.

Abstract

The Ñirihuau basin, located between 41° and 43° S, on the eastern side of the Patagonian Andes, Argentina is filled by a thick sequence of Oligo-Miocene volcanic rocks (Ventana Formation) followed by Miocene volcaniclastic, clastic, and carbonatic, mainly continental rocks (Ñirihuau and Collón Curá Formations). The Ñirihuau Formation was interpreted to be deposited on alluvial, fluvial, deltaic, and lacustrine environments and based on available U-Pb geochronological data, was constrained to the early to late Miocene (22–11 Ma). The lacustrine system was established between ~15–13 Ma (Langhian–Serravallian) and holds significance because it was deposited during a transition from an extensional to a compressional tectonic regime, which led to the initiation of the last stage of mountain building in this Andean segment; and it registers the Middle Miocene Climatic Optimum and the beginning of the subsequent Middle Miocene Climatic Transition. Therefore, this contribution aims to document and constrain the past hydrological and sedimentation dynamics and the climatic conditions that prevailed during its deposition by analyzing the limestone beds that are interbedded among the fine-grained deposits. Two detailed sedimentary logs 48 m and 15 m thick were surveyed along the Arroyo Las Bayas, both at the western and eastern flank of the David Syncline, representing similar intervals of the unit. Limestone bed sampling was carried out on both stratigraphic sections, as well as on isolated limestone beds from the Ñirihuau Formation of two other sites. For the sedimentary successions analyzed, one facies association was defined (FA1), which was interpreted as a perennial lake associated with a deltaic system and dominated by detrital clastic material from a fluvial input. It is constituted by Facies 1 (Marginal lacustrine) and Facies 2 (Lower delta plain); on both facies the presence of grainstones and calcimudstones stands out. Through the study of the petrography and cathodoluminescence of these continental carbonates, nine microfacies were identified which point to mainly bio-induced subaqueous carbonate precipitation and subordinated deposition by tractive flows with low transport on a littoral lacustrine environment. Many of them exhibit

subaerial exposure and very early diagenesis (eogenesis) with minor mesogenesis (such as cementation or chemical compaction) effects. The C and O isotope values are consistent with those recorded in the global deep-sea curve during the Middle Miocene Climatic Optimum (17-15 Ma) when most of the limestone beds were deposited. Then, based on the observed features of the limestone beds and the results obtained, it is suggested that they were deposited in a paleolake system under temperate to warm and humid conditions. These conditions are thought to have prevailed until the final Andean uplift in the Miocene, which led to an aridification due to the rain shadow effect.

Mechanism of Salinization in Lacustrine Basins and Organic Matter Enrichment Patterns in Paleolake Water with Different Salinities—A Case Study of the Bohai Bay Basin

Zhenguo QI[1]*, China University of Petroleum - Beijing (qizhg7@126.com)

Abstract

Compared to oceans, lacustrine basins, due to their relatively smaller scale, exhibit greater sensitivity to climate and geological events, leading to frequent changes in their aquatic environments. These changes significantly impact organic matter enrichment and the formation of high-quality source rocks. Notably, variations in paleosalinity can alter paleontological groups, causing water stratification and influencing paleoproductivity and paleoredox conditions. These factors determine the quality of source rocks.

The Bohai Bay Basin is the only Cenozoic super basin globally, with multiple sets of hydrocarbon source rocks. Previous studies have indicated significant variations in paleosalinity among different intervals. This study, through the analysis of total organic carbon content, major and trace elements content, sulfur isotopes, biomarkers information, and identification of microalgal fossils, elucidates the abundance of organic matter (TOC), terrigenous detrital input intensity (P/Ti), hydrothermal influence degree (δEu), paleoclimatic evolution (Sr/Cu, CIA), paleosalinity (Sr/Ba, Gam/C30H), paleoproductivity (P/Ti, CaO), and paleoredox conditions (Pr/Ph, V/Cr) of the source rocks in the Kongdian Formation(E2k), Shahejie Formation(E2-3s), and Dongying Formation(E3d) in the Bohai Bay Basin.

According to the research, paleolake water salinization in different intervals is attributed to marine transgression and climatic aridity: the E2s3 and E3s1 are influenced by marine transgression, leading to water salinization, while the E2k and the E2s4 experience salinization due to hot and arid climatic conditions. Locally, paleosalinity is influenced by deep hydrothermal activity and the intensity of terrigenous detrital inputs. the southern subsag of the Laizhou Bay Depression and the Miaoxi Depression, characterized by well-developed faults, are affected by hydrothermal activity. This results in higher paleosalinity in the E2s4 and E2s3 compared to other areas. In contrast, the northern subsag of the Laizhou Bay Depression, being closer to the sub-uplift, experiences a stronger dilution effect due to the abundance of terrigenous detrital inputs, leading to significantly lower salinity compared to other areas within the same stratigraphic interval.

Based on this study, three organic matter enrichment patterns are identified under different paleosalinity conditions: when paleosalinity ranges from 0‰ to 7‰, increasing paleosalinity leads to elevated nutrient elements in the water, causing water stratification and enhancing paleoproductivity and reducing conditions, favoring the formation and preservation of organic matter. This is considered a productivity-preservation co-control pattern. When salinity ranges

from 7‰ to 14‰, higher salinity causes some freshwater organisms in the lacustrine basin to be unable to adapt, resulting in decreased paleoproductivity but continued enhancement of reducing conditions, leading to better preservation conditions than the previous stage. This is also characterized by an increase in TOC with rising paleosalinity. This is considered a preservation control pattern. When salinity exceeds 14‰, the inability of more freshwater organisms to adapt leads to mass mortality, reducing paleoproductivity and increasing reducing conditions. However, due to extremely low paleoproductivity at this stage, characterized by a decrease in TOC with increasing paleosalinity, indicating a productivity control pattern.

Abstract

The lacustrine ecosystems are dynamic landscapes sensitive to terrestrial, insitu and atmospheric changes and hence considered as important archives of past environments. The δ13C and δ15N isotope composition along with geochemical proxies have been utilized widely in lacustrine systems to infer past fluctuations in lake productivity and terrestrial inputs linked to climate-induced environmental changes. In the present study, we investigate changes in the organic geochemical data including δ13C, δ15N isotope and C/N ratios of sedimentary organic matter (OM) from a small, hydrologically closed lake (Ahansar) in Kashmir Himalaya to investigate changes in aquatic productivity and nutrient source variations through time with respect to climate-induced environmental changes. The lake is idealistically located at the intercept between the mid-latitude westerlies (WD) and the Indian Summer Monsoon (ISM). Our organic geochemical parameters clearly excluded a significant contribution of terrestrially derived OM to the sediments, but rather evidenced the strong contribution of aquatic primary productivity to the lake. However, the records also show phases of reduced δ13C values with enhanced TOC and C/N ratios attested to wetter phases and development of vegetated catchment landscape/soil development. The records therefore demonstrate that climate-induced environmental changes influenced OM and lake productivity in this high-mountain lake throughout the sedimentary record.

Abstract

This study focused on the sediment core and surface sediments of the Hurleg Lake, Qaidam Basin, northeastern margin of the Tibetan Plateau. Based on the comprehensive analyses of the geochemical characteristics of the lake sediment sequences, the compositions of long-chain alkenone, mid-chain ketone in the sediments, and the characteristics of the paleo-DNA, paleoclimate and paleoenvironment since the Holocene in the Qaidam Basin were systematically studied. The results showed that changes in the content of mid-chain ketone series compounds revealed two typical cold events (4.2 ka and 8.0 ka), which possibly corresponded to the phase of low atmospheric CO2 concentration (Fig. 1). A comparative study of long-chain alkenones from

lakes in different regions revealed that lake alkenones in the Qaidam Basin were influenced by the species and biomass of the alkenone parent source, and further research is needed. In addition, in terms of atmospheric CO2 reconstruction, the study of original organic carbon recovery and carbonaceous gas emissions in the Xiejia profile on the northeastern margin of the Tibetan Plateau showed that the magnitude of original organic carbon burial fluxes was positively correlated with the typical warm and cold climatic environments in the geological period, where warmer/arid climatic conditions corresponded to a higher rate of original organic carbon burial, and a lower rate was found in colder climatic environments. Further attention was paid to the thermal evolution of organic matter deposited during geologic history, which was converted into carbon-containing gases (including CO2 and CH4, etc.) and released to the atmosphere. We firstly estimated the amount of CO2 emitted from Cenozoic sediments in the Xiejia section of Xining Basin, during the shallow burial stage, the amounts of CO2 emissions were 60~13910 ml/g TOC, and CH4 emissions were 2~24 ml/g TOC, which provided an important reference for calibrated values of atmospheric CO2 reconstruction. Meanwhile, the combination of the multi-proxies indicated that the climate of Hurleg Lake was warm and humid during the Last Deglacial period, cold and humid in the early Holocene, warm and humid occurred in the middle Holocene, finally, gradually cold and dry in the late Holocene. During the Holocene, the water vapor evolution in the Hurleg Lake area was controlled by the Asian Summer monsoon, showing a typical "monsoon pattern", while the long-term decline in temperature and precipitation since the late Holocene may have led to the degradation of vegetation, the advance of glaciers, and the intensification of wind-induced activities, thus affecting the ecological landscape of the region.

ANIL KUMAR GUPTA[2], INDIAN INSTITUTE OF TECHNOLOGY
SUBHASISH TRIPATHY[3], INDIAN INSTITUTE OF TECHNOLOGY KHARAGPUR

Abstract

The Indian summer monsoon (ISM) is an essential component of the global climate system. Its variability directly impacts agricultural productivity and water availability, significantly shaping the livelihoods of the South Asian population. Moreover, the intensity of the ISM has also exhibited notable fluctuations in the past. To comprehend this variability, our research focuses on two lakes situated in eastern India. Hansadanga lake (in West Bengal) is an oxbow lake located on the Lower Ganga plain and Tampara lake (in Odisha) is a coastal lake adjacent to the Bay of Bengal. Sediment core samples having length of ~ 5 m from Hansadanga lake and ~ 2.5 meters from Tampara lake were collected. The sediment cores of Hansadanga lake covers an age range from 11,000 cal yr BP to the present and Tampara lake covers an age range from 13,000 cal yr BP to the present, using radiocarbon dating method. Our multiproxy dataset from both lakes includes the parameters like grain size, major and trace element ratios (K/Al, Mg/Al, Zr/Al, Mg/Ca, Rb/Sr, Al/Ca and Chemical index of alteration), Total Organic Carbon (TOC, wt%), δ13Corg and environmental magnetism (χlf, SIRM). The records obtained from Hansadanga lake reveal distinct climate phases: a stable dry phase between 11000 to 8400 cal yr BP, succeeded by a relatively intensive dry phase extending from 8400 to 7500 cal yr BP. Afterwards, a brief wet phase is evident during 7200 to 6700 cal yr BP, followed by a moderate phase of precipitation from 6700 to 4500 cal yr BP. Subsequently, an intensified dry phase is prevailed between 4500 to 3800 cal yr BP, preceeded by an increased precipitation phase during 900 to 400 cal yr BP. Furthermore, the sediment records obtained from Tampara lake indicate three alternate phases: a strengthening of monsoonal precipitation is observed from 10600 to 8700 cal yr BP, followed by a pronounced weakening between 8400 to 3500 cal yr BP and again by strengthening from 3400 to 600 cal yr BP. Remarkably, our data from the lakes of eastern India display evidence of the 8.2 ka and 4.2 ka arid events and exhibit noteworthy correlation with each other, as well as with marine and continental records globally.

Abstract

Introduction

Chegarman Lake formed in the northeast of Khuzestan province on the hillsides of folded Zagros and under the Izeh unit in a pit. This study has been tried to by Sedimentary geochemistry analyze, Elemental ratios, identification of sedimentary facies, and identification of sedimentary environments and changes of these environments set to the reformation the climatic and environmental conditions of Chegarman wetland in the Late Holocene.

Methods and Findings

To investigate the paleoclimate and conditions of the sedimentary environment, one intact sediment cores with depth of 7.2 m collected with using Auger corer. 21sediment samples were selected for elemental analysis with ICP-OES and XRF (X-Ray fluorescence). In this study, elemental ratios of V/Cr, Mn/Al, K/Al, Rb/Al, Si/Fe, Ti/K were used to reconstruction of the paleo climatic and environmental conditions.

Results and discussion

In the studied core, 5 major sedimentary facies identified. Two wetland sedimentary and alluvial environments identified. According to the Chronology, the average sedimentation rate in the Chegarman wetland is 1.4 mm / year, which this amount is different for various depths (Darvishi et al., 2022). Due to the type of sediments, the high level water period of the Chegarman wetland has been established between 1250 and 150 years ago. The study of the facies sediments of the wetland bed shows that climate change occurred gradually (not suddenly) about 1250 years ago and this trend has taken at least 300 years. The relatively dry and cold period lasted about 1850 years from 3100 years to 1250 years ago and is confirmed with the reported dry periods in the Maharlou Lake about 1800 years ago, in the Mir Abad Lake about 1500 years ago and in the Urmia Lake between 2500 and 1500 years ago. From 4000 years ago to about 3100 years ago, stable and slow wetland conditions was prevailed. The conditions for creating a peatland environment have been provided in the wetland and were associated with increasing the amount of organic matter, vegetation and shell fossils and consequently increasing sedimentation rate. This period which lasted for about 900 years, has been accompanied by extremely humid conditions, high groundwater level and activity of springs in the region. The existence of light brown mud which has the age ranges from 4900 to 4000 years ago, indicates a dry period (900 years). This dry

period shows suitable approximate conformity with a dry event of 4200 years ago in the northern hemisphere. This period in the studied region appeared with at least 100 years of temporal delay. After this dry period, we see again a gray sequence with plant and shell fossils that continue to a depth of 7 meters (about 5000 years ago).

Conclusion

In the Chegarman wetland, at least 2 high water periods with humid climate and at least 2 dry periods during the Late Holocene were identified. Dry periods appear more suddenly and with more intensity and shorter duration than humid periods

Monitoring of the land-sea interface: Analysis of high-resolution time series from 1950 to the present-day illustrating erosion, transport, and coastal sedimentation processes on the west Atlantic coast of France.

David MENIER[1]*, University of South Brittany (david.menier@univ-ubs.fr)
Romain LE GALL[2], Geo-Ocean UMR CNRS 6538, Université Bretagne Sud, 56017 Vannes Cedex, France
Manoj Mathew[3], Department of Geography, Geology and the Environment; London, United Kingdom

Glen BULOT[5], Geo-Ocean UMR CNRS 6538, Université Bretagne Sud, 56017 Vannes Cedex, France

Abstract

The analysis of the coastline can be systematically carried out through field observation campaigns, analysis of aerial and/or satellite photographs, as well as by utilizing LIDAR data or drone surveys. Although these tools provide measurements of coastal erosion and accretion at different spatial and temporal resolutions, there is still too little scientific synthesis at the regional scale.

Thanks to recent advances in LIDAR data acquisition and drone surveys, it is now possible to obtain high-resolution time series, thus enabling fine-scale monitoring of the coastline at decimeter to centimeter scales.

Our study focuses on two study areas: the first involves monitoring over a 50-year period of the retreat of a 2km-long cliff, which exhibits a high propensity for erosion over a relatively short distance (less than 1 km), and the second sector is located on the southern shore of the Vilaine estuary, characterized by a coastline undergoing constant morphodynamic evolution. The aim here is to discuss the importance of high-resolution and high-frequency monitoring in these two study areas where erosion and sediment transport processes are observed.

The analysis results of the cliff attest to a substantial retreat of up to 60cm/year from the cliff top, with notable variations along the studied area. The eroded materials are deposited downstream, contributing to a beach with coarse to fine sediment grain sizes. The relatively strong tidal currents in this sector, combined with wave action, result in the clearance of rockfalls at the base of cliffs. These materials are then redistributed towards the second study area. The analysis of time series data from this second area between 1952 and 2020 highlights significant morphological changes, including the migration of sand spits, areas of progradation/accretion, and sectors undergoing erosion, providing a dynamic perspective of the land-sea interface. Clear retreats of over 50 meters are observed, as well as lateral shifts along the coast, consequences of littoral drift and tidal currents.

The results obtained provide crucial data for the sustainable management of coastlines and underscore the need for long-term observation measures to provide public decision-making tools

and protective measures tailored to the specific characteristics of each studied area.

Human-controlled discharge effect on hydrodynamic and benthic sedimentary processes in the tide-dominant estuary

Seong Woon JEONG[1]*, Inha University (idiq1922@gmail.com)
Ho Kyung Ha[2], Inha University

Abstract

The estuarine environment is a representative coastal system of densely-populated areas since industrialization. Accordingly, various artificial structures such as dam, harbor, and dyke were built along an estuary. The Geum River Estuary (GRE), which is located on the west coast of Korea, is no exception for the severe effect of estuarine dam on the hydrodynamic and benthic sedimentary environments. To estimate the spatial differences of human-controlled discharge and tidal effects on the GRE, three up-looking acoustic Doppler current profilers (ADCPs, Teledyne RD Instrument, Workhorse 600 kHz) were installed at upper (PC1), middle (PC5), and lower part (PC6) of the GRE during September 8–25, 2020. The primary forcing which controls high current velocity and benthic sediment resuspension was different at each mooring site. At the PC1, spring tide flood (VB: 1.12 m/s; SSCB: 261.61 mg/l) and the discharge (VB: 1.11 m/s; SSCB: 247.21 mg/l) caused almost a same level of benthic current velocity (VB) and suspended sediment concentration (SSCB). At the PC5, the effect of spring tide flood (VB: 2.05 m/s; SSCB: 649.37 mg/l) was stronger than the discharge (VB: 1.39 m/s; SSCB: 611.63 mg/l) on VB, however, the effect on SSCB was similar. At the PC6, where was farther from the GRE dam, the effect of discharge on the hydrodynamic environment was weak compared to other mooring sites. Although the discharge reinforced VB (0.91 m/s) and SSCB (158.93 mg/l), it was almost negligible compared to other mooring sites. During the neap tide, a relatively high level of SSC was observed only during the discharge (SSCB: 156.60 mg/l), which was speculated by dispersed suspended sediments from the PC1 and PC5. The results from this study indicate that the main reason for the benthic sediment resuspension could be spatially different at the GRE. The effect of the discharge from the GRE dam gradually decreased from upper to lower part of the estuary. SSCB at PC5, which was highest among the mooring sites, implies that severe sediment accumulation might have been occurred at the middle of GRE. Further analysis on suspended sediment fluxes at each mooring site will be explained during the presentation.

Seasonal controls on the channel morphodynamics in an open coast macrotidal flat, west coast of Korea

Seolhui BANG[1]*, Seoul National University (shbang@snu.ac.kr)
Seungyeon Sohn[2], Seoul National University
Luke Stefan Bisson[3], Seoul National University
Joohee Jo[4], Seoul National University
Kyungsik Choi[5], Seoul National University

Abstract

The morphodynamics of tidal channels is crucial in understanding the evolution of tidal flats, as they exert as a conduit for sediment transport and drive the geomorphic changes. However, the characterization of the channel morphodynamics remains a challenge due to the difficulties in differentiating many natural and anthropogenic factors involved in the process. The present study aims to unravel the spatiotemporal variation of the channel morphodynamics in an open-coast macrotidal flat in southern Ganghwa island by conducting a repeated survey over the two decades using an unmanned aerial vehicle (UAV) and high-precision profiling. The results showed that the channel morphodynamics tend to be more pronounced in the lower intertidal zone and during summertime rainy season when heavy rainfall coincided with spring low tides. In case the channel is linked to a sluice gate, seasonal influence on the channel morphodynamics is even accentuated in the upper to middle intertidal zone. Channels are landward-skewed and shift downstream with frequent chute cut-off and subsequent abandonment of the channel, highlighting ebb tidal currents seasonally reinforced by runoff discharge drive the long-term morphologic change. The channel morphodynamics accounts for the facies heterogeneity in the middle to lower intertidal zone of the channelized open-coast macrotidal flat.

Variations in flocs related to wind-induced turbulent shear in macrotidal flat, Asan Bay

Sun Min CHOI[1]*, Inha University (choism124@gmail.com)
Ho Kyung Ha[2], Inha University

Abstract

In the intertidal flats with macrotidal regime, in-situ mooring was conducted to reveal the variations in floc properties (e.g., floc size (davg) and density (rho_e)) under tide and wind-dominant conditions. The floc property, current, and turbulence were simultaneously measured by using a laser particle sizer, acoustic Doppler current profiler, and acoustic Doppler velocimeter, respectively. During two weeks of field campaign (October 17–31, 2021) in Asan intertidal flats, the spring-neap variations in floc was dominant, showing a continuous decrease of current velocity and water level from 5 to 2 m. The continuous decrease in davg from 275 /mum (spring) to 70 /mum (neap) was superimposed by the flood-ebb variations in davg. At each tidal cycle, the davg grew by approximately 1.6 times during the flood, and decreased during the ebb. The turbulence enhanced by winds caused changes in davg and rho_e. The floc structures during flood and ebb under strong winds (wind speed > 6 m s-1) changed depending on the sources of suspended sediments in intertidal flats. For advected floc during the early flood, the strong winds formed the floc having a similar relationship between rho_e and davg to those under weak winds (wind speed < 6 m s-1). For eroded flocs during the ebb, meanwhile, the floc supplied by bed erosion had a different relationship between rho_e and davg, showing much smaller size and denser structure compared to those under weak winds.

Tidal and seasonal influences on the morphodynamic evolution of the tidal channels in a macrotidal embayment: Garolim Bay, west coast of Korea

Seungyeon SOHN[1]*, Seoul National University (ssyhhhh@snu.ac.kr)
Seolhui Bang[2], Seoul National University
Joohee Jo[3], Seoul National University
Kyungsik Choi[4], Seoul National University

Abstract

The seasonal variation of rainfall-induced discharge is a crucial factor that affects sediment transport and morphological changes of tidal channels. This is particularly the case in macrotidal settings that are influenced by monsoons. However, our understanding of how seasonal changes affect the channel morphology and related facies architecture is still limited. To improve our knowledge, we conducted a series of field survey in Garolim Bay, located on the west coast of Korea. We used sedimentological, morphological and hydrodynamic data to investigate the seasonal influence on the geomorphic evolution of tidal channels and their stratigraphic record in a semi-enclosed macrotidal embayment with insignificant fluvial input.

During the rainy season, tidal channels actively migrate and become more sinuous. Heavy rainfalls intensify ebb currents and induce seaward flow even during flood tide, leading to frequent chute cutoff and subsequent infilling of abandoned channels. Landward-skewed tidal channels that shift downstream and inclined heterolithic stratification (IHS) dipping ebbward support overall ebb dominance. Seasonality in the IHS is cryptic but manifested by the alternation of thickly bedded, unidirectional ripple cross-laminated sand with a lack of mud drapes, representing high-energy conditions during the rainy season, and relatively thinly bedded, bidirectional ripple cross-laminated sand and interlaminated sand and mud formed during the dry season. Digital elevation models of difference (DoD) and repeated high-precision profiling indicate the tidal flats experience summertime erosion and wintertime deposition, implying net sediment export occurs during the rainy season.

Chronology of raised marine terraces at the coasts of Tamil Nadu, South India- Implications on palaeotsunmi and higher sea-level

LINTO ALAPPAT[1]*, Christ College Autonomous, Irinjalakuda, Thrissur, Kerala, India (alappatlinto@christcollegeijk.edu.in)
Monika Devi[2], Physical Research Laboratory, Ahmedabad, India, 3800093

Yadava M.G. [4], Physical Research Laboratory, Ahmedabad, India, 3800093
Naveen Chauhan[5], Physical Research Laboratory, Ahmedabad, India, 3800093

Abstract

Late Pleistocene- Holocene beach deposits have been identified at the coasts of Tamil Nadu, South India. The outcrops are located between Thoothukudi and Rameswaram at 2-3 meters above sea level. The study aims to determine the sediment depositional history, palaeo sea-level and tectonics of the area, and constrain chronology using optically stimulated luminescence (OSL) as well as 14C dating. The deposits represent medium to coarse moderately sorted sand with sub-horizontal or gently sea-ward dipping stratification. The outcrop consists of a total ~7.0 m thick succession of alternating cross laminated fossiliferous, quartzitic conglomerate with intervening sandy lenses, which are capped by aeolian sand deposits. The samples were collected from four sections in the area. An intermediate layer and a basal layer contain cemented coarse sand, gravel with abundant fossils of marine molluskan fauna. The molluscan fauna are dominated by gastropoda (families: Turritellida, Conidae, Cypridae, Naticidae, Strombidae) and Bivalvia (families: Arcidae, Ostreidae, Pectinidae, Veneridae). A poorly sorted consolidated unit of medium to coarse grained sand with gravel unit along with cross stratified troughs and hummocky stratification shows that this may have formed by high energy conditions. The remnants of former sea-level high stands at the coasts of south India are generally scarce, usually represents either last interglacial (~120 ka) or mid Holocene eustatic maximum. The samples collected at distinct sedimentary units have shown OSL ages of 6±1 ka for the upper aeolian unit, followed by 24 ± 1ka for the marine sequence and 53 ± 4ka for the basal gravel layer. The third section had given an age of deposition during 59 ± 3ka and 102 ± 8ka. The shell samples collected shows that their deposition has occurred in a marine- marginal marine conditions and the OSL ages of sediments from this units shows that their deposition has occurred during 28 ± 1ka and 59 ± 3ka. The evidences point to a high energy event, possibly a potential palaeo-tsunami, which caused deposition of marine shells within the clastic sedimentary unit. The emergence of the coast may be attributed to a higher sea-level stand that had occurred in the area during this time.

Distribution Characteristics and Accumulation Mechanism of High Saturation Gas Hydrates in the Makran Accretionary Prism offshore Pakistan

JING LIAO[1]*, Qingdao Institute of Marine Geology, CGS (qdliaojing@gmail.com)
Jianming Gong[2], Qingdao Institute of Marine, CGS

Abstract

The Makran Accretionary Prism, located in the southern maritime area of Pakistan, is the result of the Arabian Plate subducting towards the Eurasian Plate. It features a low subduction angle (3-4°), high convergence rate (40mm/year), thick sedimentation (over 7000m), and abundant gas supply, making it an ideal location for gas hydrate accumulation. To delineate the spatial distribution of high saturation gas hydrate reservoirs in this area, we interpreted the seismic data and compared it with drilling results from the Nankai Trough in Japan and the ODP204 expedition. The results reveal a clear and continuous bottom simulating reflector (BSR). Hydrates are mainly distributed in three areas: first, strong reflections located above the BSR indicating high saturation hydrates with a thickness of about 100m; second, regions related to submarine cold seep leaks where cold seep biota have been found distributed along the anticlinal ridges; third, weak reflection layers located above the BSR and beneath the seabed, which cover a relatively larger area with greater thickness but lower saturation. Additionally, strong reflections below the BSR, identified as free gas according to drilling results, are considered part of the hydrate accumulation system, with the thickness up to 1000m. The fluid migration system in the study area comprises a developed "large thrust fault-high permeability turbidite sand layers" composite migration system. High saturation gas hydrates are primarily formed by the upward migration of free methane gas along the inclined turbidite sand layers, capped below the BSR to form gas columns.

Analysis of characteristics of seaweed forest distribution area using acoustic exploration method (multi-beam echo sounder)

SoonYoung CHOI[1]*, Korea Institute of Ocean Science and Technology, Kangwon National University (sychoi@kiost.ac.kr)
ChangHwan KIM[2], Korea Institute of Ocean Science and Technology
WonHyuck KIM[3], Korea Institute of Ocean Science and Technology
ChanHong PARK[4], Korea Institute of Ocean Science and Technology

Abstract

This study performed habitat environment mapping analysis using acoustic exploration to determine the distribution of seaweed forests. The study area, inhabited by seaweed, is located around Uljin Huam Beach, which has an underwater observatory and an underwater breakwater. In April 2022, a detailed seafloor topographic survey was conducted using multibeam in the study area to obtain water depth data. The water depth in the study area ranges from approximately 3 to 25 m. The water depth gradient gradually deepens from the southwest (near the coast) to the northeast. The distribution of seafloor in the study area has sandy sediments widely distributed in all areas. Rocky areas are concentrated in shallow coastal areas and areas close to underwater breakwaters. The overall shape of the rocks is irregular, but the direction of cracks is predominantly N-S or NE-SW. In the backscattered images the difference in shade and relief between the rocky area and the sandy sediment layer is clearly distinguished. The habitat environment was classified by integrating slope, surface roughness, bathymetry, and backscatter images derived from water depth data. The habitat environment of the study area is divided into rocky bottom, gravelly sand, sand and silty sand sediments. The seaweed distribution area was identified as the location where seaweed was detected using water depth and water column data. Most of the seaweed growing in the study area are distributed in rocky areas with shallow water depths (<10 m), and are relatively rare in sandy sediments. The type of seaweed is expected to be Sargassum fulvellum, and the length of seaweed is 2 to 4 m or more. As a result of comparing the predicted location of seaweed distribution based on multibeam data and the location of seaweed confirmed by underwater camera images, the two data match well. The habitat environment of the seaweed distribution area is mainly concentrated in rocky areas and gravelly sand sediment areas.

Joo-Hyung RYU[5], Korea Ocean Satellite Center, Korea Institute of Ocean Science & Technology
Hee Cheol YANG[6], Ocean Law and Policy Institute, Korea Institute of Ocean Science & Technology

Abstract

This research explores the sedimentary dynamics within the Nakdong River Estuary (NRE), Busan, South Korea, influenced by both natural processes, such as erosion and sedimentation, and human activities, notably the construction of the NRE Dam in November 1987. Utilizing data from the Nakdong Estuary Information Service System (NEISS) from 2015 to 2021, our study aims to elucidate the terrestrial and marine interaction and detail the sedimentary characteristics of the estuarine transition zone near the NRE barrier islands. Analysis of NEISS-provided sediment distribution data reveals a predominance of sand on the ocean-facing sides of the barrier islands and muddy sand on the lagoon sides. Based on the depth-integrated net suspended sediment load during a tidal cycle, sediment transport analysis identified a seaward sediment movement of 1698 kg per meter. Net suspended sediment fluxes were calculated for the surface, mid-water, and bottom layers, showing values of -2.1 × 10 to the negative third power, -2.0 × 10 to the negative third power, and +3.3 × 10 to the negative third power kg per square meter per second, respectively. A stratification index (SI) analysis underscored a pronounced saltwater intrusion and significant stratification within the estuary, affecting both the ebb and flood tide phases. The study highlights the NEISS's role in documenting sedimentary environment alterations in the NRE through the period under review, with post-May 2015 data informing Marine Spatial Planning (MSP) efforts in the area. Furthermore, this system underscores the potential of the NEISS for ongoing monitoring of NRE sedimentary dynamics, especially in anticipation of ecological shifts after the dam's partial opening on February 18, 2022.

Deciphering Dokdo Seamount's Submarine Topography: Generation and preservation of submarine terrace structure

Duhwan KEUM[1]*, Department of Earth System Sciences, Yonsei University
(2022321202@yonsei.ac.kr)
Wonsuck KIM[2], Department of Earth System Sciences, Yonsei University

Abstract

Marine terraces, characterized by flat surfaces of marine origin bordered by steeper ascending and descending slopes on the up and down-slope sides, respectively, are products of wave erosion (IHO, 2019). Their elevation is generally accepted as a potent indicator of paleo-relative sea. Here, we aim to identify the primary contributor shaping the distribution of marine terrace elevations in Dokdo, a volcanic island in the East Sea, South Korea over geologic time.

Using a simplified one-dimensional model, we simulate the evolution of rocky coastline through the horizontal and vertical wave erosion processes. Our model considers various scenarios involving sea-level changes, tectonic movements, and wave conditions to unveil the mechanisms governing the generation and preservation of marine terrace structures.

Our findings indicate that the depth of terrace formation often correlates well with periods of prolonged sea level duration. However, the distribution of terrace elevations does not precisely align with the distribution of sea level occupation time due to the destruction of previous topography by subsequent erosional events. The influence of younger and lower erosion can erase topographic features carved earlier, leaving only the most recent features. Additionally, we identify the slope of the initial topography and wave energy conditions as crucial factors controlling the preservation of marine terrace structures. Applying our understanding through modeling, we found possibility of a very recent substantial reset of topography on Dokdo seamount, possibly within the last 300,000 years.

In conclusion, sea level occupation time, initial slope of the surface, and wave energy are crucial factors influencing terrace formation and preservation. These findings contribute to our understanding of coastal morphodynamics and offer insights into reconstructing relative sea-level history of specific regions. Applying our model to Dokdo reveals the potential for recent significant topographic events, showcasing the broader implications of our research for understanding geological history of the East Sea.

Multiscale Sea-Level Variability and Predictive Modeling in the Northern South China Sea Under Climate Change

Yilin YANG[1]*, Sun Yat-sen University (yilinyang12@foxmail.com)
Qiuming Cheng[2], Sun Yat-sen University
Yuanzhi Zhang[3], City University of Hong Kong

Abstract

Global warming has escalated sea-level rise, posing significant threats to coastal regions worldwide. This is particularly true for the northern South China Sea (SCS), where low elevation, rapid economic growth, and high population density converge, heightening the vulnerability to the ramifications of rising seas. Our research focuses on understanding the sea-level trends in this critical area and assessing the potential inundation threats to its low-lying locales.

Employing the Ensemble Empirical Mode Decomposition (EEMD) methodology, we dissected time series data from trio of tide gauges stationed along Hong Kong's coastline. This approach unraveled the complex, multidimensional nature of sea-level fluctuations within the SCS and their underlying response mechanisms. The adoption of Multifractal Detrended Fluctuation Analysis (MF-DFA) shed light on persistent correlations and multifractal features within the sea-level time series. Our study revealed distinct seasonal, interannual, decadal, and interdecadal variations, offering detailed insights into the fluctuating patterns of sea-level change.

Furthermore, the investigation into the El Niño-Southern Oscillation (ENSO) phenomena revealed a 6-month delayed correlation with local sea levels, offering insights into the regional impact of global climatic events. Spatial analysis indicated accelerated sea-level rise in proximal coastal zones and a discernible disparity between northern and southern sectors.

Advancing beyond traditional models, we introduced a novel sea-level forecasting approach by fusing EEMD with Long Short-Term Memory (LSTM) neural networks. This hybrid model underwent empirical testing in the northern SCS context, demonstrating superior predictive prowess over conventional LSTM models. By effectively filtering noise and enhancing signal fidelity, the EEMD-LSTM model offers a robust forecasting tool.

In essence, this work delves deep into the multiscale dynamics of sea-level variations in the northern SCS, and proposing an innovative predictive model that marries EEMD with LSTM. Our findings lay a solid foundation for evaluating sea-level rise risks and crafting adaptive strategies for at-risk low-lying communities.

Characteristics of surface sedimentary facies in the Watan Estuary intertidal flat, western Korea

Woo Hun RYANG[1]*, Jeonbuk National University (ryang@jbnu.ac.kr)
Jae Rin Yoon[2], Jeonbuk National University
Sol Ip Kang[3], Jeonbuk National University

Abstract

On the western coast of Korea, the Watan estuary intertidal flat is characterized by macro-tide and semi-enclosed coastal geomorphology. Variations in sediment texture and sedimentary facies of surface sediments and geomorphic topography in August 2016 and February 2017 were investigated along three transect lines to the shoreline in the Watan estuary. Surface sediments and topography were sampled and measured at 45 sites with 50 m intervals along the three survey lines in the Moraemi, Mokmaek, and Flower Garden areas. The surface sediments of the Watan estuary intertidal flat consist mainly of sand and silt sediments. In summer, terrestrial suspended clay sediments were deposited from downstream Flower Garden, Mokmaek extending to the Moraemi area of the Watan estuary. However, in winter, suspended clay sediments accumulated at the Flower Garden and Mokmaek areas in the lower reaches of the Watan stream, not extending to the Moraemi area of the Watan estuary mouth. In summer, the Watan estuary has characteristics of increases in the Watan stream discharge due to an increase in precipitation and relatively weak wave effects within the estuary. In contrast, winter shows decreases in the stream discharge and relatively strong waves. This variation may affect the seasonal sedimentation of intertidal sediments in the estuary.

Acknowledgments: This study was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (NRF-2022R1F1A1063126).

Jong Dae Do[9], KIOST

Abstract

Studying shoreface topography in coastal areas within a depth of 10 meters, where active sand movement occurs, often involves direct surveys with small boats. However, this method faces limitations in periodic monitoring due to susceptibility to weather conditions such as wave in surfzone

To address these limitations, algorithms based on satellite imagery have recently been developed for water depth estimation. Utilizing the Cubesat constellation (Planet Scope) with a daily revisit cycle and high spatial resolution enables more extensive depth estimation. However, to effectively utilize data from different satellites within the constellations, it is crucial to employ methods for cross-calibrating and fusing images from other satellite sources (Sentinel2).

This study utilized 2022 data from the coastal area of Hujeong in Uljin-gun, South Korea. An algorithm fused 25 Sentinel-2 images and 127 Planet Scope images, providing a spectrally consistent water depth estimation at a 3-meter resolution. Field depth measurements were obtained three times in May, August, and October 2022, serving as ground truth for validating the estimated values derived from satellite imagery.

Compared to traditional on-site depth measurements, which are challenging to perform multiple times within a short period, utilizing Planetscope satellite Constellation for depth estimation offers advantages in terms of cost-effectiveness, high resolution, and coverage of wide areas. This approach also facilitates daily monitoring of rapidly changing coastal topography caused by adverse weather conditions like storm wave, typhoons, and heavy rainfall.

Exploring spatiotemporal variations in sediment retention in delta evolution: A numerical experiment with Delft3D

Minsik KIM[1]*, yonsei univerisity (yukms6601@yonsei.ac.kr)
Wonsuck Kim[2], Yonsei University
Jaap Nienhuis[3], Utrecht Univeristy

Abstract

Deltas are dynamic landscapes influenced by the interplay of various factors, with their mass balance largely represented by the accommodation creation and sedimentation. Thus, the sediment retention fraction, the proportion of sediment retained on a delta compared to supplied sediment, plays a crucial role in this mass balance. While external factors such as river flux, waves, tides, and sediment type have been extensively studied on their influence on the sediment retention fraction, there remains a significant knowledge gap for understanding the impact of autogenic spatiotemporal evolution within delta morphology and growth on the sediment retention. We propose that sediment retention fraction spatiotemporally varies across delta evolution mainly due to variations in accommodation. Leveraging numerical experiments with Delft3D, we analyze the relationship between sediment retention fractions of sand and mud, along with the changes in sediment accommodation, throughout the evolutionary process of deltas from initiation to matured delta stage. Our simulation results reveal contrasting behavior between sand and mud retention: sand retention initially increases and then stops increasing, while mud retention continues to rise. Both sand and mud retention are closely tied to their accommodation, i.e., a channel for sand and an interdistributary for mud. This finding underscores the inherent difference in the depositional ratio of sand and mud throughout the delta evolution. By elucidating this relationship, we emphasize the importance of considering spatiotemporally varying sediment retention fractions in delta studies, which provides valuable guidance for delta management and conservation efforts.

Investigating and quantifying tidal effects on the formation of bifurcated channel networks in modern river deltas

Jiyoung LEE[1]*, Yonsei University (easyoung1442@yonsei.ac.kr)
Wonsuck Kim[2], Yonsei University

Abstract

Deltas have intricate networks of interconnected channels and evolve along with dynamic changes in response to natural and anthropogenic factors, such as sediment particle size, sediment supply, precipitation, vegetation growth, human activities, waves, tides, and climate change.

Especially, tide currents, one of the factors influencing sediment transport within distributary channels, continually modify the morphological and dynamic characteristics of deltas. However, quantitative measures for assessing tidal influence on delta morphology are still challenging.

Here we conducted morphodynamic simulations using Delft3D by varying the tidal amplitude and the ratio of mud and sand supply, while holding all other factors constant. Furthermore, we measured the bifurcation length, the distance between two bifurcation points along the channel centerline in natural deltas, and utilized the record of spatial pattern in bifurcation length. The results show that a higher tidal amplitude causes an increase in bifurcation length spatially when comparing channels of similar bifurcation orders, and a higher proportion of muddy composition responds more sensitively to the tidal effect.

Channel geometry, which is influenced by factors such as flow characteristics and sediment composition, can explain the observations made in this study. We propose that due to strong tidal currents and a more cohesive sediment composition, channel deepening and narrowing facilitate increasing in the advection length and thereby bifurcation length. Our study aims to analyze the spatial pattern of the branching channel network as a quantitative measure of tidal influence on delta morphology. Based on these research findings, we can enhance our understanding of the evolving shape of channel networks across different regions under varying conditions.

Effect of coastal seiches on sediment transport in a Masan Bay

JUN YOUNG SEO[1]*, Chonnam National University (eric00518@gmail.com)
Byoung-Ju Choi[2], Chonnam National University
Sun Min Choi[3], Inha University
Jongseong Ryu[4], Anyang University
Ho Kyung Ha[5], Inha University

Abstract

In-situ moorings and axial survey using acoustic Doppler current profilers in a microtidal Masan Bay were conducted to reveal the impacts of coastal seiches on sediment resuspension behaviors. The hydrodynamic circulation in the bay was dominated by sluggish tidal and residual currents, with which the coastal seiches with 1-h period were also detected. The velocity of coastal seiches (u_seiche) accounted for 30% of total current velocities, causing back-and-forth motions of water along the main channel as a barotropic structure. The useiche was insufficient to directly resuspend bed sediments without external forcings. Nonetheless, it influenced a variability of suspended sediment concentration (SSC) of turbidity maximum (SSC: ~40 mg l^-1) at central part of the bay, showing an SSC anomaly of 8 mg l^-1. Although the seiche-induced sediment fluxes were only 1% of total fluxes due to offsetting effect of bidirectional flows, they could reach up to 0.040×10^-3 kg m^-2 s^-1 at each pulse of coastal seiches. Repetitive coastal seiches lifted the sediment particles by > 4 m to the upper layer where they would not have risen if not for the vertical motion of coastal seiches. Unlike the tidal or residual currents, however, the distance that the coastal seiches can transport the suspended sediments was too short (< 57 m) compared to their transportable amounts. Even if the sediment particles within the turbidity maximum were advected by the coastal seiches, they could not leave its region, showing only redistribution within an immediate vicinity. This process was intensified toward the land as the useiche slowed down the further it moved away from the node. As long as the bed sediments were resuspended, the coastal seiches were expected to further enhance the potential for water pollution by causing repetitive sediment redistribution. This study highlights that the coastal seiches can have a significant impact on sediment behavior in microtidal bay although they are often masked by tidal and residual currents.

Impact of dike construction on sedimentary facies and morphological evolution of semienclosed macrotidal flats in the western coast of Korea

Joohee JO[1]*, Seoul National University (joohe1218@snu.ac.kr)
Dohyeong KIM[2], Korea Environment Institute
Seungyeon SOHN[3], Seoul National University
Seolhui BANG[4], Seoul National University
Kyungsik CHOI[5], Seoul National University

Abstract

Man-made structures like groins, jetties, and dikes are built to prevent storm surges and tidal waves. However, these structures can alter the natural coastal environments by interfering with the natural processes of tides, waves, and rivers. For example, the construction of dikes can cause wave reflection and lead to the formation of wave-built shelly ridges and steep-sloped tidal flat morphology on semienclosed macrotidal flats. The impact of dike construction on sedimentary successions is not yet fully understood, as it is difficult to separate the effects of human intervention from natural processes. The purpose of this study is to examine the sedimentary facies in the macrotidal flats that are affected by dikes, and to distinguish between natural processes and man-made impacts. This will help us better understand how the depositional environment has evolved over time. We collected undisturbed cores from ten locations in the Shinsi tidal flats, annually for six years. This helped us to demonstrate the spatial distribution of the sedimentary facies. We also estimated the sedimentation rate using 210Pb activities from a 2.45 m long auger core in the Wido tidal flats to detect changes in sedimentation rate before and after dike construction. The basal bioturbated muddy sands with shell fragments are interpreted to have been formed before the Saemangeum dike construction under a macrotidal regime. The basal bioturbated muddy sands are overlain by wave-built shelly ridges after the dike construction. The shelly ridges consist of alternating two beds of flood-oriented cross bedded gravels and muddy sands. The gravelly beds and muddy sands are formed during the storm and calm periods, respectively, indicating that the shelly ridges move landward in response to seasonal wave and tidal action. Rill channels formed during summertime preserve the impact of rainfall, which are developed by stronger ebb tidal currents resulting from increased surface runoff discharge. These channels exhibit channel lags overlain by thick, massive silt beds that transition upwards into parallel lamination and bidirectional ripple cross lamination. During summer rainfall, the artificial beach is eroded due to runoff discharge, leading to gravel deposition even in the upper intertidal zone. From 1890 to 2022, the sedimentation rates averaged 4.84 cm year-1. This rate has increased from 0.049 cm year-1 from 1974 to 1986, before the Wido dike construction, to 0.682 cm year-1 from 2010 to 2022. This study emphasizes that human interference complicates the regular sedimentological changes on coastal depositional environments, leading to unpredictable morphological evolution that cannot be explained solely by natural processes.

Abstract

In this study, we report volatile geochemistry data from hydrothermal fluid emitted from the 9°44'S - 15°33'S region of Central Indian Ridge (CIR), surveyed by R/V ISABU by Korea Institute of Ocean Science & Technology (KIOST) on March 2023. Through this study, we aim to enhance the understanding of hydrothermal systems generated by seawater-crust-mantle interaction and elucidate the emitting volatiles' source. From 8 vent field sites, including 7 active vent sites, we collected hydrothermal fluid samples with a Remotely Operated Vehicle (ROV) of ROPOS and buoyant plume water samples from different depths with CTD Rosette. The compositions of dissolved gases (e.g. H_2, He, CH_4, and CO_2) and their stable isotopic compositions ($^3He/^4He$, $\delta^{13}C$-CH_4, δD-CH_4, and $\delta^{13}C$-CO_2) were measured from samples. As a result, the measured helium isotope compositions were 4.60 ~ 10.23 R/Ra (7.79 ~ 10.29 Rc/Ra), indicating contributions of both upper mantle (8 Ra) and mantle plume (>9 Ra) on helium, supported by mantle tomography image. $\delta^{13}C$-CO_2 (-12.8 ~ -7.4‰ vs.PDB) also showed the presence of mantle-derived CO_2 ($\delta^{13}C$ = -6.5 ± 2.5‰). The CH_4 concentrations of hydrothermal fluid were 526 ~ 190,323 nmol/kg, which suggests severe methane generation in the hydrothermal system regarding <30 nmol/kg of ambient seawater CH_4 concentration. The $\delta^{13}C$-CH_4 (-21.6 ~ -8.1‰) and δD-CH_4 (-196.0 ~-87.0‰) of vent fluid were overlapped with abiotic CH_4 from MAR or EPR. A high concentration of H_2 (1 ~ 86 mol.%) also supports the reduction of CH_4 under a reductive hydrothermal system. Eventually, this study suggests that interactions between the upper mantle, lower mantle, and altered oceanic crust are the source of inorganic gases in the CIR hydrothermal system.

Evolution of the Eastern Gulf of Finland area through Holocene

Olga KOVALEVA[1]*, A.P. Karpinsky Russian Geological Research Institute
(olya_pavlikova@mail.ru)
Daria Ryabchuk[2], A.P. Karpinsky Russian Geological Research Institute
Alexander Sergeev[3], A.P. Karpinsky Russian Geological Research Institute
Leonid Budanov[4], A.P. Karpinsky Russian Geological Research Institute
Vladimir Zhamoida[5], A.P. Karpinsky Russian Geological Research Institute
Igor Neevin[6], A.P. Karpinsky Russian Geological Research Institute

Abstract

Evolution of the Eastern Gulf of Finland coasts (the easternmost part of the Baltic Sea) is governed by different stages of the Baltic Sea level fluctuations during Holocene and external geological processes such as a glacioisostatic movement. Series of coastal palaeo geomorphological structures marking sea-standing levels are traced onland at different altitudes. System of coastal bars forms an irregular belt mostly around the northern coast of the Gulf, their morphometry parameters are far in excess of the modern underwater bars. In areas where abundance of material existed systems of coastal accumulative forms are included palaeo dunes (height up to 10 m) and palaeo spits (length varies from 2 to 10 km) at Sestroretsk, Narva-Luga Bay, Vysokinskoe Lake. Analysis of ground penetration radar profiling showed the presence of coarse material inside some objects what indicate their glacio-fluvial origin (example, fluvial delta at Narva-Luga). Nowadays coasts of the Eastern Gulf of Finland can not replicate the same pattern of accumulative bodies development due to strong deficit of material but short-term spits are formed in the coastal zone nowadays. Postglacial development of the area are reflected off-shore – detailed marine geophysical researched revealed a complex of glacial relief features (elongated glacial till ridges, end-moraine ridges, De Geer moraine). Ananlysis of underwater sediments cores revealed erosional layers as an evidence of sea-level fluctuation. Submerged underwater terraces are indicated a deep regression during early Holocene.

Pockmark Seafloor in Hupo Basin, East Sea

Chang Hwan KIM[1]*, Korea Institute of Ocean Science & Technology (KIOST)
(kimch@kiost.ac.kr)
Soon Young CHOI[2], Korea Institute of Ocean Science & Technology
Won Hyuck KIM[3], Korea Institute of Ocean Science & Technology
Chan Hong PARK[4], Korea Institute of Ocean Science & Technology

Abstract

The Hupo Basin, continental marginal basin, of the East Sea extends to Uljin-gun and Yeongdeok-gun. The Hupo Bank, a terrain that is higher than the surrounding seabed, is located at the eastern boundary of the Hupo Basin. KIOST(Korea Institute of Ocean Science and Technology) conducted detailed bathymetry surveys in the northern, central and southern areas of the Hupo Basin from 2011 to 2013. The Hupo Basin, bounded by steep slopes of the Hupo Bank, is deepened from the west coast to the east and deepest to a maximum depth of about 250 m. A narrow seafloor channel appears in the northern, central, and southern areas with the deepest depths. Numerous pockmarks appear on the seafloor at depths of about 150 ~ 250 m in all the three areas of the detailed bathymetry surveys. These pockmarks generally have diameters of about 20 to 50 m and depths of about 4 to 6 m, with crater-like submarine topography of various sizes. Seafloor sediments in the pockmark areas consist of fine silt. Comparing the shape and size of the pockmark of the Hupo Basin with that of other regions of the world, it is considered to be classified as a normal pockmark. There are about 7 pockmarks/1 km square in the northern part of the three areas and about 8 pockmarks/1 km square in the central part. The southern part has about 5 pockmarks/1 km square. If the area with the possibility of pockmarks is extended to the depth area of about 150 ~ 250 m in the entire Hupo Basin, the number of pockmarks is estimated to be more than about 4800. The pockmark of the Hupo Basin is more likely to be generated by a fluid such as a liquid than a gas. In the future, it is necessary to study the cause of the formation and the specific marine ecosystem and environment related to the Pockmark.

Jianghao Qi[5], Qingdao Institute of Marine Geology,China Geological Survey

Abstract

Southeast Asia located in an important regional geodynamic intersection zone surrounded by curved subduction system (Li JB et al., 2021), is a natural laboratory for marine geoscientific research. Due to the complex tectonic settings, frequent and intense geohazards severely impact on the expansive and densely populated coasts of Southeast Asian countries. However, in this region marine geological survey is limited, and early basic geological-geophysical data lacks systematic analysis and in-depth interpretation. In this program, we firstly collected and sorted out the geological and geophysical data of gravity, magnetic anomaly, natural earthquake, terrestrial heat flow, crustal structure, seabed surface sediment and sedimentary rocks in the study area. Then carried out data processing and standardization for comprehensive geoscientific research. Lastly, guided by the theory of "block tectonics", nine free-air gravity anomaly divisions, seven magnetic anomaly divisions, seven geodynamic divisions, five primary tectonic plates and plate boundaries, and forty-five secondary tectonic units were displayed in the mapping area. Meanwhile, the types and distribution characteristics of surface sediments in the China-ASEAN seas and adjacent areas were systematically summarized. The results of this program are shown as "Geoscientific Map Series of China-ASEAN Seas and Adjacent Areas(1:5 million)", which not only establish a database for scientific and technological innovation in the marine geological field, but also provide an important basis and guidance for marine management, disaster prevention and reduction in Southeast Asia.

Influence of meteorological events on the sediment and microphytobenthos resuspension in intertidal flats

Hun Jun HA[1]*, Chonnam National UniversityY (hahunjun86@gmail.com)
Ho Kyung HA[2], Inha University
Tae Soo CHANG[3], Chonnam National University

Abstract

Intertidal flats are found throughout the world's coasts, which can provide important ecological and economic functions. Microphytobenthos (MPB), which is one of the major primary producers in coastal environments, could be resuspended by external forcings (e.g., tides and wind-induced waves) and considered as food sources for upper trophic level consumers. To better understand dynamic behaviors of suspended sediment and microphytobenthic chlorophyll-a (chl-a) under both fair-weather (i.e., tide-dominated) and episodic meteorological conditions, in-situ mooring systems were deployed in the Jeungdo tidal flat, South Korea. During fair-weather conditions, sediment and chl-a were simultaneously resuspended at flood tide, and advected to the tidal channel at ebb tide. The coupling and segregation between suspended sediment concentration (SSC) and chl-a were prevailed in spring and neap tides, respectively. The maxima of SSC and chl-a during storm event were about 9 and 2 times higher than those during fair-weather conditions, respectively. During rainfall event, they were about 7 and 1.2 times higher compared to fair-weather conditions, indicating that the sediment and MPB were highly resuspended by storm and rainfall events. After rainfall event, SSC and chl-a significantly increased with positive relation of the current velocity, suggesting that rainfall was associated with reduction in stabilization of sediment and MPB. Aforementioned outcomes suggest that the tides and storms are important in the dynamic behaviors of sediment and MPB in intertidal flats.

Exploring Novel Bioactive Compounds from Deep-Sea Microorganisms Originating in Marine Sediments

Ji Young LEE[1]*, Institute of Sustainable Earth and Environmental Dynamics (SEED), Pukyong National University, 365 Sinseon-ro, Nam-gu, Busan 48547, South Korea (jji123789@naver.com)
Sang-Jip Nam[2], Department of Chemistry and Nanoscience, Ewha Womans University, Seoul 03760, Republic of Korea
Songyi Lee[3], Institute of Sustainable Earth and Environmental Dynamics (SEED), Pukyong National University, 365 Sinseon-ro, Nam-gu, Busan 48547, South Korea

Abstract

New natural compounds were discovered from two types of microorganisms originating from deep-sea marine sediments. From the crude extract of Streptomyces sp. CNP-944, two new pyrazine alkaloids, actinopolymorphols E and F (1 and 2), were identified, along with previously reported compounds, actinopolymorphol G (3), and actinopolymorphol D (4). Additionally, from the culture broth of Saccharomonospora sp. CNQ-490, four new natural products, lodopyridones D - G (5 - 8), were discovered, alongside previously reported compounds, lodopyridones A - C (9 - 11), and cotteslosin A (12). The thorough investigation of these compounds' chemical constituents utilized HPLC-UV-guided fractionation. The determination of these compound's chemical structures was achieved by interpreting 1D, 2D NMR, and MS spectroscopic data. Confirmation of the weak antibacterial activity of the new natural compound, actinopolymorphol F, was attained through antimicrobial activity testing, revealing minimum inhibitory concentration (MIC) values of 16, 64, and 64 μg/ml against Kocuria rhizophila, Bacillus subtilis, and Staphylococcus aureus, respectively. These findings underscore the wealth of bioactive compounds harbored within marine bacterial sources. The discovery and structural elucidation of these novel metabolites provide valuable insights into the potential pharmacological applications of marine-derived compounds. Continued exploration of the biological activities and synthetic potential of these compounds holds significant promise for advancing drug discovery and development endeavors.

Analysis of benthic environment characteristics and microbial community structure in Suyeong River, South Korea

Hee Eun WOO[1]*, Institute of Sustainable Earth and Environmental Dynamics (SEED), Pukyong National University (hew119@pknu.ac.kr)
Kyunghoi KIM[2], Department of Ocean Engineering, Pukyong National University
Jong-Oh KIM[3], Institute of Sustainable Earth and Environmental Dynamics (SEED), Pukyong National University

Abstract

The Suyeong River Estuary, located in Busan, South Korea, serves as a vital ecosystem supporting diverse residential, commercial, and industrial activities. However, concerns regarding contamination from industrial and domestic wastewater persist due to a relatively low sewage pipe penetration rate compared to the national average. This study aims to evaluate sediment pollution levels and their environmental ramifications in this estuarine ecosystem. To evaluate the pollution levels and environmental implications, sediment samples were collected from seven stations along the estuary, spanning from the vicinity of the Dongbu Sewage Treatment Plant to the Minrak Port. These stations were categorized into three zones; SY river, Inner Bay, and Outer Bay. Analyses were conducted on various parameters including pH, oxidation-reduction potential (ORP), and nutrient concentrations (dissolved inorganic phosphate, DIP, and ammonia nitrogen, NH3-N). Metagenomic analysis was performed to characterize microbial community composition. Results reveal a notable variation in pH across stations, with higher values observed closer to the oceanic influence. Elevated concentrations of DIP and NH3-N were observed in the SY river and inner bay areas, signifying significant pollution levels. Microbial community analysis revealed varying trends across the zones, with the phylum Firmicutes exhibiting distinct abundance patterns correlating with total phosphorus concentration. It is clear from these findings that there is considerable sediment pollution in the Suyeong River Estuary, particularly in the inner bay. To ensure the ecological integrity of this important estuarine ecosystem and to maintain the sustainable coexistence of humans and nature in the region, effective management strategies are essential.

Mapping the sedimentation rates in the continental shelf – an European view to the seabed change

Aarno Tapio Kotilainen[1]*, Geological Survey of Finland (GTK) (aarno.kotilainen@gtk.fi)
Ulla Alanen[2], Geological Survey of Finland (GTK)
Anu Marii Kaskela[3], Geological Survey of Finland (GTK)
Susanna Kihlman[4], Geological Survey of Finland (GTK)
EMODnet Geology Partners[5], The European Marine Observation and Data Network (EMODnet)

Abstract

Sediment deposition and resuspension in marine environment are key processes shaping the seabed environment. Information on sedimentation rates is needed in several fields. For example, data on the location and rate of sediment accumulation is important for carbon cycle and carbon budget studies, monitoring pollutants and microplastics, and understanding changes in erosion and deposition of sediments.

EMODnet (The European Marine Observation and Data Network) Geology project is collecting and delivering harmonized data showing sedimentation rates at the seabed. The data is compiled from all available information on the rate of sedimentation in European maritime areas, provided by EMODnet Geology project partners from their national waters (including EEZ).

The focus is on the present-day sedimentation rates. That means sediment accumulations to the seabed over the past decades, since AD 1900 or so. Estimations of modern sedimentation rates can be based e.g., on established historical records of anthropogenic radionuclides (e.g., 137Cs and 241Am), lead (Pb) and stable lead isotope (206/207Pb ratios). Sedimentation rate estimations can be based also on varve/laminae counting, radionuclide 210Pb and 14C decay dating methods. In addition, local stratigraphic marker horizons, like in the Baltic Sea, horizons formed by documented Major Baltic Inflow (MBIs) events, can be used in the estimations.

Here, the information on sedimentation rates for recent sediments is presented as point-source information. This data product, sedimentation rates data, consists of more than 1600 data points at this moment.

According to data, the rate at which sediments accumulate to seabed differs greatly from place to place. Accumulation does not occur everywhere, e.g., in the Baltic Sea Basin it has been estimated that sediment accumulation areas cover approximately one-third of the seafloor. Generally, sedimentation rates in the accumulation areas of the European Seas varies from some mm/year up to some cm/year. Sedimentation rates are highest in the river estuaries and near the mouths of rivers, as well as in some deep(er) basins/depocenters. In some estuaries the sedimentation rates can be up to several cm/yr.

The current EMODnet Geology project phase is executed by a consortium of 40 partners and subcontractors from 30 countries, which core is made up by members of EuroGeoSurveys (EGS) backed up by other partner organizations with valuable expertise and data. The EMODnet Geology project is funded by The European Climate, Environment, and Infrastructure Executive Agency (CINEA) through contract EASME/EMFF/2020/3.1.11 - Lot 2/SI2.853812_EMODnet – Geology.

Cross-EEZ Cooperation, Standards and Harmonization: Compiling Spatial Data of the European Seafloor Geology and Geomorphology within the EMODnet Geology Project

Kristine E.C. ASCH[1]*, Federal Institute for Geosciences and Natural Resources (BGR)
(Kristine.Asch@bgr.de)
EMODnet Geology Team[2], Europe

Abstract

The EMODnet Geology project (European Marine Observation and Data Network) is now in its 5th phase and is encompassing more than 30 partner organizations. It focusses on producing open, high quality, harmonized marine data, interoperable and available free of charge.

Within EMODnet Geology, the German Federal Institute for Geosciences and Natural Resources (BGR) is leading the Workpackage Seafloor geology (WP4). The aims are to compile and harmonize spatial (map) data within Exclusive Economic Zones (EEZ) in Europe and beyond. The data comprise of pre-Quaternary and Quaternary off-shore geology, geomorphology and general physiographic features of the European Seas. BGR is compiling the data centrally, is processing and publishing them centrally on both, the EMODnet web portal (EMODnet Map Viewer (europa.eu)) and the BGR Geoviewer (https://geoportal.bgr.de) according to FAIR data principles. BGR collates seafloor data of the following geological properties: lithology, age, genesis (event environment/process) and faults. The geomorphology data layer comprises of features that represent the submarine landscape (“seascape”).

Because of participation of numerous partner organisations from different countries, common standards needed to be set up to create interoperable data and harmonized spatial (map) layers.

The project is financed by the European Commission, thus it is self-evident to use European Union standards, i.e. the European INSPIRE Directive Data Specifications, the INSPIRE geology data model and portrayal rules for geology wherever applicable. Where this would not suffice, standards of the global International Union of Geosciences (IUGS) Commission of Geoscience Information (CGI) are being used. In addition, supplementary vocabularies are in development to take into account specific marine seafloor features, in particular in reference to the geomorphological features.

The European Environmental Agency (EEA) provides the standard coastline used by all EMODnet geology partners and work packages.

This presentation will outline the EMODnet geology approach to compile heterogeneous map data of the European seafloor geology, describe the challenges posed to harmonize the semantically geometrically and conceptually varying data sets and show the resulting map data that are the product of a fruitful cooperation with the partner organisations.

Advancing the Understanding of Seabed Substrate Characteristics: Insights from EMODnet Geology

Susanna KIHLMAN[1]*, Geological Survey of Finland (susanna.kihlman@gtk.fi)
Anu Marii Kaskela[2], Geological Survey of Finland
Aarno Tapio Kotilainen[3], Geological Survey of Finland
Ulla Alanen[4], Geological Survey of Finland
Henry Vallius[5], Geological Survey of Finland
EMODnet Geology partners [6],

Abstract

Increasing activities and pressure on marine and coastal environments have made the easily accessible, reliable, and suitable information on marine environment essential to support overall sustainable marine management decisions, conservation, and research. The EMODnet (European Marine Observation and Data network) Geology project has been aiming to address this demand by collecting and harmonizing geological data at different scales from all the European sea areas since 2009, at present with a collaboration of about 40 partners and subcontractors.

Seabed substrate is one of the key elements in describing the marine environment. In the project, national, highly heterogeneous seabed substrate datasets are harmonized into a shared translation schema, based on the sediment grain size distribution. Currently, harmonized seafloor substrate data are available at a variety of scales, from extensive 1:1 000 000 dataset, to more localized, high-resolution datasets from 1:100 000 to as fine as 1:1 500 scale. The datasets cover all European marine areas, as well as the Caspian Sea and the Caribbean Sea, the latest regional addition to the dataset.

However, grain size alone does not define all seabed characteristics that have significance for the marine environment. As a part of the seabed substrate data, the project has also collected additional information on a variety of surface features that may have ecological, geological, or economic value, and the project partners have considered relevant, such as seagrass meadows, FeMn concretion fields, moving and bioclastic sediments. Further, the project group have recently shifted towards collecting the information on seabed dynamics, especially seabed erosion. Sedimentation rates data have been collected since the beginning of the project.

Besides collecting and harmonizing the existing data, case studies in which tools for substrate modelling and sedimentation rates have been developed. A close connection and collaboration with EMODnet Seabed habitat have been established from the beginning and the methods have been shared with the EMODnet PArtnership for China and Europe (EMOD-PACE) project (2019-2022).

A lot of work has been done to create the foundation to build on, and the work continues. The development of usable and valuable data products requires a collaboration with different stakeholders and end users, and future work should be planned with possible applications and interests in mind. At its best, this kind of data not just helps to define the seabed but provides essential tools for better understanding about the marine environment.

The EMODnet Geology project is funded by The European Climate, Environment, and Infrastructure Executive Agency (CINEA) through contract EASME/EMFF/2020/3.1.11 - Lot 2/SI2.853812_EMODnet – Geology.

Brazilian research in the Atlantic Ocean

Luciana Felicio PEREIRA[1]*, Geological Survey of Brazil (luciana.pereira@sgb.gov.br)
Patricia Reis Oliveira[2], Geological Survey of Brasil
Hortência Barbosa Assis[3], Geological Survey of Brasil
Ronaldo Gomes Bezerra[4], Geological Survey of Brasil
Vadim Harlamov[5], Geological Survey of Brasil

Abstract

In recent years, the Geological Survey of Brazil (SGB-CPRM) has been developing several activities aimed at research and exploration of marine mineral resources. The growing demands for the use of sea resources force the recognition and mapping of the submerged national territory with the aim of inventorying and directing studies, research and public policies for the adequate use and protection of wealth in a sustainable way. The technologies used to survey these underwater areas are high-resolution shallow seismic, the Light Detection and Ranging system, interferometric sonars, modern collectors, and Remotely Operated Vehicles and Autonomous Underwater Vehicles. In addition it can be used others instruments such as magnetometric sonars, underwater cameras, manipulator arm, cutter and sample collector and various sensors capable of carrying out fundamental measurements for mineral research. The Brazilian government promotes knowledge of the mineral resources of the brazilian continental shelf with two larger projects: Systematic basic geological-geophysical survey of the Brazilian Legal Continental Platform, on a scale of 1:1,000,000; and Thematic projects involving geological-geophysical surveys of sites of geo-economic-environmental interest, with detailed (1:100,000) and semi-detailed (1:300,000) research. This research covers: lithoclastics (sands and gravels), bioclastics (calcareous algae and shells), heavy mineral deposits, phosphorites and metalliferous crusts and polymetallic sulfides. Around 30,000 km2 of area on the shallow platform in the equatorial region and in the south of the country have already been mapped by the project. In the International Atlantic AREA there are two main projects: mapping the occurrence of minerals from the Rio Grande Rise, especially the ferromanganesiferous crusts rich in cobalt, and obtaining information to reveal their geological and paleoceanographic evolution, and mapping stretches of the Mid-Atlantic Mountain Range identifying possible occurrences of polymetallic sulfides. The economic exploration of bioclastic marine aggregates in shallow waters is already a reality in Brazil, even with few deposits being explored. Further, many areas are required for research into heavy minerals, phosphorites and offshore wind energy. In deep waters, many occurrences of cobalt-rich ferromanganesiferous crust have already been identified and are in the evaluation phase.

Collating and harmonizing data on geological events in European seas

Andrea FIORENTINO[1]*, Geological Survey of Italy - ISPRA (andrea.fiorentino@isprambiente.it)
Loredana Battaglini[2], Geological Survey of Italy - ISPRA
Simone Orefice[3], Geological Survey of Italy - ISPRA
Alessandra Pensa[4], Geological Survey of Italy - ISPRA

Abstract

EMODnet Geology Work Package (WP) 'Geological events and probabilities' gathers information concerning submarine landslides, earthquakes, volcanic centres, tsunamis, fluid emissions and Quaternary tectonics. The WP aim is the production of harmonized digital maps at multiple scales of events occurrences in European seas.

Each type of geological event occurrence is represented by features organized according to their geometries (polygons, lines and points). Each occurrence is complemented by a comprehensive pattern of attributes.

The elaboration of guidelines to compile the shapefiles and attribute tables, which constitute the WP layers, was aimed at identifying parameters to be used to thoroughly characterize each type of event and any additional relevant information.

Due to the different geological settings of European seas, it was necessary to elaborate a detailed pattern of attributes for the different features, in order to represent the diverse characteristics of each occurrence. Particular attention has been devoted to the definition of such attributes to achieve the best degree of harmonization and standardization complying with the European INSPIRE Directive.

The huge amount of data collated has been processed, validated and standardized. They include data deriving from national and international Projects held by Partners or by third parties. The elaboration of national contributions also promoted systematic inventories of the wealth of published data collected in the last thirty years, thanks to the significant improvement in techniques of acquisition. Collaboration and sharing of data, practices and experiences among Project Partners, which are mainly National Geological Surveys, allowed to increase the quality and detail of the information gathered.

Besides the collection of events occurrences, events probabilities were also considered. However, it is not easy to evaluate probabilities for all of the different events gathered within WP6. Probabilities are generally evaluated concerning single events and are assessed by different methods and parameters. The evaluation of "likelihood of occurrence" seemed to be the best way to obtain indications on probabilities, at least for some events. The submarine landslides layer appeared as the more suitable case for such an attempt. Based on data gathered by WP6 and on parameters obtained from EMODnet Bathymetry (such as depth, slope, curvature, etc.) a "Landslides susceptibility map" was elaborated.

Data, metadata and complementary information are displayed on the EMODnet Central Portal (http://www.emodnet.ec.europa.eu/) subdivided into layers at 1:250.000 scale, which include data

at lower resolutions, and layers at 1:100.000 scale, which include also data more detailed than 1:100.000. The Portal provides access and free download to a reliable and complete interoperable database facilitating exchange and re-use of data which may represent a baseline to elaborate additional thematic maps or support further research as well as land planning and management.

Paleobotanical zoning of exposed continental shelves as a tool to overcame geographical discontinuity of scattered paleolandscape data

Francesco Latino CHIOCCI[1]*, Sapienza, University of Rome (francesco.chiocci@uniroma1.it)
Elisa De Luca[2], Sapienza, University of Rome
Daniele Casalbore[3], Sapienza, University of Rome
Federico Di rita[4], Sapienza, University of Rome

Daniele Spatola[6], Sapienza, University of Rome
Heater Stewart[7], British Geological Survey

Abstract

In the EmodNet-Submerged Landscapes initiative, a significant challenge has arisen, which is particular to this domain but holds relevance across various disciplines whose cartography relies on spatially sparse data. EmodNet-Submerged Landscapes aims to to compile a comprehensive data repository encompassing proxies of environments characterizing the European continental shelves during the last eustatic hemicycle.

Around 20,000 years ago, during the last glacial maximum, the sea level reached the continental shelf's edge, exposing the shelf that was harboring diverse fauna and early human populations. Subsequently, over the following 10,000 years (from 18 to 8 thousand years ago), the sea level rose to its present position, inducing landward migration of the shoreline and forming a transgressive erosional surface (ravinement surface). This erosional activity obliterated paleontological remnants, prehistoric artifacts, and reshaped the landscape.

Identifying environmental indicators such as springs, lagoons, eolian dunes, paleo valleys, and other features in presently submerged landscapes relies on seafloor and subsurface sampling, dating of paleontological finds, and reconstructing paleomorphology through techniques like seismic imaging or, in absence of highstand shelf mud, utilizing high-resolution bathymorphological data.

The objective of EmodNet-Submerged Landscapes is to establish a data repository where paleoenvironmental data can be collated, standardized, or generated following uniform standards. This repository aims for easy accessibility in cartographic formats, catering not only to the scientific research community but also to the broader public. Nevertheless, creating legible maps poses challenges due to the limited, inherently uneven, dispersed, and geographically discontinuous nature of the available data.

To contextualize these site-specific data, a significant approach involves considering paleobotanical (and consequently paleoenvironmental) studies of continental shelves across various phases of sea level rise, taking into account the diverse paleoclimate and paleogeography conditions at different temporal stages.

Pollen data from continental shelves have been gathered, to establish a database where modeling techniques have been applied. These data furnish detailed insights into depositional environments, climate, and soil characteristics.

Palaeobotanical zoning (based on pollen records) offers extensive spatial data for reconstructing past land cover changes as well as for evaluating current vegetation composition trends and drivers. The objective is to integrate paleobotanical data with geological and geomorphological data to generate paleoenvironmental maps based on this information.
It is however crucial to communicate the speculative nature and interpretative limitations of the resultant cartography. Nonetheless, adopting such an approach serves to enhance map readability and offer a broader context to the site-specific, scientifically rigorous data.

Europe's marine minerals: EMODnet geology

Xavier MONTEYS[1]*, geological Survey Ireland (xmonteysv@gmail.com)
Charise McKeon[2], geological Survey Ireland
Koen Verbruggen[3], geological Survey Ireland

Abstract

Minerals are major geopolitical actors in the present world. Supply chains of strategic and critical raw materials like cobalt, copper, lithium, nickel and rare earth elements are highly concentrated, generating risks. The European Marine Observation and Data Network (EMODnet) is a long-term marine data initiative funded by the European Maritime, Fisheries and Aquaculture Fund (EMFAF) and supported by the EU's integrated maritime policy. The EMODnet Geology team released in 2023 a series of pan-European products related to marine themes including Marine Minerals. Data products are available through the integrated EMODnet Central Portal: https://emodnet.ec.europa.eu/en. Collated harmonised and standardised marine mineral types and energy resources can be grouped in 4 main categories: Marine Aggregates, Marine Critical Minerals, Marine Hydrocarbons and Hydrates, Marine non-critical Minerals. The twelve types mapped are aggregates; hydrocarbons; gas hydrates; sapropel, marine placers; phosphorites; evaporites; polymetallic sulphides; polymetallic nodules; cobalt-rich ferromanganese crust; metal-rich sediments; rock, pegmatite and vein hosted mineralisation. With Earth's population growth, efforts to meet our needs for resources with indigenous supplies continue. Many minerals and critical raw materials form important components in low-carbon and resource-efficient technologies such as electric car batteries, wind turbines and solar panels. Information on the types of minerals has relevance to engineering disciplines including extractive industries, beach nourishment and reclamation projects, and more general in Marine Spatial Planning. Environmental and marine EU policies are benefiting from the project's outcomes. The program's study area has been recently extended to include the Caspian and the Caribbean Sea demonstrating a determination to grow beyond the European waters.

EMODnet-Geology's new standards revealing Earth's seabed geology

Henry T. V. VALLIUS[1]*, Geological Survey of Finland (henry.vallius@gtk.fi)

Abstract

High-quality maritime spatial planning, coastal zone management, management of marine resources, environmental assessments and forecasting require comprehensive understanding of the seabed. Numerous national seabed mapping programmes worldwide have also demonstrated the necessity for proper knowledge of the seafloor. In response to the obvious needs already in 2008, the European Commission established the European Marine Observation and Data Network (EMODnet), which is a long-term marine data initiative funded by the European Maritime, Fisheries and Aquaculture Fund (EMFAF). It consists of more than 140 organisations assembling marine data, products and metadata to make these fragmented resources more accessible to public and private users, relying on quality-assured, standardised and harmonised marine data which are interoperable and free of restrictions on use. Becoming a new global standard EMODnet strengthened its position when it had its services fully centralised in EMODnet Central Portal in January 2023. It provides now easy and free central access to FAIR marine data, metadata, data products and services spanning seven broad disciplinary themes (lots): bathymetry, geology, physics, chemistry, biology, seabed habitats and human activities. The EMODnet Geology thematic lot, initiated as a pilot project already in 2009, is now 15 years old and is coordinated by Geological Survey of Finland (GTK). With participation of 40 partners and subcontractors from 30 countries it is providing full areal coverage of all European regional seas and is expanding to new areas, already now including data from the Caspian and the Caribbean Seas. EMODnet Geology aims at delivering the various maps at a 1:100,000 scale or finer, but also at coarser scales to ensure maximum areal coverage. Regarding presentation of the web maps a multi-scale approach is adopted where possible. The geology data compiled in the frame of the project, are available through the EMODnet Central Portal: https://emodnet.ec.europa.eu/en. It comprises a) Sea-bed substrate (sediment/rock layer at the sea floor), data on sediment accumulation rates and a sediment erosion database b) Sea-floor geology - lithology and age (bedrock geology beneath the surficial sediment: Quaternary units and pre-Quaternary) c) Geomorphological features of the sea-floor d) Coastal behaviour (migration, type and vulnerability) e) Geological events and probabilities (e.g. submarine landslides, volcanic centres, earthquakes), f) Mineral occurrences (e.g. oil and gas, aggregates, metallic minerals), and g) Submerged landscapes. The EMODnet Geology data products are also available through the European Geological Data Infrastructure (EGDI - www.europe-geology.eu), where they can be viewed in conjunction with terrestrial geological data from onshore Europe. EMODnet Geology is an ongoing dynamic project, where existing datasets are continuously updated and completed with new data. But also new types of data products in frame of marine geology are evaluated in order to be included in the project in the future. EMODnet Geology thus welcomes suggestions of improvement of the available products or addition of completely new products. Third party data submission to EMODnet Geology is

encouraged. The data can simply be submitted straight to EMODnet Geology, but also through EMODnet Data Ingestion (www.emodnet-ingestion.eu) which is reaching out to potential data providers from the public.

Hadal Trenches: highly variable geological environments on the Earth

Hiroshi KITAZATO[1]*, Tokyo University of Marine Science and Technology
(kitazatohiroshi2@gmail.com)
Katsuyoshi Michibayashi[2], Nagoya University
Hayato Ueda[3], Niigata University
Alan J Jamieson[4], Univ. Western Australia
Jaya Roperez[5], Ink.Fish LLC

Abstract

Hadal Trenches beyond 6,500 m deep occupy only 0.1 % of the oceanic areas of the Earth. The areas are distributed in a plate subduction zone where oceanic plate subsides under the continental plate. In the western Pacific, two third of oceanic trenches are concentrated. Certainly, seven trenches are recognized around the Japanese Islands facing to the Pacific.

Tectonic activities are actively occurred along the trenches. We should investigate hadal trenches what kinds of tectonic activities are taken place for monitoring and reducing disaster risks. As hadal trenches are quite deep, there are limit to use regular oceanic research gears. Multi Beam Echo Sounding System (MBES) are commonly used for figuring out precise submarine topography. It is good to use AUVs, ROVs or HOV's for precise observations, measurements, and sample collections. In parallel to operations of these underwater vehicles, it is effective to use lander deployments for long term measurements or observations.

On 2022, we had a chance to have a research cruise along the Japanese Island arcs by DSSV Pressure Drop with full depth HOV Limiting Factor and three hadal landers of Caladan Oceanic / Inkfish LLC. Even though the Japanese Trenches have long been investigated by different HOVs such as French Bathyscaphe, Nautiles, Japanese Shinkai 2000 and 6500, any scientists have never visited hadal depth beyond 6,500m.

We dived at 7 localities of Ryukyu, Ogasawara, off Boso, Japan Trench deepest points and Great East Japan Earthquake Epicenter areas by MBES, full depth landers and full depth HOV Limiting Factor. By using with different gears and instruments, we succeeded to figure out vivid seascapes of hadal trenches in detail. Hadal trenches along the Japanese Islands are extremely variable geological and biological features in comparison to other deep-sea areas.

Need for the uniform information in multinational marine areas - Experiences from the harmonization within seabed substrate data

Susanna KIHLMAN[1]*, Geological Survey of Finland (susanna.kihlman@gtk.fi)
Anu Marii Kaskela[2], Geological Survey of Finland
Aarno Tapio Kotilainen[3], Geological Survey of Finland
Ulla Alanen[4], Geological Survey of Finland
Henry Vallius[5], Geological Survey of Finland
EMODnet Geology partners [6],

Abstract

Efficient and sustainable management of large sea areas, research and conservation require multidisciplinary information on the marine environment though it is commonly hampered by lack of data, or comprehensive information on the sea areas. Seabed substrate is one of the key elements in forming the marine environment and EMODnet Geology project has produced harmonized seabed substrate data products for the European marine areas since 2009. The work started with the seabed substrate data products at scales of 1:250 000 and 1:1 million. Currently, the project offers harmonized seafloor substrate data at a variety of scales, from 1:1 000 000, to high-resolution datasets as fine as 1:1 500 scale covering all European marine areas, the Caspian Sea and the Caribbean Sea. To reach this point, plenty of work has been done, especially at the beginning of the project when the foundations for the future work were laid.

The harmonization process includes the translation of the original national seabed substrate data, conforming to various standards into a shared, uniform EMODnet substrate classification schema (i.e., the Folk sediment classification) describing the uppermost part of the seabed (30 cm). The Folk classification was chosen because it is internationally prevalent, especially in sedimentological studies, serves the needs of habitat mappers and could be delivered by all partners, facilitating the harmonization process across national borders.

The modified Folk sediment classification with three granularities of 15, 6 and 4 classes, each supplemented with an additional class of “rock and boulders”, forms a simple hierarchy of the straightforward union of 16 classes into 7 or 5 classes. If national datasets were classified using the Folk sediment triangle, no conversion was needed. However, if the original data was not initially in the Folk classification, data points could be reclassified based on sample analysis or description, or mapped units could be translated into the most likely Folk class using expert-based prediction. To preserve the data origin, these details about the original substrate and possible reclassification are included as a metadata in the attribute table of the data. A confidence assessment, based on sampling amount, remote sensing coverage and distinctness of substrate boundaries, was applied to characterize the information that underpins the geological interpretations.

Over fifteen years since the beginning of the project, EMODnet Geology has become a key producer of publicly available, harmonized datasets covering broad areas. The methodology is widely recognized, and close collaboration with other EMODnet themes, have contributed the spread to new areas such as Beibu Gulf in South China Sea. Ongoing data collection as a part of EMODnet Geology and European wide consortium with well-established co-operation and the development of the data products within the project, e.g., adding new scales and geographical areas, including new useful attributes to complete the data, will sustain its relevancy in the future.

The EMODnet Geology project is funded by The European Climate, Environment and Infrastructure Executive Agency (CINEA) through contract EASME/EMFF/2020/3.1.11 - Lot 2/SI2.853812_EMODnet – Geology.

Harmonizing marine geological data to support the sustainable use of the maritime areas and their resources - EMODnet Geology as an example

Anu Marii KASKELA[1]*, Geological Survey of Finland (anu.kaskela@gtk.fi)
Henry Vallius[2], Geological Survey of Finland
Susanna Kihlman[3], Geological Survey of Finland
Aarno Tapio Kotilainen[4], Geological Survey of Finland
Ulla Alanen[5], Geological Survey of Finland
EMODnet Geology Partners [6],

Abstract

The European Marine Observation and Data Network (EMODnet) is a network of more than 120 organizations supported by the EU's integrated maritime policy. Since 2009, it has been assembling fragmented and partly inaccessible marine data into coherent, interoperable, and freely available data products covering European marine areas. As the resulting data products are open to use, the program supports European maritime activities contributing to the sustainable use and management of the European seas, including e.g., Blue Economy, Maritime Spatial Planning, Green Deal, and European Critical Raw Materials Act. Today, the EMODnet Central Portal (https://emodnet.ec.europa.eu/en) provides free access to collected marine data, metadata and data products and services spanning seven broad disciplinary themes (lots): bathymetry, geology, physics, chemistry, biology, seabed habitats and human activities.

The EMODnet Geology thematic lot is delivering integrated and harmonized marine geological data products containing seabed substrate, sediment accumulation rates and seabed erosion index database, sea floor geology including lithology and stratigraphy, Quaternary geology and geomorphology, coastal behaviour, geological events such as submarine landslides and earthquakes, marine mineral resources, as well as submerged landscapes of the European continental shelf at various time frames. It focuses on delivering harmonized interpreted data layers (i.e., maps) rather than the underlying data. The metadata provides information on the data holder in case user needs to access the raw data. The aim is to produce data products at 1:100,000 scale or finer, but also at coarser scales to ensure maximum areal coverage. The EMODnet Geology thematic lot is providing the full areal coverage of European seas and is expanding to new areas, as also the Caspian and the Caribbean Seas are included in the geographical scope of the project. It is a dynamic project, where existing datasets are continuously updated with new data.

The current EMODnet Geology project phase (2023-2025) is coordinated by the Geological Survey of Finland (GTK), and it is executed by a consortium of 40 partners and subcontractors. The core of the partnership is formed by members of the EuroGeoSurveys network, supported by other partner organizations with valuable expertise and data. EMODnet Geology also supports third-party data submission. Third party data can be submitted either straight to EMODnet

Geology or through EMODnet Data Ingestion (www.emodnet-ingestion.eu), which is reaching out to potential data providers from private bodies and public.

The EMODnet Geology project is funded by The European Climate, Environment and Infrastructure Executive Agency (CINEA) through contract EASME/EMFF/2020/3.1.11 - Lot 2/SI2.853812_EMODnet – Geology.

Abstract

The EMODnet-Geology project, funded by the European Union, is assembling marine geological data and producing harmonised maps of the European regional seas for public and private users. The project has recently expanded to new areas as the Caribbean Sea and since 2023 some geological maps of this region are available at the website of the project (https://emodnet.ec.europa.eu/en/geology). In order to improve the coverage and quality of the map products in this region, a working group comprising geological surveys of Caribbean countries (Colombia, Costa Rica, Cuba, Dominican Republic, Guatemala, Honduras, Mexico) and Spain was promoted by the project and has been set up with the support of the Association of Iberoamerican Geological and Mining Surveys (ASGMI). Considering the increasing interest for marine geological resources, the first aim of the group has been to collate data from different sources regarding mineral deposits and hydrocarbons in the Caribbean Sea. A map of occurrences is presented revealing a considerable lack of information in the region on metalliferous mineral deposits, which contrasts with the growing interest aroused by the global increasing demand for

strategic and critical raw materials. In order to overcome the observed gaps, a second map of potential mineral deposits distribution (cobalt-rich ferromanganese crusts, polymetallic nodules and sulfides, phosphorites, marine placers) has been developed, on the basis of several bathymetric and geomorphological criteria and the age of the oceanic crust. Recognition of knowledge gaps and determination of potential areas for marine mineral occurrences is a useful and key issue to address strategically exploration and scientific research studies in the next future, considering the large investments and efforts required in the framework of the geologic and tectonic evolution of the Caribbean plate.

Abstract

Pockmarks, characterized by a negative relief resulting from fluid escaping the seafloor, are prominent features discovered for the first time in the Nova Scotian shelf by using echo-sounder records. They have diverse shapes, including U- and V- cross sections, with diameters up to several kilometers and internal depths exceeding 100 meters. These submarine morphologies vary in planform shape from circular to elongated, and in vertical shape profile from flat-bottomed to conical. Despite numerous hypotheses, the mechanisms driving pockmark formation and growth in marine environments remain poorly understood. To address this gap, studies have collected geophysical, morphological, sedimentological, and geochemical data from marine areas hosting pockmarks, offering valuable insights into their genesis and evolution.

In this study, we conduct a comprehensive review of pockmark distribution along the Italian continental margins, selecting 5,932 pockmarks to investigate their relationship with environmental and geological factors. Our analysis considers physical parameters such as morphology, slope gradients, water depth, and sea-level changes, as well as geological features/processes like fractures, fault systems, and seafloor sediment distribution. To enhance understanding and prediction, we employ a deep learning model incorporating geological information such as morphology, distance to faults, sediment type, slope gradients, sedimentary thickness, and water depth. The model generates the first "Predicted Pockmark Susceptibility Map" for the Italian continental margin, identifying the upper continental slope as particularly susceptible.

Our findings highlight the higher number of pockmarks are mainly located in flatter seafloor areas (less than 4°), composed mainly of sandy mud, with a Plio-Quaternary sedimentary layer up to 400 meters thick, and in close proximity to fault systems. We also observe the influence of salt

tectonics, notably related to the Messinian Salinity Crisis, although the retrieval of the thickness of Messinian evaporites poses challenges.
Beyond enhancing our understanding of pockmark formation, our study underscores the broader implications for climate change dynamics, marine biodiversity, and economic considerations. Pockmarks release significant gases, impacting the greenhouse effect and affecting the biosphere, hydrosphere, and atmosphere. Additionally, they hold economic significance due to their association with hydrocarbon deposits but pose threats to offshore installations and navigation safety. Our investigation also addresses the impact on marine biodiversity, emphasizing the conservation importance of deep-sea habitats. The susceptibility map generated can aid in delineating regions suitable for submarine infrastructures and identifying areas requiring reinforcement with safety measures, thereby contributing to marine spatial planning and conservation efforts.

Abstract

Ice wedges, unique underground V-shaped ice formations, result from the infiltration of atmospheric moisture or precipitation through frost cracks in permafrost. They are valuable in reconstructing past winter temperatures, much like how scientists analyze ice cores from polar ice regions. However, there has not been sufficient research into understanding how ice wedges form and where they come from. This lack of understanding could pose significant challenges in interpreting the isotopic composition of meltwater and, consequently, in reconstructing paleotemperatures. The way moisture isotopes are fractionated can vary depending on whether the ice forms from compacted snow or hoarfrost, or from water freezing in frost cracks.

To better understand how ground ice forms, we can use a geochemical indicator called the δ(N2/Ar) molar ratio of occluded gas. This can help distinguish between ground ice formed by the compaction of hoarfrost or snow (where δ(N2/Ar) is ~ 0%) and ice formed by freezing water (where δ(N2/Ar) is ~ -60%). To analyze this, we used a system that melts and refreezes the ice and extracts occluded gas along with Gas Chromatography equipped with a Thermal Conductivity Detector to determine the gas molar ratios.

Our study examined various types of ground ice from East Siberia and Alaska. The δ(N2/Ar) molar ratio of open-cavity ice, formed from vapor sublimation in void spaces, was close to those of the atmospheric, ranging from -8.53% to 1.93%. In contrast, intrusive ground ice, created by the freezing of groundwater due to gravity, had δ(N2/Ar) molar ratios ranging from -63.25% to -27.82%, indicating that the gas originated from dissolved gases. Ice wedges displayed a range of values falling between two extremes, suggesting that they formed in mixed conditions involving various sources such as snow, hoar, and liquid water, depending on the δ(N2/Ar) signal.

Our study may reveal valuable chemical characteristics of ground ice that help identify how it forms. By linking δ(N2/Ar) with stable water isotopes, we might gain insights into paleoclimatic interpretations, particularly when analyzing ice wedges from regions in the permafrost zone.

A comparison of the geochemistry between the Chokurdakh ice wedge and the central Yakutian ice wedges formed during the Last Glacial Maximum (LGM)

Nayeon KO[1]*, Seoul National University (rhskdus88@naver.com)
Jinho Ahn[2], Seoul National University
Go Iwahana[3], International Arctic Research Center (IARC)
Hyejung Jung[4], Ewha Womans University
Jeonghoon Lee[5], Ewha Womans University

Abstract

In this study, we examined the geochemistry of the Chokurdakh ice wedge near the Northeast Siberian Sea and compared it with that of ice wedges from the inland Siberian region, especially in the Yakutsk area (referred to as central Yakutian ice wedges hereinafter). The ages of the central Yakutian ice wedges correspond to the Last Glacial Maximum (LGM; with a mean of 20300 years before present [BP], present = 1950 CE), and the Chokurdakh ice wedge also corresponds to the LGM, with an age of 24710 ± 150 years BP. Regarding the δ(N2/Ar) ratios, Chokurdakh ice wedge exhibits a range from -3.53 to 2.39 %, with a mean of -1.20 % (n=6), which is similar to the range observed in the central Yakutian ice wedges (-0.17 to 5.73 %, with a mean of 2.45 %, n=11).The δ(N2/Ar) ratios close to 0% indicate that these ice wedges primarily formed through hoarfrost accretion or dry snow compaction. Most of the ice wedges show δ(O2/Ar) ratios of -80 to -100%, indicating that oxygen gas was largely consumed by microorganisms within the ice wedge. In terms of the co-water isotope relationship (δ18O- δD). Both the Chokurdakh (δD= 5.93*δ18O-61.48, R2= 0.41) and Cyuie ice wedges in central Yakutia (δD= 6.90*δ18O-29.93, R2= 0.85) follow similar regression lines, with average d-excess values of 1.06 ±1.33 and 3.45 ± 1.53 ‰ for Chokurdakh and Cyuie ice wedge, respectively. Regarding greenhouse gas (GHG) composition, the Chokurdakh ice wedge exhibits an average CO2 mixing ratio of 5.0%, roughly half the value of 10.4 % observed in the central Yakutian ice wedges. Conversely, the average CH4 mixing ratio for Chokurdakh is 913.5 ppm, nearly 60 times higher than the value observed in central Yakutian ice wedges, which is 16.2 ppm. However, the N2O mixing ratio of both ice wedges is comparable, with averages of 27.9 ppm for Chokurdakh and 25.6 ppm for central Yakutian ice wedges. The central Yakutian ice wedges show a broader range of N2O values, with a standard error of 34.92, compared to the Chokurdakh ice wedge's standard error of 12.98. In future studies, a more detailed geochemical comparison will be undertaken, taking into account the distinct environmental conditions during the formation of the Chokurdakh and central Yakutian ice wedges. This will offer further insights into the interpretating paleoclimate conditions in the Siberian region during the LGM period.

Abstract

Geologically, Antarctica is the least explored place on earth. A thick ice sheet covers 98% of the continent, and the harsh environment has slowed the exploration of the interior of the Antarctic ice sheet and its beds for decades. Currently, electrical and electromagnetic methods including Magnetotelluric(MT) and transient electromagnetic (TEM) et al., methods are being used for experimental measurements in Antarctica, which can provide 2D or 3D tomography/images of the subsurface in a fast and non-invasive manner. However, subglacial rocks in Antarctica differ significantly from those in other regions. Using available core data, it is possible to find that the subglacial rocks are composed of materials in four different phases: two solid phases (rock/soil matrix and ice), a liquid phase (unfrozen pore water with some ions), and air-filled pore spaces and cavities in Antarctica. Unlike the freezing of bulk water, liquid water in porous media doesn't completely change phase to solid ice below the freezing temperature. The primary reason for this is the decrease in the melting point of water induced by adsorption on the surface of the skeleton particles and the curvature These unfrozen waters provide channels for the migration of ions, which is directly responsible for the conductivity of subglacial rock and key to the evaluation of electrical conductivity. Hence, applying electrical and electromagnetic methods for geo-environmental studies in cold regions requires more experimental and modeling studies of the electrical conductivity of subglacial rock.

In this study, the unfrozen water was categorized as free pore water and film water. The conductivity of pore water is affected by a combination of concentration and temperature. When the temperature decreases, a salting effect occurs, resulting in a decrease in conductivity. The electrical conductivity of thin-film water is determined by the Gibbs-Thomson equation and the specific surface conductance between the solid surface-liquid water and bulk ice-liquid water interfaces. Subsequently, two microscopic models were developed: a skeleton model and a pore network model using the FEM method to simulate the electrical response characteristics of subglacial rock. By comparing the electrical response characteristics of the two models, the characteristics of the effects of the unfrozen water content, initial water content, temperature, mineralization, and porosity on the electrical resistivity of subglacial rock were analyzed. In addition, the specific contribution of free pore water and film water to resistivity under different conditions is discussed, revealing further the importance of free pore water and film water in the conductivity process. These studies contribute to a deeper understanding of frozen porous media's

electrical properties and open new possibilities for characterizing the distribution and dynamics of liquid water in frozen environments using geoelectric and electromagnetic techniques.

Time-series deformation monitoring of post-glacial rebound using space-based synthetic aperture radar observations

Seong-Woo JUNG[1]*, Pusan National University (swjung@pusan.ac.kr)
Sang-Hoon HONG[2], Pusan National University

Abstract

Glaciers worldwide have been melting steadily for approximately 20,000 years since the last glacial maximum, and recent global warming has accelerated this trend. Post-glacial rebound, also known as glacial isostatic adjustment (GIA), occurs as glaciers melt and thin, causing a decrease in the load on the Earth's surface and resulting in ongoing deformation. Greenland significantly contributes to global sea-level rise, with substantial mass loss annually. Despite being seismically quiet and structurally stable, Greenland undergoes continuous deformation due to mass loss and glacial isostatic adjustment following glacier retreat. Iceland, where approximately 11% of the land is covered by glaciers, also undergoes deformation due to various processes such as plate spreading, post-glacial rebound, and localized volcanic activity. Global Navigation Satellite System (GNSS) data is available even in polar regions, however its sparse distribution poses challenges in observing large areas comprehensively.. Synthetic aperture radar (SAR) satellites offer advantages for continuous observation, as they can acquire surface images regardless of weather conditions and day-night cycles, even in geographically inaccessible regions. SAR interferometry provides a technique to measure displacements with high accuracy ranging from a few millimeters to centimeters over large areas. In this study, we observed post-glacial rebound deformation in Greenland and Iceland using Sentinel-1 and ALOS-2 PALSAR-2 data acquired over several years, employing the Small Baseline Subset technique (SBAS) and compared the results with GNSS measurements.

Understanding Intra/inter-regional Heterogeneous Glacier Retreat and Glacier-Climate Synthesis over the Himalayas

Parvendra KUMAR[1]*, Department of General and Applied Geography, Dr. Harisingh Gour University, Sagar, Madhya Pradesh, India (parvendra.jnu@gmail.com)
Milap Chand Sharma[2], Centre for the Study of Regional Development, Jawaharlal Nehru University, New Delhi

Abstract

Himalayan glaciers support the most populous region of the world as well as provide an opportunity to understand the climate change in the region. Glaciers in the Himalayas are reported in a general state of retreat from the 19th century. However, glaciers have recorded a heterogeneous pattern of retreat over the Himalayas. Consequently, a glacier-climate synthesis has not been developed yet. Therefore, the present study aims to understand intra-regional and inter-regional diverse patterns of glacier retreat caused by topographical and climatic factors to develop Glacier-Climate synthesis over the Himalayas. To understand the intra-regional heterogeneity in retreat patterns, the study assesses the terminus retreat of medium-sized glaciers (1988 to 2018) using geospatial dataset and inputs from fieldwork in Sikkim Himalaya which is under the direct influence of the Indian Monsoon. Glaciers have retreated at a diverse rate in a range from 63.9 m yr-1 to 3.9 m yr-1 and lost a total area of ~3.95 (±0.35) km2 (~2.53%, 0.08% yr -1) during 1988-2018 in Sikkim. Being located in similar climatic conditions, the intra-regional heterogeneity in glacier retreat in Sikkim seems to be caused by topographical factors as glaciers with a shorter length, smaller area, higher terminus altitude, lesser slope gradient, possessing a simple form, having lakes and oriented in E, SE and S have retreated the most over the entire observation period. A comparison of glacier retreat in Sikkim with other parts of the Himalayas reveals a declining gradient of retreat from the northwest to the eastern Himalayas with a lower rate of glacier retreat in Sikkim, broadly. This inter-regional disparity in the retreat rate of glaciers seems to be caused by existing climatic regimes over the different parts of the Himalayas. The results are helpful in comprehending the Glacier-Climate synthesis over the Himalayan region.

Effect of varying the fluidity parameter in Glen's Law on ice sheet dynamics using 2D finite element software, Elmer/ice.

Su-Jeong LIM[1]*, Kangwon National University (aa049600@kangwon.ac.kr)
Byung-Dal So[2], Kangwon National University

Abstract

The dynamics of ice mass change are closely linked to the movement of the grounding line in the transition zone between ice sheets and ice shelves. These dynamics are controlled by external factors such as ice discharge, accumulation and ablation, and gravity-driven ice flow. The position and movement of the grounding line, as well as ice discharge and flow, depend critically on the viscosity of the ice. Viscosity is a function of several factors, including bed topography, ice geometry, and hydrostatic pressure, due to the nonlinear relationship between ice viscosity and both stress and temperature. Ice viscosity parameterizes the rheological behavior of ice through Glen's law, a power law relationship where strain rate is proportional to the Glen exponent (n) squared of the deviatoric stress. The fluidity parameter (A), typically a parameter of Glen's law, depends on temperature, interstitial water content, and hydrostatic pressure in modeling ice sheet dynamics. Traditionally, ice sheet dynamics modeling has used a Glen exponent value of n=3, which has been effective in reproducing observed ice flows. However, recent analyses suggest that a more accurate exponent may be n=4, based on correlations with ice velocity and sea level rise data. Laboratory experiments suggest a wide range of A for n = 4. We constrain the wide range of fluidity parameters to identify the appropriate ice viscosity for modeling ice sheet dynamics when n = 4. We performed the numerical simulations solving the full Stokes equations (Elmer/Ice) to calculate the flow across the ice sheet and ice shelf. We developed two-dimensional models with simple slope and actual Antarctic ice topography. Variation of the fluidity parameter controls ice velocity, ice area, and ice thickness. Identifying the fluidity parameter, a parameter of Glen's Law, to accurately estimate ice viscosity is necessary to predict ice mass change and future sea level change.

Exploring the Soft-Sediment Deformation Structures (SSDS) in Glacial Environments: Insights from Physical Dropstone Deposition's Simulations

Ana Beatriz Dias JARDIM[1]*, Universidade de Brasília (abjardim97@gmail.com)
Elder YOKOYAMA[2], Universidade de Brasília
Ingrid de Souza HOYER[3], Universidade de Brasília

Abstract

Anthropogenic activities have exacerbated global climate change. The impacts of rising global temperatures are noticeable globally, with polar regions experiencing significant effects, as seen in the diminishing ice caps. Melting ice reduces marine salinity in affected areas and increases the deposition of terrigenous sediments. Within these sediments, extrabasinal clasts, known as dropstones, are deposited. Dropstones are rock fragments dislodged from ice rafts and icebergs as water temperatures increase. Upon reaching the bottom sediments, they trigger the formation of structures called soft-sediment deformation structures (SSDS). The morphology of these deformations is influenced by factors, such as water column thickness, density, and salinity. SSDS has the potential to be a new paleoenvironmental proxy, helping with paleoclimatic interpretations. Recent studies using numerical simulations have clarified dropstone deposition and SSDS formation processes. These studies had limited variation in physical parameters, like water salinity, leading to outcomes that differed from geological reality. The current study uses physical simulations to provide new insights into the formation and implications of SSDS in the paleoenvironmental context. Lead ellipsoids (LE) with an average long axis of 2 cm and weighing 17.5 g were used as dropstones. The water column was simulated using a one-meter-high acrylic tube with a 10 cm diameter. Deformation test specimens comprised alternating layers of kaolin sheets dyed with hematite and kaolin, each layer averaging 0.4 cm in thickness. The specimens underwent LE dispersion based on water column thickness, replicated for both fresh and saltwater. Recordings during the experiment were analyzed using ImageJ software to determine the path and speed of the LE throughout the trajectory. This analysis, conducted for various water column thicknesses, showed a final deformation rate of 75% and 96% in the top layer for a 30 cm water column thickness with fresh and saltwater, respectively. At 60 cm, the deformation rate increased to 89% for fresh water and 96% for saline water. In a 90 cm freshwater column, a final deformation rate of 97% was observed. High deformation values were observed in deeper layers for all three water column thicknesses when only fresh water was present, suggesting penetration and ruptures in the sediment layers. The thickness of the water column with saline water resulted in a smoother penetration pattern and fold formation in the layers, showing the impact of environmental salinity and creating more distinct features in the initial sediment layers. To assess the impact of the water column on sediment deformation, an experiment without water showed only a 2% deformation rate in the top sediment layer, showing that water plays a direct role in SSDS formation. This study highlights the significance of comprehending the connections among melting processes, dropstone deposition, and SSDS structure formation in glacial environments,

enhancing our understanding of the effects of future global climate change.

Elevation changes of the ice sheet above subglacial lakes around David Glacier in East Antarctica measured using Sentinel-1 DDInSAR

Taewook Kim[1]*, Kangwon National Univercity (tw960215@kangwon.ac.kr)
Hyangsun Han[2], Kangwon National University

Abstract

The change in water level of a subglacial lake, driven by water filling and draining activities, results in the elevation change of the overlying ice sheet. The ice sheet elevation change due to the subglacial lake activities has been widely analyzed through time-series observations from satellite altimeters. However, the revisit times of satellite altimeters, spanning a few tens to hundreds of days, are insufficient for capturing small changes in ice sheet elevation over short periods due to lake activity. Differential Interferometric Synthetic Aperture Radar (DInSAR) with shorter temporal baseline offers a valuable tool for observing precise surface displacements of the ice sheet above a subglacial lake. In this study, we generated time-series DInSAR images using Sentinel-1 SAR imagery at ascending and descending nodes from March 2016 to December 2023 around David Glacier in East Antarctica, where subglacial lakes named David 2 (D2), David 3 (D3), and an uncharted subglacial lake (hereafter referred to as K1) are located. DInSAR-derived displacement contains both horizontal ice flow and vertical elevation change due to subglacial lake activity. To observe the vertical displacement due to subglacial lake activity, we applied the Double Differential InSAR (DDInSAR) technique, which differentiates between two DInSAR images assuming constant ice flow, to the DInSAR images. First, for each subglacial lake, we identified a reference DInSAR reflecting no elevation change due to stable water levels in the subglacial lake, guided by ICEsat-2 altimeter observations. We then generated DDInSAR images by subtracting the remaining DInSAR images from the reference one. The DDInSAR images effectively reveal the temporal variations in vertical displacement due to variations in subglacial lake activities, with minimal ice flow variations. Integrating the time-series DDInSAR-derived displacements, we found that the ice sheet elevations changes over the subglacial lakes, as measured by integrating DDInSAR-derived displacements, although some discrepancies were possibly attributed to uncertainties in the ICEsat-2 observations and residual ice flow effects in the DDInSAR. The ice surface over D2 and D3 uplifted approximately 8 m and 3.5 m, respectively, from March 2016 to May 2020. The uplift of the ice surface over D2 and D3 continued, but it was only by an additional 0.5 m and 0.2 m, respectively, over the three years following May 2020. The ice surface over K1 was uplifted by about 0.5 m from March to July 2016 and experienced repeated cycles of uplift and subsidence of approximately 0.2 m until May 2020. Subsequently, it subsided by about 1.5 m from May 2020 to March 2021. After that period, the ice surface over K1 was uplifted by about 0.4 m. The analysis of DDInSAR-derived surface displacements enables precise observations of ice sheet elevation change caused by subglacial lake activity in short period, which can help better understand the subglacial water filling-draining system.

An Innovative Experiment of Geophysical Measurements with Low-Altitude UAV in the Ingrid Christensen Coastal Ice Sheet

Changchun ZOU[1]*, China University of Geosciences (Beijing) (Zoucc@cugb.edu.cn)
Yuanyuan Zhang[2], China University of Geosciences (Beijing)
Chang Peng[3], China University of Geosciences (Beijing)
Hongjie Zhang[4], China University of Geosciences (Beijing)

Abstract

99.82% of the Antarctic continent is covered by ice, resulting in a limited understanding of the underlying geology. Aimed at the extremely poor climatic environment and complex geologic conditions, the research carried out polar geophysical studies and independently developed key technologies and equipment for integrated geophysical Measurements with UAVs, which have become a favorable tool to unveil the mysteries of the bedrock beneath the Antarctic ice.

During the 40th China's 40th Antarctic Expedition, the study conducted ground-breaking under-ice electromagnetic detection using unmanned aerial vehicles in the Larsemann Hills region of East Antarctica. The exposed bedrock test area at Law Base and the ice cap test area off the coast of Ingrid Christensen were selected as detection targets, and seven flights were efficiently completed at a flight speed of 5 m/s, collecting electromagnetic detection data for 16 lines totaling 4.19 km. Additionally, ground magnetic surveys were also used to complement the investigation, providing lithologic features and magnetic anomaly data, which assisted in the interpretation of electrical anomalies. After data processing, the electrical parameters of the subglacial bedrock were successfully calculated and a high-resolution 3D resistivity image of the subglacial bedrock was reconstructed. The results show that the subsurface resistivity values in the exposed bedrock sounding area of Law Base are relatively low, indicating an overall low resistivity character, which is also exhibited in the deeper parts. In the Ingrid Christensen Coastal Ice Sheet Test Area, the resistivity is relatively high at shallow depths and relatively low at deeper depths, consistent with the distribution of seawater beneath the test area.

The successful application of this detection technology has provided an unprecedented "CT" scan of the bedrock beneath the ice. In the future, with further improvements and applications of the technology, more breakthroughs and discoveries will be made in the field of Antarctic scientific research, which will contribute more to global climate change and other scientific subjects.

Diel variations in isotopic and chemical compositions of stream water in Antarctica

Hyejung JUNG[1]*, Ewha Womans University (hyejeong.chung@gmail.com)
Hyoungseok LEE[2], Korea Polar Research Institute
Chaeyoung KIM[3], Ewha Womans University
Jeonghoon LEE[4], Ewha Womans University

Abstract

Global warming is accelerating the thawing of permafrost in high latitudes, leading to alterations in hydrological pathways. An important implication of the increased active layer thickness is that groundwater is likely to play an increasingly important role in polar terrestrial freshwater systems. These changes have a significant influence on predicting chemical weathering and hydrologic pathways in river systems. A study conducted in 2022 documented diel (24-h) variations of δ18O and chemical species observed in a stream on King George Island in Antarctica. The purpose of this study was to expand on these earlier findings by conducting high resolution monitoring for chemical components. The most important findings of this study include: (1) diel δ18O decreased during the night and increased during the day, in agreement with previous work; (2) these changes were negatively correlated to diel changes in Cl- and NO3- concentrations (r = -0.6); (3) diel pH decreased during the night and increased during the day due to aquatic plants and microbes; and (4) pH was positively correlated to diel variation in Cl- and NO3- concentrations (r = 0.4). Additional interpretation is required to better understand how future climate change could impact river systems aspects for chemical weathering and hydrologic pathways in this region.

Development and benchmarking of ice sheet dynamics model using COMSOL Multiphysics® compared to Ice Sheet System Model (ISSM)

Yi-Jeong BAEK[1]*, Kangwon National University (yijung0320@kangwon.ac.kr)
Byung-Dal So[2], Kangwon National University

Abstract

Numerical simulation of ice sheet dynamics is essential for assessing glacier mass balance and sea level rise. Ice flow is attributed to the complicated interaction between grounding line migration, calving, basal friction, and topography. Previous studies using massive geophysical observation, including IPR (Ice Penetrating Radar), InSAR (Interferometric Synthetic Aperture Rada), and heat flow exploration, highlight the need to develop a sophisticated numerical model. For quantitative simulations of continental-scale ice sheets, such as Antarctica and Greenland, ice-flow models rely on the Shallow Shelf Approximation (SSA). We have developed an SSA module using COMSOL Multiphysics®, named COM-SSA. To verify the applicability of COM-SSA as software for ice sheet dynamics, five subdivided cases are compared with ISSM. In Cases 1 and 2, which dealt with nonlinearity problems, we confirmed that the convergence of viscosity and basal friction was successfully handled. Case 3 tested the ice thickness evolution calculated by the conservation of mass equation. Case 4 investigated the grounding line migration with time-dependent ice thickness changes. In both cases, a pattern similar to ISSM was shown. This indicates that COM-SSA could precisely implement ice sheet dynamics. After the validation of COM-SSA by comparison with ISSM, we have demonstrated its capabilities in the case of the application to the Pine Island Glacier, Antarctica. COM-SSA successfully performs 300 years of velocity, ice thickness evolution, and grounding migration for the PIG.

Meltwater influence on sulfur isotope composition of sulfate in ice wedge

Hyeonjeong JEONG[1]*, School of Earth and Environmental Sciences, Seoul National University, Seoul, Korea (hyeonwjd@snu.ac.kr)

Abstract

Ice wedges, formed through repeated crack and infilling processes, serve as valuable archives complementing the limitations of traditional ice cores, offering insights into paleoenvironmental and paleoclimate reconstruction. Like other ice archives, ice wedges are effective proxies for preserving past atmospheric aerosols, including sulfate. Since sulfate behaves as a conservative component in oxic conditions — atmosphere and Earth's surface environment — sulfur isotope ratios of sulfate have provided understanding of atmospheric sulfate origins and further enabled deductions about past changes in atmospheric circulation. However, uncertainties remain regarding the ice wedge infilling process, leading us to consider the case that snow meltwater, having interacted with vegetation and sediments, infiltrates cracks. Therefore, evaluating whether the snowmelt infilling of ice wedges can reflect their past sulfur isotopic composition without alteration, as it passes through the surface and active layer, becomes important for applying sulfur isotopes geochemistry as a proxy for ice wedges. In this study, we aim to analyze the sulfur isotopic composition of dissolved sulfate in ice wedges collected from the Sulgachchy region in Central Yakutia, Northeast Siberia, with a focus on identifying differences influenced by the degree of contribution of liquid water. In the Sulgachchy ice wedges, the depleted $\delta(N_2/Ar)$ values, which vary between -13% and -15%, indicate the contribution of meltwater during ice formation, and the sulfur isotope compositions of sulfate show a range of approximately 8‰. However, there is no apparent correlation between $\delta(N_2/Ar)$ and $\delta^{34}S_{SO_4}$. In addition, ice wedges of similar age in the nearby Myndagay region have near-zero $\delta(N_2/Ar)$ values, suggesting minimal meltwater influence, but their sulfate sulfur isotope compositions are largely consistent with those of the Sulgachychy ice wedges. This preliminary study demonstrates that the $\delta^{34}S_{SO_4}$ values in ice wedges preserve past sulfate aerosol independently of the infilling process, thus confirming the potential of sulfur isotopes as proxies in ice wedges, which can contribute to the reconstruction of paleoenvironments.

Abstract

Bellsund is a fjord system connected to the van Mijenfjorden (northeastern), van Keulenfjorden (eastern), and Recherchefjorden (southern) in southern Spitsbergen, Svalbard. This study investigates changes in provenance in response to the past behavior of fjord glaciers by analyzing lithology and mineralogy in a sediment core (HH19-877-GC) from Bellsund. Our results reveal variability in depositional environments and terrestrial sediment input after ca. 12,000 years BP. From 12,400 to 9,500 years BP, turbidity currents and meltwater discharges dominated Bellsund, with strong variations in plagioclase and dolomite. This depositional pattern suggests terrestrial inputs to Bellsund from its tributaries in a rapid phase of glacial retreat. The early to middle Holocene (9,500 to 3,500 years BP) has been identified as a sediment deficit with increased sand content under open marine conditions. The late Holocene (after 3,500 years BP) was characterized by hemipelagic deposition with tidewater glacial influences in the tributaries, with relatively low and constant plagioclase and a gradual increase in dolomite. Plagioclase and dolomite may have been derived from siliciclastic rocks of van Mijenfjorden/van Keulenfjorden and various carbonate rocks of Bellsund/Recherchefjorden, respectively. In this context, the terrestrial input to Bellsund during the late Holocene was likely mainly from the Bellsund coasts and Recherchefjorden. Furthermore, we expect that the ratio of plagioclase to dolomite can serve as a geological proxy for estimating provenance changes in southern Spitsbergen based on the regional distribution of bedrock geology.

Abstract

The cold Arctic Ocean allows CO2 to dissolve more readily than in other regions, leading to accelerated ocean acidification with profound environmental and socio-economic impacts. For instance, decreasing pH reduces the saturation states of aragonite and calcite in seawater, compromising biogenic calcification. Accurately predicting future carbonate system states remains challenging due to a limited observational record of Arctic seawater history and poorly-constrained processes that impact local ocean biogeochemistry.

The boron isotopic composition (δ11B) of marine carbonates provides a way to assess past Arctic Ocean seawater pH in response to natural climate changes and varying atmospheric CO2 levels. Here, we present δ11B measurements of the planktic Arctic foraminifer *Neogloboquadrina pachyderma* from central Arctic Ocean sediments. We present a new Arctic-specific calibration of the δ11B proxy and reconstruct central Arctic carbonate chemistry over the last glacial-interglacial transition (i.e., the past 20,000 years), and earlier Pleistocene interglacials that include warmer-than-pre-industrial climates with seasonally ice-free conditions.

Our δ11B record reveals that central Arctic pH variations were broadly consistent with the deglacial (i.e. 17,500-11,000 years ago) atmospheric CO2 increase of ~80 ppmv as documented in ice cores. This demonstrates the feasibility of δ11B investigations of Arctic Ocean acidification. While rising atmospheric CO2 was the primary driver of Arctic Ocean carbonate system states during the deglaciation, we also identify the transient influence of other environmental factors such as changing sea ice regimes, vertical upper ocean mixing, water column stratification, and the release of terrestrial organic matter from thawing Arctic permafrost. Examining these past carbonate system states will contribute to better understanding the boundary conditions of the Arctic Ocean system.

Abstract

Despite its remoteness and harsh conditions, the natural environment of the northern polar region received increased attention in the last two decades. In recent years considerable effort has been invested by several groups and institutions to make various data and results available online and to use it for science, education and outreach. Examples include: the Arctic Observing Viewer which is a web mapping application in support of U.S. SEARCH, AON, SIOS, and other Arctic Observing networks (https://
arcticobservingviewer.org/); Arctic Research Mapping Application (https://armap.org/) and the NSF Arctic Data Center (https://arctic data.io) for locating projects and data supported by US funding agencies; Svalbox (www.svalbox.no), a database for digital outcrop models from Svalbard, the comprehensive PANGAEA database (https://www.pangaea.de), a data publisher for Earth and Environmental sciences; and GeoMapApp (http://www.geomapapp.org/), a map-based application for browsing, visualizing and analyzing a diverse suite of curated global and regional geoscience data sets.

While a wealth of data can be located and viewed in these databases and data repositories, the scientific community and geoscience educators may benefit from a collection of geological and geophysical data that can be easily visualized, analyzed and used for a quick assessment of present-day geodynamic setting and further for paleogeographic reconstructions in the circum-Arctic region. A group of scientists from four Arctic countries and their collaborators aimed to consolidate and further develop the Arctic-related common scientific basis and educational programmes under the auspices of the Norwegian Research Council programme INTPART (International Partnerships for Excellent Education, Research and Innovation).The project NOR-R-AM (https://norramarctic.wordpress.com/), established in 2017, focused on assessing the openly available information accumulated at participating institutes. Here we will present the resulting digital Circum-Arctic geodynamics platform. that incorporates geological and geophysical data and models, tomographic and kinematic models and paleogeography and paleoclimate indicators

in openly accessible formats that are compatible with GPlates, GeomapApp and Google Earth. Examples of how this platform can be used for reconstructing the Arctic's tectonic and paleooceanographic evolution will be part of the presentation.

Brackish and anoxic environments in the western Arctic Ocean during the last glacial period: insights from authigenic calcites

kwangchul JANG[1]*, Yonsei University (kj@yonsei.ac.kr)
Kyung Sik Woo[2], Kangwon National University
Seung-Il Nam[3], Korea Polar Research Institute

Abstract

The past hydrology in the Arctic Ocean has primarily been considered as typical seawater – both saline and oxic conditions. However, recent research on the thorium excess minima introduces the glacial Arctic freshening hypothesis, which challenges this prevailing view. This study presents the geochemical properties of authigenic calcites formed in-situ within sediments from the Mendeleev Ridge of the western Arctic Ocean back to 76 ka. Authigenic calcites exhibit low Mg (< 4 mol%) concentrations and light oxygen isotope ratios exclusively during cold intervals of the last glacial period (e.g., MIS 2 and MIS 4 to early MIS 3). These characteristics strongly suggest brackish Arctic hydrology during these times.

Additionally, the corresponding positive excursion of carbon isotope contents, attributed to early diagenetic methanogenic processes, suggests that the western Arctic Ocean was also accompanied by anoxic deep-sea conditions. It appears that the oxygen-depleted subglacial meltwater discharged from adjacent ice sheets could have generated a high-density sediment-laden flow, which intruded and filled up the deep-water column, ultimately resulting in brackish and anoxic environments. Further investigation of Arctic sediments from older periods is necessary to understand the potential impact of these hydrological changes in the Arctic Ocean on the global carbon cycle in the past.

Abstract

The Atlantic Water plays an important role in regulating the climate system associated with depositional environments in Arctic Svalbard fjords. In troughs off Svalbard fjords, the inflowing Atlantic Water can be steered by seafloor topography. This study examines the impact of topographically steered currents on depositional patterns in the trough off Kongsfjorden by analyzing multi-proxies on a glacimarine sediment core (KH17-GPC01). Additionally, we compared sediment records between the center of the trough and its outer rim, near the glacier front. Our results present that sediment input to the Kongsfjorden trough has been primarily influenced by the interaction between glacier melting, current sorting, and sea ice drifting. Interestingly, core KH17-GPC01 from the center of the trough exhibits a relatively higher sedimentation rate compared to sediment cores from the outer rim. Despite their proximity to the glacier front, the relatively low sedimentation rate in the outer rim possibly resulted from sediment sorting by the enhanced current flows, suggesting that this depositional pattern was contributed by rapid current flow along the outer rim of the trough. Conversely, the center of the Kongsfjorden trough appears to act as a depocenter. These findings provide the importance of considering the effects of current-induced sediment transport for reconstructing depositional environments around the complex Svalbard fjord systems.

Abstract

The Svalbard Archipelago is located at the gateway between the North Atlantic and the Arctic Ocean. Spitsbergen, the largest island of the Svalbard Archipelago, is presently covered with glaciers, accounting for about 57% of its area. Also it is strongly influenced by the West Spitsbergen Current (WSC), which supplies warm Atlantic water to its fjords. Furthermore, fjords are hotspots of organic carbon (OC) burial due to high sedimentation rate and terrestrial inputs from land-terminating and tidewater glaciers. Thus, fjords in Spitsbergen are considered the most sensitive areas to the recent global warming and are among the supersites for studying the responses of the Arctic system to further climate changes. In this study, we investigated three multicores collected in Kongsfjorden during HH22 and HH23 cruises aboard RV Helmer Hanssen in 2022 and 2023, along with soil and bedrock samples collected in its surrounding land areas. We analyzed lignin phenols along with conventional bulk indicators such as TOC, Norg/TOC ratio, d13Corg, and Δ14Corg, and assessed the relative contribution of OC sources employing a four-end-member approach. We will present reconstructed variations in aged-soil derived organic carbon input into Kongsfjord over recent centuries. Our results will provide new insight into OC dynamics in the Kongsfjorden.

Young Jin Joe[3], Korea Polar Research Institute
Dahae Kim[4], Korea Polar Research Institute
Young Keun Jin[5], Korea Polar Research Institute
Jong Kuk Hong[6], Korea Polar Research Institute

Abstract

Cold seepages act as windows for the emission of deep subsurface hydrocarbon gases, mainly methane, fluids, and a complex mixture of sediments. Recently, the morphological features, such as gas hydrate-bearing mounds related to methane seeping, have been discovered on the Chukchi borderland in the western Arctic Ocean. Together with geological evidence within mound structures, such as the occurrence of shallow gas hydrate layers, we investigated the biogeochemical signatures of methane-related microbial communities along discriminative lithological structures using geochemical properties, including bulk elements and microbial lipid compounds. Since the deposits of the Laurentide iceberg discharge event during the last deglacial period, referred to as a distinct dark grayish coarse layer, which may have been deposited by the Laurentide iceberg discharge event during the last deglacial periods, the 13C-enriched organic carbon patterns showed significantly discriminative properties involved in the formation of authigenic carbonate formed during methane emission. Furthermore, the predominance of 13C-depleted lipid compounds (archaeol, sn-2-hydroxyarchaeol, GDGT-1, -2 and -3) within last deglacial deposits may reflect the increased methane-consumption activities that occurred during methane emission, compared to those of reference sites. Thus, our results infer that the increase of methanotrophic activities may be related to the dissociation of gas hydrate after the last deglacial warming.

Monica Winsborrow[3], University of Tromsø
Seung-Il Nam[4], Korean Polar Research Institute

Abstract

The past existence of a continuous Arctic Ocean ice shelf has been inferred from submarine landscape features and geochemical records; however, fundamental aspects of its characteristics, impacts and timing remain highly debated. We test the pan-Arctic glaciation hypothesis by investigating Ocean Drilling Program (ODP) Site 910, drilled northeast of the Fram Strait, the principal gateway between the Atlantic and Arctic Oceans. Source-specific biomarkers reveal no evidence for a continuous ice shelf at this site over the past ~750 000 years. They rather document the presence of seasonal sea ice and spring phytoplankton blooms in surface-waters, with spring sea-ice concentrations typically 10-50%. The most extensive sea ice cover occurred during the Last Glacial Maximum (LGM, ~20 000 years ago) and glacial marine isotope stage (MIS) 16 (~676 000 - 621 000 years). MIS 6 (~190 000 - 130 000), the large-scale penultimate glaciations, is characterized by variable sea ice and continuous transport of northward flowing Atlantic water masses into the Arctic Ocean. Thus, in contrast to the pan-Arctic glaciation hypothesis, these data demonstrate, unequivocally, the prevalence of marginal sea ice conditions in the gateway region across a series of glacial-interglacial cycles following the middle Pleistocene climate transition. If ever the Arctic Ocean was covered by continuous ice shelf, it has likely occurred during the mid-Pleistocene transition between 1.300 000 and 750.000 years ago.

Abstract

Large magnitude volcanic eruptions are of great interest due to their substantial impact on the global climate. The reflection of incoming solar radiation by volcanic sulfate aerosols can induce temporary global cooling lasting several years by reflecting solar radiation through sulfate aerosols. The Millennium Eruption (ME), one of the biggest volcanic eruptions of the Common Era (CE), occurred in late 946 CE from Mt. Baekdu. Despite its large magnitude, temperature reconstructions based on tree rings have not revealed significant anomalies related to the eruption. The reasons for this lack of response are not fully understood and remain an active area of research. Here, we present glacio-chemical findings from the NGRIP1 (North Greenland Ice Coring Project) core. A shift from rhyolitic-dominant to trachytic-dominant tephra shards associated with the ME were identified and we suggest that this transition occurred within 86 days. The absence of a significant sulfur mass-independent fractionation signal and the lack of a substantial temporal delay between insoluble particles and sulfur concentration in the NGRIP1 core suggest that the aerosol transport of the ME was confined to the upper troposphere/lower stratosphere. Besides the fact that the eruption occurred during winter, we attribute the observed absence of temporary global cooling to the limited or negligible amount of stratospheric sulfur released during the ME.

Abstract

The precise reconstruction of past atmospheric greenhouse gas (GHG) concentrations, including CO2 and CH4, from polar ice cores is crucial to understand the climate system of the Earth. Hence, it is important to examine potential mechanisms for altering GHG concentration within polar ice cores. In recent observations, it has been found that shallow ice (<10 m) from blue-ice areas (BIAs) in Antarctica has shown higher concentrations of CO2 and CH4, as well as lower levels of CH4 compared to other unaltered ice core records of the same gas ages. However, the mechanisms of GHG alteration within shallow ice cores are poorly understood. We aim to decipher the processes of GHG alteration in the shallow ice from Larsen BIA. The CH4 concentration records of the shallow ice core from Larsen BIA generally show an increasing trend from the subsurface to a depth of around 0.35–1.15 m. Afterward, the concentration gradually decreases until it reaches the levels corresponding to ancient atmospheric CH4 values at around 4.6 m depth. In contrast, CO2 concentrations exhibit a gradual decrease from the subsurface until a depth of approximately 4.6 m where the concentration variation stabilizes, but still has a 10–20 ppm difference with other existing unaltered ice core records. Here, we show that modern air/aerosol intrusion were not sufficient to explain the GHG alterations according to measurement results of δ15N-N2 and Pb isotopic ratio. Based on the depleted δ18Oatm measurement results of shallow ice, it appears that microbial respiration had not contributed to the increased CO2 concentrations. Instead, the rise might have resulted from a degradation of organic matter through photochemistry. In order to determine if the organic matter is indeed responsible for the increased levels of CO2, we will conduct measurements of the δ13C-CO2 in the surface ice of Larsen BIA. Additionally, to investigate the potential impact of photochemistry on the alteration of greenhouse gas (GHG) concentrations, we will expose ice samples to UV light and measure the concentration of GHGs within them.

Abstract

The decade 1450 stands out as one of the coldest decades in the Northern Hemisphere during the Common Era (CE) as a consequence of volcanic forcings of the second largest atmospheric sulfate event of the past millennium. Initially, this volcanic event was thought to be the result of the massive eruption of the Kuwae caldera, Venuatu, in 1452/53 CE as evidenced by acidity and sulfate peaks observed in both Greenland and Antarctic ice cores between 1450 and 1464 CE. This pronounced Kuwae eruption signal was also commonly used as a temporal marker for dating polar ice cores. However, based on recent well-chronologically constrained highly resolved sulfur concentration and records from Greenland and Antarctic ice cores, the bipolar sulfate peak has been dated to the year 1458/59 CE, which is not coincident with the Kuwae eruption that was previously assigned to the date of 1452/53 CE for this event. This suggests the need to revise the date of the Kuwae eruption to 1458/59 CE. However, the 1458/59 CE volcanic signal must be identified for the Kuwae eruption before its revision. This study examined the geochemical characteristics of cryptotephra in the ice associated with the pronounced 1458–1461 CE sulfate peaks from a firn core (VK22) drilled at Vostok Station (78.465°S, 106.835°E, 3,490 m above sea level) in the East Antarctic Plateau. The analysis was performed using a novel quantitative scanning electron microscopy coupled with energy dispersive X-ray spectrometry (SEM-EDX) technique that allows measuring < 10 μm-diameter glass shards without the need for the polishing process, which can be achieved by using Monte Carlo calculations combined with reverse successive approximations to determine X-ray intensities generated from individual elements within the glass shards. Then, the obtained geochemical signatures were compared with those of the Kuwae tephra deposits.

Assessing Artificial Intelligence Techniques to Simulate Atmospheric CO2 Concentration from Antarctica Ice Core Records During MIS 1 to 5

Nasrin SALEHNIA[1]*, Seoul National University, School of Earth and Environmental sciences (salehnia61@gmail.com)
Jinho Ahn[2], Seoul National University, School of Earth and Environmental sciences

Abstract

Ice cores serve as a vital archive, recording atmospheric concentrations of Greenhouse Gases (GHGs) spanning the last 800 thousand years. Studying climate change by reconstructing and modeling atmospheric CO2 offers valuable insights to scientists striving to understand climate-carbon cycle interactions. The relationship between temperature and GHGs, as deduced from ice core data, has the potential to enhance the precision of simulating CO2 fluctuations. The objective of this study was to investigate modeling approaches for accurately forecasting atmospheric CO2 levels and addressing CO2 data gaps using methane (CH4) concentration and temperature proxies (δD and δ18O) derived from Antarctic ice cores, utilizing Artificial Neural Networks (ANN) and Wavelet Transform (WT) methodologies as a hybrid method. Two distinct ice core datasets were employed: The Dome Fuji (DF) core spanning 9-120 thousand years ago (ka), and the EPICA Dronning Maud Land (EDML) core covering the period from 70 to 115 ka. To evaluate the effectiveness of the hybrid model for DF, the training phase was conducted during Marine Isotope Stages (MIS) 1, 2, 4, and 5, followed by the simulation phase for MIS 3. The conclusive findings demonstrated a precise correspondence between the model and original CO2 data during the training phase, yielding an R2 of 0.98 and an RMSE of 4 ppmv. During the simulation phase corresponding to MIS 3, the model reproduced trends similar to those observed in the CO2 data. The R2 was recorded at 0.74, with an RMSE of 6.91 ppmv. For the EDML core, during the training phase, CO2, CH4, and δD data from MIS 5a-MIS 5b and MIS 5d were utilized. Subsequently, the developed hybrid model was applied to simulate the CO2 concentration during MIS 5c. The results revealed an R2 value of 0.54 and an RMSE of 8.78 ppmv based on the training phase. The simulated phase confirmed an R2 of 0.47 and an RMSE of 3.31 ppmv. This study demonstrated the efficacy of utilizing AI techniques to simulate past climate CO2 concentrations based on ice core records.

Abstract

Temporal variability of snow accumulation rates (SARs) over Antarctica is closely linked with changes in the mass balance of the Antarctic ice sheet and ultimately in global sea levels. However, model-based long-term changes in the volume of Antarctic ice sheet remain poorly constrained mainly due to the limited amounts of spatial and temporal SAR records that can be provided by well-dated Antarctic ice cores. This study presents a comprehensive ice chronology for the top 108.6 m of a 210.5 m-deep ice core drilled at the Styx Glacier plateau (SGP; 163^0 41.22′E, 73^0 51.10′S; 1,623 m above sea level) in northern Victoria Land, East Antarctica. The ice chronology for the top 98.5 m, covering from 1259 to 2013 CE, was established by counting annual layers of highly resolved impurity records (non-sea-salt SO4 (nssSO4), nssSO4/Na, Na, and meltwater conductivity). The manual layer counting result was further constrained by using well-known time markers of two 239Pu peaks associated with large-scale atmospheric nuclear tests and 14 volcanic events identified by pronounced nssSO4 peaks. Meanwhile, as counting layers is difficult in the deep part of the ice core (98.5–108.6 m), the deep part that covers the time frame of 1150–1259 CE was dated using an age-dating model based on absolute age tie points of 239Pu peaks, volcanic events, the Rittmann tephra layer at a depth of 99.2 m, assigned to be 1252 CE, and gas chronology. The maximum dating uncertainties are estimated to be ± 8 years for the top 98.5 m and ± 10 years for the deep part of the core. The precise ice core chronology achieved by counting annual layers in combination with absolute dating of radioactivity peaks and volcanic events has allowed us to reconstruct historical SAR variability at the SGP over the past 755 years. The water equivalent annual mean SAR was estimated to be 113 ± 39 mm and showed an overall long-term increasing trend with inter- to multi-decadal fluctuations. Future study will provide deeper insights into various climatic drivers that led to variability and trends in historical snow accumulation at different temporal scales at the SGP.

Geochemical characterization of East Siberian ice wedges : Implications of their origin and paleoenvironment

Subon Ko[1]*, Yonsei University (rhtnqhs8@yonsei.ac.kr)
Jinho Ahn[2], Seoul National University
Alexander Fedorov[3], Melnikov Permafrost Institute
Giehyeon Lee[4], Yonsei University

Abstract

Ice wedges in permafrost are subsurface ice structures that have been considered to be formed by frozen natural precipitation mixed with airborne dust and soil particles. This mixture then flows through the active layer into the cracks and grows by repeated thermal contractions in the deeper permafrost layer over time. Recently, ice wedges receive growing attention as archives for reconstructing paleoclimate and paleoenvironment due to their more widespread distribution and remarkably higher solute and solid concentrations compared to those of glacier ice cores. In this study, the paleoenvironmental conditions during ice wedge formation and the origin of both ice wedges and their solid particles were investigated. For these, we obtained ice wedges samples collected from Cyuie, Churapcha, and Zyryanka in East Siberia by the Laboratory for Ice Core and Paleoclimate at Seoul National University.

The geochemical properties of the ice wedge samples were characterized by analyzing the pH, electrical conductivity (EC), alkalinity, solid content, and dissolved ion concentrations after melting the samples. The solid particles trapped in the samples were also analyzed for their mineralogy (X-ray diffraction), chemical composition (X-ray fluorescence and inductively coupled plasma mass spectrometry), particle morphology (scanning electron microscope), and the types and composition of Fe- and Mn-solid phases (X-ray absorption fine structure). The relative ratios among the solute concentrations of the ice wedge samples were significantly different from those in common natural precipitation but comparable to those of general soil porewaters, indicating that the ice wedge samples were not simply originated from the natural precipitation but likely substantially affected by the chemistry of the surrounding soil. In addition, various geochemical proxies, sortness, and roundness of the solid particles successfully implicated their provenance, proximity from the source rocks, and the paleoenvironmental conditions. This study provides basic information on the origin of ice wedges and their solid particles and thereby understanding the paleoenvironmental conditions during the ice wedge formation.

[Keynote] Microplastics and nanoplastics in groundwater: the essential role of the hydrogeologists

STEFANO VIAROLI[1]*, University of Pisa (stefano.viaroli@unipi.it)

Abstract

Micro and nanoplastic (MNP) pollution is receiving a growing interest in environment due to its pervasiveness and persistence. In the beginning, the MNP research focused on oceans and fresh-water bodies due to their convenient accessibility and evident contamination levels.

Groundwater was not initially studied as it was considered protected by the filtration mechanisms occurring in soils and aquifers. The first experimental article that testified the presence of MNPs in groundwater was published only in 2019. From that year onwards, only a limited number of publications presented data about MNPs contaminating the groundwater. The literature results are difficult to compare due to different sampling and treatment procedures as heterogeneous hydrogeological settings. Some studies in fact focus on the possible MNP contamination of deep aquifers tapped for drinking purposes, while others investigate MNPs in shallow aquifers for environmental research.

Future development of the MNP research will follow three main directions: assessing the exposure and the toxicology risk of the MNPs for human, animals, and plants (I), improvement of the analytical techniques to easily detect nanoplastics (II), environmental analyses about MNP contamination and mobilization dynamics (III).

The first two research topics mostly deal with toxicologists, chemists, and physics. Hydrogeologists may provide their valuable contribution in environmental studies, especially characterizing the MNP contamination in groundwater. Infiltration, transport, and dispersion of MNPs in groundwater mainly depends on the hydrogeological setting of the subsoil and the sources of contamination related to the human activities.

At the current stage, the characterization of MNP contamination is mostly limited to the sampling points with few attempts defining the areal distribution. Future research on MNP contamination of groundwater should be expanded up to the catchment scale. The definition of the hydrogeological conceptual model of the studied aquifer is therefore essential to understand the main discharge directions of the aquifer and the surface waters – groundwater relationships. The hydrogeological scheme, combined with the characterization and quantification of MNPs, might provide a more comprehensive understanding of their dynamics.

A Comprehensive Analysis of How Drought Affects Groundwater Microplastics

WAINKWA CHIA Chia ROGER[1]*, Kangwon National University
(wainkwa2020@kangwon.ac.kr)
Jin-Yong Lee[2], Kangwon National University
Jihye Cha[3], Kangwon National University
Venant Atem Ntegang[4], Kangwon National University

Abstract

The world currently faces four major problems: environmental pollution, hunger, health and drought. Among these issues, two that geologists are now concerned about are microplastic (MP) contamination of groundwater and drought. This is because groundwater plays a significant role in providing tap water in urban and rural regions and in meeting the global community's water demands. Additionally, MPs have been found and documented in groundwater around the world. However, to the best of my knowledge, there haven't been many studies on how drought contributes to and affects the occurrence of MPs in groundwater environments. Therefore, the purpose of this study is to verify the impact of drought on MP distribution in groundwater. An extensive analysis of original research from 2016 to 2024, documenting sources of changes in MPs in groundwater, was performed using PubMed, Web of Science, and Google Scholar. The findings of this investigation demonstrated that drought significantly enhances direct sources of MP contribution, such as wastewater treatment effluents, landfills, plastic mulching, and land application of biosolids, more than indirect sources, which include atmospheric deposition, biodegradation, weathering and fragmentation, and runoff from surfaces lined with plastic. Further research is necessary to study the mechanisms associated with drought's influence on groundwater MP contamination, based on the results of this study. This work was supported by the Research Institute for Earth Resources through the Basic Science Research Program of the National Research Foundation of Korea (NRF) funded by the Ministry of Education (No.2019R1A6A1A03033167).

Microplastic pathways into bedrock aquifers: focusing on groundwater well management in Korea

Eunju JEONG[1]*, Kangwon National University (jej8377@kangwon.ac.kr)
Hyobin Lee[2], Kangwon National University
Jiwook Jang[3], Kangwon National University
Jin-Yong Lee[4], Kangwon National University

Abstract

Previous research has shown that microplastics exist in groundwater. Meanwhile, there are still uncertainties regarding microplastic contamination in bedrock aquifers, which are often overlooked in favor of porous aquifers. Despite the perceived difficulty of microplastic infiltration into deep bedrock aquifers, our previous and related studies have surprisingly detected these particles at depths exceeding 100 meters. We suggest three main pathways of microplastics into bedrock aquifers: vertical infiltration through the interface between weathered rock/unconsolidated aquifers and bedrock aquifers(in Korea, the unconfined aquifers are common, and it is common for screens in bedrock groundwater wells to extend from the weathered rock to the bedrock aquifers to ensure an abundant supply of groundwater), direct enter through the entrance of the groundwater wells due to the absence of well cap, and corrosion of groundwater wells made of plastics. To support these suggestions, we compared the distribution of microplastics based on hydraulic connectivity between bedrocks and overlying weathered rock/unconsolidated aquifers, as well as groundwater well specifications. Our analysis of microplastic concentration, size, shape, polymer type, and specific surface area highlights the potential impact of aquifer characteristics on their distribution. Microplastics can exceed the typical size range commonly detected in groundwater (the size commonly detected in groundwater is <100 um) when they are introduced directly through well entrances or generated from corrosion of plastic well materials. Additionally, if a significant amount of microplastics identified aligns with the groundwater well materials, it suggests that it was generated from long-term groundwater well corrosion. Our insights provide a clearer understanding of microplastic distribution in bedrock groundwater. This understanding highlights the consequences of inadequate groundwater well development and management, specifically the risk of microplastic contamination in bedrock aquifers. This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (No.2019R1A6A1A03033167).

Ntegang Venant Atem[5], Department of Geology, Kangwon National University, Chuncheon 24341, Republic of Korea

Abstract

This study presents a comprehensive review of worldwide research on the occurrence, concentrations, and characteristics of per- and polyfluoroalkyl substances (PFAS) in groundwater, conducted through literature searches on databases such as Google Scholar and Web of Science. PFAS and microplastics (MPs), known for their persistence and ecological toxicity, have become a global concern for environmental safety. By synthesizing the findings from diverse studies, we aimed to gain insights into the global trends of PFAS and MPs in groundwater. The literature review highlighted variations in PFAS and MPs concentrations, occurrence patterns, and specific compound characteristics across different geographical regions. Understanding the environmental factors influencing PFAS and MPs presence in groundwater was a key focus, and potential sources and transport mechanisms were explored. The results of this review contribute to a comprehensive understanding of the global distribution of PFAS and MPs in groundwater, shedding light on potential hotspots and areas of concern. We discuss the implications of varying geological and hydrological conditions on PFAS mobility and accumulation. Additionally, an analysis of different MPs and PFAS compounds and their distribution patterns provides valuable information for assessing environmental contamination sources. Our presentation offered insights into the global perspective of PFAS and MPs in groundwater, facilitating knowledge exchange and fostering discussions on potential mitigation and management strategies. We anticipate that this contribution will enhance awareness and collaborative efforts towards addressing the global challenges posed by PFAS and MPs contamination in groundwater. This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (No.2019R1A6A1A03033167).

Viviana Re[9], Department of Earth Sciences, University of Pisa, Pisa, Italy

Abstract

Pollution caused by micro- and nanoplastics (MNPs) is increasing attention in environmental research due to its widespread presence and persistence. The MNP investigations in groundwater suffer from the absence of common protocols for sampling and analysis as already faced by surface water research. To avoid potential contamination, the use of plastic tools and devices has been refrained during all the research steps (sampling, collection, treatment, and analysis). This plastic-free approach, however, limits the realization of groundwater studies. Groundwater well casings, pipes, gaskets, and other tools of hydrogeological practice are often made of plastic. In addition, groundwater observations are limited to monitoring wells (MWs) and water wells (WWs) that are usually few and heterogeneously distributed throughout a study area.

The construction schemes of MWs and WWs are various and depend on the hydrogeological context and the economic budget. MWs and WWs are often constructed with polyvinyl chloride (PVC) casings and pipes due to their convenient cost-quality ratio but pose concerns about their use within MNP research. Via a literature analysis, it is demonstrated that there is no evidence of large contamination of the groundwater samples from the PVC casings and pipes. Therefore, these wells could be strategic in future MNP investigations. Our statistical analysis of the available data suggests that a PVC concentration higher than 6% may require additional investigations (e.g. additional purging of the well, visual inspection of the MNPs, and fragment size analyses) in MWs and WWs with PVC casings. Proposed suggestions can aid in the planning of environmental research in groundwater, enhancing the comprehension of the MNP transport in aquifers.

Comparative adsorption characteristics of Pb and Cd by microplastics based on particle size

Taejung Ha[1]*, Pukyong national university (taejung_ha@pukyong.ac.kr)
Changmin Kim[2], Pukyong national university
Junyong Heo[3], Pukyong national university
Minjune Yang[4], Pukyong national university

Abstract

Microplastics, with a particle size of less than 5 mm, persist in aquatic environments, adsorbing heavy metals and potentially impacting human health through the food chain. As annual demand for microplastics continues to rise, especially with High-density polyethylene (HDPE) production accounting for 12.5% of global plastic production, understanding their interactions with pollutants has become increasingly urgent. This study evaluates the adsorption characteristics of lead (Pb) and cadmium (Cd) on microplastics, focusing on the impact of particle size. HDPE microplastics were categorized into three groups based on size: Group 1 (2.5–1.0 mm), Group 2 (1.0–0.3 mm), and Group 3 (< 0.3 mm). The specific surface area of these microplastics was measured using BET (Brunauer, Emmett, Teller) analysis. Following adsorption experiments with Pb and Cd at different concentrations (0, 0.5, 1, 5, 10, and 30 mg/L), the results were analyzed using ICP-OES (Optima 7000 DV, Perkin Elmer) at the Integrated Analytical Center for Earth and Environmental Sciences. The data were then evaluated utilizing the Langmuir, Freundlich, and Sips adsorption isotherm models. The Sips model ($R^2 > 0.97$) most suitably represented the adsorption behavior of Pb and Cd across all groups. The results showed that smaller particle sizes correlate with higher specific surface areas, in the order of Group 3 > Group 2 > Group 1, and an increase in adsorption capacity. Specifically, Group 3 showed the highest adsorption rate constant (Kf) and adsorption intensity (n^{-1}) for both heavy metals (Pb Kf: 0.028 mg1-1/nLn/g, Pb n^{-1}: 0.225, Cd Kf: 0.031 mg1-1/nLn/g, Cd n^{-1}: 0.178), confirming the influence of particle size on adsorption capacity. Although Pb and Cd demonstrated comparable adsorption capacities in HDPE, Pb showed higher adsorption than Cd in Group 3. The results of this study showed differing adsorption mechanisms for Pb and Cd in HDPE with the particle size of microplastics and the type of heavy metal being significant factors in adsorption efficiency. Given that microplastics can serve as carriers for heavy metals, further research into environmental factors (such as pH, and temperature) affecting adsorption is necessary.

Jihye Cha[4], Research on Microplastics in Groundwater (RMPG), Kangwon National University, Chuncheon 24341, Republic of Korea

Abstract

Microplastics (MPs), particles smaller than five millimetres, pervade our surroundings have been recently identified even in crucial human organs like the liver, blood, and feces. While the last decade witnessed significant documentation of MPs in marine environments, researchers are now turning attention to their presence in the terrestrial ecosystems. However, there's a notable research gap regarding MPs in soil to groundwater MP occurrence and their potential impact on human health. So, in this study, data spanning from the year 2017 to 2023 and databases like Pubmed/Medline, Web of Science, Elsevier, SpringerLink, and Google Scholar, was examined. Also, through this study recent developments in understanding the movement of MPs through the food chain and assesses methodologies were employed to identify and measure MPs in soil and groundwater We observed that, MPs from the atmospheric deposition, agricultural practices, and urban runoff which infiltrate into the terrestrial and then groundwater environment has potential human health effects. Also, it was observed that MPs can traverse plant tissues, infiltrating various trophic levels and raising diverse health concerns, from toxicity to reproductive issues. Through this study, the interaction between MPs and human health was emphasized. Also, through this study, the need for further research to comprehend accumulation patterns and long-term impacts was emphasized. Urgent measures, including enhanced waste management practices, rigorous risk evaluations, and legislative initiatives, are essential to mitigate the dangers associated with MP exposure. This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (No.2019R1A6A1A03033167).

Seasonal dynamics of groundwater Arsenic pollution: A multivariate statistical approach of One-way ANOVA and Shannon entropy weight

Imran Khan[1]*, Department of Geology, AMU, Aligarh (imranalig.iitk@gmail.com)
Rashid Umar[2], Department of Geology, AMU, Aligarh

Abstract

This study primarily investigates the spatiotemporal variation in Arsenic (As) concentrations with its speciation and influencing mechanisms, including chemical behaviors of selected physicochemical parameters (pH and Eh) in parts of the Ghaghara River basin, India. A novel tool, Shannon's Entropy-Weighted Heavy Metal(loid) Index (EW-HMI), has been employed, together with a critical analysis of the conventional pollution indices to quantify groundwater pollution at each of the monitoring sites. Measured As concentrations show that around 55% and 47% of groundwater samples have increased levels (>10 µg/L; WHO) for pre- and post-monsoon seasons, respectively. The results obtained through One-way ANOVA analysis indicate a significant seasonal difference in the mean concentrations of As. This seasonal variation is primarily attributed to the dilution effect due to significant monsoonal recharge of groundwater. The correlation between As and pH revealed an unexpected lack of a substantial relationship during both seasons. Similarly, the correlation between As and redox potential (Eh) was weak during both seasons, suggesting the existence of anaerobic conditions in the shallow aquifers of Bahraich, India. Moreover, results of As(III) and As(V) speciation suggest that around 68% of samples had higher As(III) values than As(V), revealing a noteworthy risk of As(III) toxicity, which is more harmful to human health. GIS-based spatial distribution maps highlight regions along the Ghaghara River, such as Mahasi, Shivpur, Phakharpur, Kaisarganj, and Visheshwarganj blocks are more prone to higher As pollution compared to other regions.

Appraisal of groundwater quality for drinking and irrigational purposes from parts of Warora tehsil, Chandrapur district, Maharashtra state, India.

Alka Kumari MISHRA[1]*, Geological Survey Of India (alka.mishra@gsi.gov.in)
Jaya Rashtrapal Chavhan[2], Geological Survey Of India
Niketan Prakash Khedkar[3], Geological Survey Of India

Abstract

Groundwater is the primary source for domestic, agricultural and industrial uses in many countries, and its contamination has been recognized as one of the most serious problems. In India, most of the rural and urban areas are dependent on groundwater for drinking and irrigational needs, and overexploitation has placed significant strain on the quality and quantity of groundwater resources. Maharashtra is the third largest state of India and about 58% of the state's population is in rural areas, 80% of whom are dependent on agriculture for their livelihood.

Various studies have shown that the drinking water in different parts of Chandrapur district, has high fluoride content. In such scenario, knowledge of irrigation water quality is critical for the understanding of management changes that are necessary for long-term productivity. Meanwhile, concentration of major ions and other parameters like Fluoride, Nitrate, Arsenic etc, that are hazardous to human health needs to be evaluated for providing safe drinking water. Hence an attempt has been made in the present study to demarcate the quality of irrigation water as well as its suitability for drinking purpose. For this reason, a total of 248 groundwater samples were collected from parts of Warora area, Chandrapur district in order to evaluate its suitability for drinking and irrigation purposes.

The suitability of groundwater for irrigation was evaluated with the help of sodium adsorption ratio, percent sodium, residual sodium bicarbonate, magnesium ratio and Kelley's. Wilcox plot was used to determine the viability of water for irrigation purposes. Based on different irrigational indices and Wilcox plot, all groundwater samples were found to be suitable for irrigation purposes. Wilcox plot made for the study area shows that the most of the water samples have medium to high sodium hazard with low salinity hazard such type of water can be used only on soils with adequate drainage and special management for salinity control may be required. Plants with good tolerance for high salinity should be selected. In case of salinity hazard, low salinity water (C1) can be used for irrigation with most crops on most soils with little chances of soil salinity development.

To understand the quality of water for drinking, a rating parameter known as Water Quality Index (WQI) was calculated. WQI gives an overall idea by considering the contribution of different parameters like pH, TDS, Total hardness, Ca2+, Mg2+, HCO3-, NO32-, Cl-, SO42-, F-, Fe and Mn. Since the other contaminants are well within the acceptable BIS limit of drinking water, those were not taken into consideration for calculating WQI. With value index of 71.48, the groundwater of the study area falls under Poor category of Water quality for drinking purposes and purpose it is observed that untreated groundwater of the study area is not suitable for

consumption as drinking water.

Kinetic, Thermodynamics and Equilibrium studies on adsorption of perchlorate ion on SIR-110-HP resin in groundwater.

BHAGIRATHI BEHERA[1]*, Geological Survey of India,NER,Chemical Division,Shillong,Meghalaya, India (bhagirathi.behera@gsi.gov.in)
Mira Das[2], ITER,SOA University,Bhubaneswar,Odishay

Abstract

The adsorption of perchlorate ion on SIR-110-HP resin in groundwater was investigated using batch experiments and mechanisms were drawn by using sophisticated instrument like, FTIR, Ion Chromatography, XRD and SEM etc. The effects of various parameters such as different pH, contact time of different concentration, coexisting anions were studied. The kinetics data signifies that the perchlorate adsorption process reached equilibrium within 60 min of adsorption. Removal of perchlorate was 98% even if pH varies from 3 to 10.The rate of adsorption at different pH is as in the order: 3pH>5pH>7pH>8pH>10pH. The removals of perchlorate from groundwater were above 99% at 60 min at even 3 pH, whereas 54%, 36%, 32%, 30% at different pH i.e. 5, 7, 8 and 10 at 60 min respectively. Major anions present in ground water reduced perchlorate adsorption on resin in the order of NO3->Cl->SO42-. In presence of nitrate, chloride and sulphate the removal efficiency of perchlorate ion decreased from 24.98 mg/g to 1.5 mg/g, 11.24 mg/g and 15.26 mg/g respectively. In pseudo second order kinetics value of qe(exp) (mg/g) and qe (cal) (mg/g) are very close to each other for all concentration where as difference value between of qe(exp) (mg/g) and qe(cal) (mg/g) are very large for all concentration of pseudo first order kinetics. Hence kinetics studies shows that adsorption followed pseudo second order kinetic model with coefficient correlation R2=0.99 with different concentration. The values of mean free energy (E) in D-R isotherm model were found 2.357, 2.357 and 2.5KJmol-1 at 25°C, 30°C and 35°C respectively which is E < 8 KJmol-1 that indicates adsorption is physical adsorption. The sorption values (1/b) in Elovich model are in erratic in nature and all points are not passes through line and origin. Hence data of Dubinin-Radushkevich and Elovich isotherm model indicates that the adsorption of perchlorate ion on SIR-110-HP resin was physical adsorption along with ion exchange. The negative ΔG° values indicated that the adsorption of perchlorate on anion exchange resin was thermodynamically feasible and was a spontaneous process. The positive values of ΔH° and ΔS° confirmed that the adsorption of perchlorate on resin was an endothermic process in nature and the randomness degree at the solid and liquid interface increases after adsorption. The value of activation energy (Ea) of adsorption of different concentrations varies from 2.8 to 15.01KJ/mol which is < 40 KJ/mol that shows adsorption is physical adsorption. The good fit of the experimental data and the values of correlation coefficients (R2) indicated the applicability of Langmuir model to perchlorate adsorption in the present study and also satisfied the condition of 0<RL<1. The perchlorate was adsorbed mainly in the form of monolayer coverage on the surface of the adsorbent means resin (SIR-110-HP).

Groundwater based drinking water scarcity: a geomorphological approach

Bhagyashri Chandrakant MAGGIRWAR[1]*, Savitribai Phule Pune University / Groundwater Surveys and Development Agency (bhagyashri.maggirwar@gmail.com)
Milind Herlekar[2], Savitribai Phule Pune University

Abstract

Karha River basin is a semi-arid catchment where groundwater is the main source of drinking, domestic and agriculture use. Increasing water demands for these purposes leads to increased use of groundwater extraction. Moreover, the catchment in basaltic hard rock terrain puts on limitations on the availability of groundwater. The situation gets aggravated by the erratic and scanty rainfalls. The groundwater availability is mostly catered through the open large diameter dug wells by tapping the phreatic aquifer. Every year, the terrain faces water scarcity that puts a lot of stress on the government functionary. It needs to be addressed though an early warning system so that the government can timely plan the mitigation measures. It calls for an advanced and more precise tool for efficient management of groundwater resources. The study considers the geomorphological parameters to develop a model that can highlight the hotspots and vulnerable areas. It is found that the basaltic hard rock terrain has the influence of drainage density and slope.
In the catchment area, the drainage density was observed to range from 0.00 to 7.44 km km-2. The number of cells and drainage density are plotted according to a normal distribution. The area has been reclassified into three distinct zones based on this distribution. Additionally, each density zone's groundwater recharge has been calculated using data from the observation wells. Lower groundwater recharge in the high density zone and a progressive increase in recharge as the drainage density lowers are shown in the plot of mean groundwater recharge against low, moderate, and high density classes. A substantial association (R2= -0.943) between groundwater fluctuation and drainage density is supported by a scatter-plot of the groundwater fluctuation between and after the monsoon season.
This observation is taken into account in the current study as one of the contributing factors to the scarcity of drinking water. The risk of inadequate groundwater recharge leading to early drying up of drinking water sources or poor groundwater yielding is greatly reduced by the spatiotemporal heterogeneity of drainage density and groundwater depletion that this study produced. Therefore, drainage density should be included to enhance shortage prediction and support water management decision-making, as it is a crucial indicator of groundwater availability in hard rock terrain.

Groundwater salinization in the dry zone of Sri Lanka and its impact on food security and livelihood: A case study from the Medderambawa cascade irrigation system

Chirath CHANDRARATHNA[1]*, Department of Geology, Faculty of Science, University of Peradeniya, Peradeniya, Sri Lanka (chirathc@outlook.com)
Sachintha Senarathne[2], Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU), Department Geographie und Geowissenschaften, 91054, Erlangen, GeoZentrum Nordbayern, Schlossgarten 5, Germany

Rohana Chandrajith[4], Department of Geology, Faculty of Science, University of Peradeniya, Peradeniya, Sri Lanka

Abstract

Groundwater is the only reliable water source in rural areas of South Asia, which are considered vulnerable to the impacts of climate change. Among South Asian countries, Sri Lanka is one of the regions where groundwater resources will be severely affected by climate change scenarios. In Sri Lanka, groundwater is vital as over 90% of the arid rural population relies solely on domestic and agricultural purposes. In recent years, groundwater salinization has been reported in several regions, notably in drier areas, with severe impacts on agriculture and domestic water supplies. This study used geochemical and statistical approaches to identify the primary sources of salinization, selecting the highly salinized Medderambawa irrigation system in the northwestern dry zone of Sri Lanka. Groundwater samples were collected from 25 wells, and geochemical parameters, including trace elements and stable water isotopes (δ2H and δ18O), were analyzed. The electrical conductivity (EC) of the groundwater varied between 398 and 7920 µS/cm (mean = 1762 µS/cm). Accumulations of Na-Cl-type water were identified, particularly in regions with large-scale agricultural activities. In contrast, Na-HCO3, Ca-Mg-Cl and Ca-HCO3 type water were predominant in the surrounding areas. The EC showed a significant positive correlation with Na (r=+0.90) and Cl (r=+0.97) contents, indicating their dominance in groundwater geochemistry. 48% of wells exceeded the maximum allowable fluoride level (1.0 mg/L), posing a significant risk of fluoride-related health problems in communities. 36% of samples exceeded the guideline value for Mn (100 µg/L). Other trace elements, such as Al, Cd, Cr, Se, As, and Pb, remained below their guideline values. 72% of samples exceeded the maximum allowable hardness levels (250 mg/L) for drinking purposes. The Water Quality Index calculation showed that 36% of groundwater samples were unsuitable for human consumption. The sodium adsorption ratio (SAR) varied from 0.50 to 141, while 20% of samples belonged to the SAR categories of high and very high. The groundwater is oversaturated with calcite, aragonite and dolomite and undersaturated with gypsum, anhydrite and halite. The δ2H and δ18O compositions of groundwater varied from -39.8 to -7.43‰ and from -6.23 to -0.36‰, respectively. Water Isotope pointed out that most highly saline groundwater is directly recharged by rainfall without further modification, as shown on the local meteoric water line (δ2H=8.95δ18O + 15.1, r = 0.95). Results of this study suggest that the

dissolution of aquifer materials causes groundwater salinity in the region, while chloride is derived mainly from fertilizers. Large-diameter shallow wells constructed for irrigation can increase soil salinization due to regular fluctuations in groundwater levels. Currently, some groundwater in the region is unsuitable for agricultural purposes due to high SAR levels (>9), suggesting a risk of developing harmful levels of exchangeable Na. Deterioration in groundwater quality significantly affects the livelihoods of rural populations and has a negative impact on food security in the region. To address the problem and increase the resilience of rural communities to climate variability, the introduction of salt-tolerant crops and artificial recharging of groundwater are recommended.

Hydrogeochemical Assessment of Groundwater Quality in N'kapa, Littoral Region Cameroon: Implications for Sustainable Domestic, Agro-Industrial, and Irrigation Use

Virgine Ajindong EBIA[1]*, University of Buea (virgineebia@gmail.com)
Ngai Nfor Jude[2], University of Buea
Kenah Rosemary Ziah[3], University of Buea
Wotany Engome Regina[4], University of Buea

Abstract

This study investigates the hydrogeochemical characteristics of groundwater in N'kapa, Cameroon, with a focus on its suitability for domestic, agro-industrial, and irrigation purposes. Employing hydrogeochemical tools and physicochemical parameters, including Gibbs diagrams, Piper diagrams, Durov diagrams, and water quality indices, 20 groundwater samples were collected from boreholes for analysis.

Results indicate that Electrical Conductivity (EC), Total Hardness (TH), and Total Dissolved Solids (TDS) fall within WHO-permissible ranges. However, pH levels consistently exceed WHO limits. Major ion concentrations generally adhere to guidelines, except for nitrate (NO_3^-) levels, which exceed limits in 15% of the samples. The abundance sequence of major ions reveals $Na^+ > Ca^{2+} > K^+ > Mg^{2+}$,$Cl^- > HCO_3^- > SO_4^{2-} > NO_3^-$. Hydrogeochemical processes involve simple dissolution and ion exchange, contributing to ionic content from ion exchange and rock weathering. Dominant water types are Na-Cl (80%) and Mixed Ca-Mg-Cl (20%).

Groundwater quality assessment for domestic and drinking purposes using parameters like pH, EC, TDS, TH, and groundwater quality index (GWQI) indicates that 90% of samples have good quality, except for pH levels. For agro-industrial purposes, parameters such as residual sodium carbonate (RSC), plasticity index (PI), magnesium absorption ratio (MAR), and sodium absorption ratio (SAR) suggest suitability, though soluble sodium percentage (SSP) and Kelly's ratio (KR) exceed set limits in 55% and 70% of samples, respectively. The Wilcox diagram suggests excellent to good suitability for irrigation.

Given N'kapa's status as a major agro-industrial zone in Cameroon and Central Africa, reliant on extensive irrigation-based agricultural initiatives, these findings have significant implications. Further research into the biological composition of groundwater in the area is recommended for a comprehensive understanding and sustainable management.

Groundwater exploration for the development of agricultural irrigation in Wang Nam Yen District, Sa Kaeo Province

Chunintorn CHAMATHONG[1]*, Department of Groundwater Resources
(chunintorn@hotmail.com)
Kankanith Tumprasert[2], Department of Groundwater Resources
Sirikanlaya Chinklang[3], Bureau of Groundwater Resources Region 9

Abstract

Thailand is experiencing drought conditions due to the El Nino phenomenon, leading to decreased moisture levels in farmland crucial for cultivating key crops. More than half of the Thai population engaged in agricultural occupations. Surface water resources are inadequate for utilization during the dry season, making groundwater a vital substitute. The study area is situated in Ban Khlong Phatthana, Thung Maha Charoen Subdistrict, Wang Nam Yen District, Sa Kaeo Province.

The objective of this study was to explore hydrogeology and conduct geophysical surveys to select suitable areas with groundwater potential for the development of abstraction boreholes to be used in constructing irrigation systems for agriculture and to ensure food security. The approach began with the identification of regions experiencing repetitive drought challenges. The evaluation of the overall groundwater capacity utilized Geographic Information System (GIS), which the visualization of maps illustrating groundwater potential and water quality scaled at 1:50,000 were applied. Subsequently, one dimensional geophysical resistivity survey was conducted for mapping the groundwater depth and locating potential drilling sites in order to reduce potential risks during the borehole construction such as drilling into dry or low-yielding zones.

From the hydrogeological study, it was found that Ban Khlong Phatthana is supported by a Triassic Metasediment Aquifer, which provides a plentiful supply of groundwater. The water quality is within good standards, with a general discharge rate exceeding 20 m3/hour and a total dissolved solids (TDS) level below 500 mg/l. The geophysical survey employing the Schlumberger electrode setup involved conducting sounding measurements at 11 locations, each with a depth span of 100-150 meters. The data was then analyzed using IP2WIN software to determine the suitable drilling depth. Six boreholes were constructed in the area. The distribution system equipped with solar panels combined with a power generator and two water storage tanks with a capacity of 120 cubic meters each were installed. The groundwater quality assessment conducted in the Thung Maha Charoen Subdistrict revealed persistent high levels of total hardness. Additionally, elevated levels of nitrates and chloride were found in certain areas.

In summary, the Department of Groundwater Resources has delivered an irrigation system to local authorities and continued monitoring groundwater quality. Water quality in the study area remains suitable for agricultural use, though adjustments are needed for domestic consumption. Sustainable groundwater management relies on collaboration with all stakeholders.
