This study is focused on the La Escondida Creek, at the southern part of the Las Higueras-Las Peñas range, which represents an unusual area where neotectonic contractional structures can be documented from the main morphogenic thrust zone at range-piedmont junction to the younger propagating splays within the alluvial plain. This constitutes an outstanding opportunity to characterize and quantify the deformation of the most recent contractional structures. These data assess the shortening of the area and enable the understanding of how the active thrust front is growing. The mountain-building processes can be elucidated by understanding how the footwall splays migrated from west to east and describing the associated scarp morphology. Furthermore, the contribution of shortening rates in this section of the LPTS trace addresses the gap in shortening rates knowledge. These data presented here, together with the rates available by the bibliography could elucidate whether variations in these rates are temporally and/or spatially correlated, contributing to different approaches for addressing the characterization of fault activity. Hence, the neotectonic analysis of LPTS at the piedmont relies mostly on topographical techniques, Trishear modeling, and retrodeformation of geometric markers, such as alluvial surfaces. The field evidence so far analyzed suggests a clear propagation of the splays into the piedmont area as discontinuous branches showing the great activity of the Las Peñas Thrust System. The calculation of shortening rates for three different alluvial surfaces ranges from 0.1 mm/y to 2.0 mm/y for the last ~18, 12, and 3 thousand years.

Active tectonics of the Yuli Fault in the central Longitudinal Valley area, eastern Taiwan

Siang Duan[1], Department of Geosciences, National Taiwan University
Yu WANG[2]*, Department of Geosciences, National Taiwan University (wangyu79@ntu.edu.tw)
Nai-Wun Liang[3], Department of Geosciences, National Taiwan University
Tsz Yau Amundsen Lam[4], Department of Geosciences, National Taiwan University
J. Bruce H. Shyu[5], Department of Geosciences, National Taiwan University

Abstract

Using topographic survey data, historical topographic maps, and digital elevation models (DEMs), we mapped the active tectonic features associated with the long-term activity of the Yuli Fault that ruptured during the 2022 Mw 6.4 and Mw 6.8 earthquakes in Eastern Taiwan. Although the recent co-seismic surface rupture of the Yuli fault shows a highly oblique nature of its fault slip close to the surface, and its fault trace cannot be mapped in detail prior to the earthquake, our retro-investigation results show systematic geomorphic features along its entire fault trace, suggesting the long activity of the Yuli fault within the central Longitudinal Valley. These features include the wrapped and the tilted alluvial fan surfaces, the flexure and fault scarps, springs, and dammed-lake depositional surfaces. All of these features are well aligned with the 2022 co-seismic surface ruptures. Together with pressure ridges and channel deflection found before the earthquake, our result confirms the Yuli fault is a major left-lateral and reverse fault in the central part of the Longitudinal Valley, with its slip rate yet fully constrained by the geodetic and geologic analyses. The left-lateral and reverse active behavior of the Yuli fault is very similar to the active behavior of the previously proposed Central Range Fault at the base of the mountain range, which also showed flexure scarps and uplifted terraces along its proposed fault trace. This leads us to believe both faults originated from the same structural system with the slip partitioned close to the surface. Further investigations are needed to confirm the slip rate of both faults and their structural relationship close to the surface.

Wedge confinement; a brittle faulting process for the accommodation of active block movements in the interior of continents

Esmaeil SHABANIAN[1]*, Department of Earth Sciences, Institute for Advanced Studies in Basic Sciences (IASBS), Zanjan 45137-66731, Iran (shabanian@iasbs.ac.ir)

Abstract

Deep-seated strike-slip faults play significant structural rolls in the accommodation of active deformation in the interior of continental plates such as the Turkish-Iranian and Tibetan plateaus. In several cases, these crustal structures take up the oblique convergence of continental blocks through pure strike-slip faulting, with negligible internal deformation. In some cases like in Central Iran, there are pure strike-slip faults nearly perpendicular to the direction of relative motion of surrounding continental blocks, while the overall block motion is mainly transferred across these strike-slip block boundaries. This study presents the 'wedge confinement' tectonic model, which is based on geological and tectonic geomorphology observations from the Iranian plateau and explains how block-bounding strike-slip faults can accommodate active shortening caused by oblique convergence without the need for main folding processes and thrust faulting, as well as book-shelf block rotations around vertical axes. The process of wedge confinement at the corner of converging blocks allows accommodating the internal deformation not absorbed by the lithospheric scale tectonic boundaries. The block adjustment requiring for the accommodation of this internal deformation is done through conjugate to crosswise faulting along dextral and sinistral fault sets. The structural significance of these nearly orthogonal fault sets depend upon the angle between the overall shortening and the fault sets strike. However, the simultaneous activity of these fault sets is mechanically impossible; therefore, the fault sets must be operating in sequence. The wedge confinement process also leads to the development of contractional (reverse/thrust) fault zones perpendicular to the overall direction of oblique convergence accommodating both along-strike and across-strike components of the convergence. This process implies that such slow-slipping orthogonal strike-slip faults are capable to produce high seismic risk in the interior of continents despite their insignificant structural and geodynamic roles.

A short review on geologic evidence of pre-historical large earthquakes in S. Korea

Jin-Hyuck CHOI[1]*, Korea Institute of Geoscience and Mineral Resources (cjh9521@kigam.re.kr)

Abstract

The Korean peninsula is tectonically slow-deforming yet active region, as evidenced by large earthquakes inferred by historical documents and geologic records of earthquake surface rupture in pre-historical periods. After the 2016 Mw 5.5 Gyeongju earthquake, the biggest instrumental seismicity in S. Korea, it is highlighted to investigate the records of past large earthquakes and to assess the earthquake hazards. Indeed, multidisciplinary paleoseismological investigations were conducted to understand characteristics of large earthquakes along the major fault system in S. Korea. This study introduces the major results and research trends of the paleoseismic investigations: 1) history and characteristics of paleoearthquakes along the Yangsan-Ulsan Fault System in the southeastern part of the S. Korea, 2) newly identification of geologic records of paleoearthquake along the Gongju Fault System crossing the central S. Korea, and 3) patterns of up-dip rupture terminations and their tectonic implications. Together with those observations, this study presents the on-going research on fault model and slip-rate estimation, which are essential information for seismic hazard assessments. Moreover, this study introduces the research trends and results of the remote sensing-based investigations of the large earthquakes. Based on the short review, we discuss future research directions for understanding the characteristics of large earthquakes in slow-deforming regions.

Developing Fault Models for Seismic Hazard Assessment in Slow-Deforming Intraplate Regions: A Case Study of the Yangsan Fault, Korea

Taehyung KIM[1]*, Korea Institute of Geoscience and Mineral Resources (adrian0305@kigam.re.kr)
Jin-Hyuck CHOI[2], Korea Institute of Geoscience and Mineral Resources

Abstract

For Seismic Hazard Assessment (SHA), it is essential to present simplified fault models that can represent the complex geometry of faults. However, in slow-deforming regions such as intraplate areas, creating fault models can be challenging due to the lack of surface ruptures. This study reviews research from leading countries in fault model development, proposes methods for developing fault segment models in intraplate settings, and applies these methods to the Yangsan Fault (YF), a long-lived fault on the Korean Peninsula. The Korean Peninsula is an intraplate region with relatively stable crust, but the YF is an active fault that has undergone multiple reactivations during the Quaternary, according to paleoseismic research. Following our proposed workflow, the YF can be divided into 11 to 15 unit-segments. By integrating existing research, we aimed to enhance the fault and deformation models by adding lateral slip rate information. Most studies on the slip rate of the YF have predominantly focused on rates calculated using vertical separation and fault orientation from trench wall. Recently, the significance of lateral slip rate studies, derived from geomorphic offset, has been increasingly emphasized, leading to research efforts aimed at obtaining lateral slip rates. Additionally, attempts have been made to conduct 3D trench survey along the YF. We have reviewed these studies to incorporate slip rate information into the fault model of the YF that we propose. However, the availability of lateral slip rate data is still limited, and improving this could significantly benefit fields such as SHA in the future.

Space and time variability of styles of continental shortening: new insights from 3D seismic interpretation in the Jura fold and thrust belt

Miller Zambrano[1]*, Geology Division, School of Science and Technology, University of Camerino, Italy (miller.zambrano@unicam.it)
Stefano Mazzoli[2], Geology Division, School of Science and Technology, University of Camerino, Italy
Jon Mosar[3], University of Fribourg, Department of Geosciences, Switzerland

Abstract

The Jura fold and thrust belt is characterised by a competition and combination of thin-skinned and thick-skinned thrusting, and represents a paradigmatic example of the switch from detachment-dominated thrusting of the sedimentary cover to crustal bulk shortening in the outer zone of collisional orogens. Recent high-quality 3D seismic data from siting of a Deep Geological Repository in Switzerland provided the opportunity to obtain insights from the easternmost termination of the Jura fold and thrust belt.

The aim of this study is to document the modes and timing of contrasting thrusting styles in this peculiar fold and thrust belt, which is located in the Alpine foreland north of the Swiss Molasse basin. The results of seismic interpretation point out that the tectonic setting of the siting region (Nördlich Lägern) is characterised by localised (0.5 to 2 km wide) fold-thrust zones involving the Triassic-Jurassic epicontinental platform succession and the stratigraphically overlying Cenozoic Molasse Basin deposits, separated by almost undeformed (at the seismic scale) rock volumes. The location of the shortening zones appears to be controlled by variable interaction between the detachment level hosted in the Triassic evaporites of the Muschelkalk Group and normal faults linked to an underlying Permo-Carboniferous half-graben. The structures interpreted in the 3D seismic data range from a ~ 2 km wide pop-up located above a step produced by a normal fault of the underlying Permo-Carboniferous half-graben, to a ~ 0.5 km wide zone of multiple thrusts and backthrusts forming a series of fishtail structures arranged in a steep belt involving the Mesozoic strata. The latter fishtail zone is located above a series of reverse faults that appear to have propagated from the underlying Permo-Carboniferous basin fill into the overlying Mesozoic succession, probably because of mild basin inversion. Salt mobility and associated salt weld development may have further contributed to a degraded quality of the detachment at this location. Different degrees of interaction between the evaporite décollement and underlying inherited faults, which produced a marked contrast in structural style (different pop-up and triangle zone geometry), appear to characterise the switch from detachment-dominated thrusting of the sedimentary cover to bulk crustal shortening ahead of the Alpine orogen.

Abstract

The eastern section of the Central Asian Orogenic Belt (CAOB), located between Siberia and the North China Craton, has undergone a complex evolution process of multi-tectonic system domain superposition and multi-cyclic ocean-land transition. Although there have been many research carried out in the Northeast China and Far East Russia, the tectonic pattern and geodynamics has still been controversial. Based on the tectonic properties of tectonic units and their formation process, combined with the evolution of regional tectonic belts, this paper redefines the basic tectonic pattern of the Northeast China and establishes a tectonic evolution model of the eastern section of the CAOB. The results show that the main tectonic units in the Northeast China during the Paleozoic period were composed of two ancient blocks with Precambrian basement, the Erguna block and the Jiamusi-Khanka block, and two Paleozoic accretionary terranes, namely the Xing'an accretionary terrane and the Songliao accretionary terrane, and the Zhangguangcailing continental margin arc, which were divided by Xinlin-Xiguitu ocean, Hegenshan-Nenjiang ocean, Longfengshan ocean and Solonker ocean. During the Early Paleozoic, the southeastern part of the western Erguna block was a western Pacific active continental margin, with the development of oceanic islands such as Gaxian-Jifeng-Huanyu inner arc and Toudaoqiao oceanic island. To ~500 Ma with the closure of Xinlin-Xiguitu ocean, these intraoceanic arcs and islands were collaged and accreted to the southeastern margin of the Erguna block. Subsequently, the subduction and retreat of the Hegenshan-Nenjiang ocean formed a series of trench-arc-basin systems, and the continuous subduction led to the collision of the arc-land and the accreted to the continental margin, forming the main body of the Xing'an accretionary terrane. At the same time, an Andean-type subduction active continental margin of the Longfeng Shan ocean is developed on the west side of the Jiamusi block, and a continental margin arc of the Zhangguangcailing is formed on the

western edge of the Jiamusi block. Along with the subduction of the oceans and the accretion of the continental margin, the Erguna and Jiamusi blocks and their continental marginal accretion zones together constitute a chain of continental blocks in the Early Paleozoic. In the Solonker ocean to the south of the block chain, the subduction accretion occurred surround continental margin of the Xilinhot-Longjiang ancient fragment, forming the prototype of the Songliao accretionary terrane. The Solonker Ocean underwent bidirectional subduction and continental margin accretion through arc-land collisions. During the Late Paleozoic, along with the subduction and final closure of the Paleo-Asian Ocean and the subduction of the Mongolian-Okhotsk Ocean and the Pan-Ocean, the block chain formed during the Early Paleozoic experienced large-scale rotation and bending, and finally formed a large-scale orocline structure with the Erguna block and the Xing'an accretionary terrane as the west flank, the Jiamusi block and the Zhangguangcailing continental margin arc as the east flank, and the Songliao accretionary terrane as the core.

[Keynote] Subduction dynamics and overriding plate deformation

Wouter Pieter SCHELLART[1]*, Vrije Universiteit Amsterdam (w.p.schellart@vu.nl)

Abstract

Many subduction zone systems are characterized by active overriding plate deformation. Most experience extension, resulting in the formation of a backarc basin (e.g. East Scotia Sea, North Fiji Basin, Aegean Sea), while some experience shortening, sometimes associated with the formation of an orocline, resulting in a massive cordilleran mountain range (e.g. Andes). It is unclear why some overriding plates experience shortening and others extension, and why extension occurs more frequently than shortening. Numerical geodynamic simulations of subduction evolution in 3D space are presented together with global subduction zone statistical analyses, investigating the control of slab width, time and subduction depth on overriding plate deformation. The numerical models demonstrate that shortening only occurs at very large subduction zones that have subducted into the lower mantle, while overriding plate extension occurs more frequently, taking place both for small and intermediate size subduction zones throughout their evolution, and for large subduction zones in the early (upper mantle) stage of their evolution as well as near their lateral slab edges during the middle stage of their evolution. The models also demonstrate that the plate boundary curvature is dependent on slab width, with wide subduction zones forming an orocline in the centre (convex towards the overriding plate), while narrow subduction zones form a concave geometry. The model results are compared with global datasets of active subduction zones, providing an explanation for the present-day deformation style and subduction kinematics at these subduction zones. The investigation also provides explanations why parameters other than slab width, such as slab dip angle, are correlated with overriding plate deformation, and why some parameters, such as slab age, show low to negligible correlations with overriding plate deformation and subduction kinematics. Finally, the comparison between models and global datasets provides an explanation for the more frequent occurrence of extension and backarc basin formation in the overriding plate compared to shortening and cordilleran orogeny.

Along-strike change of erosion and sedimentation in the Longmenshan FTB, SE Tibetan Plateau, evidence from analogue experiments

Bin DENG[1]*, Chengdu University of Technology (dengbin3000@163.com)
Hongbin GUO[2], Chengdu University of Technology
Zijun LIU[3], Chengdu University of Technology
Hemin Koyi[4], Uppsala University

Abstract

Tectonic–erosion–sedimentation interaction and their coupling relationships control the evolution of fold-and-thrust belt and foreland basin system at different time and space scales. In this study, we use analog experiments to investigate the influence of erosion and sedimentation of fold-and-thrust belt, in particular, the along-strike change of erosion–sedimentation in the Longmenshan fold-and-thrust belt, SE margin of the Tibetan Plateau. The along-strike change of surface processes results a strong erosion in wedge hinterland, reactivation of faults and out-of-sequences thrusting, some of faults and related pop-up structures joint together along strike, to form lateral faults (or transfer faults). Displacement and angle of boundary faults increase along-strike due to multistage reactivation of faults as a results of erosion. Furthermore, along-strike change of erosion accommodates faults in the wedge hinterland overturned, even normal faults. The stronger of erosion, the bigger change for the faults in the hinterland. Extensional deformation is found across the Longmenshan fold-and-thrust belt, which could be accounted by the along-strike change of erosion occurred in the Cretaceous to Cenozoic time. In particular, the along-strike change of erosion induces low-angle faults reactivated, and out-of-sequence thrusting in the southwestern Sichuan basin. Thus, we argue that the tectonic shortening and surface processes have significant influence on the architecture of the Longmenshan.

The formation of the Mongolian Orocline in Central Asia: slab-driven or overriding-plate-driven?

Pengfei Li[1]*, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences (pengfeli@gig.ac.cn)

Abstract

Orogenic curvatures, which are also referred as to oroclines, have been widely recognized in ancient and modern orogens. The formation of such curvatures has a significant impact on orogenic architecture, paleogeography, magmatism, as well as subduction dynamics in 4D. However, how relatively linear orogenic belts become tightly curved, remains enigmatic. Alternative mechanisms, including overriding-plate-driven orogenic buckling or bending, as well as along-strike variation of slab rollback, have been proposed. Here, I investigate this issue by studying the tightly-curved Mongolian Orocline that involves oroclinal bending of ~6000 km Andean-type subduction system. The research outcome shows that the formation of the Mongolian Orocline involved a relatively low strain as demonstrated by the lack of a penetrative fabric parallel to the axial plane of the orocline. Combined with available geological and geophysical data, we conclude that oroclinal bending occurred in a period of Permian to Jurassic, and its formation can be attributed to the along-strike variation in trench retreat, which was either driven by negative buoyancy of the subducted Mongol-Okhotsk oceanic slab, or linked to relative convergence and rotation of the Siberian and North China cratons. The latter is preferred given that the crustal thickness along two limbs of the orocline progressively increased during oroclinal bending, which suggests that the absolute trench retrench associated with the formation of the Mongolian Orocline, was forced by the relative convergence and rotation of overriding plates.

Slab Subduction and Pull Link Magmatism at Active and Passive Continental Margins

Li-Qun DAI[1]*, University of science and technology of China (lqdai@ustc.ustc.cn)
Zi-Fu Zhao[2], University of science and technology of China
Guo-Chao Sun[3], University of science and technology of China

Abstract

Subduction leads to voluminous arc magmatism at active continental margins; however, the potential far-field geodynamic connections with coeval magmatism along opposing passive margins, are rarely investigated. In this study, we found that large-scale alkali mafic dike swarms on the South Qinling passive continental margin are associated with a series of parallel faults. Based on the estimated pressures and temperatures of the mantle sources of these dike swarms, we found that the thick and cold subcontinental lithospheric mantle beneath the passive continental margin was gradually replaced by thin and hot one during the early Paleozoic. In addition, arc magmatism on the active margin slightly precede the dike swarms in passive continental margin. We suggest the subduction of the Proto-Tethys oceanic lithosphere led to arc magmatism along the active margin, while rift-related magmatism occurred along the passive margin of South Qinling. Subsequent continuous ridge subduction, mantle upwelling and slab rollback increased the tensional forces on the passive margin, eventually triggering large-scale rift-related magmatism and the opening of the ocean. Thus, we suggest the slab pull associated with subduction, and mantle upwelling geodynamicaly link the active and passive continental margin magmatism and leading to the opening of new ocean basins at passive margin.

Abstract

Deciphering the intricate processes underlying the formation and stabilization of continental crust during the Archean era is vital for understanding Earth's early geological history. Here, we present a comprehensive analysis integrating new geochemical, isotopic, and geochronological data from granitoid rocks within the Archean basement of the Southern São Francisco Paleocontinent, southeastern Brazil (SFP). Our study endeavors to unravel the complex evolution of continental crust in this region. We delineate a significant shift in crustal genesis mechanisms, transitioning from Archean melting of hydrous basalts to melting of enriched mantle peridotite, driven by metasomatic processes. The emplacement of sanukitoid rocks during this epoch underscores deep interactions between metasomatized mantle material and crust-derived magmas. Employing a suite of analytical techniques encompassing U-Pb dating, Lu-Hf, Sm-Nd, and Sr isotopic analyses, oxygen isotopic compositions, and Zr trace element analysis, we elucidate the temporal and compositional evolution of continental crust within the Campos Gerais Complex during the Paleoarchean era. Notably, our study identifies the oldest known sanukitoid rock, dating back to 3.3 Ga, characterized by mantle oxygen isotopic signatures and chondritic Lu-Hf and Sm-Nd isotopic compositions. Furthermore, our analyses suggest the stabilization of proto-cratonic crustal blocks during the subsequent Mesoarchean period (3.2–2.8 billion years ago), often accompanied by extensive reworking of pre-existing granitoid crust. We propose a comprehensive model for the origin of sanukitoids, implicating the opening of the mantle wedge after a period of shallow subduction, fostering interactions between metasomatized mantle material and crust-derived magmas. Our study underscores the dynamic interplay between mantle and crustal processes during the Paleoarchean era, highlighting the importance of localized geological investigations in elucidating broader geodynamic processes. Additionally, our findings shed light on the temporal relationship between subduction initiation and the establishment of modern plate tectonics, highlighting the unique nature of these processes during Earth's early history. The chronology of our results, complemented by prior data, delineates a complete orogenic cycle, featuring a 3.3 Ga sanukitoid, succeeded by High-K Granites, 2.9 Ga TTG, sanukitoid, and High-K granites.

Abstract

The São Francisco Paleocontinent, ESE Brazil, includes Archean nuclei surrounded by Paleoproterozoic magmatic arcs systems (ca. 2.4–2.1 Ga), lately amalgamated between 2,1 to 2.05 Ga, with collapse related bimodal magmatism extending until 1.9 Ga. This complex orogenic system is known as Minas-Bahia Orogen (MBO). New data, including detailed mapping, petrology, geochemical and geochronological studies carried out at the southern segment of the MBO, revealed a diachronic history of juvenile and continental magmatic arcs accretion and collisional episodes with the Archean nuclei. From NW to SE these tectonic units are the southern SFC Meso-to Neo Archean nuclei, The Mineiro Juvenile to Evolved Magmatic Arc and related basins, the Piedade Archean Microcontinent and the Mantiqueira-Juiz de Fora Magmatic Arc System that encompass minor Archean Inliers.

The Southern SFC include Meso-to-Neo Archean TTG complexes and volcano sedimentary basins. The oldest complexes occur westwards, with ages reaching 3.9 Ga, including sanukitoid rocks. U-Pb, Sm-Nd and Hf data indicates even old episodes of crustal rock generation and contribute to discuss tectonic models for the Early Earth. The Piedade microcontinent has TTG and Sanukitoid rocks of 2.7-2.6 Ga and besides 2.5 Ga intraplate basic rocks.

The MBO display a complete Paleoproterozoic orogenic cycle, from subduction-accretion to diachronic collisions, followed by a pervasive bimodal magmatism during the collapse episode. The accretionary period has IAT rocks of 2.4 Ga and ca. 2.3 Ga sanukitoids in the so-called magmatic lull period, besides a high proportion of crustal accretion and reworking in the magmatic arc systems between 2.2 and 2.08 Ga. Diachronic colisional episodes attached the Archean nuclei and passive margin units with the magmatic arc systems between 2.1 and 2.05 Ga. All magmatic arc systems have several coeval pulses of sanukitoid, TTG and common magmatic calcalkaline series, together with IAT basic rocks generation suggestive for flare-ups episodes.

The available zircon Hf isotope data set from Archean and Paleoproterozoic magmatic and metasedimentary rocks of the southern São Francisco craton (Brazil) is interpreted as evidence of accretionary and collisional plate tectonics since at least the Archean-Proterozoic boundary. We show that the crust of the amalgamated Paleoproterozoic tectonostratigraphic terranes that make up the southern São Francisco craton were generated from different proportions of mantle and crustal isotopic reservoirs. Plate tectonic processes are implied by a consistent sequence of events

involving (1) the generation of juvenile subduction-related magmatic arc rocks, followed by (2) collisional episodes and remelting of older crust, and (3) post-collisional bimodal magmatism.

Abstract

Large-scale orogenic collapse as a consequence of crustal overthickening or changes in plate boundary conditions is well documented in modern collisional systems or the classic Neoproterozoic Grenvillian orogens but is rare in earlier Paleoproterozoic orogens that have been thought to be insufficiently widely elevated in temperature to extend. We utilize data from four crustal-scale magnetotelluric, gravity and magnetic studies, the Hudson Bay Seismic experiment, and regional tectonometamorphic and structural-tectonometamorphic data to elucidate the late syn-collisional geometry and architecture of the 1.87-1.80 Ga Trans-Hudson orogen in Arctic Canada, which, owing to substantial post-collisional erosion, affords a window into geometry inaccessible in many other systems.

The Trans-Hudson Orogen formed as a result of closure of the Manikewan Ocean during assembly of the supercontinent Nuna and culminated in collision of the Superior plate with a composite, 2500 km long upper plate comprising Archean Rae and Nain cratons and accreted arcs and microcontinents including Hearne craton. Thickening of the upper plate propagated over 800 km north and formed under MP or barrovian conditions up to high pressure granulite and local eclogite. Extension focused in two domains over what was once the overthickened plateau: a preserved transtensional subaerial volcanic basin flanked by two large metamorphic core complexes, and a pair of narrow elongate extruded panels thrust back towards the foreland. Gravity and magnetic studies show the discrete, 150-400 km long core complexes have the classic arched geometry that accommodated exhumation of mid crustal rocks and enabled formation of accommodation space for the ca. 1.83-1.80 Ga Baker Lake basin, host to the world's largest ultrapotassic volcanic province. The complexes are characterized by granulites or retrograded granulites, large volumes of decompression melt and regional-scale folds of foliations, straight gneiss, mylonite, and blastomylonite, all bounded by discrete shear zones. The length of this coupled system imaged in magnetotelluric, magnetic and gravity datasets extends for 1400 kilometers between the syntaxes of the butterfly-shaped Superior collider. Contemporaneous with formation of the basin and core complexes, the minimum 12 kbar Kaminuriak and Nowyak domains were exhumed between west Hudson Bay and southwestern Nunavut. The south-vergent basal thrust localizing extrusion of these narrow, 50 km across but 450 long, mid to lower crustal panels extends to the Moho in the vicinity of the original suture between Rae craton and Hearne

microcontinent. Tens of kilometre-scale sheath-like internal folds accommodated the strongly vergent geometry of transport, with exhumation of the panels forming inverted metamorphic isograds in overthrust Hearne craton. Although the geometry of a main principal thrust and structurally higher high-grade metamorphic complex is analogous to the Main Central Thrust and Higher Himalayan Crystalline Sequence of the modern Himalaya, unlike the latter, the Trans-Hudson exhumed deeper crust is localized above the principal discontinuity well inside the upper plate: the distinct Rae-Hearne sub-continental mantle lithospheres accreted some 80 million years earlier. The combination of core complex formation and extrusion to accommodate late-synorogenic collapse presented here may be a function of ongoing indentation by Superior into the assembled upper plate during continued south and eastward growth

Abstract

The geochemical and geophysical properties of most Holocene volcanoes in the Sunda and Banda arcs are consistent with formation via mantle wedge metasomatism. However, the Holocene volcanoes Toba, Ungaran, Muriah, Rinjani, Tambora, Sangeang Api, and Batu Tara are (1) located above sections of slab considered too deep to induce subduction-driven metasomatic melting, (2) characterised by enriched and alkaline geochemical compositions that are atypical of arc lavas, and/or (3) responsible for producing unusually explosive eruptions during Quaternary time. Associated with these 'anomalous' volcanoes are several world-class Pliocene–recent porphyry ore deposits, whose occurrence in an island arc juxtaposes current models of porphyry genesis that favour intra-crustal garnet fractionation (which is typically restricted to thick continental arcs) as a metal-enriching mechanism. In this study, we integrate a diverse suite of geophysical and geochemical data sets to propose that slab tearing has contributed to the formation of these anomalous Indonesian volcanoes and porphyry ore deposits. Excursions to greater slab depth and discontinuities in slab seismic tomography anomalies below Toba are interpreted as expressions of a sub-vertical slab tear, formed due to the subduction of the mechanically weak Investigator Fracture Zone, that feeds volcanism via poloidal mantle flow. Ungaran, Muriah, Rinjani, Tambora, Sangeang Api, and Batu Tara are also associated with depth-to-slab excursions and/or positioned at the margins of slab seismic velocity discontinuities (located at depths of 185–400 km) that likely represent elongate slab windows created during the subduction of unusually buoyant oceanic lithosphere. Based on the geophysical and geochemical data, we propose that poloidal asthenospheric flow along slab segment boundaries has triggered deep, low-degree partial melting with varying contributions of slab melt, sediment, and fluid, ultimately producing sub-alkaline and alkaline lavas with trace element patterns enriched in incompatible elements relative to the 'normal' arc volcanoes. Considering the spatial, temporal, and geochemical relationships between slab tearing and the Pliocene–recent Indonesian porphyry ore deposits (as well as the absence of geochemical evidence for slab melting in the formation of these deposits), we also propose that slab tearing produced oxidised magmas (geochemically akin to those of thick continental arcs and areas undergoing slab melting) by facilitating mantle melting in the garnet stability field. Furthermore, we hypothesise that slab tearing locally enhanced magma flux, facilitating extremely violent Quaternary eruptions at Toba, Rinjani, and Tambora.

Exhumation of the Hogem Batholith, north-central British Columbia, Canada

Ruohong JIAO[1]*, University of Victoria (rjiao@uvic.ca)
Xi Wang[2], University of Victoria
Luke Ootes[3], British Columbia Geological Survey

Abstract

The Hogem Batholith is an intrusive igneous complex in the Quesnel terrane in north-central British Columbia. The batholith intruded during the Mesozoic, as four lithologic suites that contain various lithology, such as diorite, monzodiorite, syenite, clinopyroxenite, tonalite, granodiorite, and granite. Zircon U-Pb ages of rocks from the four suites suggest that the batholith had a long emplacement history, ranging from 207 to 125 Ma. We report new apatite fission-track (AFT) data from six bedrock samples, which yield apparent ages between 96 and 40 Ma. We modelled thermal histories of these samples using the AFT age data and track length distributions. The results suggest that following the initial cooling during the Jurassic and Early Cretaceous, the rock samples had remained within the AFT partial annealing zone or underwent moderate reheating until the Eocene. Since the Early Eocene, slow unroofing of the batholith occurred, and the samples have undergone continuous cooling to their present states. We infer that this period of slow exhumation reflects the uplift and denudation of the host terrane. No substantial changes in the exhumation rate over the Cenozoic imply that changes in the Pacific-North American Pate convergence regime had no significant impact on the deformation of this part of the Canadian Cordillera.

Orogenic Evolution and Plate Tectonic Significance of the East African Orogen of Turkana, N. Kenya

Morgan L. BLADES[1]*, The University of Adelaide (morgan.blades@adelaide.edu.au)
Alice McIntyre[2], The University of Adelaide
Samuel Boone[3], The University of Sydney
Laura Morrissey[4], The University of South Australia
Alexander Simpson[5], British Geological Survey
Alan S. Collins[6], The University of Adelaide

Abstract

The East African Orogen is the largest mountain belt known of the last billion years. The evolution of this orogen marks the sharpest rise in ocean water radiogenic Sr isotope testifying to the global significance of this orogen in changing Earth surface systems. The correspondence of the EAO with incredible changes to the climate and biosphere are likely linked, but it is only by much better understanding these links that any causality will be able to be modelled.

Here we present extensive new U-Pb zircon, titanite and apatite age data. These are coupled with novel laser ICP MS/MS Lu-Hf garnet dating, fieldwork and a thermobarometric study of granulite-facies metasedimentary and meta-igneous rocks that form the basement to Tukana region in northern Kenya. The data reveal a complex Neoproterozoic origin and evolution that fills in an East African orogenic ‘missing-link’.

Protoliths to the Turkana basement gneisses define an eastern metasedimentary belt that is delineated west of Lake Turkana by a broad N-S meta-igneous terrane that we call the Lodwar Arc due to the volcanic-arc nature of its protoliths and Neoproterozoic origin. A second metasedimentary belt occurs to the west of the Lodwar Arc that separates it from the Pokat suture and putative ophiolite.

High pressure granulite rocks crop out directly east of the Lodwar Arc in the Lokhone block. Phase equilibria modelling indicates that these rocks underwent peak granulite-facies metamorphism at pressures of 8.4–10.6 kbar and temperatures of 750–830°C. Peak metamorphic conditions have been directly dated by Lu–Hf isotopic analysis of garnet (625 ± 7 Ma and 621 ± 5 Ma), and by U–Pb isotopic analysis of metamorphic titanite (604 ± 8 Ma and 622 ± 16 Ma) and metamorphic zircon rims (612 ± 14 Ma). P-T conditions indicate a moderate geothermal gradient of 78 – 98°C/kbar (17-30°C/km), consistent with metamorphism during crustal thickening. U–Pb apatite geochronology yields ages between ca. 540 and ca. 560 Ma, interpreted as post-peak cooling after metamorphism. These data suggest slow cooling of 2.5 - 9.5°C/Myr, consistent with slow exhumation. U–Pb dating of detrital zircons suggest that at the time of formation, the Lokhone region was not connected to any pre-Neoproterozoic terrane.

Cenozoic uplift of Luxi Uplift and the Qinghai-Tibet Plateau and their geological significance

Fengdi GUO[1]*, China University of Petroleum (East China) (2422863672@qq.com)
Li Li[2], China University of Petroleum (East China)

Abstract

A series of NW normal faults developed in the Luxi Uplift, East China from south to north, such as Mengshan fault, Lianhuashan fault and Taishan fault, whose activities led to the uplift of Taishan, Lianhuashan and Mengshan mountains. The uplift history of the Luxi Uplift was revealed by combining the activity time of the faults and the uplift time of the mountain. In Western China, the collision between the Indian plate and the Asian plate caused the Cenozoic uplift of the Qinghai-Tibet Plateau. Also influenced the tectonic pattern of Eastern China. Therefore, the uplifting history of the Qinghai-Tibet Plateau was further compared to explore the deep dynamic background of the extended orogenic belt in Eastern China and the collision orogenic belt in Western China.

The rock samples of Mengshan Mountain, Lianhuashan Mountain and Taishan Mountain (from the footwall of the normal fault) in Luxi Uplift were analyzed by means of fission track dating and T-t simulation. Combined with the active time of NW normal faults, the Cenozoic uplift of the Luxi Uplift was divided into the following periods: 65~60Ma, 49~40Ma, 30~24Ma and 10Ma. It revealed the time of extension orogen in Eastern China. According to previous studies, the uplift history of Qiangtang Basin in the central Tibetan Plateau was 44.4~30.8Ma, 26.1~22.6Ma, 10.3Ma. The uplift history of the southern Tibetan Plateau was 45~38Ma, 26~18Ma, 13~8Ma. It revealed the time of collision orogen in Western China. The Cenozoic extensional orogen of the Luxi Uplift was compared with the Cenozoic collision orogen of the central and southern Tibetan Plateau, it was found that the uplift of the two was quasi-simultaneous, and both had a uplift sequence from south to north. From the perspective of plate motion, the collision between the Indian plate and the Asian plate caused the uplift of the Tibetan Plateau. The remote effects of the collision affected the uplift of the Luxi Uplift through the flow upwelling of the deep mantle. And with the subduction of the Pacific plate to the Asian plate, the east-west replenishment of the mantle was accelerated. The quasi-simultaneity of the uplift history between the two reflected the possible deep tectonic dynamic response between the eastern and western orogenic activities in China.

[Keynote] The structure and breakup mechanism of the South China Sea: the feature of subduction related rifting

Zhen SUN[1]*, South China Sea Institute of Oceanology (zhensun@scsio.ac.cn)
Fucheng Li[2], South China Sea Institute of Oceanology
Jiangyang Zhang[3], South China Sea Institute of Oceanology
Minghui Zhao[4], South China Sea Institute of Oceanology

Abstract

As one of the largest marginal seas in the Western Pacific, the structure and evolution of the South China Sea will provide important reference to the marginal sea research. In order to decode the continent-ocean transition and seafloor spreading process of the South China Sea, 3 normal and 1 extended IODP drilling expeditions were carried out from distal margin to the relict ridge of the South China Sea. However, large controversies still exist due to the lack of enough drill site-coordinated geophysical investigation to calibrate the drilling results. 30 active source OBSs were deployed along the 300 km long drilling transect and then a 3D network with ~60 OBSs were deployed in the Continent-Ocean transition zone. The velocity models deduced from the OBSs suggest that thick and widespread magmatic underplating occurred below the northern continental margin, with the thickest underplating occurred below the continental slope where the crustal thickness is over 20 km. Correlated with the sedimentary history, the strong magmatic underplating is supposed to happen at late Eocene and caused strong uplift and erosion of early syn-rift sequences. Quantitative analysis suggests that up to 10 km thick magmatic underplating below the thick crust requires a highly attenuated if not fully devastated mantle lithosphere below the continental slope during Eocene. Therefore, the breakup of South China Sea is supposed to experience an earlier mantle breakup and then a crust breakup to generate the spreading ocean. In comparison with Atlantic, the mantle below the northern continental margin might be more wet to generate such an enormous syn-rift magmatic underplating. Forward mathematical modeling suggests that a pre-rift subduction may provides the mechanism of both unsteady lithospheric and more saturated mantle. This might explain why marginal sea basin usually has much wider underplating and more magma supply than the same spreading rate passive margin and ocean.

Tectonic-controlled sedimentary basins in NE Iran

Mohammad Reza SHEIKHOLESLAMI[1]*, Research Institute for Earth Sciences
(rezasheikholeslami@yahoo.com)

Abstract

Geological studies indicate close relationship between tectonic events, related to Paleotethys evolution, and generation of different sedimentary basins in NE Iran. Several tectonic controlled sedimentary basins are recognized during Paleotethys evolution from rifting, subduction and collision stages between Central Iran and Turan plates. These basins have been developed in response to the relative movements of the of Eurasia and Gondwana supercontinents.

The main litho-stratigraphic units of the NE Iran, including eastern part of the Kopeh-Dagh and Binalud, are examined in terms of various tectonic events. The resulted tectono-stratigraphic column is composed of different units ranging from the Early Paleozoic at the base to the Quaternary deposits on the top. Each unit may include several formations or rock units formed in a similar tectonic setting.

The sedimentary basins related to different tectonic setting have been determined as follow:

1- Passive marginal basins, including post-rift passive marginal basin of Prototethys ocean, Middle Ordovician to Devonian Paleotethys rift basin and Devonian-Carboniferous platform sediments of Turan plate.

2- Subduction related basins containing trench and forearc continental shelf basin, remnant arc, arc intra-arc basin (Fariman and Darreh-Anjir complex) and Permian-Triassic back arc basin (Aghdarband Group).

3- Collisional basins and associated rocks, including collisional magmatism, Late Triassic-Early Jurassic Peripheral foreland basin and Middle Jurassic intramontane basin.

4- Post collisional basins containing Kashafrud rift basin, Upper Jurassic to Eocene Carbonate platform, Oligocene-Pliocene foreland basin and post-orogenic molasse- type basin.

The evolution of Eastern Paleotethys Ocean on Hainan Island, South China

Dai ZHOU[1]*, China Geological Survey; China University of Geosciences
(zhoudai@mail.cgs.gov.cn)
Niu Zhijun[2], China Geological Survey
Wang Lei[3], China Geological Survey
Song Fang[4], @mail.cgs.gov.cn

Abstract

Accompanying the closure of the Eastern Paleotethys Ocean, numerous terranes such as South China, North China, Indochina, Qiangtang, etc. were collaged together, constituting the prototype of the East Asian continent. Hainan Island is in the easternmost part of the Jinshajiang-Ailaoshan-Song Ma suture belt (also branch ocean basin) of the Eastern Paleotethys Ocean, therefore crucial to understanding the evolution of the Eastern Paleotethys Ocean. We have rebuilt the stratigraphic sequence and sedimentary environment from Silurian to Triassic on the Hainan Island, as well as investigated the clastic sources in the area by detrital zircon U-Pb dating. The Silurian stratum on Hainan Island consists only of the Lower Silurian, the Tuolie Formation at the base is a charcoal-sandy-siliceous turbidite formed on the continental slope and abyssal plain, which is overlain by a suite of littoral and neritic facies sandstone-conglomerate-graywacke dominantly. The Lower Silurian in the Sanya and Dongfang areas is dominated by clastic sources over 1.0 Ga, while the rest of the area is dominated by similar clastic sources of ~435 Ma and ~950 Ma, showing affinities with Cathaysia and Indochina terrane, and paleomagnetic evidence suggest that they are all located in the northern margin of East Gondwana. Since Devonian, there has been a significant stratigraphic difference between Hainan Island and the Cathaysia terrane, indicating the separation between them. The Lower Devonian of Hainan Island is a volcanic-clastic sedimentary assemblage with typical turbiditic features, meanwhile the volcanic component is mainly intermediate-acidic, and the volcanic eruption age (which approximates the deposition age) is ~400 Ma. This is close to the time of rifting of the South China Plate from the northern margin of the East Gondwana indicated by paleomagnetism, which may represent the formation of the continental rift and corresponds to the opening of the East Paleotethys Ocean. The lower part of the Triassic Lingwen Formation is a disorganized sandstone-conglomerate with typical molasse feature, which contains a larger proportion of Early Silurian slate gravel and Late Devonian granite gravel, and the upper part of Lingwen Formation is a mudstone-siltstone squence. The clastic rocks sources of the Lingwen Formation are mainly of ~370 Ma and share similar clastic source (most likely derived from the Late Devonian magmatic belt of Hainan Island with subduction-magmatic feature) with the Kaiping, Yong'an, and Yongning Triassic basins at the southern margin of the Cathaysia, suggesting that the Hainan Island was collapsed with the Cathaysia in Early Triassic, which corresponds to the closure of the Eastern Paleotethys Ocean. The evolution of the volcanic-sedimentary basins on Hainan Island corresponds well to the opening-subduction-closure of the Eastern Paleotethys Ocean.

The Late Cretaceous tectonic evolution of the Southern Central Andes: insights from the Malargüe area (36°S)

Matias BARRIONUEVO[1]*, IANIGLA-CONICET (matbarrionuevo@yahoo.com.ar)
José Francisco Mescua[2], IANIGLA-CONICET
Julieta Suriano[3], IANIGLA-CONICET
Laura Beatriz Giambiagi[4], IANIGLA-CONICET

Abstract

The Andes are the prime example of a subduction-related orogen, located at a long-term convergent margin where oceanic plates subduct beneath the South American plate. Despite being a long-lived subduction, its main phase of construction occurred during the Cenozoic. Here, we focus on the Southern Central Andes (36°S) where the Late Cretaceous deformational phase marks the onset of orogenic processes. There is general consensus on the initiation of this contractional phase, but its magnitude and extent remain under debate. At this latitude, the Late Cretaceous synorogenic deposits are represented by the Neuquén Group. These sedimentary rocks have been interpreted as deposited in two distinct foreland basin domains. One interpretation, based on the presence of alleged growth strata, proposes a Late Cretaceous wedge-top domain located at the present-day orogenic front. The second interpretation postulates a foredeep position for these deposits, suggesting that the orogenic front for the Late Cretaceous was close to the present-day watershed. We present new structural and thermochronological data to contribute to this debate and evaluate both alternatives.

We surveyed two outcrops of the Neuquén Group strata on the eastern slope of the Cordillera, which were previously recognized as growth strata. We could not recognize either of them as growth strata. The first outcrop consists of reddish to yellowish sandstones and mudstones, dipping consistently to the NW with dips ranging from 38-44°. No systematic changes in dip or thickness nor progressive unconformities have been recognized there. The second outcrop, farther east, consists of conglomerates and sandstones, dipping consistently to the east, with values around 74-88°. As in the previous outcrop, there are no changes in dip or thickness.

Furthermore, we obtained data from apatite-fission track (AFT) in three samples along the 36°S transect. These samples show, although some dispersion, Neogene exhumation ages. Considering their location, it is unlikely that, after the proposed Late Cretaceous exhumation, these rocks were reheated again due to burial and totally reset to record just the Neogene exhumation.

Based on these results, we cannot account for the proposed evidence of synorogenic growth strata as indicative of the location of the Late Cretaceous orogenic front at 36°S. Although preliminary, the thermochronological data do not show exhumation supporting this wide orogen, reaching nowadays orogenic front. Thus, the hypothesis that the Late Cretaceous shortening phase was restricted to the present-day watershed at this latitude is more plausible.

Degree of coupling in 3D multilayer lithospheric buckling: Implications for tectonic environments

Seok-Hyeon DO[1]*, Kangwon National University (tvdo@kangwon.ac.kr)
Byung-Dal So[2], Kangwon National University
Young Hong Shin[3], Korea Institute of Geosciences and Mineral Resource

Abstract

The interaction between the lithospheric strength gradient and tectonic compression induced by relative plate motion is a significant driver of buckling instability. Examining lithospheric buckling alongside plate tectonic history is crucial for deducing lithospheric strength. Through extensive 3D viscoelastic numerical simulations, we delved into the morphology, symmetry, and interplay of layers subjected to intricate stress regimes, varying according to distinct strength configurations within multilayer models. Our simulations encompassed two robust layers sandwiching weaker layers within a matrix of low strength, mimicking simplified lithospheric strength profiles. We applied additional extension or compression boundary conditions perpendicular to the primary compression direction. We observed that boundary conditions predominantly dictate the overall geometry and symmetry. Conversely, the strength and thickness of the layers dictate the extent of layer coupling. Boundary conditions inducing extension resulted in smaller cylindrical buckling structures compared to models subjected solely to uniaxial compression. In models of biaxial compression, the proportion of shortening along each axis dictates the axis of symmetry. The presence of a thicker, weaker layer sandwiched between stronger layers led to decoupling of buckling structures in terms of wavelengths and amplitudes, shedding light on the detached lithospheric buckling beneath the Tibetan Plateau. Simultaneous deformation of the two robust layers generated a spatially dynamic pressure gradient within the weak layer, potentially triggering buckling-induced intraplate volcanism.

Sedimentation and subsidence history of the Gosau Group, Austria: Implications of Late Cretaceous subduction and sea level fluctuations

xinxuan Xiang[1]*, University of Vienna (xiangxxcumtb@hotmail.com)
Eun Young Lee[2], University of Vienna
Wagreich Michael[3], University of Vienna

Abstract

At a subduction zone, the geodynamic mechanisms are responsible for the deformation and movements of the overriding plate. The near-surface evolution, including the uplift, subsidence, and paleoenvironment, can be recorded in the sedimentary deposits on the overriding plate. The Gosau Group is such deposits formed on top of the Northern Calcareous Alps during the Late Cretaceous to Eocene, which is closely associated with the subduction of the South Penninic Ocean below the Austroalpine units. This study investigates the sedimentation profiles and subsidence curves of the Gosau Group at different sites, which provide insights into the subduction process and the complex history of the Eastern Alps. The Gosau Group exhibits the evolution of the depositional environment from fluvial-lacustrine, nearshore and shallow marine (Lower Subgroup) to deep marine (Upper Subgroup) setting, which corresponds to the continuous tectonic subsidence of the plate margin. During the Santonian to Campanian, inconsistencies in the onset of the deep marine environments as well as the trends of subsidence rates are likely associated with the differential structural deformation and vertical movements of the northern margin of the Ausroalpine units along the subduction zone. In the Lower Gosau Group, variations of the depositional system and waterdepth indicate relatively short-term topographic changes, which can be attributed to structural deformation and sea level fluctuations.

Late Cretaceous Tectonic and Paleogeographic Evolution of the Southern Central Andes: Insights from the Diamante Formation at 34°40’S

Federico Exequiel Martos[1]*, University of Buenos Aires (martos.fede@gmail.com)
Lucas Martin Fennell[2], CONICET-UBA
Maximiliano Naipauer[3], CONICET-UBA
Andres Folguera[4], CONICET-UBA

Abstract

The Andes represent the most extensive orogenic system associated with an active subduction margin. While this mountain range has been the focus of study for over a century, its genesis and evolution remain subjects of debate. Some authors propose that during the Cretaceous, there was an increase in the absolute velocity of the South American plate towards the west in response to the opening of the Atlantic Ocean, which would have generated the necessary convergence conditions for the development of a mountain chain. Within the Southern Central Andes, the initial stage of contraction capable of generating an orogenic system and an associated foreland basin took place during the Late Cretaceous.

In this work, we present a detailed investigation into the tectonic and paleogeographic evolution during the Late Cretaceous of the Southern Central Andes at 34°40'S. A multidisciplinary approach integrating sedimentological, geochronological, structural, and provenance analyses was employed to reconstruct the architecture of the first Andean foreland basin. The results provide new evidence of the early uplift history of the Andean orogen.

We focused on an Upper Cretaceous sedimentary succession, the Diamante Formation, which represents the first synorogenic deposits of the foreland basin at theses latitudes. We studied outcrops previously unrecognized, located in a western position of the foreland basin, making it a strategic locality for understanding sedimentary processes near the topographic front of the Cretaceous orogen.

Field surveys allowed the recognition of growth strata associated with bivergent contractional structures (east and west verging). Additionally, progressive unconformities with offlap relationships between discontinuity surfaces were analyzed, which indicates an uplift rate greater than the sedimentation rate at the time of deposition.

Two samples for U-Pb ages on detrital zircons of the Diamante Formation allowed us to determine that this unit has a maximum depositional age of 98.4 ± 2.1 Ma in the basal section and ca. 95 Ma in the upper section. Furthermore, from the provenance age patterns, a primary source area derived from the recycling of Mesozoic sedimentary and volcanic units, likely exposed in the incipient orogen and volcanic arc located to the west, was recognized. Subordinately, a contribution of Permian-Triassic zircons from basement rocks possibly exhumed towards the east was observed.

Integration of the results with previous works allowed for a detailed reconstruction of the basin architecture along an orogenic transect at 34°40’S, showing the evolution of the Andean foreland

basin during the Late Cretaceous, where the main depozones and sediment source areas were delineated. Particularly, the study region represents a wedge-top depozone of the Cretaceous foreland basin, where sedimentation was synchronous with the deformation and advance of the orogenic front towards the east.

Structural evolution of Mud-intrusive and -extrusive System: Insights from 2D seismic reflection data of Makran Accretionary Wedge

SYED AHSAN HUSSAIN GARDEZI[1]*, Key Laboratory of Ocean and Marginal Sea Geology, South China Sea Institute of Oceanology, Chinese Academy of Sciences, Guangzhou 510301, China (gardezisah@scsio.ac.cn)
Xiwu Luan[2], College of Earth Science and Engineering, Shandong University of Science and Technology, Qingdao, 266590, China
Zhen Sun[3], Key Laboratory of Ocean and Marginal Sea Geology, South China Sea Institute of Oceanology, Chinese Academy of Sciences, Guangzhou 510301, China

Abstract

The Mud-intrusive and -extrusive system (MIES) serves as a significant mechanism for the exchange of matter and energy between deep and shallow sequences, making it a key medium for the accumulation and migration of hydrocarbons. The convergence of the Arabian plate beneath the Eurasian plate gave rise to the Makran accretionary wedge (MAW), which hosts a typical MIES spanning kilometers within the offshore and coastal regions. This offers a unique opportunity to study the structural evolution of MIES within the ultra-slow subducting system on earth. In order to define the structures associated with whole edifice (mud-volcano) and its feeder network that links the volcano to its source rock unit, we utilized two-dimensional seismic reflection profiles, bathymetric and satellite data to analyze MIES in MAW. The main results include: i) the MIES is primarily sourced from hemipelagic muds originating from the Oligocene to Early-Miocene Himalayan turbidite deposits (HTDs) overlain by thick Makran sands (middle-Miocene to Pliocene), ii) during the renewed subduction in the middle-Miocene, the MAW was primarily comprised of overpressured shales, which diapirically move upward along weak zones and syn-depositional accumulation of mud initiated within the Makran sands, followed by subsequent phases of mud volcanism, iii) Some mud-volcanoes are characterized by deep source and high energy, erupting directly from HTDs, while others with shallow sources and low energy initially accumulated in mud-chambers within Middle-Miocene to Pleistocene rocks before resurfacing in multiple episodes, iv) Up-pulling of sediments along mud-volcanos and mud-diapirs collaborated in the formation of mini basins within Makran sands, which further exacerbated gravity collapse/ normal faulting in the coastal region, and v) mud pipes/ fluid escape conduits extend to the seafloor, exhibiting conical and bifurcating geometries tapering upwards like Christmas-tree structures, with widths narrowing from a significant base and inclination angles ranging approximately between 75° to 105° relative to horizontal plane. The MIES varies from east to west, primarily due to the convergence rate of the Arabian plate, underplating and high sedimentation rates. The extensive mud flows indicating significant gas generation within the accretionary deposits, fueling the occurrence of MIES.

Long-range effects of mid-ocean ridge dynamics on earthquakes, magmatic activities, and mineralization events in plate subduction zones

Qiuming Cheng Cheng[1]*, IUGS/China University of Geosciences (Beijing)/Sun Yat-sen University (qiuming.cheng@iugs.org)

Abstract

The deep processes of plate subduction zones are closely related to extreme geological events in continental magmatic arcs. The processes of plate subduction and mountain building can lead to events such as earthquakes, magmatic activity, and mineralization. The occurrence of these extreme events is closely related to factors such as crust-mantle interaction, mantle wedge formation, partial melting of the lithosphere, and tectonic magmatism during subduction. However, little is known about the long-term and long-range effects of heterogeneities or innate defects in the newly formed crust at mid-ocean ridges on the extreme events described above. During the formation of new crust at mid-ocean ridges, due to plate expansion, pressure reduction, and asthenospheric material upwelling, the temperature of the new crust increases, pores and cracks develop, the density decreases, and the structure is complex. Therefore, the newly formed crust has heterogeneities in density, strength, temperature, thickness, etc. These crustal differences will influence and determine the behavior of plates during expansion and subduction, with long-term effects on events such as earthquakes, volcanoes, and mineralization caused by plate subduction. Analysis of the Pacific subduction and the Andes orogen has found that sudden changes in plate movement speed, plate subduction angle, plate tearing, lithospheric thickness, Moho depth, etc., have long-range effects on the spatiotemporal distribution of earthquakes, volcanoes, and porphyry copper mineral deposits. These understandings are of great significance for predicting the spatiotemporal distribution of extreme geological events in plate subduction and collision zones.

Unveiling the Evolution of the West Philippine Basin with Massive High-Resolution Seafloor Mapping Data

HANJIN CHOE[1]*, Pusan National University (explorist@pusan.ac.kr)
Hyeonuk Shin[2], Pusan National University

Abstract

The West Philippine Basin, an oceanic basin half the size of the Philippine Sea Plate, lies in the western part of the plate. It subducts beneath the Eurasian Plate and the Philippine Islands bordering the Ryukyu Trench and the Philippine Trench with 25-50% of this basin already consumed. However, the opening history of the basin's southern region is still ambiguous due to insufficient marine geophysical data. we collected the open-source multibeam bathymetry data from various data centers(JAMSTEC-DARWIN, NOAA-NCEI, IFREMER-SISMER) and obtained a new dataset by R/V Isabu in September 2022. By analyzing high-resolution multi-beam echo-sounding data, we confirmed that the non-transform discontinuity due to the propagating rift dynamically evolved in the entire basin. In the early stage of basin extension, the Amami-Sankaku Basin was rotated 90 degrees clockwise from its current orientation. This result is contradictory to the previous paleomagnetic analysis that the basin rotated 90 degrees counter-clockwise using sediment cores obtained from the Amami-Sankaku basin. As a result of reconstructing the basin evolution process based on these two conflicting results, the dynamic evolution process of the West Philippine Basin was confirmed. In the beginning stage of the opening, the Amami-Sankaku Basin separated from the Palau Basin while the spreading of the West Philippine Basin began with a counter-clockwise rotation. This indicates that the non-transform discontinuities formed by a sudden change in magma supply due to the drift of the Philippine Sea Plate and simultaneously with the rapid changes in the spreading direction from ENE–WSW to N–S. We performed a combined analysis using high-resolution multi-beam bathymetry and satellite gravity data to uncover new insights into the evolution of the West Philippine Basin. This study illuminates the complex plate interactions and provides a crucial contribution toward understanding the opening history of the basin and the Philippine Sea Plate.

Abstract

The last version of the World Digital Magnetic Anomaly Map (WDMAM v. 2.0) endorsed by IAGA and CGMW was released in 2015 (Dyment et al., EPSL, 2015; Lesur et al., EPS, 2016) with the mandate to update it using the same methodology when new data become available. After a provisional version 2.1 that was including a minor error released in 2023, the new version 2.2, compiled at 5 km interval, at 5 km altitude above the continents and at sea-level over the oceans, includes new datasets: (1) the complete digital aeromagnetic map of Brasil made available by ANP; (2) an improved version of the aeromagnetic map of Russia prepared by V-SEGEI; (3) the second version of the Antarctic Digital Magnetic Anomaly maP (ADMAP; Golynsky et al., GRL, 2018) which results from a remarkable international effort during and after the Second International Polar Year; (4) a new map of the Caribbean Plate and Gulf of Mexico (Garcia and Dyment, EPSL, 2021, 2022); (5) the updated Magnetic Anomaly Map of Eastern Asia prepared by the CCOP (MAMEA; Ishihara and Uchida, 2021); and (6) a new marine magnetic anomaly data compilation prepared by T. Ishihara and coworkers. The remaining data gaps are filled with a satellite anomaly model (Thebault et al., GRL, 2021). Long wavelengths of degree and order lower than 120 are filtered and replaced by those computed between order and degree 16 and 120 using the same satellite magnetic anomaly model from CHAMP and Swarm data. The new map is presented and its significant improvements over the previous version are discussed, with examples of how the map can be used to address geological questions. The version 2.2 of the WDMAM will be available at wdmam.org. This presentation is dedicated to the memory of Manuel (Manen) Catalan who co-chaired the WDMAM task force for the last 10 years and passed away in December 2023.

Can an extraterrestrial body impact affect plate tectonics? The case of Chicxulub and the Yucatan Basin

Jerome DYMENT[1]*, CNRS - IPGP - UPC (jdy@ipgp.fr)
Andreina GARCIA-REYES[2], CNRS - IPGP - UPC

Abstract

The Yucatan Basin is a triangular basin located between Yucatan, Cuba, and the Cayman Trough. Its age and origin remain unsolved so far. The Cayman Trough is an narrow basin formed by ultraslow seafloor spreading between two long transform faults that define the northern boundary of the Caribbean Plate since 50 Ma (Leroy et al., GJI, 2000). This basin cuts across the Yucatan Basin and is therefore younger. Further North, seafloor spreading opened the Gulf of Mexico between 150 and 140 Ma (Garcia-Reyes and Dyment, EPSL, 2022); further South, the Caribbean Large Igneous Province formed by seafloor spreading between ~120 and 73 Ma in the Pacific before being drifted eastward (Garcia-Reyes and Dyment, EPSL, 2021). We therefore expect that the Yucatan Basin formed between 73 and 50 Ma.

Marine magnetic profiles in this area have been collected in the 1970s and are poorly navigated. Only a few profiles are conveniently oriented. We identify anomalies 29r to 28 off southern Cuba. A set of complex short-wavelength anomalies observed off Yucatan do not fit the wide anomalies expected between 73 and 50 Ma. We interpret them as "tiny wiggles" generated by geomagnetic intensity fluctuations usually depicted on fast-spreading spreading centers. This area is underlain by a strong regional gravity anomaly typical of magmatic crust formed at fast spreading centers. A fossil ridge is clearly identified on the gravity. By comparison with "tiny wiggles" recognized globally (Bouligand et al., EPSL, 2006), we date this area to Chron 26r. The Yucatan Basin was therefore formed by seafloor spreading between Chrons 29r and 26r (65-59 Ma) in two stages, first at an intermediate rate of ~40 km/My, then at a fast rate of ~100 km/My. The collision of Cuba with the Bahamas platform at 59 Ma resulted in a plate reorganization, with Cuba being attached to the North-American plate and the remaining Caribbean Plate moving due east.

The Greater Antilles Arc, ahead of the Caribbean Plate in its northeastward motion between the North and South American plates, was split by the opening of the Yucatan Basin between Jamaica-Hispaniola and Cuba at Chron 29r (~66 Ma). The coincidence in time and location with the Chicxulub impact is striking and suggests that sometimes regional plate tectonic events may result from major impacts with extraterrestrial bodies.

Investigating the Chemical Mechanism for Magnetization Reduction in Subducting Oceanic Crust through Hydrothermal Alteration of Magnetic Minerals

Sunhwa HONG[1]*, Pusan National University (ovooo41@pusan.ac.kr)
Hoon young JEONG[2], Pusan National University
Hanjin CHOE[3], Pusan National University

Abstract

The subduction zones are the area where tectonic movements with related natural disasters such as volcanic eruptions, earthquakes and tsunamis actively occur. The extreme conditions in subduction zones induce the changes in physical and chemical characteristics in the subducting oceanic crust (i.e. the hydrothermal alterations of magnetic minerals). In the initial stage of its formation, the oceanic crust exhibits strong magnetization due to the formation of titanomagnetites when the magnetic mineral meets seawater. The hydrothermal circulation alters the magnetic minerals as a result of significantly decrease of the strength of magnetic intensities. Over time, the formation of anhydrous minerals block the seawater circulation in the oceanic crust and finally the weakening magnetizations are stabilized. Subsequently, in the subduction zone, it was observed that magnetization of oceanic crust gradually decreases up to 20% from the top of the outer rise to the trench by rejuvenated hydrothermal circulations from bending related re-opening faults. However, the quantitative impact of chemical alteration on magnetic minerals within the oceanic crust, associated with the reactivation of hydrothermal circulation, remains unquantified. Therefore, we conducted hydrothermal experiments to investigate the extent of alteration in major magnetic minerals, namely magnetite and titanomagnetite, prevalent in the oceanic crust. These experiments involved subjecting these minerals to reactions with artificial seawater at varying particle sizes and temperature conditions. Additionally, Gas Chromatography analyses were performed at regular intervals to monitor gas generation and observe mineral alteration, while X-ray diffraction (XRD) was utilized to examine resultant mineral samples for any mineralogical changes. Furthermore, we assessed the magnetic susceptibility of these minerals before and after the experiments using a magnetometer. These results, obtained through quantitative measurement of chemical alteration in magnetic minerals within the oceanic crust, are anticipated to advance our understanding of the interaction between hydrothermal circulation and magnetic minerals in subduction zones, thereby providing fresh insights into the formation and evolution of subduction zone environments.

Inside the Central Cordillera of Colombia: La Línea Tunnel

Jorge GÓMEZ TAPIAS[1]*, Servicio Geológico Colombiano (mapageo@sgc.gov.co)
Carolina MORALES FERNANDEZ[2], Servicio Geológico Colombiano
Daniela MATEUS ZABALA[3], Servicio Geológico Colombiano

Abstract

The La Línea tunnel crosses the axis of the Colombian Central Cordillera at approximately 4.5° north latitude and is part of the road corridor that connects Bogotá with Buenaventura, the main harbor of Colombia in the Pacific Ocean. The tunnel was constructed at an altitude of 2400 meters above sea level, has a length of 8.6 kilometers, a width of 12.5 meters, and reaches a maximum depth of 900 meters below the highest point, the summit of La Línea. The importance of the tunnel lies in its ability to provide a comprehensive geological record of the Central Cordillera, which is otherwise concealed beneath surface vegetation and the volcanic ash deposits of the Cerro Machín Volcano.

The geological map of the La Línea tunnel was carried out at a scale of 1:10000 and covered an area of 42 km2. It was developed based on the description of 8595.3 linear meters of exploratory cores from the tunnel, the geological characterization of areas without tunnel wall coverings, and the description of approximately 300 outcrops in the vicinity.

To the east of the San Jerónimo Fault, La Línea Diorite was identified. La Línea Diorite is in faulted contact with the Cajamarca Complex. The Cajamarca Complex consists of intercalations of quartz muscovite schists with varying amounts of graphite, chlorite and amphibole schists, and amphibolites in greenschist to amphibolite facies.

To the west, the Cajamarca Complex is in contact with the Quebradagrande Complex along the San Jerónimo Fault. The most representative lithologies of the Quebradagrande Complex in this region consist of interbedding of crystal and volcanic lithics tuffs, hornblendic andesites, with fewer occurrences of agglomerates and volcanic breccias. Additionally, there are deformed sedimentary rocks characterized by interbedding of conglomerates with granules, sandstones with convolute stratification, load structures, and gradation, and mudstones exhibiting plane–parallel stratification structures. The tuffs have undergone metamorphism into greenschist facies with the formation of talc, chlorite, and tremolite–actinolite. Various new porphyritic bodies were mainly recognized to the east of the San Jerónimo Fault in intrusive contact with rocks of the Cajamarca Complex.

New U–Pb dating of detrital zircons from rocks of the Cajamarca Complex indicates maximum depositional ages ranging from the Middle to Late Jurassic, with populations showing inherited characteristics from the Paleozoic era. Geochemical analysis of the greenschists reveals a

predominant oceanic affinity, characterized by intermediate Th/Yb and Nb/Yb ratios falling between N–MORB and E–MORB type basalts. In the tuffs of the Quebradagrande Complex, geochemistry suggests a magmatic arc affinity, while the zircons display Early Cretaceous ages and inherited Triassic characteristics, indicating a continental contribution. The La Línea Diorite exhibits a crystallization age from the Jurassic period, the porphyries have a Miocene age, and a newly discovered volcano at the summit of the tunnel shows a Pleistocene age.

Understanding postseismic deformation patterns in the Korean Peninsula following the 2011 Tohoku-Oki earthquake: Insights from viscoelastic numerical simulations

Sungho LEE[1]*, KIGAM (slee29@memphis.edu)
Eunseo Choi[2], University of Memphis
Minkyung Son[3], KIGAM
Seok Goo Song[4], KIGAM
Demian D. Gomez[5], Ohio State University

Abstract

The 2011 Tohoku-Oki earthquake caused geodetically detectable co- and post-seismic surface deformations across Northeast Asia and might be responsible for the enhanced seismic activity reported for the southern part of the Korean Peninsula (SKP). Here, we conducted a series of viscoelastic numerical simulations to explain the complex spatial and temporal distribution of the postseismic deformations in the SKP captured by the Global Navigation Satellite System (GNSS). We used the GNSS data published by a previous study but newly calculated yearly velocity gradient tensors for five years since the Tohoku earthquake using the extended linear trajectory modeling method. Our numerical models were composed of two layers, lithosphere and asthenosphere. The lithospheric thickness and elastic properties were taken from LITHO1.0; and those of the crust, embedded within the lithosphere, from CRUST1.0. For simplicity, each layer's viscosity was assumed to be uniform and constant. The lithospheric viscosity was set to be 10^23 Pa s. Based on the root mean square error with respect to the low-pass filtered GNSS-derived strain rate fields, we found that 5 x 10^18 Pa s is the best-fitting asthenospheric viscosity. In the GNSS data, three regions of the SKP—northwest, southwest, and southeast areas—exhibited particularly large maximum shear strain rates relative to the best-fitting model. Noting the spatial coincidence of those regions with the low-velocity anomalies at depths of 60-120 km in two regional seismic tomography models, we modified the best-fitting model by introducing a low (10^19 Pa s) viscosity at the locations of the low-velocity anomalies and found the difference from the GNSS data significantly reduced. Finally, we show that the magnitudes of maximum shear strain rate for the first year since the Tohoku earthquake in a numerical model could approach those from the GNSS data only with an asthenospheric viscosity as low as 2-3×10^18 Pa s while 5×10^18 Pa s is the best-fitting value for years 2-5. This result suggests that post-seismic stress relaxation in the region's asthenosphere is strain rate-dependent.

The critically stressed state of the earth's crust and the associated response to anthropogenic impact

Andrian Sergeevich Batugin[1]*, NUST MISIS (batugin.as@misis.ru)

Abstract

An industrial large-scale impact on the subsoil and the earth's surface is accompanied by such hazardous technogenic geodynamic phenomena as induced earthquakes, rock bursts, gas migration to the surface in mining areas and reactivation of tectonic faults. In some cases, the induced nature of geodynamic phenomena cast no doubt, as, for example, in the extraction of minerals in mines. At the other extreme are geodynamic phenomena, the technogenic nature of which is being questioned. This mainly concerns strong earthquakes with magnitude M> 5 and with a large depth of the hypocenter. The main argument against the technogenic nature of such earthquakes is insignificant stress changes at the depth of the hypocenter and the overly strong response of the earth's crust to the technogenic impact. Based on several examples from the author's experience and published data, this presentation considers the hypothesis of the occurrence of strong induced earthquakes with a major depth of the hypocenter. Among the examples are earthquakes with magnitudes of 5 to 8, the nature of which is under discussion. The hypothesis is based on the concept of the critically stressed state of the earth's crust, which occurs in a layer located at a certain depth from the earth's surface. During the study, it was found that the occurrence of induced earthquakes with a magnitude of more than 5 and the fault reactivation can be explained through the concept of critically stressed state of the earth's crust. The results obtained comply with understanding of the nature of technogenic geodynamic phenomena and can be used to develop recommendations for zoning of the induced geohazards. This study was supported by grant № 22-27-00728 from the Russian Science Foundation (RSF), https://rscf.ru/en/project/22-27-00728/

[Keynote] Properties, nature and outlook of intraplate earthquakes in the eastern margin of Eurasian plate around the Korean Peninsula

Tae-Kyung HONG[1]*, Yonsei University (tkhong@yonsei.ac.kr)
Junhyung Lee[2], Yonsei University
Seongjun Park[3], Yonsei University
Byeongwoo Kim[4], Yonsei University
Jeongin Lee[5], Yonsei University
Dong Geon Kim [6], Yonsei University

Abstract

The tectonic loading rate in stable continental regions is low, which causing low earthquake occurrence frequency in intracontinental regions compared to interplate regions. However, large earthquakes may still occur within geological structures in stable continental regions. The Korean Peninsula and its neighboring regions belong to a stable intracontinental regime located in the eastern Eurasian plate. A series of major earthquakes occurred over time in the Korean Peninsula after the 2011 Mw 9.0 Tohoku-Oki megathrust earthquake. There is increasing concern regarding the possible occurrence of major events that may cause fatal damage to large cities. Historical seismicity may provide valuable information on the seismic hazard potentials for earthquakes with long recurrence intervals. There are historical literatures that describe seismic damage and earthquakes during the Joseon dynasty in 1392–1910, presenting moderate and large earthquakes of long recurrence intervals. Most earthquakes in the continental lithosphere occur in the upper crust, while mid- to lower crustal earthquakes rarely occur in intraplate regions due to ductile deformation. The rate of seismicity is low, and the seismicity is spatially diffuse. The focal depths of these events are 4–20 km, mostly within ~4–8 km in the peninsula and Yellow Sea and 2–30 km (mostly 12–20 km) in the East Sea (Sea of Japan). The seismicity appeared to increase after a megathrust earthquake. Episodic earthquake swarms occur in low seismicity regions. After a megathrust earthquake, mid to lower crustal earthquakes increased. The midcrustal and lower crustal events occurred in regions where the seismicity was low before the events. On the other hand, the earthquake occurrence is relatively low in the usual high seismicity regions. The feature may happen due to the stress balancing in the crust after the megathrust earthquake. Also, changes in the properties of the medium caused major earthquakes to occur at relatively early times. Successive ML5 earthquakes occurred on the outskirts of high-seismicity regions. The identification of potential earthquake locations is important for seismic hazard mitigation. Paleo-tectonic structures develop as earthquake-inducing faults, which may be important for seismic hazard mitigation in intraplate regions.

Effect of postseismic deformation following Tohoku-Oki earthquake on the East Asian intraplate due to the strength of the East-Sea (Japan Sea).

Hyeon-Seob KIM[1]*, Kangwon National University (hskim_knu@kangwon.ac.kr)
Byung-Dal So[2], Kangwon National University

Abstract

Stress transfer between faults caused by seismic events has triggered or induced aftershocks and subsequent earthquakes. Following Mw 9.0 Tohoku-Oki great earthquake on March 11, 2011, near the coast of Eastern Japan, led to increased seismic activity within intraplate faults of the Eurasian plate. The Korean Peninsula, located more than 1200 km from the epicenter, occured microearthquakes and the >Mw 5 middle earthquakes since 2011. Geodetic, seismological, and geophysical investigations have demonstrated that the great earthquake induced static, dynamic, and quasi-static stress changes in faults within the peninsula.

Viscoelastic relaxation of the rheological structure, in response to earthquake stress, causes disturbance in the stress field over a wide upper plate, a long duration, and identified as a primary factor in the stress change of intraplate faults from previous numerical modeling. However, the laterally homogeneous layered structure model representing the Eurasian plate may overlook the effects of viscoelastic behavior due to the rheological contrast between the 1000 km wide back-arc and the continent. The East Sea (Japan Sea) back mantle, where undergone expansion, showed a thickness difference of more than 30 km with the Korean pennisula., even rheological strength weakening through the interaction of the uplifted mantle. We compare the effects reflecting the heterogeneity of the back mantle using a three-dimensional numerical model incorporating the Japanese subduction zone and the vast Eurasian plate. Our study discusses the remote stress stransfer between interplate and intraplate faults due to the extended back mantle in the subduction zone.

Permian magmatism and Triassic and Jurassic metamorphism recorded at the western margin of Gondwana, Colombia

Jorge GÓMEZ TAPIAS[1]*, Servicio Geológico Colombiano (mapageo@sgc.gov.co)
Carolina MORALES FERNÁNDEZ[2], Servicio Geológico Colombiano
Daniela MATEUS–ZABALA[3], Servicio Geológico Colombiano

Abstract

New detrital U–Pb LA–ICP–MS ages carried out in Colombia in recent years have allowed us to separate the Cajamarca Complex, previously assigned to the Paleozoic, composed of quartzites, schists, and amphibolites that make up a large part of the basement of the Central Cordillera, into two geological units. The first one has a Triassic metamorphism as indicated by Ar–Ar ages. The second one has an age range from Late Jurassic to Early Cretaceous? This age is assigned based on detrital ages ranging from 167 to 138 Ma and the fact that these rocks are intruded by the Mariquita Stock with an age of 130 to 143 Ma. The second unit is in the middle of two blocks of the first unit and its boundaries are the Palestina and Ibagué Faults. These boundaries are interpretative because no new geological mapping has been carried out in this region.

Similarly, new U–Pb ages on the eastern flank of the Central Cordillera and the Sierra Nevada de Santa Marta have enabled the split up of several Permian igneous bodies that define a non–continuous, north–south–oriented arc. The Ortega Batholith stands out, which was previously considered part of the Jurassic Ibagué Batholith.

Various xenoliths of medium to high–grade metamorphic rocks in the Jurassic Ibagué Batholith were dated by U–Pb LA–ICP–MS. These xenoliths, previously lacking data, have been assigned to be of Stenian–Tonian age, related to the Putumayo Orogeny. These rocks consist of granulites, orthogneisses, paragneisses, migmatites, and amphibolites. Our results show that these orthogneisses contain igneous zircons with a Permian crystallization age and a Middle Triassic metamorphic overprint.

These new data suggest that the western margin of Gondwana experienced a Permian magmatism and a Middle Triassic metamorphic event associated with the assembly and breakup of Pangea. Additionally, a Late Jurassic or Early Cretaceous metamorphic event is reported, which may be allochthonous and raises new questions about the evolution of this part of the northwestern corner of South America.

A review of the retroarc foreland metasediments associated with the Devonian-Mississipian west Patagonian magmatic arc, Argentina

Carlos Jorge Chernicoff[1]*, CONICET-SEGEMAR (Council for Scientific Research, Argentina)
(cc_jorge@yahoo.com.ar)
Eduardo O. Zappettini[2], Servicio Geològico-Minero Argentino

Abstract

37 IGC , Republic of Korea. 2024. T4: Tectonophysics, Session 13: General Topics.
Abstract #142

In the central segment of the North Patagonian Massif, Argentina, where limited outcrops of Paleozoic metasediments of the Colo Niyeu Formation are exposed, new zircon U-Pb SHRIMP dating has been carried out, yielding a Devonian age; notably, this unit was formerly regarded as Cambrian.

The rock analyzed is a low-grade metasandstone sampled at 40°43´51´´ S / 68°36´56´´ W, from which 27 detrital zircons have been analyzed. Most of the grains are late Neoproterozoic (n=11) and late Mesoproterozoic (n=9) in age, followed by Cambrian (n=3) and Ordovician (n=2); the oldest grain is Rhyacian. The age of the youngest detrital zircon grain is Silurian (430 ± 6 Ma; Wenlock Epoch), indicating the maximum age for the onset of sedimentation of the protolith of the Colo Niyeu Formation.

In the context of the Colo Niyeu Formation occurring ca. 120 km to the east of the NNW-trending late Devonian-Mississipian, Western Patagonian Magmatic Arc, it is likely that this unit could pertain to a retroarc foreland basin associated with the latter arc, subjected to deformation and low-grade metamorphism during the Middle Carboniferous collisional event occurred in that region. The partly coeval and relatively nearby metasediments of the Cushamen and Colohuincul Formations are comparable to the Colo Niyeu Formation, though located in a forearc position.

Newly dated Neoproterozoic-Cambrian Las Pacas Complex at the boundary between the Cuyania and Chilenia terranes, southern Mendoza province, Argentina

Carlos Jorge Chernicoff[1]*, CONICET-SEGEMAR (Council for Scientific Research, Argentina) (cc_jorge@yahoo.com.ar)
Eduardo O. Zappettini[2], Servicio Geològico-Minero Argentino

Abstract

37 IGC, Republic of Korea. 2024. T4: Tectonophysics, Session 13: General Topics. Abstract #150

The Las Pacas Complex is formed mostly by metasediments poorly exposed at the southern Mendoza province of Argentina (ca. 35° 45´S / 68º 19`W). They have been dated using the U-Pb SHRIMP method, yielding the following results.

The main rock unit studied is a low-grade metapelite/metasandstone, from which 22 detrital zircons have been analyzed, representing the main populations, i.e. 27.2 % Paleoproterozoic (13.6 % Statherian, 13.6 % Orosirian) and 72.7 % Mesoproterozoic (4.5 % Ectasian, 68.2 % Calymmian).

The youngest zircón is ca. 1235 Ma (Late Ectasian; Tdm-Hf 1.42 Ga –Late Calymmian-, épsilon Hf +9.73). In spite of the latter Late Ectasian age, the regional context strongly suggests that the maximum age for the onset of sedimentation of the protolith of the Las Pacas metasediments is Late Neoproterozoic-Cambrian, probably representing the southern continuation of the likely equivalent Guarguaraz Complex, also exposed at the boundary between the Chilenia and Cuyania terranes, ca. 200 km to the south. If correct, the Las Pacas Complex would also represent a segment of the same collisional accretionary prism as proposed e.g. by Willner et al. (2008; Chemical Geology 253:114–129) for the Guarguaraz Complex.

In addition, in the same area of poor exposures, although with field relationships still undetermined, there are sparsely distributed metabasites which have been dated at 1424 Ma. In the geological context, both local and regional, these scarce metabasites are herein regarded to probably pertain to upthrust basement slivers, tectonically imbricated with the Las Pacas metasediments.

A study on magnetization vector inversion modeling of Dokdo submarine volcanic body

SoonYoung CHOI[1]*, Korea Institute of Ocean Science and Technology, Kangwon National University (sychoi@kiost.ac.kr)
ChangHwan KIM[2], Korea Institute of Ocean Science and Technology
WonHyuck KIM[3], Korea Institute of Ocean Science and Technology
ChanHong PARK[4], Korea Institute of Ocean Science and Technology

Abstract

To understand the formation and evolution processes in Dokdo submarine volcanic body, we studied a magnetic model around the study area using bathymetry and magnetic data. Volcanic body regions have complex structures due to magma eruption and intrusion during the formation process. We performed modeling using the magnetization vector inversion (MVI) method, which can consider both remanent magnetization and induced magnetization, to determine the accurate three-dimensional spatial magnetic distribution and magnetic structure of the volcanic body region. The Dokdo submarine volcanic body is a flat seamount measuring approximately 26(N-S)x21(E-W)km and is divided into the summit, slope, and base. There are two small islands at the center of the summit of the Dokdo submarine volcano (Dongdo and Seodo). About four small craters that are inferred to be parasitic volcanoes appear. The magnetic characteristics of Dokdo submarine volcanic body, derived from the total magnetic intensity, show that the low anomaly zone is distributed in the central part of the submarine volcanic body and a high anomaly zone surrounds it. The boundary area between the summit and slope is almost matched with the boundary area between the high-anomaly zone and the low-anomaly zone. At the summit, a low anomaly zone appears in most areas east and south of Dokdo, including around Dokdo, while a relatively high anomaly zone appears in the north and northwest areas of Dokdo. The slope area, with a different pattern from the summit area, shows that all areas except the eastern area are distributed in a high anomaly zone. The magnetic modeling range of this study is 21x18x10km, and the modeling results are expressed as magnetic susceptibility and magnetization vector. As a result of analyzing the magnetic susceptibility and magnetization vector, It is expected that strong magnetic material that affected the Dokdo submarine volcanic body was moved from the deep seafloor layer to the shallow layer in the central area of the summit and the south-southeast area of the slope. Meanwhile, small anomalous zones appear dispersed in the west-southwest-south near the base, which is considered to be a possible influence of strong residual magnetization created by lava flows at the time of volcanic body formation. The result of the magnetic intensity and magnetization vector by clip (>0.02) indicates the overall high-abnormality patterns of the shallow and deep layers. In addition, the expected movement path of strong magnetic materials is more clearly visible in two regions (the central region of the summit and the southeast-southeast region of the slope). The opposite magnetization vector directions of the two regions suggest that the source location and eruption time of the magnetic material in the two regions might be different.

Abstract

The emplacement mechanism of the Deccan Continental Flood Basalt (DCFB) in India has been extensively debated among researchers, with proposed models including the Plume model, Mantle convection theory, and fissure eruption theory. The DCFB comprises three major dyke swarms i.e., the Western Coastal dyke swarm (N-S trending), the Narmada-Satpura-Tapi (N-S-T) dyke swarm (E-W trending), and the Nasik-Pune dyke swarm (randomly oriented). This research focuses on the Pachmarhi and Nandurbar-Dhule (N-D) dyke swarms, located on the Eastern and Western sides of the N-S-T dyke swarm, respectively. The primary objectives are to develop a comprehensive geodynamical model of the N-S-T dykes, explain flow dynamics within these dykes, and identify the locations of magma chambers that feed them.

The Pachmarhi and N-D dykes have maximum lengths of 22 km and 79 km, respectively, with both having mean lengths of ~5 km. These dyke swarms are emplaced within preexisting fractures, exhibiting a discernible preferred orientation along an ~E-W trending trajectory. This alignment corresponds to the general trend of the Narmada-Son lineament (NSL) and is perpendicular to the direction of the minimum horizontal stress ($\sigma 3$). This $\sigma 3$ direction aligns with the ~N-S trending paleoextension during the period of dyke emplacement. Anisotropy of magnetic Susceptibility (AMS) and rock magnetic analysis have been deployed for the dyke swarms which aims to determine the direction and sense of magma flow, providing insights into the depth, number, and spatial distribution of magma chambers. The rock magnetic studies conducted on the dykes have revealed the presence of high-titanium magnetite particles, primarily of Pseudo-Single Domain (PSD) nature. However, in the case of the N-D dykes, low-titanium magnetite particles with Multi-Domain (MD) grains were observed.

To determine magma flow direction and sense in dyke margins with different fabric shapes, magnetic foliation plane imbrication (dip and strike of the K1-K2 plane) is used for oblate fabric, and magnetic lineation (plunge of the K1 axis) imbrication is used for prolate fabric. When one dyke margin has an oblate shape and the other has a prolate shape, magnetic foliation is used for the former and magnetic lineation for the latter. This analysis reveals various magma flow trends, mostly vertical or inclined, suggesting proximity to magma sources. Few dykes show a sub-

horizontal flow pattern. The intersection of imbrication within the margins of each dyke provides valuable information about the flow geometry, suggesting the presence of multiple shallow subcrustal magma chambers. This finding aligns with earlier conclusions based on structural attributes, such as the length and thickness of dykes, quantifying magmatic overpressure and the depth of the magma chamber. The multiple trends of flow indicate a polycentric flow pattern for both the Pachmarhi and N-D dykes. Thus, it can be inferred that dyke emplacement in the NSL region was primarily facilitated by a "polycentric flow" mechanism through sub-crustal magma chambers, where magma was injected through crustal fissures, leading to a significant volume of magma being generated in the DCFB.

Abstract

The timing and mechanism of uplift in the southeastern Tibet Plateau have long been subjects of debate. The Gongga Shan region, positioned at the convergence of the Songpan-Ganzi, Chuandian, and Yangtze blocks, serves as a crucial vantage point for unraveling the evolutionary history of the southeastern Tibet Plateau. Nevertheless, the uplift history of the Gongga Shan region remains shrouded in uncertainty. By employing multivariate trace element ratios and reconstructing crustal thickness using zircon Eu/Eu* based on the timeline established by detrital zircon U-Pb, our research has unveiled distinct periods of crustal thickening and thinning events. Within the time span of ~240–160 Ma, a discernible thickening trend emerged from ~35 to ~45 km between ~240 and ~ 215 Ma, followed by a relatively stable phase from ~215 to ~170 Ma, and subsequently a decline from ~170 to ~160 Ma, reducing the thickness from ~45 to ~30 km. In the period from ~55 to ~5 Ma, an initial increase in thickness occurred from ~30 to ~60 km between ~55 and ~ 30 Ma, succeeded by an overall thinning from ~60 to ~35 km between ~30 and ~ 10 Ma. Moreover, based on our reconstructed crustal thickness data, we have traced the paleo-elevation changes in the Gongga Shan region from the Cenozoic to the present, revealing a fluctuation from ~0.5 to ~4.5 km. We attribute the Triassic-Jurassic crustal thickening and subsequent thinning to the Triassic orogeny and post-collision extension following the closure of the Paleo-Tethys Ocean. Our findings further suggest that during the Eocene-Oligocene period, the Gongga Shan region experienced significant crustal thickening and surface uplift, indicative of intense compression. This phenomenon likely resulted from the northeast-directed compression of the Indian- Eurasian plate, causing substantial crustal shortening and thickening in specific areas of the southeastern Tibet Plateau, leading to rapid surface uplift. Subsequently, during the Oligocene-Miocene, the detachment and subsidence of the lithospheric mantle triggered rapid crustal thinning in the Gongga Shan region. This phase was accompanied by relatively stable and

slight surface uplift, signifying a shift in the plateau uplift mode of the southeastern Tibet Plateau from compression to lateral extrusion.

Evidence of crustal scale fracture system in Central Indian Precambrian (Bastar) Craton, India: Inference from airborne magnetic data analysis and modelling.

AJIT SINGH[1]*, GEOLOGICAL SURVEY OF INDIA (ajit.singh4@gsi.gov.in)
RAJESH KUMAR[2], GEOLOGICAL SURVEY OF INDIA

Abstract

The Central Indian Precambrian Craton (Bastar) holds a unique position in Indian plate tectonics evolution owing to its complex crustal architecture, poly deformational history and spatial proximity to mega scale tectonic features viz. Godavari Graben, Mahanadi Graben, Eastern Ghat Mobile Belt (EGMB) and Central Indian Tectonic Zone (CITZ), bounding it from all sides. This study utilizes high resolution airborne magnetic data to comprehend the subsurface geology, structural trends and overprinting relationships through magnetic data interpretation.

The processing of high-resolution aeromagnetic data has enabled delineation of a number of parallel, E-W trending Trans Central Indian Craton Airborne Magnetic Lineaments (TCIMLs) extending for a strike length of 250-300 km, traversing through varied litho-structural domains encompassing Archean Tonalite-Trondhjemite-Granodiorite (TTG) suite of Amgaon and Bengpal Gneisses, supracrustal rocks sequences of Bailadila Group of Neo-Archean to Paleoproterozoic age, Paleo-Mesoproterozoic Dongargarh Supergroup, Bimodal volcanics of Nandgaon Group, 2.5 Ga Malanjkhand and Dongargarh granitoids, Kotri-Dongargarh Belt, Sakoli Group and Meso-Proterozoic Chhattisgarh basin. Filtering techniques viz. horizontal derivative of magnetic field (THDR) and Tilt derivative (TDR) have revealed edges and systematic E-W orientation of these TCIMLs. First vertical derivative (FVD) map revealed a large number of NW-SE, NE-SW and N-S trending, subtle magnetic anomalies cross cut by the TCIMLs which are relatable with small scale dykes, brittle ductile shear zones, faults, etc. A substantial depth persistency up to 3000 - 4000 m is recorded for most of these mega linears in matched filtered radially averaged power spectrum maps. Source Parameter Imaging (SPI) and Euler deconvolution method using dyke parameters reveal a maximum depth in a range of 500 m with gradual increase in depth of solutions from west to east, indicating a general eastward dip. The inverse modelling using profile data at few locations across these TCIMLs have depicted the slope, height, width, strike, dip, plunge and magnetic susceptibility of these lineaments.

Field evaluation of TCIMLs in and around Kotri-Dongargarh belt, where the anomalies are most prominent, reveals negligible surface manifestation of the TCIMLs substantiating their deep seated nature. To create such a huge magnetic susceptibility contrast, the TCIMLs must accommodate a huge volume of Fe and Mg rich materials. It is further reasoned by the presence of positive gravity anomalies caused by high density material in most parts of the CIPC except for the south eastern part, revealed during regional gravity data studies in the past. Creation of such large scale fracture system require a major tectonic impetus which is present in the form of suturing of two continental blocks along Central Indian Tectonic Zone (CITZ) during the

Precambrian. A close spatial proximity as well as a comparable trend of these TCIMLs with CITZ suggest a possible association between them. The fracture system, so created might have been impregnated with mafic magma during later phases of basaltic magmatism as mega dykes.

ML-based volumetric conversion of 2D seismic sections for comprehensive seismic interpretation

Min Je LEE[1], Seoul National University
Jun-Woo Lee[2]*, Seoul National University (crusaider0614@snu.ac.kr)
Yongchae Cho[3], Seoul National University

Abstract

A conventional two-dimensional (2D) seismic survey is often more economical than a three-dimensional (3D) seismic survey and therefore employed in regional initial subsurface structure characterization. In contrast, a 3D seismic survey is employed in a specific region selected based on the potential reservoir characterization due to its costly nature (up to several million USD). These lead to 2D seismic sections distributed throughout the region while 3D seismic volume only occupies a minuscule, limited portion of the survey site compared to 2D seismic sections.

Rather than performing an additional 3D seismic survey, which can cost a substantial amount of resources, image-training- and machine-learning-based volumetric conversion of 2D data into 3D data volume can significantly reduce the monetary and computational cost. Furthermore, the obtained 3D data volume can be used to analyze the potential sites and to structurally interpret the subsurface geology. If an additional seismic survey were to be performed, such supplementary information can aid in decision-making processes.

The conventional volumetric conversion method has several limitations. The result of the converted volume heavily depends on the prior interpretation, which may vary based on the interpreter. This may pose a problem in analyzing large-scale seismic data. Each seismic vintage has a different seismic source waveform and a migration velocity model. These lead to misties which refer to misfits between 2D seismic data. By utilizing image-training- and machine-learning-based volumetric conversion, a seismic data volume that is 1) independent of prior interpretation, 2) robust to the misties, and 3) computationally effective can be obtained.

By training the correlation between the volume and line data in the same location, the region without seismic volume data can be estimated. This additional information can help interpreters in the decision-making process in hydrocarbon reservoir exploration. In this study, an extrapolation technique estimating the external region of the seismic volume by incorporating line and volume data is proposed. Here, methods used in image outpainting are utilized since an extrapolation of seismic volume is similar to image outpainting since the objective of both methods is to generate an image outside of the original image.

The applicability of the proposed method is tested in two cases: 1) a regular grid where data points of line data are in perfect alignment with data points of volume data, and 2) an irregular grid with random 2D section position. In both cases, the extrapolation performance was plausible near the original volume data. However, after repetitive estimation and expansion of the extrapolation area, a performance degradation was observed. Nonetheless, the final extrapolated result on the entire region provided sufficient information for improved subsurface structure interpretation. The

extrapolation technique in an irregular grid showed degraded performance compared to that of the regular grid.

Hyper-extended basins controlled by low-angle normal faults in Marginal Seas: 3D structure and tectono-sedimentary evolution

Geoffroy MOHN[1]*, CY Cergy Paris Université (geoffroy.mohn@u-cergy.fr)
Jean-Claude Ringenbach[2], Totalenergies, CSTJF
Etienne Legeay[3], CY Cergy Paris Université
Nick Kusznir[4], University of Liverpool
William Vetel[5], Totalenergies
François Sapin[6], Totalenergies, CSTJF
Julie Tugend[7], Commission for the Geological Map of the World

Abstract

This contribution explores the formation and evolution of hyper-extended basins controlled by low-angle normal faults active at <30°. Based on high-resolution industrial 2D and 3D seismic reflection surveys along the southern margin of the South China Sea (Dangerous Ground), we mapped and analyzed the 3D geometry of low-angle normal fault systems and the related stratigraphy. A series of hyper-extended basins were documented, filled locally by up to 6 km of sediments including pre- to post-rift sequences. The observed normal faults on depth migrated seismic sections show an average dip angle of 30° and appear planar, characterized by continuous reflections with no clear steepening at depth and sole-out on distinct decollement levels. Detailed fault surface mapping reveals the occurrence of corrugation together with large wavelength undulation. The geometry of intra-basement reflectors is compatible with occurrence of Mesozoic nappe stacks in agreement with the inferred geodynamic setting during this period. Reactivation of former thrust faults is interpreted as enhancing the formation and development of low-angle normal faults as reported in others SE Asia rift basins.

The stratigraphic infill of the hyper-extended rift basins is characterized by several syn-rift sequences controlled by development of the low-angle normal faults. The first syn-rift sequence appears as chaotic and discontinuous packages that has been dismembered and fragmented during the activity of low-angle normal faults. The second syn-rift package shows unexpected sedimentary wedges developing successively towards the footwall and the hangingwall. This geometry results from the interplay between the main low-angle normal fault and antithetic faults defining a so-called extensional fishtail. Our structural interpretations are tested using kinematic forward lithosphere deformation model allowing the production of flexural isostatically compensated as well as balanced cross-sections. Such models enable us to validate our structural interpretations but also test several kinematic scenarios.

Our study brings new observations and constraints on the development of hyper-extended basins controlled by faults initiated and active at low-angle that are common in SE Asia marginal Seas.

Cenozoic tectonic history of SE Korea during the evolution of the East Sea (Japan Sea)

Min-Cheol KIM[1]*, Pusan National University (igumany@pusan.ac.kr)
Moon Son[2], Pusan National University
Cheol Woo Song[3], Busan Metropolitan City
Youngbeom Cheon[4], Korea Institute of Geoscience and Mineral Resources
Hong Gyun Kim[5], National Forestry Cooperative Federation
Hee-Cheol Kang[6], Pusan National University

Abstract

The geology of SE Korea offers an exceptional opportunity to study the Western Pacific Cenozoic tectonic events, preserving diverse evidence for interpreting the evolution of the East Sea (Japan Sea). The sea is a semi-enclosed marginal back-arc basin separated from the Pacific Ocean by the Japanese Islands. The southeastern margin of the Korean Peninsula was subject to dextral shear stress due to the NNW-SSE opening of the sea during the late Oligocene to Middle Miocene. A number of Miocene sedimentary basins were formed by pull-apart openings with a series of NNW-trending dextral strike-slip (PDZs: Principal Displacement Zones) and NE-trending normal faults. Although these basins occur close to one another, they are mostly bordered by faults and show different lithologies, ages, and sedimentary processes of basin fills. The basin fills consist of the Early Miocene dacitic and basaltic volcanogenic rocks and the intercalated terrestrial sediments (ca. 23-18 Ma) and the Middle Miocene (non-volcanic) terrestrial to marine sediments (ca. 17-10 Ma). The Early Miocene volcanic rocks are primarily sub-alkaline, whereas a series of Middle Miocene basalt (ca. 15-13 Ma) is sodic alkaline phono-tephrites. Since at least 23 Ma, parallelogram-shaped Early Miocene onshore basins formed between the NNW-trending PDZs, accompanied by southwestward propagation rifting, northwestward block tilting, and clockwise horizontal block rotation. At about 17 Ma, wedge-shaped Middle Miocene basins were produced by the NNW-trending strike-slip activation of the Yeonil Tectonic Line (YTL) and NNE-trending normal reactivation of the northern extension of the Yangsan Fault zone. These vigorous basin extensions in SE Korea continued until the collision of the Philippine Sea Plate and SW Japan at around 15 Ma. This tectonic inversion from a tensional to a compressive stress regime in East Asia resulted in the cessation of the East Sea opening and the subsequent gradual uplift of the crust in SE Korea, with a compositional change of magmas from sub-alkaline to alkaline. The basin fill sedimentation finally ceased at about 10 Ma. Meanwhile, the region has been undergoing continuous E-W to ENE-WSW compression since around 5-3.5 Ma, due to the eastward movement of the Amurian Plate (ca. 1-1.5 cm/y) and the westward low-angle subduction of the Pacific Plate.

Morphodynamic interaction between canyons and fans in a Basin and Range setting: the roles of tectonics, bedrock incision and alluviation

Gary PARKER[1]*, University of Illinois Urbana-Champaign USA (parkerg@illinois.edu)
Li Zhang[2], North China Electric Power University, China
Jeffrey Nittrouer[3], Texas Tech University, USA

Abstract

Basin and Range provinces consist of subparallel mountain ranges and valleys undergoing alternate relative uplift and subsidence. Canyons are incised into the uplifting mountains. The canyons deliver sediment to adjacent subsiding fans (bajadas) that occupy the valleys, where it deposits. We use the example of Rainbow Canyon and the adjacent Panamint Valley, Death Valley National Park, USA as a motivator for a study of general canyon-fan interaction. We use a morphodynamic model for this purpose. Tectonics is imposed externally. Incisional processes are modeled with the MRSAA saltation-abrasion-alluviation formulation, according to which moving sediment can act as tools to erode bedrock under conditions of partial alluvial cover. Depositional processes are modelled using a standard Exner formulation for sediment conservation and a sediment transport relation. The model illustrates the following. Canyon uplift can enhance the upstream migration of a bedrock-alluvial transition, rather than push it out toward the subsiding receiving basin. If the rate of accommodation space creation by subsidence in the receiving basin is large enough, a scarp (waterfall) is exposed at the canyon-fan transition. If the basin is open at a set outflow elevation, the long profile of the fan stabilizes in just such a way that the bedrock of the canyon is shaved off so as to balance uplift there. We also illustrate incipient conditions for inselberg formation.

Tectonic evolution and depositional environments of the southernmost continental shelf basins of Korea, the northern East China Sea

Seok Hoon YOON[1]*, Jeju National University (shyoon@jejunu.ac.kr)
Gi Bom KIM[2], Pusan National University
Jae Hyuk LEE[3], Pusan National University
Chang Seong KOH[4], Jeju Research Institute

Abstract

This study focuses on the seismic stratigraphy, tectonic evolution, and depositional environments of Jeju and Socotra basins in the southern continental shelf of Korea, based on the analyses of seismic stratigraphy, geologic structures, and seismic facies on the multi-channel seismic profiles. The basins commonly occur as the local basement lows surrounded by large-scale basement highs. The basin-filling sedimentary sequences are divided into 4 megasequences (MS1 to MS4) by regional unconformities and their correlated conformities. Chronostratigraphy of the megasequences from Eocene to Plio-Pleistocene is established based on biostratigraphic data from the existing hydrocarbon exploration wells. Geologic structures in the Socotra Basin are characterized by rift-stage normal faults involved with basement rotation, and subsequent folds and local normal faults in Oligocene sequence interval, The Jeju Basin, by contrast, shows predominant occurrence of reverse faults and folds within Eocene to Miocene sequences.

Based on the acoustic characters and reflection geometries, 6 types of seismic facies are classified, and interpreted as geologic basements (B1), volcanic-sedimentary complexes (B2), inner-shelf deposits (S1), fluvio-lacustrine deposits (S2), coastal deposits (S3), and volcanic sills or volcanic edifices (S4), respectively. Interpretation of these sedimentary facies and the correlation with biozones in drilling wells are suggestive of diverse depositional environments including terrestrial lowland (Eocene), lower coastal and oceanic environments (Oligocene), open lowland and middle coastal environments (Miocene), and shoreface and marine settings (Plio-Pleistocene). By integrating all these results, we present the reconstructions of tectonic evolution in the basins as follows. Initial rifting began in the Late Cretaceous building a series of grabens and half-grabens in the Socotra Basin, whereas basement subsidence without significant structural deformation occurred in Jeju Basin at the same time. Regional uplift and folding (e.g. Yuquan movement) in Late Eocene to Early Oligocene terminated the initial rifting in Socotra Basin and subsidence in Jeju Basin regions. In the Early Oligocene, the rifting and subsidence started again in the Socotra Basin and Jeju Basin respectively, which interrupted by uplift and folding in Early Miocene, marking the transition to the post-rift phase. Regional subsidence continued in Early to Late Miocene period. In the Late Miocene, a tectonic inversion (e.g. Longjing movement) occurred interrupting the subsidence in Jeju Basin region. At the end of the Late Miocene, the entire area entered a stage of regional subsidence again.

A novel coupled model for rift basin evolution: Integrating tectonics, sea-level cycles, and multiple sediment sources

Wonsuck KIM[1]*, Yonsei University (delta@yonsei.ac.kr)
Jaehyung Lee[2], Yonsei University
Bitna Park[3], Yonsei University
Yujin Kim[4], Yonsei University

Abstract

Sequence stratigraphy has been used to identify and interpret patterns in stratal records and understand how sea levels and environmental conditions have changed over time, providing valuable insights for paleo-environmental changes and resource exploration. For rift basins, the focus typically revolves around understanding tectonic controls such as faulting, crustal extension, and subsidence on sedimentary facies, but the sea-level controls are often ignored, or the ExxonMobil's traditional stratigraphic model was simply applied in the rift-basin stratal interpretation. In rift basins, however, the coupling of axial and transverse systems plays significant roles in controlling sedimentation patterns, basin architecture, and evolution, which was not thoroughly considered in the traditional stratigraphic model. Understanding the spatial distribution and activity of these systems along with tectonic and sea-level controls is crucial for interpreting the depositional history of rift basins, and thus identifying potential hydrocarbon reservoirs. Here, we present a basin model that integrates both axial and transverse systems under rift basin tectonics and sea-level cycles to provide a new stratigraphic model for rift basins. Modeling results under sediment sources from multiple directions, and different tectonic and sea-level conditions indicate timing and distribution of key horizons, such as sequence boundaries and maximum flooding surfaces are distinguished from the traditional model and provide valuable insights into the complex interactions between tectonics and sedimentation in rift basin settings.

Depositional Age and Provenance of the Jeju Basin Sediments Inferred by Detrital Zircon U-Pb Geochronology

Taejin CHOI[1]*, Korea National University of Education (tchoi@knue.ac.kr)

Abstract

This study investigates the depositional ages and provenance of sediments in the Jeju Basin on the northeastern margin of the East China Sea Basin by detrital zircon U-Pb dating. The East China Sea Basin was formed as a back-arc basin in the Cretaceous due to the tectonics between the Eurasian and paleo-Pacific plates. The Jeju Basin was formed by rifting in the Oligocene and received sediments in changing depositional environments from terrestrial to shallow marine. Detrital zircons were separated from 10 cutting samples obtained from three boreholes in the Jeju Basin, and U-Pb isotopic compositions of 1100 zircon grains were analyzed.

The analytical results show that the detrital zircons in the Jeju Basin have a wide age range from 3561 Ma to 7 Ma, covering the Archean to Cenozoic. Most samples are dominated by Neogene, Paleogene, Mesozoic, Paleozoic, Neoproterozoic, and Paleoproterozoic zircons. Paleoproterozoic zircons are the most abundant, accounting for at least 15% of all samples. However, the proportions of zircon age groups show spatial variance and temporal changes. The maximum depositional ages of the Jeju Basin sediments estimated from the youngest zircon age groups range from 28 to 8 Ma, depending on the depth. This is mostly consistent with the previous report based on fossils. However, the uppermost sample of the Okdom-1 core shows a younger maximum depositional age than the fossil age. These results provide essential data for the stratigraphy and depositional environment of the Jeju Basin sediments.

Subduction Initiation under the Neotectonic Regime of the Western East Sea (Sea of Japan) Margin

Jae-Hyuk LEE[1]*, BK21 School of Earth and Environmental Systems, Pusan National University, Busan 46241, Republic of Korea (dooi3232@gmail.com)
Seok-Hoon YOON[2], Department of Earth and Marine Sciences, Jeju National University, Jeju 63243, Republic of Korea
Yoon-Mi KIM[3], Marine Geology & Energy Research Division, Korea Institute of Geoscience and Mineral Resources, Daejeon 34132, Republic of Korea
Byung-Dal SO[4], Department of Geophysics, Kangwon National University, Chuncheon 24341, Republic of Korea
Gi-Bom KIM[5], Department of Geological Sciences, Pusan National University, Busan 46241, Republic of Korea

Abstract

The East Sea (Sea of Japan) is one of the marginal seas on the western Pacific region, surrounded by eastern Eurasia and Japanese islands. The sea has been under regional E–W compressional stress regime since the Early Pliocene (c. 4 Ma). Under this neotectonic stress regime, compressional deformation is concentrated on the western (Korean side) and eastern (Japanese side) margins of the East Sea, and induced subduction initiation along the both margins. Here, we introduce a case of earliest stage of subduction initiation on the western East Sea margin in detail, and estimate the possibility to evlove into self-sustained stage of this case. Stratigraphic and structural analyzes using multi-channel seismic reflection data obtained from the eastern Korean margin and the Ulleung Basin regions revealed three key juxtaposed neotectonic components: 1) the Ulleung Major Thrust, 2) the Ulleung Syncline, and 3) the East Korean Thrust Belt. The Ulleung Major Thrust, marked by the NS-elongated west-dipping reverse tri-shear zone along the back-arc–continent transitional zone, is considered as an embryonic subduction interface that guides subductive movement of the Ulleung back-arc crust and obductive movement of Korean continental crust. As the Ulleug Major Thrust nucleated, the westernmost downbuckle in the Ulleung Basin became asymmetric and formed the Ulleung Syncline, regarded as a proto-trench. Thrusting down of the Ulleung back-arc crust gave rise to regional uplift of the overriding eastern Koran margin, which were accommodated by an array of east-dipping thrust faults, named the East Korean Thrust Belt. The east-dipping thrusts of the East Korean Thrust Belt elevated thrust sheets, by which numerous post-Miocene neotectonic piggyback basins were formed.

Although there is no evidence indicating that the lithosphere of the western East Sea margin is failed, the apparent asymmetry of the Ulleung Syncline and the tri-shear deformation in the Ullueng Major Thrust imply that the compressional deformation on this margin started to be localized into the back-arc–continent transitional zone. This means that the western East Sea margin is under the earliest stage of subduction initiation after already passed through simple crustal buckling stage.

The subduction initiation on the western East Sea margin appears destined to fail, because a more

mature case of subduction initiation exists on its opposing side (Japanese side of the sea). However, lines of evidence, such as uplifting marine terraces and compressional earthquakes by Quaternary faulting, imply that the subduction initiation on this margin has the fate to be failed soon but has not yet failed.

Characterization of Igneous Bodies around the Jeju Basin, the East China Sea: Igneous Stratigraphy and Tecto-Magmatic Implications

Yun-Hui JE[1]*, Division of Earth Environmental System, Pusan National University (yhje1@pusan.ac.kr)
Gi-Bom KIM[2], Department of Geological Sciences, Pusan National University, Busan 46241, Repulic of Korea

Abstract

The East China Sea Shelf Basin (ECSSB), which has a high hydrocarbon potential, has evolved with repetitive volcanic activities since the Late Cretaceous in association with multi-phase tectonic evolution. In this study, we investigated variable types of igneous bodies found in the northern ECSSB using multi-channel seismic reflection data and drill cores. The igneous bodies were primarily classified into extrusive and intrusive types and sub-categorized into nine facies groups (i.e., E.cone, E.sheet/E.flood, E.comp, E.rift for extrusives and I.con, I.sau, I.step, I.stock, I.lac for intrusives) depending on their emplacement styles. The nine facies groups of igneous bodies were mapped using PETREL™ (Schlumberger, Ltd., France) software to visualize their spatio-temporal distribution and fundamentally understand their relationship with the evolution of the ECSSB. Based on the biostratigraphic correlation and isotope ages of volcanic rocks, we categorized the igneous bodies into four stratigraphic groups (IG).

Igneous bodies of IG-1 (Igneous Group 1), recognized as discontinuous/high-amplitude reflectors, are distributed near the acoustic basement of subbasins throughout the ECSSB region. The IG-1 is interpreted as basaltic lava/sill-sediment complexes formed by fissure eruption alongside with the boundary faults at the time of early stage of the ECSSB opening. IG-2 comprises sheeted (or flooded) lava flows and complex of sills and dikes emplaced during the early Miocene, when the tectonic inversion, so-called Huagang Movement, caused local compressional uplift. IG-3 consists of a variety of monogenetic volcanic edifices, showing linear NNE–SSW distribution, parallel with the Taiwan-Sinzi Tectonic Belt. Stratigraphic correlation with the existing chronostratigraphic framework may imply that the IG-3 is related to the paleo-Ryukyu Arc volcanisms, terminated in association with the formation of Okinawa Trough around 5 Ma. IG-4 comprises complex of sills, dikes and extrusives, distributed locally on the south of Jejudo volcanic island. Apparent seafloor deformation, caused by the igneous bodies of IG-4, indicates that IG-4 volcanism is still active. This further implies that the IG-4 volcanism has an identical tecto-magmatic origin to Jejudo.

The Distinctive History of the Attu region of the Western Aleutian Arc in the Western Pacific Region

Suzanne Mahlburg KAY[1]*, Cornell University (smk16@cornell.edu)
Suzanne Mahlburg Kay[2], Cornell University

Abstract

A distinctive part of the Aleutian arc is the Attu region in the western Pacific section of the arc, where the oldest known ages (~42.5 Ma) are from Eocene to early Oligocene volcanic and plutonic rocks with Marianas arc-style trace element features (La/Sm=1.6-1.9; La/Ta=100-120) and depleted MORB-like pillow lavas, breccias and dikes (La/Sm < 1.8; La/Ta=10-40) in the backarc. These sequences are followed by early Miocene mafic flows with depleted light REEs, ~16 Ma rhyolites and granites and light REE enriched mafic rocks and ~7-5 Ma calc-alkaline andesites. Epsilon Nd 9.5 to +10 in the arc-like rocks as high as +10.6-11.7 show the backarc lavas are isotopically depleted relative to Aleutian magmatic rocks to the east where maximum values rarely reach ~+9.5. The arc further east also differs in lacking backarc lavas and in exclusively having light REE enriched arc-like magmatic rocks that include late Eocene to Recent calc-alkaline units. Xenoliths in Kanaga Island arc basalts show that at least part of the central Aleutians is underlain by a metamorphic plutonic basement that could be as old as Eocene. Overall, the distinctive western Attu region is best explained as evolving in a distinctive depleted part of the Aleutian arc with a distinct history from the central and eastern Aleutians in contrast to some structural and tectonic models that suggest the Attu region has been translated up to 1000 km to the west. The older evolution of the Attu region is generally consistent with the plate evolution scheme in Vraes et al. (2019) in which Eocene to Oligocene Attu magmas formed as a westward moving Kronotsky arc reached the Aleutian trench at ~ 40 Ma and broke apart to block the Aleutian trench and create the Bowers Ridge arc.

[Keynote] Trench kinematics and the opening of backarc basin

claudio faccenna[1]*, GFZ Potsdam UniRoma TRE (claudio.faccenna@uniroma3.it)
Adam Holt[2], University Florida
Thorsten Becker[3], UT Texas
Serge lallemand[4], University Montpellier

Abstract

Trench motions represent the surface expression of the interaction between subducting plates and the underlying mantle, but the inherent dynamics are not fully understood. Here, we will revise first the main process leading to trench migration, revising the trench migration in the western Pacific. We will then focus on the case of the migration of the Izu- Bonin-Marianas trench (IBM) that accommodates the subduction of the Pacific beneath the Philippine Sea Plate (PSP), which is in turn subducting beneath the Eurasian plate along the Ryukyu trench. The history of the IBM trench is dominated by fast, episodic retreat from 40 to 15 Ma. However, around 10–5 Ma, the IBM trench reversed its motion from retreat to advance. Here we run 2-D numerical experiments to test the influence of the Ryukyu slab on the established IBM subduction zone. The results from our geodynamic model compare favourably with the reconstructed trend, indicating that the switch in trench motion along the IBM trench may indeed be related to the onset of a new subduction zone along the Ryukyu trench. Our analysis substantiates the idea that advancing trench motions in the western Pacific are due to the establishment of a double subduction system. Further analysis of such dynamics provides insights for the mechanisms controlling subducting plate and trench motions and mantle force transmission.

Subduction Initiation process of a young marginal sea: a case study of the North Sulawesi subduction Zone

Tianyao HAO[1]*, Institute of Geology and Geophysics, CAS (tyhao@mail.iggcas.ac.cn)
Jian ZHANG[2], University of Chinese Academy of Sciences
Miao DONG[3], Institute of Geology and Geophysics, CAS

Abstract

marginal sea: a case study of the North Sulawesi subduction Zone

The transition of a passive continental margin into a subduction zone remains a hypothesis because few geological cases have been reported. The North Sulawesi subduction zone (NSS) is a 5-9 myr system in Southeast Asia that has evolved from a passive continental margin and has long been overlooked by studies of passive to active margin transitions. Interestingly, no Quaternary arc volcanoes have been found to be associated with the NSS.

We conducted a comprehensive survey, collecting original geophysical data from the southern South China Sea to the North Sulawesi subduction zone. Utilizing various modeling techniques and joint inversion, we obtained insights into the deep structures of subduction zones in North Borneo and the Celebes Sea. Additionally, the subduction process in the study area was reconstructed through dynamic numerical simulations.

Our investigation reveals two main insights:

1The NSS is characterized by "induced" subduction initiation and "spontaneous" trench retreat. At the initial stage of subduction, the young Celebes sea plate must be driven down by external forces in the horizontal direction. As the oceanic crust descends to approximately 60 km, it undergoes gradual eclogization, with the principal stress governing subduction transitioning to the negative buoyancy of the subducting plate. Subsequently, the self-sustained subduction of the plate, trench retreat, and continental crust extension are primarily controlled by the negative buoyancy of the subducting plate itself.

2The absence of arc magma in the NSS could be explained by the little water influx and the shallow water dehydration of the subducting slab. Our findings also suggest that, when the angle between a young slab and the overriding plate is small, a long arc magma history will not be observed during the early subduction stage. We speculate that the "hot" and "light" nature of the overriding plate contributes to this small initial subduction angle.

Abstract

Marginal seas are widespread along the western Pacific region, with various evolutionary stages and associated geological characteristics. Geothermal field could provide important clues for understanding regional tectonics, thus revisiting the geothermal regime of the marginal seas in western Pacific region is in demand, and is also available with the increasing heat flow data. Combing the updated global heat flow dataset of International Heat Flow Commission (IHFC) and other geological and geophysical observations, heat flow and thermal structure of the western Pacific marginal seas are analyzed. Our results demonstrate that heat flow varies much among the marginal seas, and the average values for the Okhotsk Sea, Sea of Japan, Okinawa Trough and South China Sea are 80 mW/m2, 93 mW/m2, 210 mW/m2 and 75 mW/m2, respectively, indicating their different ages. In addition, high heat flow anomalies are also observed within the marginal seas, as a result of fluid circulation and recent volcanic activities. While the subduction zones exhibit similar geothermal patterns, with relatively low heat flow in the fore-arc regions, extremely high but variable heat flow in the volcanic arcs, and generally high heat flow in the back-arc regions. High temperature and large heat flow in the back-arc regions can be attributed to the heat contributions from the mantle. In general, the heat flow verse crustal age relation for the western Pacific marginal seas can be roughly expressed by Q(t)=585.8 t-1/2. It seems that this Q-t relation for marginal seas does not significantly differ from that for oceanic basins. Given the uneven coverage in heat flow data and vagueness in crustal age of some marginal seas, this expression needs confirmation with more observations in further study.

An Analysis of Karst Model and its Controlling Factors of Carbonate Buried Hill: A Case Study from the Weixinan Sag, Beibuwan Basin, South China Sea

Yanying LI[1]*, China University of Petroleum (East China) (b18010016@s.upc.edu.cn)
Kongyou WU[2], China University of Petroleum (East China)
Yannan DU[3], China University of Petroleum (East China)

Abstract

Paleokarst is a modification effect of water on soluble rocks, which is widely developed in soluble rocks such as carbonates. With the discovery of paleokarst-related oil and gas reservoirs in a series of large carbonate oil and gas fields, the relationship between paleokarst and carbonate oil and gas reservoirs has attracted extensive attention from petrologists. The previous research on paleokarst oil and gas reservoirs mainly focused on two aspects, paleogeomorphic restoration and vertical zoning. Carbonate buried hills are developed in the Weixinan Sag of the Beibuwan Basin in the western South China Sea, and multiple buried hills have been discovered as oilfields or oil-bearing formations. This study analyzed the characteristics and the main controlling factors of karst development in carbonate buried hills by combining drilling core, thin section, logging and seismic data. This study is of great significance to the exploration work of finding new types and strata of oil and gas reservoirs. The research has three outcomes. (1) The karst processes of carbonate buried hills have multi-phase cyclicity, and each cyclicity can be subdivided into surface karst zone, vertical seepage zone and horizontal underflow zone. (2) The exposed-phase karst was developed in the No. 1 fault zone, while the exposed-phase karst and buried-phase karst were developed in the No. 2 fault zone. (3) The karst in the carbonate buried hills is influenced and constrained by multiple factors such as sedimentation, diagenesis, tectonics, karst, and paleogeomorphology, etc, and the karst development model of the carbonate buried hills in the study area has been established.

The Formation and Evolution of the Central Uplift in the South Yellow Sea Basin and Its Geological Significance for Oil and Gas

zhangjin CHEN[1]*, CNOOC China Limited, Tianjin Branch (hellochenzhj@163.com)
qinxun WU[2], CNOOC China Limited, Tianjin Branch
yongqiang YAO[3], CNOOC China Limited, Tianjin Branch
zhiqiang LI[4], CNOOC China Limited, Tianjin Branch
shaowei CHEN[5], CNOOC China Limited, Tianjin Branch

Abstract

The South Yellow Sea basin, located in the northeast of Yangtze plate, it is a typical sea land superimposed basin with four primary tectonic units of two depressions and two uplifts. As one of the positive units, the central uplift is characterized by shallow burial and relatively complete preservation of marine strata, which has great exploration potential. According to statistics, the distribution of large and extra large gas fields in the marine craton basin is closely related to the paleo-uplift in the craton. The so-called "paleo uplift" refers to the uplift structure formed in the evolution stage of craton basin. So is the central uplift a paleo-uplift?

Based on the research approach of combining the macroscopic laws with the local characteristics of the Yangtze Plate, by combining the macroscopic laws of the development of paleo-uplift in the cratonic basin of the Yangtze Plate with the local structural characteristics of the South Yellow Sea Basin, it is proved that the central uplift of the South Yellow Sea basin is an inherited paleo-uplift. The formation and evolution of the central uplift can be divided into three stagesFormation period, Strengthening period and Renovation period. From Sinian to Middle Ordovician, the whole Yangtze basin had a tectonic pattern of two basins and one platform, the central uplift is located on the platform, and the seismic profile shows typical reflection characteristics of platform margin facies. During the late Ordovician to Middle Triassic, under the influence of Caledonian and Hercynian movements, the amplitude of the central uplift has been further strengthened, and the thickness of Silurian system was thin in the middle of the central uplift, thickened in the north and south sides, with upward displacement observed. Drilling reveals biogenic algal tuff limestone of the Carboniferous platform margin facies. Since the Late Triassic, the paleo uplift ended the marine deposition and underwent the compression and extension transformation stages, forming the present structural pattern of two depressions and two uplifts in the South Yellow Sea basin.

As an inherited paleo-uplift, the central uplift is the direction area for long-term migration of oil and gas. Firstly, large traps developed in the central uplift before the reservoir forming stage. Secondly, the unconformity formed during the formation of the central uplift is an important pathway for oil and gas migration. Thirdly, the reflection characteristics of platform margin reef beach facies can be seen in multiple sections of the central uplift, and three periods of unconformity can be identified, it can be seen that the reservoirs of the central uplift reef shoal facies and karst reservoirs are developed.

Abstract

The Mesozoic-Paleozoic structures in the central uplift of the South Yellow Sea Basin are very complex, and the overall quality of seismic data is poor. The understanding of the structural deformation laws of the central uplift since the Indosinian period is unclear, which restricts the exploration process. By means of geochemical analysis, structural analysis, and numerical simulation, the deformation laws of the central uplift structure have been clarified, and a differential deformation structural model of "obstruction of ancient uplifts and detachment of double detachment layers" has been innovatively established. (1) Differential deformation under the obstruction of ancient uplifts: Strong thrust phenomena such as limited extension of the front fault, pushing out of the surface, and huge repetition of strata are observed above the ancient uplifts; The back front of the ancient uplift is constrained and obstructed by compression deformation, and the structural deformation is relatively weak and stable;Double detachment layer detachment differential deformation: There are two sets of detachment layer systems, Cambrian gypsum rock and Silurian thick mudstone. The decoupling effect of upper and lower structural deformation of the detachment layer is obvious, showing a differential deformation characteristic of "strong compression deformation above the detachment layer and relatively stable below the detachment layer". Considering the different distances from the orogenic belt and the varying levels of stress, stratigraphic compression analysis was conducted to ultimately clarify that the three factors of "orogenic belt ancient uplift detachment layer" jointly control the differential deformation of the central uplift structure in the South Yellow Sea Basin.

Geochemistry and U-Pb chronology of Silurian clastic rocks from boreholes in the Yellow Sea, Western Pacific Marginal Seas: Geological data evidence that the Yellow Sea belongs to the Yangtze Block

LI ZHIQIANG[1]*, China National Offshore Oil Group (zhiqiangligeo@163.com)
ZHANG RUCAI[2], China National Offshore Oil Group
GAO XILONG[3], China National Offshore Oil Group
CHEN XINYI[4], China National Offshore Oil Group

Abstract

It seems that the Yellow Sea belongs to the Yangtze block only some seismic data support, there is no actual geological data to support the above conjecture. Silurian clastic rocks from ultra-deep boreholes in the Yellow Sea provide a possibility for understanding the tectonic evolution in this area. To understand the provenance and tectonic evolution of the Early Paleozoic foreland basin, the Silurian clastic rocks have been analyzed by means of major, trace and rare earth elements and zircon U-Pb chronology. The results show that the Silurian clastic rocks are mainly composed of mudstone and argillaceous siltstone, with high content of feldspar and quartz minerals in mudstone, linear contact of siltstone particles, chemical alteration index (CIA) range of 70.04-77.4, index of compositional variation (ICA) range of 0.72-1.03, indicating high compositional maturity in the source rocks. The trace and rare earth element indicator source area is mainly feldspar igneous rock with island arc tectonic background, suggesting source area may be an accretionary orogenic belt. The Th/U ratio of 526 zircons is greater than 0.1, indicating magmatic origin. These zircons exist in three age ranges: 2500-1800 Ma, 980-820 Ma and 580-430 Ma, with the peak of 980-820 Ma. The three age peaks coincide with the three major geological units of the Yangtze block, namely the craton basement, the Neoproterozoic Jiangnan Orogenic belt and the early Paleozoic Wuyi-Yunkai orogenic belt. Longitudinally, the zircons of synorogenic age (460-430 Ma) are only found at the top of Silurian stratum. These geochemical characteristics and chronological data are consistent with the geological data published earlier in the Lower Yangtze Block, indicating that a Neoproterozoic (980-820 Ma) accretionary orogenic belt like Jiangnan orogenic belt was the main provenance of the early Paleozoic foreland basin. Our data confirm the existence of an accretionary orogenic belt in the Yellow Sea formed by the Neoproterozoic (980-820 Ma) collision of the Cathaysian Block and the Yangtze Block, combined with the published geophysical data of the surrounding area, confirm that the Yellow Sea and the Lower Yangtze Block have similar tectonic evolution processes, indicating that the Yellow Sea should belong to the Yangtze Block. Our study provides a substantiality geological archive to reveal the attribution of the Yellow Sea.

Thick-skinned tectonics in southern Ulleung Basin (East Sea) through gravity data analyses

Yoon-Mi KIM[1]*, Korea Institute of Geoscience and Mineral Resources (ymkim1@kigam.re.kr)
Gi-Bum KIM[2], Busan National University

Abstract

The Ulleung Basin (UB), located in the southwestern corner of the East Sea, served as a key locus that accommodated the Miocene back-arc extension and subsequent tectonic inversion between Korean Peninsula and southwestern Japanese Island. A pull-apart-style opening of the UB began with the subduction of the old and thick Pacific Plate during the Early Miocene. Subsequently, during the Middle Miocene, as the young Philippine Sea Plate converged along the Ryukyu trench, a tectonic inversion from extension to contraction occurred. Since the Pliocene, compressional forces acting in the E-W direction have prevailed in the UB. Notably, the southern UB exhibits significant compressional geological features, including the Dolgorae Thrust-Fold Belt, the Tsushima and Goto islands, and the Gorae anticlines. This study examines the gravity anomalies of the southern UB, a distinctive geological site, to better understand crustal deformations induced by such inversional forces. Our analysis shows that the Bouguer gravity anomaly highs correlate well with the compressional structures in the San'in Folded Zone in the southern UB. After calculating the Moho depth from the Bouguer anomalies corrected for bathymetry and sediment thickness, the variations in the Moho depth closely mirrors those of sediment basement in the cross section across the fold-and-thrust belts of the southern UB. This suggests that in the southern UB, thick-skinned tectonics involves thrust faults reaching down into the crust. Also, we interpret the sedimentary structures to analyze shallow to deep structure deformation caused by tectonic inversion at multiple scales. The integrated analysis of sedimentary layers and crustal structure offers crucial implications for understanding how the UB has undergone tectonic deformation processes involving tectonic development.

Phanerozoic tectonic evolution and mineral system formation in East Asia

Xuanhua CHEN[1]*, Chinese Academy of Geological Sciences (xhchen@cags.ac.cn)
Shuwen Dong[2], Chinese Academy of Geological Sciences
Qi Zhou[3], Chinese Academy of Geological Sciences
Yan Ma[4], Chinese Academy of Geological Sciences

Abstract

Mineral system is always tectonics related, which could be called tectono-metallogenic system. In eastern Asia, the mineral systems are always related to the tectonic evolution and plate convergence in this area. They are important relics of tectono-metallogenic systems preserved in the continental Asia. Most of them have experienced the whole life Wilson cycle of plate tectonics. Especially, they could be identified as mineral systems which are related to plate subduction, collision orogeny, post orogenic extension, and stable cratons. Based on temporospatial analyses of deep structure, tectonic events and mineralization of the East Asia continent in Phanerozoic, plate convergent-related mineral systems are preliminarily constructed in East Asia. Due to continuous interactions of the three tectono-metallogenic regimes such as the Paleo Asian Ocean (Central Asia), Tethys-Himalaya and West Pacific tectono-metallogenic regimes, a unique tectonic system, which is named as the East Asia plate convergence tectonic system, and several tectonic-related mineral systems, such as the collisional orogenic Qinghai-Tibet Plateau, accretionary orogenic western north China, and composite orogenic northeastern China mineral systems, have formed in the continental China in Phanerozoic. Meanwhile, craton-related tectono-metallogenic systems, such as the North China craton destructional and South China intracontinental mineral systems, have formed in eastern China. Several mantle plume mineral systems, such as the Emei, Tarim, and Songliao-Bohai Bay ones, have formed due to the superposition of multiple mantle plumes on plate convergence-related mineral systems. Temporospatial transition of tectonic dynamic systems may result in significant mineralization, and the craton margins is always the most favorable locations for mineralization. Porphyry copper and orogenic gold deposits may form in multiple stages of the plate tectonics, especially in the post-orogenic extensional stages.

Adaptive mesh-free approach for gravity inversion

Yan LIU[1]*, 010-68999481 (liuy@cags.ac.cn)
Qingtian Lü[2], 010-88333292
Yao Huang[3], 14708294710
Jiayong Yan[4], 13552350590

Abstract

We proposes a method of gravity inversion based on an adaptive mesh-free approach by using a modified radial basis function (RBF). Traditional mesh-based methods discretized partial differential equations (PDEs) based on tessellated meshes. The subsurface space is generally discretized into regular grid cells, where mesh-free methods can avoid the expensive mesh generation and manipulation required in those traditional approaches. In most mesh-free methods a cloud of unconnected nodal points that do not coincide at any time is introduced. Our adaptive mesh-free method is an unstructured method of inversion that mitigates ill-conditioned inversion by reducing the number of model parameters. The nodes are adaptively refined during the inversion process to better recover the abnormal bodies. To deal with the unstructured nodal discretization of problems, we uses a mesh-free discretization strategy to establish a mapping of subsurface grid cells to a cloud of discrete points. The radial basis functions is modified by the distance reweighting method so that they are similar to the orebodies in terms of shape, inclination, and dip. In addition, to solve RBF's ill-conditioned system of equations in case of the interpolation of large datasets, we propose a hybrid kernel based on multi-quadric and cubic kernels. The results of tests on 2-D and 3-D synthetic models showed this mesh-free inversion can be used to accurately reconstruct anomalous bodies and its results of inversion are stable. The proposed method was applied in the Nihe iron ore deposit (eastern China), and its results agreed well with the geological information.

Heterogeneous lithospheric mantle: A geophysical perspective

Irina M. ARTEMIEVA[1]*, SinoProbe Lab, China; GEOMAR, Germany (iartemieva@gmail.com)

Abstract

The lithosphere makes both a thermal boundary layer atop mantle convection and a chemical boundary layer formed by mantle differentiation. The thicknesses of thermal and chemical boundary layers vary significantly both globally and regionally, reflecting thermal and compositional heterogeneity of the lithospheric mantle both in continents and oceans. Thermal anomalies are usually thought to have stronger effect than compositional anomalies on rock seismic, electric, and density properties, especially at near-solidus temperatures; however physical parameters determined by geophysical sensing are sensitive to both thermal and compositional heterogeneity. Thus, geophysical constraints on mantle compositional heterogeneity require subtracting the lithosphere thermal signal.

Here I present examples for lithosphere thermal and compositional heterogeneity in continental and oceanic regions, with highlights from North Atlantics, the Arctic shelf, Iceland, Europe, Arabia, Asia and southern Africa. Joint interpretation of various geophysical data indicates a number of conventionally unexpected features, such as possible formation of ocean spreading below the Arabian Shield, an extremely high-density (possibly eclogite-bearing) lithospheric mantle below deep sedimentary basins in Europe and Siberia, strong correlation between diamondiferous regions in the southern Africa and high-density mantle anomalies, and strong thermos-chemical heterogeneity of the lithosphere of Tibet and the North China craton, inconsistent with models of lithosphere destruction in the NCC.

Cratons are not all that stable!

Hans THYBO[1]*, SinoProbe Laboratory, CAGS (h.thybo@gmail.com)

Abstract

Exciting geoscientific transects have contributed significantly to our understanding of geodynamic processes in active tectonic regions. Cratons have received much less attention because their tectonic significance is not evident from surface observation, being old and stable parts of the interior of the continents. However, abundant evidence shows that 'stable' cratons are modified substantially during their existence. I will present several examples where integrated geoscientific interpretation around seismological models shows significant modification of cratonic lithosphere:

1. The Baltic Shield formed during the Svecofennian orogeny c. 1.7 Ga with later reworking of its western parts. Recent geophysical interpretations show a large eclogitic body of crustal material beneath the Moho in the central shield. This body probably formed after the initial cratonization (Buntin et al., 2021).
2. The isopycnicity hypothesis proposes that a trade-off between composition and temperature of the lithospheric mantle maintains constant topography in cratons (Jordan, 1978). However, gravity data from Siberia shows that kimberlite pipes solely modify cratons in isostatic equilibrium (Artemieva et al., 2019). Therefore, kimberlite sampling is non-representative, and the real composition of most cratonic mantle lithosphere is unknown.
3. Strong seismic anisotropy is observed in many cratons and is commonly attributed to the mantle due to frozen-in lithospheric features or asthenospheric flow. Recently it was demonstrated that a major part of the anisotropy resides in the crust of the Kalahara craton and that the fast axes are parallel to the strike of young major dyke swarms and orogenic fabric (Thybo et al., 2019). This finding indicates significant craton modification by magmatic intrusion.
4. Modification by external stresses and induced magmatism may even split existing cratons. Integrated interpretation of existing data and geodynamic modelling show that a linear sequence of volcanic harrats in the Arabian craton potentially represents the formation of a new plate boundary (Artemieva et al., 2022). It is probable that the extension in the northern Red Sea rift will jump to the volcanic lineament, which eventually will develop into new ocean spreading and effectively split the existing craton.

Multi-scale velocity structures of crustal-mantle beneath South China and its constraint on deep mineralization mechanism

Guoming JIANG[1]*, China University of Geosciences, Beijing (jiang_guoming@cugb.edu.cn)
Guibin Zhang[2], China University of Geosciences, Beijing

Abstract

South China is one of the most rich regions of polymetallic mineral resources in China, and has become a rare world-class metal province in the world, especially in the Middle and Lower Yangtze River metallogenic belt dominated by Fe and Cu, and the Nanling metallogenic belt dominated by W, Sn, Mo, Bi, Pb, Zi, Rare earth and U. The geological background and mineralization of the Mesozoic granitic system, the large-scale Mesozoic low temperature metallogenic system and the late Paleozoic continental mantle plume metallogenic system in the South China have been studied by previous researchers, and a relatively common theoretical framework and metallogenic model of regional mineralization has been established. However, the deep mechanism and geodynamics of the large-scale Mesozoic mineralization in South China is still not clear.

In this study, the seismic tomography method and the teleseismic full waveform inversion method were used to study the crust-mantle velocity structure at large, medium and small scales in South China. The spatial resolutions were divided into 1°, 0.5° and 0.3°, respectively. The three scales of crust-mantle velocity structures reveal the characteristics of the overall tectonic background and material migration channels under the metallogenic belt in South China. The large-scale velocity structure results show that there are obvious low-velocity anomalies in the upper mantle beneath the Cathaysia block, while the lower middle and upper Yangtze block is dominated by high-velocity anomalies, which may represent mantle-derived hot materials and lithospheric roots respectively. There is a low-velocity anomaly in the crust beneath the Jiangshao fault between the Cathaysia and Yangtze blocks. There are obvious low-velocity anomalies in the upper mantle below the metallogenic belt in the middle and lower Yangtze River. The middle and small-scale velocity structures show that there is an obvious high-velocity anomaly at a shallow depth of 70 km in the land of the Cathaysia block, while there is a thicker high-velocity body below the coastal area. There are obvious low-velocity anomalies in the upper mantle. These low-velocity anomalies match well with the surface metallogenic belt and might represent the upwelling channels of mantle hot material. The velocity characteristics obtained in this project are related not only to the subduction of the paleo-Pacific plate in the Mesozoic , but also to the westward subduction of the Cenozoic Philippine Sea plate, and even to the Hainan mantle plume. In addition, hot material from deep upper mantle underplates into the lithosphere, which may cause the thinning of the eastern lithosphere and provide material and heat sources for deep mineralization.

New insights into asthenospheric flow beneath the Qinling Orogenic Belt and adjacent areas revealed by a three-dimensional Magnetotelluric study

Gaofeng YE[1]*, China University of Geosciences, Beijing (ygf@cugb.edu.cn)
Cheng Liu[2], China University of Geosciences, Beijing
Sheng Jin[3], China University of Geosciences, Beijing
Ji'en Dong[4], China University of Geosciences, Beijing

Abstract

The Qinling Orogenic Belt, formed by the convergence of the North China Craton and the Yangtze Craton, is located in the middle part of mainland China. It is a critical window to clarify the formation and evolution of the composite collision orogenic belt and to observe the northeastward extrusion and escape of material caused by the collision of Indian and Eurasian plates. Using 872 magnetotelluric sounding stations, we obtained for the first time a high-resolution three-dimensional resistivity model of the lithosphere of the Qinling Orogenic Belt and its surrounding areas. The model shows that the near EW direction anomalies dominate the electrical structure of the middle-upper crust of the Qinling Orogenic Belt, and high-resistivity anomalies are arranged at intervals along regional faults and plate suture zones, which show obvious low resistivity. The lower crust and upper mantle show electrical structural characteristics mainly in the near SN direction. Based on these, we propose that the "overpass-structured" electrical structure indicating the crust-mantle decoupling of the Qinling Orogenic Belt was formed under the influence of the asthenospheric flow escaping from the northeast of the Tibetan Plateau. The three-dimensional lithospheric resistivity model also shows that the high-conductivity anomaly in the middle and lower crust of the northeastern margin of the Tibetan Plateau terminates in the West Qinling Orogenic Belt at about 106.5°E and continues to migrate eastward in the form of asthenospheric flow. High conductors penetrating the crust and mantle are also found in the Weihe Graben, the East Qinling Orogenic Belt, the circular rift zone around the Ordos Basin, and even the northern Ordos Block, which was considered to be a stable craton. This may represent upwelling of northeastward escaping asthenospheric flow along rift zones and areas of structural weakness. We propose that this asthenospheric flow and upwelling transformed the lithospheric mantle in the Qinling Mountains and the central and western parts of the North China Craton through thermal erosion.

Deep Researches of the North Eastern Eurasia: Russian geotransects – results and perspectives

Ivan KUDRIAVTCEV[1]*, VSEGEI (ivan_kudryavtsev@yahoo.com)
Evgeniia Milshtein[2], VSEGEI
Sergey Kashubin[3], VSEGEI
Viktor Tatarinov[4], IMGRE
Roman Serzhantov[5], VNIGNI

Abstract

Russian Geotransects Program of the Deep Researches has seventy-years history and includes more than 150 thousand kilometers of the seismic profiles. Three stages were carried out within this period in Russia but only the results of the last stage (since 1995) are most significant today. Researches of this stage is aimed mainly to the Earth crust.

The important feature of the modern stage is multidiscipline field experiments within geotransects. It provides three types of field data acquisition along onshore profiles – two seismics (deep seismic sounding and near-vertical reflection) and magnetotelluric. Along offshore profiles, field experiments comprise of two types of seismic survey. The unity of the frame network is ensured by the spatial intersections of geotransects. The state geotransects network is the basis for the geophysical surveys within the local profiles and networks.

Within the North Eastern Eurasia there is the most extensive and representative frame network, which crosses tectonic structures from Eastern Siberia to Chukotka and the south of the Russian Far East. These transects could be used as the elements of the global Earth crosssections which aimed to the whole Eurasian continent researches.

Reflection seismic data provide the most detail information about the deep structures and processing of this data requires special methods, oriented to the highly heterogeneous crystalline crust. Since 2021 we use new stand-alone equipment for three-component registration of seismic signals during deep seismic soundings, which has made it possible to reduce the spacing of receivers and significantly increase the reliability of new data. For magnetotelluric data processing the constraint inversion is used and the other geophysical data play important role in this process.

Density sections which provided by 3D modelling technology are based on gravity surveys data and represents the important part of the geophysical dataset. These sections are crucial for studying horizontal heterogeneity of crust. All geophysical sections are used for complex analyses and represents the basis for the geological interpretation.

For the geological interpretation magnetic anomalies and gravimetric maps, including detail aeromagnetic surveys materials, are used, as the geological maps of different scales. Theoretical models of the earth's crust developed within the tectonophysics, as well as the principles of structural geology, are also considered for the correct interpretation. This approach leads to the need to consider deep structures in three-dimensional models using data over a large area, not limited to a narrow strip along each transect.

The crustal thickness, crust types and sedimentary cover thickness maps, which are the result of a

synthesis of all geophysical data, including regional seismic profiles, are used for areal interpretation. These materials are very important for the complex geological interpretation and demonstrates relationships between the structures of fold belts and the configuration of blocks of the crystalline crust. So three-dimensional models of large tectonic provinces have to be the main result of deep researches. Such a systematic approach seems to be the most perspective in the Earth's crust studying.

The geodynamic process of the eastern Tibetan plateau revealed by a 3D structure extracted by the Wavegradiometry Method

Chuntao LIANG[1]*, Chengdu University of Technology (liangct@cdut.edu.cn)
Feihuang Cao[2], Chengdu University of Technology

Abstract

The Wave Gradiometry (WG) method measures the spatial gradients of the wavefield within a subarray to extract phase velocity, wave propagation direction, geometrical spreading and radiation pattern within a subarray (Langston 2007). An azimuth-dependent dispersion curve inversion (ADDCI, Liang et al. 2020) is used together with the WG method to extract both 3D velocity and 3D azimuthal anisotropy. Additionally, the geometrical spreading extracted by the WG method is used to find the attenuation of the materials.

The method is applied to the three phases of Chinarray programs (including the Western Sichuan Array, Himalayan Arrays I and II) conducted in the eastern Tibetan plateau. The arrays have an average station spacing of 30km. The phase velocity and azimuthal anisotropy maps for periods 5-20s are inverted using ambient noise tomography, while that for periods 20-80s are obtained from WG method (Cao et al. 2020). The phase velocity dispersion curves for different azimuths with periods 5-100s are then constructed to obtain a 3D velocity and anisotropy model.

Our results show large variations in fast propagation directions (FPD) and magnitude of anisotropy (MOAs) with depth and blocks. The FPDs are positively correlated with plate directions measured by GPS, and are also positively correlated with strikes of regional faults for the South Chuandian block. The low-velocity zones (LVZs) in middle to lower crust are widely distributed in the Songpan Ganze Terrence, the north Chuan-Dian block. But the LVZs are not well present across the Kunlun fault to the NE Tibetan plateau, and across the Lijiang-XIaojinghe fault to the SE Tibetan plateau. The coexistence of LVZs in middle-lower crust and uppermost mantle surrounding the Sichuan basin is dramatic and it may suggest that large-scale deformation is coupled vertically from surface to uppermost mantle. Meanwhile, the FPDs in the lower crust are not aligned well with the assumed flow directions as required by the lower crust flow model. This observation may further suggest that the pure shearing crust shortening model, which involves the thrusting and folding of the upper crust and the lateral extrusion of blocks, may be the major mechanism causing the growth of the eastern Tibetan Plateau.

Zhen-Xing Yao[7], IGGCAS

Abstract

The Altai orogen is a typical intracontinental orogen in Central Asia that experienced far-field deformation associated with Indian-Eurasian plate convergence. This region is characterized by an uplift comparable to that of the Tianshan Mountains but has a distinct strain rate. Half of the Indo-Asia strain is accommodated by the Tianshan Mountains, whereas the Altai Mountains accommodate only 10%. To elucidate how the Altai Mountains produced such a large amount of uplift with only one-fifth of the strain rate of the Tianshan Mountains, we constructed a detailed crustal image of the Altai Mountains based on a new 166.8-km deep seismic reflection profile. The prestack migration images reveal an antiform within the Erqis crust, an ~10 km Moho offset between the Altai arc and the East Junggar area, and a major south-dipping (30° dip) thrust in the lower crust beneath the Altai Mountains, which is connected to the Moho offset. The south-dipping thrust not only records the southward subduction of the Ob-Zaisan Ocean in the Paleozoic but also controlled the Altai deformation pattern in the Cenozoic with the Erqis antiform. The Erqis antiform prevented the extension of deformation to the Junggar crust. The south-dipping thrust in the lower crust of the Altai area caused extrusion of the lower crust, generating uplift at the surface, thickening of the crust, and steep (~10 km) Moho deepening in the Altai Mountains. This process significantly widened the deformation zone of the Altai Mountains. These findings provide a new geodynamic model for describing how inherited crustal structure controls intraplate deformation without strong horizontal stress.

Study on the deep geological structure of the southern section of the Kyushu-Palau Ridge based on the combined gravity, magnetic and seismic inversion method

KE QIN[1]*, qinke_003@126.com (qinke_003@126.com)
Qizhen Du[2], multicomponent@163.com

Abstract

The investigation of the deep structure and dynamic mechanism of the Kyushu-Palau Ridge is crucial for comprehending the dynamic evolution of the Philippine Sea plate, and holds significant importance in resolving the scientific inquiry regarding how subduction occurred and developed from the paleo-Pacific plate to the West Philippine Sea plate. In this study, a comprehensive analysis and examination of the deep geological structure in the southern section of the Kyushu-Palau Ridge is conducted using a combined approach involving gravity, magnetic, and seismic inversion methods. This approach aims to address challenges related to multiple solutions derived from single geophysical data as well as limitations associated with each technical method. Furthermore, it seeks to overcome difficulties arising from multiple inferred geological solutions caused by insufficient clear imaging of rugged submarine oceanic crust structures within the Kyushu-Palau Ridge due to seismic events. Establishment of a fine crust-mantle geological-geophysical model for the study area. The findings presented in this paper unveil distinctive characteristics pertaining to crustal structure within the Kyushu-Palau Ridge, thereby establishing a foundation for understanding initial subduction mechanisms and dynamic processes involved in paleo-Pacific plate interaction with Philippine Sea plate. Additionally, these findings contribute towards reconstructing formation and evolutionary processes associated with the Kyushu-Palau Ridge.

Three-Dimensional Tomography: Unveiling the Tectonic and Mantle Dynamics Beneath the Mendocino Triple Junction

Ziqiang YANG[1]*, Chang'an University (yangzq@chd.edu.cn)

Abstract

The Mendocino Triple Junction (MTJ) is a geologically significant area situated on the coast of Northern California. It represents the intersection of three tectonic plates: the North American, Pacific, and Gorda-Juan de Fuca (G-JdF) plates. These geological features play a crucial role in shaping the seismic and tectonic activity in the region, which records the latest tectonic deformation patterns resulting from the interaction between the Pacific, Gorda, and North American plates, making it an ideal area for understanding plate interactions and deep dynamic processes. Utilizing a substantial dataset of high-quality P-wave travel times from local and teleseismic events, we have constructed a detailed three-dimensional model of P-wave anisotropic tomography for the crust and upper mantle beneath the Mendocino Triple Junction. Our findings reveal the existence of a slab window, where upwelling asthenospheric material directly interfaces with the surrounding tectonic plates. A high-velocity anomaly, indicative of a fragment of the Monterey microplate associated with the detachment of the Farallon plate, is discernible at depths of approximately 300-400 *km beneath the triple junction. The upper mantle displays seismic anisotropy that varies with depth and exhibits a circular pattern, primarily attributed to the three-dimensional mantle flow around the southern edge of the Gorda plate. The mantle wedge presents a subduction-driven corner flow. Following the initial contact between the Farallon and North American plates, the fragmentation of the Farallon plate led to the formation of a slab window. Subsequently, the Pacific plate captured the remnant of the plate and moved northwestward in unison. The Monterey plate then fractured, descended into the mantle, and under the influence of shearing forces from both the Pacific and North American plates, relocated to its present position.*

Earth CT: Intergrating Deep Earth Profiles to Make Global Transections via Wide Open Collaboration

Qi ZHOU[1]*, SinoProbe Lab CAGS (1437922567@qq.com)
Shuwen DONG[2], SinoProbe Lab, Chinese Academy of Geological Sciences
Larry BROWN[3], Cornell University
Hans THYBO[4], SinoProbe Lab, Chinese Academy of Geological Sciences
Xuanhua CHEN[5], SinoProbe Lab, Chinese Academy of Geological Sciences

Abstract

The Earth CT initiative originates from initial discussions during the International Symposium, DEEP-2018. Earth CT Program- the 3D Global Probe International Program is a new big scientific collaboration program of deep earth exploration and practice in global scale after Global Geo-Transects (GGT) program led by ILP in last 80th. Deep Earth processes control the geological evolution, including the formation of natural resources, natural disasters, and large-scale environmental changes at the surface of the Earth. The Earth CT programme aims to globally construct long range profiles in wide corridors to image the lithosphere by integrative interpretation of geoscientific data. The programme will integrate data from structural geology and tectonic interpretation at global and continental scales, geochemical surveys in geotransect corridors to define their crustal and lithospheric composition, deep seismic I reflection and refraction/wide -angle reflection profiling to identify I crustal and upper mantle structure and composition, magnetotelluric(MT) sounding for the electrical structure, broadband passive seismic tomography techniques for global and regional velocity structure and receiver functions for crustalupper mantle structure, as well as gravity and magnetic regional and global interpretation. Scientific dilling for deep earth sampling and detection of anomalous features in key tectonic belts will be based on the interpretation of the I above data and will add substantially to the uniqueness of the global and regional interpretation. The aims of the propject are to reveal the deep structure of the lithosphere, recognize the deep processes of plate movement and their control and influence on the surface system, explore energy and mineral resources at depth, and provide insight into geoscience frontier issues, such as the mechanisms controlling natural disasters and their intrinsic dynamics. This program would play a leading role in the development of the world geosciences.

At the DEEP-2018, DEEP-2021, 2019–2023 AGU FMs, and EGUs as particular sessions, there has been much discussion of the Earth CT initiative. The following approach has been supported by lots of international scientists, several societies, academic institutions and research facilities specializing in contouries, as well as proposed by Shuwen Dong, Larry Brown, Hans Thybo, Oleg Petrov, and many worldwide leading scientists. SinoProbe-Ⅱ, the new deep earth exploration program will be one of the important funder to contribute this Global Probe Program.
(1) To construct global "Big Cross" of the lithosphere by integration of intercontinental and regional geoscience transects based on reflection,frofiles.

Seismic discontinuities in the Australian upper mantle: a Bayesian approach using receiver functions and multimode dispersion of surface waves

Kotaro TARUMI[1]*, Hokkaido University (tarumi.kotaro.x5@elms.hokudai.ac.jp)
Kazunori Yoshizawa[2], Hokkaido University

Abstract

The Australian continent is composed of the western cratonic region formed in the Archean and Proterozoic eras and the eastern Phanerozoic orogen, drifting rapidly to the north with a speed of about 6-7 cm/year, which is a key to understanding the evolution of the continental lithosphere. The past formation and deformation process can be reflected in the upper mantle structures, such as anisotropic properties and seismic discontinuities (e.g., LAB: Lithosphere-Asthenosphere Boundary; L-D: Lehmann discontinuity). In this study, we aim to map the spatial distribution of LAB and L-D from the joint analysis of body and surface waves using permanent seismic stations in Australia.

We have performed the joint Bayesian inversions of multimode surface-wave phase speeds and azimuth-dependent receiver functions for permanent seismic stations in Australia. The LAB and L-D under the Australian continent are identified clearly in our retrieved models beneath each station. In eastern Phanerozoic Australia, significant S-wave speed drops, suggesting the LAB, are generally observed at shallow depths (70-80 km). In contrast, the estimated LAB becomes deeper (130-140 km) at the north and west of a station located near the margin with the western cratonic region, where the lithospheric thickness becomes thicker. Below the LAB, we could detect seismic discontinuities accompanied by an S-wave velocity increase, which can be interpreted as L-D. Compared with LAB, L-Ds are generally flat but appear in multiple interfaces. On the other hand, in the western cratonic region, LAB is distributed at deeper depths (110-180 km) than in eastern Australia, although S-velocity drops are not very clear. In addition, L-D can be detected as a single interface at around 300km depth in these regions.

As expected from the previous research, the radial anisotropy (xi=(Vsh/Vsv)^2) increases underneath LAB, indicating the effects of horizontal flow in the asthenosphere. On the contrary, radial anisotropy becomes weaker below the L-Ds, suggesting the transition from dislocation to diffusion creep across the L-D, as suggested in mineral physics. Thus, the L-Ds may be related to the base of the ductile asthenosphere under the continental plate.

Yaolin Shi[6], Key Laboratory of Computational Geodynamics, University of Chinese Academy of Sciences, China

Abstract

The thermal-rheological structure of East Asian continental lithosphere is critical for understanding its diffuse and variable intracontinental deformation in the Cenozoic. Here, we present a three-dimensional thermal-rheological of the lithosphere in East Asia, using the latest thermal parameters, strain rate measurements in mainland China. The results show great lateral heterogeneity of lithospheric temperature and rheology. The crust of orogenic belts such as the Tibetan Plateau, the Mongolia Plateau, and the Tian Shan orogeny is generally characterized by high temperature and low viscosity. The cratons, including Tarim, North China craton, Yangtze craton, have low temperature and high viscosity. The heat sources for the crust also vary. In the Tibetan Plateau, high crustal temperature results from radiogenic heat production within the thick crust, indicting the influence of continental collision. However, high heat flow from the upper mantle is the main cause of high surface heat flow in the eastern part of East Asia, suggesting the role of the Pacific-Eurasian Plate convergence. The rheological structure show that a weak lower crust with low effective viscosity is ubiquitous in East Asian continent. The complicated rheology is helpful to understand the broad and diffuse deformation in the interior of continents, which is a challenge to the theory of plate tectonics.

Upper-mantle velocity and anisotropy under the Mongol-Baikal region

Hanting WU[1]*, Nanjing University (whting@smail.nju.edu.cn)
Zhouchuan Huang[2], Nanjing University

Abstract

The Mongol-Baikal region is located in the western segment of the Central Asian Orogenic Belt. This area experienced multiple periods of extensive compression starting from the Proterozoic. In the Cenozoic, the study region was modified by neotectonics, featuring large extensional rifting (the Baikal rift zone) and plateau uplift (the Hangai Dome). However, the deep mechanisms of the onset of rifting and doming are still debated. We performed high-resolution 3-D P-wave tomography under the southwestern Baikal and western Mongolia. The images show distinct low-velocity anomalies under the Baikal Rift at ~60 km depth, the Hangai Dome at ~200 km depth, and beneath the Siberian craton. This may indicate that potential mantle flows ascended from the deep Siberian MTZ to shallower levels, influencing the rifting of the Baikal rift zone and the lithospheric process of the Hangai Dome. We then further determined the seismic anisotropy of the upper mantle under western Mongolia using SKS splitting measurements. The study region is dominated by NW-SE trending fast polarization directions (FPD), which indicates consistent compressional and transitional stress among the whole study area. Small delay times in the Hangai Dome spatially coincide with the low-velocity anomalies, supporting remarkable asthenosphere upwelling. However, the local Hangai upwelling did not affect the general anisotropic structures significantly, indicating that the lithospheric process only occurred in a limited area.

Determining three-dimensional Vp/Vs model for the Longmenshan fault system and adjacent areas, Sichuan, China

Junjie HAO[1]*, University of Science and Technology of China (Lydia_Hao@mail.ustc.edu.cn)
Haijiang Zhang[2], University of Science and Technology of China
Ying Liu[3], University of Science and Technology of China

Abstract

It is known that 2008 Wenchuan Mw7.9 earthquake and 2013 Ms7.0 Lushan earthquake occurred along the Longmenshan fault system in Sichuan, China, both of which caused great casualties. Although detailed Vp and Vs models have been developed around the Longmenshan fault system, reliable Vp/Vs model is still lacking. Compared to separate Vp and Vs models, Vp/Vs is more sensitive to the distribution of fluids and partial melting in the crust and upper mantle. Although Vp/Vs could be derived directly from dividing Vp by Vs, it may contain some artifacts due to different Vp and Vs uncertainties.

In this study, we aim at using the Vp /Vs model consistency-constrained double-difference tomography method of Guo et al. (2018) to determine reliable three-dimensional Vp/Vs model for the Longmenshan fault system and adjacent areas in Sichuan, China. This method uses P, S and S-P arrival times to simultaneously determine earthquake locations, Vp, Vs and Vp/Vs models. The advantage of this method is to not only determine a reliable Vp/Vs model, but also has a comparable resolution to Vp and Vs models. Here we assembled high-quality seismic body wave arrival time data on permanent and temporary seismic stations to ensure a good data coverage for the region.

The result shows that the middle and lower crust of the eastern margin of the Tibet Plateau is associated with low Vp, low Vs and high Vp/Vs, indicating the existence of partial melting or fluids. Along the Longmenshan fault system, it shows clear velocity segmentations, with large coseismic slip areas correlating with high velocity anomalies. In general, the seismicity in this region is located in low Vp/Vs anomalies. This study will be useful for better undertanding structural changes in the crust and their correlations with seismic behaviours.

Lithospheric structure beneath the Hoh Xil block in the northern Tibetan Plateau revealed by deep seismic reflection profile

Zhanwu LU[1]*, SinoProbe LabInstitute of Geology, Chinese Academy of Geological Sciences (luzhanwu78@163.com)
Wenhui LI[2], SinoProbe LabInstitute of Geology, Chinese Academy of Geological Sciences
Xiaoyu GUO[3], School of Earth Sciences and Engineering, Sun Yat-sen University
Rui Gao[4], School of Earth Sciences and Engineering, Sun Yat-sen University

Abstract

The Hoh Xil block in the hinterland of the Tibetan Plateau is viewed as a window into lithospheric connections between the Indian and Eurasian plates (Ding et al., 2013; Wang et al., 2016). The Hoh Xil block has attracted wide interest among geologists who focus their attention on identification of its crustal architecture and therefore the deep lithospheric interactions between the Indian and Eurasian plates. However, the crustal-scale structures at depths beneath the Hoh Xil block remains unknown, partly owing to its typically high elevation and therefore difficult logistics. In this study, we conducted a 170km-long deep reflection profile and high resolution crustal-scale architecture was obtained beneath the Hoh Xil block.

Seismic reflection profile clearly shows the mid-to-lower crustal structures (6-22 s, t.w.t) beneath the Hoh Xil block. One of the prominent reflections appears beneath the northern Qiangtang terrane, where are presented with a sequence of north-dipping reflections in the lower crust and a sequence of top-to-the south overthrusting reflections in the middle crust. These overthrusting reflections can be traced upward to the surface, where are coincident with the Tanggula Mountain. Meanwhile, in the lower crust beneath the Hoh Xil block, there is presented with a sequence of south-dipping reflections, which is in sharp contrast to the reflections beneath the Qiangtang terrane. The overall reflections for a “funnel-shaped” Moho geometry constitute a deformation pattern calling upon face-to-face convergence between the Qiangtang terrane and the Hoh Xil block. A similar convergence pattern has been ever identified in the western Kunlun orogenic belt (Gao et al., 2000) but has never been recognized yet within the plateau’s interior before. Therefore, this newly obtained seismic reflections shown has captured the deep geodynamics for an opposite convergence of the lithosphere (handshake) between the Indian and Eurasian plates.

This study was supported by the Second Tibetan Plateau Scientific Expedition and Research Program2019QZKK0701-02National Natural Science Foundation of China91962109,4157409141590863.

Film formation behavior of a hybrid silicate and its anti-hydration performance under a high-temperature environment

Mingyi Guo[1]*, Jilin University (gmyjlu@gmail.com)
Ying Li[2], College of Construction Engineering, Jilin University
Maosen Wang[3], College of Construction Engineering, Jilin University
Yinghui An[4], College of Construction Engineering, Jilin University

Abstract

Forming a protective layer on shale surfaces is a promising method to maintain wellbore stability in oil and gas drilling operations. In this study, we explored a novel hybrid silicate, consisting of potassium methylsilicate (PMS) and inorganic silicates (R2SiO3, R= K, Na, Li), as a shale stabilizer to inhibit shale hydration. Comprehensive tests are performed to evaluate the film-forming performance of the hybrid silicate system. The testing results show that, compared to the inorganic silicates, the hybrid silicate system yields a 58-68% reduction in the linear swelling rate of sodium bentonite (Na-Bt). Moreover, the hybrid silicate demonstrates a higher shale cutting recovery rate of 103% at 180°C due to the film formation on shale surfaces. The hybrid silicate system can spontaneously in-situ crystallize to form a quartz film on shale surfaces. The film was identified as crystalline silica (quartz) composed of reticulate nanofibers with alignment controllable morphology, and the size depended on the alkali cations in the hybrid silicate. Hybrid silicates have superior shale inhibition properties than inorganic silicates only, which can be ascribed to the chemical synergy effect between the potassium ions and the methyl group, and the formation of a unique film on shale surfaces at elevated temperatures higher than 150°C.

Double-difference Seismic Tomography Using Variational Inference Method and its Application

Hao YANG[1]*, University of Science and Technology of China (youngh_geo@mail.ustc.edu.cn)
Xin ZHANG[2], China University of GeosciencesBeijing
Haijiang ZHANG[3], University of Science and Technology of China

Abstract

Seismic tomography is an important method for determining subsurface structures at different scales. However, in practice it often faces challenges of high nonlinearity and non-uniqueness. Therefore, quantifying the velocity model uncertainties is crucial for a more accurate interpretation of seismic tomography results. However, the travel time seismic tomography method generally cannot provide reliable velocity model uncertainties. Monte Carlo sampling methods can be used to determine reliable velocity model uncertainties, but they need high computational costs when dealing with large datasets or high-dimensional spaces. In comparison, Bayesian variational inference is an effective method for approximating posterior probability distributions and has been applied to 2D travel-time tomography problems.

This study incorporates the variational inference method with the double-difference seismic tomography method (tomoDD). Synthetic tests demonstrate that the newly developed inversion method based on variational inference can achieve solutions comparable to tomoDD but without regularization constraints, thereby avoiding the generation of artifacts. This approach can rapidly and approximately provide velocity models with reliable uncertainty estimates. Compared to traditional checkerboard resolution tests, the resulting uncertainty estimates can more accurately measure the stability of the solution.

We have also applied the new method to local dense seismic array datasets around the SAFOD site along the San Andreas Fault at Parkfield. Similar to tomoDD, the velocity models show significant velocity contrasts across the fault. More importantly, the new method also produces velocity uncertainties, which are on the order of 0.2-0.4 km/s(Vp) and 0.1-0.3 km/s(Vs). Overall, double-difference seismic tomography based on variational inference method provides a powerful and efficient tool for determining seismic velocity structure with reliable uncertainty estimates.

Structure, rheology, and evolution of the Martian lithosphere across the crustal dichotomy in and around the Tharsis-Valles Marineris provinces

Ratheesh Kumar RT[1]*, Cochin University of Science and Technology (ratheesh@cusat.ac.in)
Dhananjay Ravat[2], Department of Earth and Environmental Sciences, University of Kentucky, Lexington, 40506, USA
Paul Morgan[3], Colorado Geological Survey, Colorado School of Mines, 1801 Moly Rd. Golden, CO 80401, USA.
Zhang H.L.[4], Hubei Subsurface Multi-scale Imaging Key Laboratory, Institute of Geophysics and Geomatics, China University of Geosciences, Wuhan, China.

Abstract

We have analysed flexural rigidity of the Martian lithosphere using a space-domain convolution method and mapped high-resolution spatial variation of elastic thickness (Te) and crust-mantle interface (CMI) in and around the Tharsis-Valles Marineris provinces. We tested the convolution method using Bouguer and free-air gravity anomaly-based computations and obtained consistent results. Also, we studied the variability of Te by testing with different parameters, including CMI models, density variations, and window sizes that gave rise to optimal results. These models mainly suggest a bimodal lithospheric setting across the highlands-lowlands boundary which we attribute to rheological differences with the aid of lithospheric strength envelope models. The predominantly large-Te (>150 km) and CMI depth (~ 65 – 88 km) characteristic of the major volcanoes in the Tharsis province are attributed to a significantly strong lithosphere having a coupled crust-mantle rheology that supports relatively recent volcanic loads. In contrast, significantly low-Te (< 5 km) and thin crust (CMI ~ 25 – 27 km) of the northern lowlands correspond to a decoupled crust-mantle rheology that was flexurally frozen into the lithosphere during its ancient formation under the influence of a high-thermal gradient. A relatively small-Te and thinned crustal structure in the central part of Valles Marineris, with inferred layered plutons, flood basalts, and mafic dikes are suggestive of a rift-like evolution. We find that Te correlates well to the first-order published geological and geophysical constraints (e.g., age, lithology, and crustal magnetic signatures) that characterize unmodified, magmatism-modified, and impact-altered lithosphere.

Abstract

Lunar ore minerals host noble and base metals crucial for the self-sustainability of future human colonies on the Moon. Pyrite and troilite, which are sulfide minerals, have various technological applications and use cases. They can be used as a raw material source for producing new solar panels, which are readily available on the Lunar surface. Ilmenite is the primary source of iron and titanium ore on the Moon, which can provide helium-3 for nuclear fusion and oxygen for rocket fuel.

The most important ore minerals have prominent absorption peaks in a narrow far-infrared (FIR) wavelength range of 20–40 μm. This is much stronger than the spectral features of other common minerals, including significant silicates, sulfates, and carbonates. Simulations based on both the linear mixing and the single-scattering albedo/Hapke modeling of ore minerals with the silicates mentioned above indicate that areas containing at least 10–20 vol.% pyrite or ilmenite could be detected from orbit in the FIR range.

The MIRORES (Multiplanetary far-IR ORE Spectrometer) instrument proposed here would operate with a resolution down to <5 m, making it possible to detect areas covered by 2-3 m2 of pyrite (or ilmenite) on a surface of ~17 m2 from an altitude of 50 km. This creates possibilities for detecting large and local smaller orebodies along with their stockworks. The Cassegrain optical system enables this capability. MIRORES will measure radiation in eight narrow bands (0.3 μm in width) that can include up to five bands centered on the ore mineral absorption bands. For instance, MIRORES can measure 24.3, 24.9, 27.6, 34.2, and 38.8 μm for pyrite, marcasite, chalcopyrite, ilmenite, and troilite, respectively. The instrument's size is 32 x 32 x 42 cm, and the mass is <10 kg, which fits the standard microsatellite requirements. The instrument has been selected as the priority payload for the Polish Lunar Mission and will be integrated into a satellite launched to the Moon by the Polish Space Agency between 2028 and 2029. The prototype construction for Earth-based tests started in 2021, and its laboratory testing began in 2022. The Earth test of the prototype from the drone started in December 2023 in Warsaw.

Foundations for Lunar Landing Sites: Estimating the Bulk Density of Near-surface Lunar Regolith Through Cone Penetrometer Testing of Simulants

Michael P LUCAS[1]*, Notre Dame (mlucas9@alum.utk.edu)
Clive R Neal[2], University of Notre Dame
Jared Long-Fox[3], University of Central Florida
Daniel Britt[4], University of Central Florida

Abstract

Purpose: Future exploration and infrastructure development on the lunar surface will demand a firm understanding of the geotechnical properties, structure, and stratigraphy of the near-surface regolith. Long duration stays on surface of the Moon will require the use of regolith as construction material and as the unrefined material for resource extraction during in situ resource utilization (ISRU) activities. To prepare for these activities it will be essential to perform geotechnical testing using regolith simulants in Earth-based laboratories, which will help identify: the most applicable regolith analogue(s) for a particular landing region; laboratory measurements that are able to predict and replicate the structure and stratigraphy of near-surface regolith, and methods to calibrate the in situ geotechnical testing necessary to guide future excavation, construction, and ISRU activities.

Introduction: Soil mechanics experiments conducted during the Apollo 14-17 missions revealed that regolith density significantly increases with depth. These experiments also indicated that although near-surface regolith stratigraphy varies locally at Apollo landing regions, regolith stratigraphic layers display a general similarity in that the top several cm consists of a fluffy, unconsolidated layer (e.g., think astronaut boot prints); a firm layer at ~5-10 cm below the surface; then a denser, stronger layer is encountered at depths of 20-40 cm. Therefore, to understand how regolith can enable, but must withstand, surface activities, it will be critical to understand the geotechnical properties and the density profile of the regolith while performing Earth-based testing. Here, we use Exolith Lab regolith simulants to develop correlations between cone penetrometer testing (CPT) measurements and bulk density (ρB); correlations essential for replicating the near-surface regolith conditions of the Moon in Earth-based test beds.

Methods - Cone Penetrometer Measurements: We used a Rimik CP40II penetrometer to obtain Cone Index (CI) penetration resistance values (stress in kPa) vs. depth for regolith simulants packed at various ρB in clear, acrylic test bins. We used an ASAE standard cone area of 1.29 cm2. We measured CI values at 10 mm intervals to depths of ~150-200 mm to estimate the slope parameter (G), which is the slope of CI values vs. depth measured from the surface to 100 mm depth.

Results - G Derivation for Lunar Simulants: We measured CI values of simulants packed at

specific ρB to determine their range of strength in terms of G. At present, we have developed correlations for three variations of lunar highland simulant: LHS-1 Dried (dried at ~110±5°C for 4 hr), LHS-1 Undried, and LHS-1E Engineering Grade Undried. LHS-1E is a “simplified”, lower-cost simulant (i.e., high-fidelity LHS-1 minus trace minerals). We also developed correlations for lunar mare simulants LMS-1 Dried and LMS-1 Undried. All data sets yield strong exponential relationships (R2 values of 0.91 to 0.98); fitted using the least squares method (Equations 1-5; solved for ρB):

LHS-1 Dried: $\rho B = (\ln G + 16.6)/10.524$ (Eq. 1)
LHS-1 Undried: $\rho B = (\ln G + 13.2)/8.451$ (Eq. 2)
LHS-1E Undried: $\rho B = (\ln G + 15.8)/9.934$ (Eq. 3)
LMS-1 Dried: $\rho B = (\ln G + 18.3)/10.18$ (Eq. 4)
LMS-1 Undried: $\rho B = (\ln G + 15.9)/8.978$ (Eq.

Lunar Dust Removal using a Gecko Roller

Charles T Pett[1]*, University of Maryland at College Park (pett@umd.edu)
Colby C Merrill[2], University of Maryland at College Park
Christine M Hartzell[3], University of Maryland at College Park

Abstract

Humans and robotic assets landing, exploring, and living on the Moon during the Artemis era will be immersed in a hazardously dusty environment. Lunar dust is notoriously abrasive and creates challenges for almost every lunar surface procedure, including negative optical and thermal effects. The hazard of charged dust in situ was captured by Apollo 16 astronaut, John Young, who remarked, “Dust is the number one concern in returning to the moon” (Gaier, 2007). Mitigation technologies that quickly and effectively remove dust particles (down to microns in size) with minimal consumables, as well as meet tight mass, volume, and power constraints, are needed for future long-term lunar and martian exploration and habitability. We present a novel technology to remove lunar dust from spacesuit, optical, and solar panel surfaces. The Gecko Roller is a handheld device that functions in the same way as a common terrestrial lint roller, but with an elastomeric gecko skin-inspired membrane replacing the adhesive sheet. The synthetic gecko skin membrane is a silicone elastomer with micron-scale molded hair-like structures that increase the adhesion between the dust and the elastomer. The gecko roller requires no power when operated by an astronaut, but can become reusable via electrostatic cleaning if power is available. Preliminary work has demonstrated that the gecko roller is able to effectively remove dust from hard surfaces as well as a spacesuit fabric swatch at lab temperature and pressure. The clean gecko roller was able to consistently remove over 90% of the lunar dust simulant from flat surfaces and spacesuit material at 1 atm. The gecko roller is currently at TRL 4. A recently awarded Lunar Surface Technology Research (LuSTR) 2023 grant aims to raise the technology to TRL 5 after testing in a lunar relevant environment in ultra-high vacuum at subzero temperatures.

Gale crater Mars – 3.7 billion years of Mars history from the Curiosity Mars Rover mission

Horton E Newsom[1]*, University of New Mexico (newsom@unm.edu)

Abstract

For almost 12 years Curiosity has been roving across the Gale Crater on Mars. The data from Curiosity, along with orbital data has revealed amazing results from the formation of the crater to literally the daily weather on Mars. Perseverance has also been roving Jezero crater and studying Martian environments for several years, with the intent to eventually return important samples to the Earth. Key discoveries by Curiosity and recent studies of Gale Crater, Mars include evidence of aqueous processes spanning a long duration of Mars history, with evidence for alluvial fans and lakes that may be as young as 500 M.Y. Along the rover traverse evidence of lake deposits and even mud cracks have been found. The Mt. Sharp group rocks have also been altered by circulation of groundwater and deposition of abundant veins of Ca-sulfate and other mineralization. Rippled shallow lake deposits are even found at the Marker Band. Further evidence for water includes the possible role of glaciation, including rock glaciers. Aeolian processes have led to substantial erosion of the Mount Sharp group along the rover traverse up Gediz Vallis, as seen through the presence of ventifacts, and tilted block fields.

Spectrally Feldspathic Detections on Mars: A Review and New Discoveries

Michael Steven PHILLIPS[1]*, The University of Arizona (phillipsm@arizona.edu)

Abstract

Over the past decade, several studies have reported detections of visible to short wavelength infrared (VSWIR) spectra dominated by the ~1.25-μm absorption feature of Fe2+-bearing plagioclase on Mars. These “spectrally feldspathic” detections are intriguing because: i) Mars has long been considered a basalt-covered world with little petrologic diversity and these detections may represent rock types that are more evolved than basalt; and ii) these detections occur primarily in ancient rocks (pre- and early Noachian, > 4.1 Ga) suggesting a connection to early crust forming processes on Mars.

Mars is large enough to have experienced mantle overturn processes during differentiation and yet still preserves a record of its earliest crustal products on the surface. Thus, Mars is the best, and perhaps only, planetary body in the Solar System that experienced Earth-like differentiation and where observations can be compared to models of primary crust formation processes (i.e., a magma ocean, cumulate mantle overturn, and post-overturn melting). Understanding the composition of ancient spectrally feldspathic outcrops is key for constraining models of planetary differentiation on Mars, and by extension planetary bodies that underwent mantle overturn.

In 2013, Wray et al. and Carter and Poulet first reported spectrally feldspathic outcrops on Mars north of Hellas basin, which were interpreted as granitic and anorthositic, respectively. Since 2013, six more publications have reported similar VSWIR spectral detections across the southern highlands of Mars: in the walls of Valles Marineris (Viviano et al., 2017, Flahaut et al., 2023), in western Arcadia Planitia domes (Farrand et al,. 2021), across many massifs north of Hellas basin (Phillips et al., 2022), in Nili Patera caldera and Terra Sabaea (Rogers and Farrand, 2022), and in Terra Sirenum/Cimmeria (Payre et al., 2022). The geologic contexts of spectrally feldspathic materials reported in the abovementioned publications are different from one another and different interpretations for the rock type and mechanisms of emplacement were given in all cases.

In this presentation I will review the different examples of spectrally feldspathic regions on Mars, discuss the possibility that they are related or represent distinct processes and compositions, as well as present new detections in massifs north of Argyre basin.

Estimation of Lunar Rock Strength: Integrating Regression Analysis and Machine Learning with Apollo Mission Data

Tae Young KO[1]*, Kangwon National University (tyko@kangwon.ac.kr)
Se Jin PARK[2], Kangwon National University
Ji Hye HWANG[3], Kangwon National University
Yun Seong KANG[4], Kangwon National University
Jeong In KWON[5], Kangwon National University

Abstract

This paper introduces an innovative approach for the estimation of lunar rock strength, utilizing the dataset of density and P-wave velocity values obtained from lunar samples collected during the Apollo missions. The primary objective of this study is to develop a predictive model that can accurately estimate the mechanical strength of lunar rocks, leveraging the advanced capabilities of machine learning-based regression analysis. To achieve this, we have meticulously compiled a comprehensive dataset, which includes the physical properties of lunar rocks as well as analogous terrestrial rock data, to serve as a foundation for our analytical models.

The methodology encompasses a two-pronged approach: first, conducting a detailed regression analysis to understand the fundamental relationships between the physical properties of the rocks and their mechanical strength; second, employing sophisticated machine learning algorithms to refine these relationships and enhance the predictive accuracy of our model. The machine learning component particularly focuses on exploring various algorithms, including linear regression, decision trees, and symbolic regression, to determine the most effective model for predicting lunar rock strength based on the identified physical properties.

Furthermore, this study delves into the validation and testing of the developed model using a subset of the dataset, ensuring its reliability and accuracy in estimating the strength of lunar materials. The implications of this research are manifold, offering not only a deeper understanding of the geomechanical behavior of extraterrestrial materials but also paving the way for the practical application of these findings in the planning and construction of future lunar habitats and infrastructure. By providing a robust and accurate tool for assessing the strength of lunar rocks, this research significantly contributes to the field of space exploration and in-situ resource utilization, marking a pivotal step towards sustainable human presence on the Moon.

Volume estimation of specific types of Martian glaciers which may be related to the paleo-environment of Mars

AKIRA SAWADA[1]*, Waseda University (sukatea2022@gmail.com)
HIROTO NAGAI[2], Department of geography, Faculty of Geo-environmental Science, Rissho University (1700 Magechi, Kumagaya, Saitama, Japan 360-0194)

Abstract

It is widely accepted that an ocean existed on ancient Mars. Also, a lot of explorations and research show that, the water remains as a subterranean ice on Martian surface until now. According to some reports, over 10000 ice-related terrains called viscous flow-features, were already found around the mid-latitude of Mars. One of the type is glacier-like forms, which looks like debris-covered glacier on Earth.

Research for the ice is extremely important for understanding the evolution and water cycle on Mars, as well as exploring the possibility of extraterrestrial life and for the smooth progress of human migration projects in the future. Especially, knowing the total quantity of water ice on Mars is important for reconstructing the initial water level related to paleo-environment of Mars.

However, scientific data of Martian surface is almost satellite images. This make estimation of total ice volume on Mars so difficult. Even there were some research done this recent years, they had difficulty on gaining more precise value.

So, we tried the new method for estimating Martian ice volume, especially terrain shaped like valley glacier, using the symmetry between flow direction and width direction of the glaciers due to mostly or absolutely not flowing over several million years, correlation between glacier area and volume called volume-area scaling, and theorized two-dimensional perfect plastic ice sheet model. This method can be useful for Martian glaciers which, only single low-resolution image data exists.

We selected over 50 terrains look like valley glacier, and then obtained parameters for volume-area correlation. The images were taken by NASA's MRO (Mars Reconnaissance Orbiter). The theory of glacier model is based on perfect plastic theory. Also, some of data quoted from the studies done by other researchers before.

The results show that, the estimated total volume of the ice obtained by the method was within acceptable order and range around 400 to 2000 square km including possible 20% error, similar to the value reported by another researcher. Additionally, this result might mean that some of previous study may have overestimated the total volume of the Martian glaciers between 45 to 70%. Also, this may support the theory espouses the possibility that the origin of these subsurface ice was not directly supplied from the ancient ocean existed on low lands of northern hemisphere but from snow, mostly water once dissipated into atmosphere and redeposited as ice and carbon dioxide mixture.

However, there are no on-site measurement data, and the specific properties or physical quantities such as heat flux around ice-rich terrain and ice-debris ratio remain unknown. Also, we used

simplified model and data not considering possible complex underground structure and recession of them. In addition, some of latest research reported the existence of ice-related terrains on low and high latitude of Mars. Thus, we must wait for global terrain survey on Mars, direct close observations and sample returns in future exploration mission for more updates. Also, we want to discuss more about this field with sedimentology and rover data after entering doctoral course.

The >3700 km long Great Dyke of Atla Regio, Venus: the longest traced individual dyke in the solar system

Hafida EL BILALI[1]*, Carleton University, Canada (hafidaelbilali@cunet.carleton.ca)
Richard Everett ERNST[2], Carleton University, Canada

Abstract

The Great Dyke of Atla Regio (GDAR) is traced for ~3700 km on Venus, as surface graben (narrow troughs) interpreted to overlie a continuous laterally-emplaced underlying mafic dyke (vertical magma-filled crack). The GDAR is part of a giant radiating graben/fissure/fracture system (dyke swarm) associated with the Ozza Mons volcano of the Atla Regio plume centre. On the basis of this dyke interpretation the GDAR is the longest individually traced dyke so far recognized on Venus (and also in the Solar System). The GDAR is traced from an interpreted magma reservoir located ~600 km south of the Ozza Mons plume centre, which may have been fed initially from closer to the plume centre. A 50-degree counter-clockwise swing of the GDAR trend at 1200 km from the centre is consistent with 1200 km radius for the underlying Ozza Mons mantle plume head, and a stress link to the 10,000 km long Parga Chasmata rift system. Our discovery of the >3500 km long Great Dyke of Atla Regio, should spur the search for additional long continuous single dykes on Venus (and Earth), with implications for estimating plume head size, locating buffered magma reservoirs, mapping regional stress variation across a large region of Venus (and Earth) at a geological instant, and revealing relative ages (through cross-cutting relationships) over regional-scale distances.

Abstract

The Moon-forming impact (MFI) and subsequent formation of the global magma ocean would have set the last major constraints in the chemical and physical co-evolution of the mantle and the core. Based on the scenario that the core of the impactor merged into the proto-Earth, we have investigated depth-dependent partitioning of hydrogen into iron under impact-driven reaction environment between the metallic core of the impactor, e.g., iron, and the volatile component in the post-giant impact Earth, e.g., H2O. Iron compressed with H2O at pressures of 8, 12, 24 and 53 GPa, corresponding to depths of ca. 200, 300, 750 and 1200 km, respectively, was irradiated by high-brilliance X-ray free electron laser (XFEL) pulses to pump and probe the chemical reactions at 2.2 MHz and 30 Hz repetitions. Through fast heating process in pico-to-nanosecond range, we have observed depth-dependent formations of iron oxides (FeO and Fe3O4), hydrides (γ-FeHx, ε'-FeHx and FeH2) and hydroxides (γ-FeOOH and hydrohematite) in partially-quenched states. We find that the molar ratio of H with respect to Fe in all the reaction products shows ~5 fold decrease in the depth range between from 300 and 750 km. This suggests significant modulation in hydrogen partitioning into the iron compounds in the region including the present-day mantle transition zone (MTZ). The resulting abundance of hydrogen in this region would have enabled the formation of hydrous silicates such as wadsleyite and ringwoodite to explain ca. 34.4% of the water storage capacity in the present MTZ. On the other hand, the H/Fe molar ratio shows over 50% hydrogen partitioning into the iron compounds at depths below 1200 km, which would have migrated downwards to form the early core to explain ca. 3.51% of its present light element budget.

Formation and evolution of the protolunar disk

Razvan CARACAS[1]*, CNRS, IPGP (caracas@ipgp.fr)

Abstract

Giant and large-scale impacts are ubiquitous features of early solar systems that dominate the end of the accretion stage. The last major accretion event in Earth's history was the Moon-forming giant impact. Depending on the impact parameters, the outcome of this impact was the formation of such a protolunar disk. During cooling, liquids and gases separate according to the liquid-vapor stability dome. The liquid droplets rain toward the center, forming the planet as a magma ocean (MO). The leftover gas forms the hot dense disk atmosphere.

We study the formation and condensation of the disk and the evolution of the MO using molecular dynamics simulations based on ab initio calculations. We work on a multicomponent silicate fluid with bulk silicate Earth composition. From the pressure-density variation and the Maxwell construction, we determine the limits of stability of the molten silicate and the position of the critical point. We find that the Earth's protolunar disk reached the supercritical state of the silicate mantle. Then we follow the chemical evolution of the disk during its cooling.

We characterize the structure and behavior of the MO. The onset of a mushy layer rich in bridgmanite crystals profoundly marks its evolution. This layer exhibits neutral buoyancy and effectively separates the MO at middle depths into a shallow MO and a basal MO that evolve separately.

We also compute the composition of the disk atmosphere and find that it is extremely rich in molecular species. Oxidized phases like SiO, O, O2, MgO, and cations like Na and Mg dominate the gas phase. But a plethora of other phases are present in the system, with lifetimes that allow them to play a role in the chemical and isotopic exchanges. Many of the gas molecules that we find in our simulations are not present in databases like JANAF. This suggests that a huge field of investigation lies bare ahead of us.

Dyke swarm history and associated plume centres of Anala and Irnini Montes in Central Eistla Regio, Venus

AASTHA MISHRA[1]*, Indian Institute of Technology Bhubaneshwar, Odisha, India (22gg05007@iitbbs.ac.in)
Richard Ernst[2], Carleton University, Ottawa, Canada
Hafida El Bilali[3], Carleton University, Ottawa, Canada

Abstract

Dyke swarm history and associated plume centres of Anala and Irnini Montes in Central Eistla Regio, Venus

Mishra, Ernst, El Bilali, Srivastava

Venus provides a unique opportunity for mapping dyke swarms and their relationship with mantle plumes because of the absence of plate tectonics and any significant erosion. Dyke swarms are recognized by their surface expression as grabens. Central Eistla Regio is an important mantle plume region on Venus with multiple magmatic centres. Here we focus on two important volcanic centres, Anala and Irnini Montes. Previous geological mapping of our study area in Quadrangle V-20 was done at reconnaissance scale (1:5,000,000). In the present study we focus on detailed mapping of Anala and Irnini Montes grabens (interpreted to overlie dykes) 10x more detailed than in previous studies. We have so far mapped about 10,000 grabens, which have been provisionally grouped into radiating, circumferential and linear dyke swarms.

Anala Mons (11.0°N 14.1°E, 525 km in size) is a complex volcanic centre with multiple radiating and circumferential swarms. About 300 km to the east, there is a broad circular feature (170 km in diameter) interpreted as an older corona which has been filled by younger lava flows emanating from Anala Mons. These flows mostly cover the swarms radiating to the east, but some Anala Mons grabens were apparently large enough that they were not completely filled by the younger flows and remain visible. One particular graben can be traced for >550 km, initially trending radially to the NE from Anala Mons; at a distance of about 350 km this dyke swings clockwise 45 degrees towards an ESE trend. A second partially flooded radial graben trends east from the Anala Mons centre and at approximately the same 350 km distance also swings to an ESE trend. Additional smaller graben segments also support this pattern of a radial swarm swinging into a linear trend. Such a pattern can be used to estimate the extent of the domal uplift which proxies the size of the underlying plume head. In this case the graben (dyke swarm) pattern indicates a plume head radius of about 350 km. The recognition of a linear ESE dyke trend beyond this distance indicates a regional ESE-trending maximum compressive stress in the region east of Anala Mons.

Some grabens (dykes) in the interior of the other major centre, Irnini Mons, also show a similar swing in trend at about the same 350 km distance away from Anala Mons, and we are investigating whether these could belong to a north-trending sector of the main Anala Mons radiating swarm.

Irnini Mons (14.6°N 16.0°E, 475 km in diameter) is characterized following our detailed mapping by radiating and circumferential swarms. However, major linear sets of grabens on the western side and on the northern sides of Irnini Mons are not linked to this Mons, but instead these dyke swarms are provisionally interpreted to be part of a huge radiating swarm associated with Belet-ili Corona located more than 1000 km to the south.

Crustal extension due to dyke swarm emplacement: Influence on Venusian surface topography including the formation of annular rims/troughs characteristic of coronae

Richard E. ERNST[1]*, Carleton University, Canada (richardernst@cunet.carleton.ca)
Hafida El Bilali[2], Carleton University, Canada
Kenneth L. Buchan[3], 273 Fifth Ave., Ottawa, Ontario, Canada
James W. Head[4], Brown University, Providence, USA

Abstract

Graben systems are extensive on Venus and have been interpreted both as purely structural features, and alternatively as underlain by mafic dykes. In many cases a dyke origin can be clearly demonstrated based on the eruption of lava flows from the grabens. Here we consider the implications of crustal extension (mostly 1-5%, but ranging up to 10%) under the dyke swarm interpretation. A key reason that dyke emplacement can cause such a major crustal extension is that the majority of dyke swarms on Venus (and Earth) have vertical extents estimated between 10 and 60 km (linked to lateral emplacement) and widths ranging from 20 to 200 m.

We base our study on field observation of dyke swarms on Earth, theoretical treatments of radial dike swarms, and the mapping of graben patterns on Venus. Our analysis benefits from the unique opportunity that Venus offers to compare the primary surface topography (preserved in the absence of erosion) with crustal extension inferred from dyke swarm emplacement.

We consider the effect on surface topography of crustal extension due to dyke emplacement in five scenarios. These examples are associated with all three types of major dyke swarms: radiating, circumferential and linear.

1) Formation of annular rims and troughs characteristic of coronae: Crustal extension associated with circumferential dyke swarms that encircle most coronae may be sufficient to explain the annular folding of corona rims and troughs, and complement other folding mechanisms based on modelling of plume dynamics.

2) Preservation of domal uplift above plumes/diapirs: Crustal extension associated with emplacement of a radiating swarm above a plume/diapir contributes to preservation of the plume-generated domal uplift. On the other hand, in the absence of dyke emplacement, once the thermal anomaly fades the original topography could be restored.

3) Formation of arachnoids: Some magmatic centres are associated with radiating ridge systems (termed arachnoids). Such radial compressional features could develop from collapse of dyke-extended domal uplift, with thrust faults partly utilizing the preexisting radiating dykes as zones of weakness.

4) Elevation of fracture belts (lineae, groove belts): Fracture belts are interpreted as older failed rifts, but often have an elevated topography. Emplacement of rift-parallel dykes and the resulting crustal extension within a failed rift zone could represent a mechanism for linear uplift.

5) Formation of km-scale undulations in topography: Many areas on Venus display multiple cross-

cutting graben sets, which appear analogous to regions of terrestrial Precambrian shields that exhibit multiple crosscutting dyke swarms of different ages. The superimposition of crustal extension from each of the multiple crosscutting trends is predicted to cause complicated patterns of km scale undulations in the surface topography. We are investigating possible examples on Venus.

Abstract

The cores of Earth and other rocky planets are believed to be composed of light elements, including silicon, oxygen, sulfur, hydrogen, and carbon, constituting approximately 5 to 22 wt.% of their overall composition. Notably, sulfur emerges as a dominant element in the cores of smaller terrestrial bodies like Mars, Ganymede, and Vesta. To gain insight into the evolutionary processes of sulfur-rich cores amid the presence of other light elements, we conducted extensive in-situ high-temperature and high-pressure experiments on the Fe-S-O-H system. These experiments spanned a broad range of conditions, encompassing pressures from 18 to 44 GPa and temperatures from 1258 to 2981 K, aiming to simulate the pressure-temperature (P-T) conditions characteristic of the Martian core. Employing ferrous sulfide (FeS) and brucite (Mg(OH)2) as proxies, our investigations unveiled the formation of distinct phases including FeSHx(IV), FeS2, and Fe(Mg)O, suggesting a preferential incorporation of hydrogen into the FeS structure within sulfur-rich environments. Moreover, our analyses revealed a segregation of the Fe-S-H and Fe(-Mg)-O phases, driven by temperature gradients and characterized by a density contrast of approximately 3.1%. Building upon these findings, we propose a crystallization pathway for the Martian core, positing a scenario where the lighter Fe-S-H layer gradually supersedes the denser Fe-O layer during the core's cooling process. This study contributes valuable insights into the complex dynamics governing planetary core formation and evolution.

Experimental seismic velocity measurements of chlorite and antigorite using the PE press

Nicholas Backhouse[1]*, UCL (nicholas.backhouse.20@ucl.ac.uk)
Andrew Thomson[2], UCL
John Brodholt[3], UCL
Craig Wilson[4], AWE

Abstract

Chlorite (ideal formula (Mg,Fe)5Al(Si3Al)O10(OH)8) and antigorite (ideal formula (Mg,Fe)3Si2O5(OH)4) are both hydrous silicate minerals believed to exist in downwelling subducting slabs. In hot slabs these minerals will decompose and release their water into the overlying mantle wedge, leading to arc volcanism and/or ore formation. Alternatively, if temperatures are sufficiently cold they can deliver water directly to the asthenosphere, ultimately reducing mantle viscosity and facilitating deep focus earthquakes (1). Detailed seismic studies of subduction settings (2) appear to be consistent with the presence of hydrous minerals, however, this interpretation is uncertain due to the scarcity of available data on the seismic velocity of chlorite and antigorite. Prior to these experiments, published high-pressure velocity measurements of antigorite were limited to room temperature (3), while similar measurements of chlorite are all from a single study performed at pressures of 1.8 and 3.8 GPa (4).

Seismic velocity and X-ray diffraction measurements of natural chlorite and antigorite were collected up to ~6 GPa and 700 °C in a Paris-Edinburgh press at HPCAT, APS, Chicago. The antigorite sample was a randomly oriented polycrystalline sample from Syros, while the chlorite measurements were taken on schists, both perpendicular and parallel to the lattice-preferred orientation (LPO). This allows for some evaluation of the acoustic anisotropy and the effect of chlorite composition on the seismic velocity. At each PT step, velocities were measured using pulse-echo ultrasonics at 16-60 MHz frequency, with sample lengths determined from X-ray radiography. Energy dispersive X-ray diffraction was used to measure sample density and monitor pressure via volume of an MgO sleeve surrounding the sample. Temperature was determined using power curves established at HPCAT for this assembly. These data were used to fit a 3rd-order Birch-Murnaghan equation of state and determine the bulk modulus of the samples. This allows us to reevaluate seismic observations from the Lesser Antilles, and the evidence for hydrous phases in downwelling assemblages.

Numerical simulation of planetary core formation using FEniCS Project for extending 3D modeling

Kyeong-Min LEE[1]*, Kangwon National University (euntm97@kangwon.ac.kr)
Hyo-Im Kim[2], Gyeongsang National University
Deok-Kyu Jang[3], Kangwon National University
Byung-Dal So[4], Kangwon National University

Abstract

Heat sources such as impact heating cause the partial melting of rocky planet interior, rendering a rheological multiphase system. This is due to the difference in phase stability between metals and silicates. Since the melting temperature of metals (i.e., iron-nickel alloys and Fe-FeS system) is typically lower than that of silicates, the metals are initially segregated into liquid phases from solid silicate-metal mixtures. Due to the higher density of fluid metal compared to solid phases, the segregated liquid metals descend towards the center of the planetary bodies. In this study, we propose several numerical simulations to understand the process of core formation. We created a model implemented in FEniCS project via scripting the weak forms of governing equations. The differentiation of silicate and iron metal has been simulated by solving the two-dimensional Stokes and Darcy equations. Case 1 corresponds to planetary evolution triggered by impact heating in early terrestrial bodies with a homogeneous metal fraction. In Case 2, the model mimicked a scenario depicting post-evolutionary impact heating by assuming heterogeneous metal fractions. The results of Case 2 simultaneously represent the behavior of the solid mixture based on the density contrast and multiphase flow of the solid matrix and metallic pores. The checkerboard test (Case 3) was used to evaluate the resolution of the numerical model, indicating consistent spatial resolution for the mesh sizes we employed. Time-dependent model was developed by simulating the multiphase advection scheme, demonstrating the rapid descent of metal phases and the relatively slower movement of silicate phases. Finally, we expanded the 2D FEM model to compute the velocity fields of silicate, Darcy, and iron metal in a 3D model featuring an impact heating case.

Abstract

Impact-induced isotopic variation provide insights into the accretion processes of terrestrial planets. One observational fact is that average lithium isotopic values of all terrestrial planets are higher than those of chondrites. This is perplexing since chondrites are thought to be the building blocks of planets and Li isotopes are less fractionated during the accretion evaporation or core-mantle differentiation. One alternative process is that isotopically light Li was partially lost during collisional erosion, defined as the mass loss of melting material of planetesimals during accretion. The key, but still not understood point for this scenario is whether Li isotope fractionation occurs during impact melting.

Here, Li isotope systematics of six suites of heavily shocked ordinary chondrites were investigated. Shock melt pockets (SMP) show resolvedly light Li isotope compositions relative to the adjacent unmelted portions of chondrites. The results strongly suggest that Li isotopic fractionation occurs during impact melting and that isotopically light Li migrates into melts. This finding is consistent with the theory of collision erosion, which predicts a partial loss of a melted material with light Li isotope compositions. The Li isotopic bias of ~2‰ between chondrites and terrestrial planets can thus be reconciled by a mass loss of 15~25% crust of planetesimals.

Petrochemical and shock heterogeneity in Shergotty achondrite

ARINDAM DUTTA[1]*, GEOLOGICAL SURVEY OF INDIA (arindam.dutta@gsi.gov.in)
Anindya Bhattacharya[2], Geological Survey of India

Abstract

Shergotty achondrite was a meteorite fall near Shergotty town ($24^0 33' 00'' N$; $84^0 50' 00'' E$), Gaya district, Bihar, India on 25th August 1865 (09:00:00 Hrs.). In the scope of present study detailed petrochemical observation and shock calibration of Shergotty achondrite has been attempted to identify chemical and structural inhomogeneity at micro domain level. Shergotty achondrite consists of clinopyroxene + maskelynite + Fe – Ti oxides (titanomagnetite, ilmenite and magnetite), phosphates (apatite and merrillite) ± K-feldspar ± quartz (melt or glass). Clinopyroxene is the most abundant mineral in the Martian Shergotty meteorite with subequal content of maskelynite. Clinopyroxene consists grains of pigeonite and sub-calcic augite, both are strongly zoned. The core compositions of clinopyroxene (Wo11.2 - 36 En44.3 – 59.6 Fs19 – 29) differ significantly from Fe-rich rims (Wo13 - 23.6 En24 – 40.6 Fs46 – 58.7). The clinopyroxene in Shergotty contains K-feldspar inclusions, mostly sanidine in composition. The elemental distribution patterns (Ca, Fe, Mg and Si) within a single clinopyroxene grain show strong compositional zoning for Ca and Mg (gradually increase towards core), whereas Fe increases towards rim compared to core. The preservation of extreme chemical zoning in clinopyroxene indicates rapid cooling from basaltic magma as evident in X-ray mapping. Maskelynite formed after plagioclase varies in composition (labradorite to andesine) within the range of Ab44 – 52 An43.5 – 54 Or1 – 4.5. Preferential orientation of clinopyroxene and maskelynite is observed in Shergotty resembling an igneous texture. Numerous K-feldspar inclusions within clinopyroxene and titanomagnetite, and presence of silica grain (Si metal) at the interface of maskelynite – ilmenite suggest magmatic origin for Shergotty achondrite. Intense fracturing, undulose extinction and mosaicism in clinopyroxene suggest this achondrite is heavily shocked (S4-S5 Stage, $Stöffler\ et\ al.$ 1991), but not brecciated as evident from microstructure. For Shergotty achondrite, the clinopyroxene peak near 670 cm-1 varies from 658 – 669 cm-1, whereas the strong asymmetric peak near 1000 cm-1 shows considerable peak shifts from 990 – 1013 cm-1, resulted from characteristic compositional zoning of clinopyroxene coupled with structural disordering. Plagioclase itself is a sensitive indicator of shock and thermal history. Transformation of plagioclase into maskelynite and diaplectic glass with complete isotropization can testify peak shock pressures at ~ 25 – 34 GPa ($Stöffler\ et\ al.$ 1991).

Aluminium-Magnesium Ages of Evolved Achondrites

Zoltan VACI[1]*, Washington University in St. Louis (zoltanvaci@gmail.com)
Clive M. Jones[2], Washington University in St. Louis
David A. Fike[3], Washington University in St. Louis

Abstract

The oldest igneous rocks in the Solar System are evolved achondrites which originate from the crusts of unknown planetesimals. While on Earth, the formation of evolved rocks such as andesites, trachyandesites, and dacites requires plate tectonic processes and the interaction of volatiles such as water and CO2, it is unclear how such rocks form on small bodies in the early Solar System. While primary melting and differentiation of chondritic material by the decay of aluminium-26 can produce basaltic to andesitic compositions, the diversity of igneous material in the achondrite record, especially in trace element composition, precludes simple melting models and likely involves core formation and multiple melting episodes. The crystallization ages of evolved achondrites are important pieces of evidence for understanding the magmatic histories of early planetesimals.

The oldest igneous rock in the Solar System is currently Erg Chech 002, which has been dated using multiple radiochronometers. However, several other evolved meteorites such as Northwest Africa (NWA) 6698, NWA 11119, NWA 11575, Erg Atouila 001, and the Almahata Sitta trachyandesite clast ALM-A, have either not been dated or have only been dated using one method. As several different labs have been involved in dating these meteorites, generally using 26Al-26Mg, the possibility for age discrepancies exists between different samples. We have applied the 26Al-26Mg chronometer to many of these achondrites using a single instrument in order to find the crystallization ages for the undated samples and to resolve any discrepancies in crystallization ages due to any analytical heterogeneities between different laboratories.

To determine the crystallization ages of ungrouped evolved achondrites, we used a CAMECA 7f GEO ion microprobe to measure 27Al, 24Mg, 25Mg, and 26Mg. Linear isochrons were constructed by plotting 26Mg/24Mg against 27Al/24Mg, and ages were determined relative to the formation of calcium-aluminium inclusions (CAI) using the canonical initial Solar System value of $5.23 \pm 0.13 \times 10\text{-}5$. Instrumental mass fractionation effects were corrected in feldspar using a Miyake-Jima plagioclase standard and in pyroxene using a Norton County enstatite standard. Microprobe measurements adjacent to SIMS spots on standards were used to determine a relative sensitivity factor for 27Al/24Mg fractionation. All SIMS spots were pre-sputtered using a spot size of 20 μm to remove surface contamination and gold coating, after which analyses were performed using a spot size of 15 μm.

Our analyses confirm that Erg Chech 002 is the oldest igneous rock in the Solar System, with an age that falls in between a previous SIMS analysis and a measurement done by mineral separation and ICP-MS. We also find significant radiogenic 26Mg excesses in NWA 6698, 11119, and 11575, indicating that they all crystallized within the first few Ma of Solar System history. We

continue to measure the Al-Mg isotopic systematics of Erg Atouila 001 and additional ungrouped achondrites that represent the evolved crusts of planetesimals.

Maximizing the Value of Meteorite Data for Future Science

Kerstin Lehnert[1]*, Columbia University (lehnert@ldeo.columbia.edu)
Jennifer Mays[2], Columbia University, USA
Dominik Hezel[3], University of Frankfurt, Germany
Lucia Profeta[4], Columbia University, USA
Annika Johansson[5], Columbia University, USA
Peng Ji[6], Columbia University, USA
Griffin Danninger[7], Columbia University, USA
Juan David Figueroa[8], Columbia University, USA

Abstract

Meteorite specimens are among the most precious specimens we study in our labs, but the data generated by laboratory analysis of meteorites has not always been shared openly and remains difficult to access and reuse. Rigorous curation, archiving, and open dissemination of these data will be vital to maximize their utility and impact on science and society now and in the future, supporting new scientific inquiry and providing learning opportunities beyond the immediate research community working on meteorites for researchers, students, and instructors from other disciplines and the general public.

The Astromaterials Data System (Astromat) has been developed with funding from NASA since 2018 to preserve and provide access to data from astromaterials, including meteorites, and was recently designated as NASA's primary archive for laboratory analyses of astromaterials samples. Over the past 5 years, data for meteorites curated at the NASA Johnson Space Center, for lunar samples from the Apollo missions, and other astromaterials such as cosmic dust have been compiled into a searchable synthesis database that now contains over 1.3 million chemical measurements, including major and trace elements, and radiogenic and stable isotope ratios measured on bulk samples, minerals, and other components of astromaterials samples such as premolar grains and chondrules. The MetBase database of meteorite compositions merged with Astromat in 2023 and all MetBase data will become available as part of the Astromat synthesis in summer 2024. Currently underway are enhancements to Astromat's cloud infrastructure, data curation procedures and policies, and organizational structure to ensure standards-compliant, scalable, and adaptable archiving services for the widest range of lab analytical data including image data and spectra, and to fully support NASA's Scientific Information policy SPD-41A. Community engagement is a high priority to establish and promote best practices for FAIR lab analytical data of astromaterials samples. Beyond FAIR, Astromat will offer end-users access to FAIR-AR data through the Astromat Synthesis, a comprehensive, fully integrated, machine-readable, and analysis-ready (AR) data store allowing advanced data exploration and computational analysis (e.g. Machine Learning, Neural Network Analysis).

Chemical evidence for the melting of alkali feldspar in a lunar meteorite DEW 12007

Hyeong Gyu KIM[1]*, Department of Geoenvironmental Sciences, Kongju National University (kimhyeonggyu@kongju.ac.kr)
Changkun Park[2], Division of Earth Sciences, Korea Polar Research Institute
Hwayoung Kim[3], Division of Earth Sciences, Korea Polar Research Institute

Hyun Na Kim[5], Department of Geoenvironmental Sciences, Kongju National University

Abstract

Understanding the high-pressure shock events on lunar crustal materials is critical for interpreting the lunar geological history. Feldspar, which contains traces of impact metamorphism, is an abundant mineral in the lunar crustal igneous rocks. Amorphous feldspar in meteorite can be formed as a diaplectic glass by solid phase transitions under high-pressure, and also as a glass by melt-quenched process under high-temperature. The distinction between these two glass types has generally been based on the textural observations. However, as demonstrated by Kim et al. (2019), it can be resolved by chemical differences between the crystalline and glass phases of partially amorphized plagioclase grains. In this study, we investigated whether these chemical differences can also be applied to the formation of amorphous alkali feldspars in meteorite.

Using backscattered electron (BSE) imaging and Raman spectroscopy, we distinguish between crystalline and amorphous phases of alkali feldspar, providing insight into the amorphization mechanisms under shock metamorphism. The crystalline region contains the pronounced cracks, however, these are confined to the interior and do not lead into amorphous region, except for the large-scale fracture. The amorphous region has no fracture, which has a relatively dark gray with glassy surface. For detailed observation of changes in crystallinity and chemical composition, line analysis was performed using 2D mapping of Raman and WDS. In crystalline, which has a high Raman 283 cm-1 peak intensity, the content of Ca and Na is low and the content of K is high, while in amorphous region, which has a low 283 cm-1 peak intensity, the content of Ca and Na is relatively high and the content of K is low compared to crystalline. Quantitative analysis using EPMA shows that alkali feldspars have sanidine composition, with a wide range from Or81.7Ab17.6An0.7 (crystalline) to Or57.2Ab38.3An4.5 (amorphous). The crystalline region has a high Or and a low Ab component, and as we move into the amorphous region, the Or component decreases and the Ab component increases. These results confirm the causal relationship between crystallinity and chemical composition of shocked alkali feldspar, and the presence of amorphous phase feldspar formed by impact-induced partial melting in DEW12007.

Our study highlights the importance of integrating textural and compositional analyses to distinguish the formation processes of shocked feldspar in lunar meteorites. We envisage that the crystalline and amorphous alkali feldspar in lunar meteorites will be vital for estimating the detailed P-T conditions during shock metamorphism.

Experimental Method for Measuring Cohesion of Regolith via Electrostatic Lofting

Charles T Pett[1]*, University of Maryland at College Park (pett@umd.edu)
Christine M Hartzell[2], University of Maryland at College Park

Abstract

The hypothesized electrostatic lofting of individual regolith grains on the Moon and asteroids has been investigated extensively in laboratory studies. Cohesion may dominate how regolith behaves on these small, airless bodies, yet the magnitude of this force remains uncertain. We induce the electrostatic detachment of dust as a mechanism to break cohesive bonds between individual zirconia-silica microspheres in order to measure the interparticle cohesive force between them. A high-speed camera imaged centroid positions of the lofted microspheres over time. Using the centroids from the initial detachment, we numerically calculated initial accelerations to solve for the cohesion that had been restraining the microspheres. Unexpectedly, the electrostatic lofting of clumps of particles was observed and experimental results showed that clumps were a non-negligible portion of the lofted object population. We have demonstrated a new method for measuring interparticle cohesion by eliminating aeolian effects in vacuum and using electrostatic forces to break cohesive bonds. This experiment also quantified the electrostatic lofting of dust clumps formed from 200−300μm spherical particles in vacuum for the first time. Clumps comprised at least 8% and as much as 35% of the lofted objects, which included individual grains, in our six experimental runs. Within the lofted clump population, we observed that 2-grain clumps form most frequently. The average cohesive force and tensile strength for individual grains was 0.5 μN (STD = 0.2 μN) and 5.3 Pa (STD = 2.1 Pa). Similarly, cohesion and tensile strength for clumps was 1.1 μN (STD = 0.8 μN) and 10.7 Pa (STD = 8.1 Pa), respectively. The analysis of two independent methods for calculating cohesion based on cleanliness and particle weight yielded similar cohesion values. If electrostatic lofting does in fact occur in the low gravity fields on small, airless bodies and if cohesion is indeed a non-negligible force, then clumps may likely be a non-negligible component of the lofted object population. If clump lofting does in fact occur in situ, it could have significant implications for the evolution of small body surfaces. Should clump lofting occur, then electrostatic lofting events may remove more material than previously estimated. If clumps loft from asteroids, it could give insight into how cohesion scales with other forces on rubble pile asteroids. Moreover, quantifying cohesion may inform the conditions required for preferential formation and lofting of clumps rather than individual grains on asteroids. We have shown that a bulk structure will remain intact despite active surface movement, which agrees with current assessments of granular flows on asteroids. For future missions that may observe clump lofting in situ, we have shown that if the trajectory of these lofted objects can be resolved, then we can solve for interparticle cohesion as well as estimate the bulk cohesive properties of the parent body.

Ore prospecting in planetary analog using remote sensing data

Marta CIAZELA[1]*, Polish Academy of Sciences (marta.ciazela@twada.pan.pl)
Jakub Ciazela[2], Institute of Geological Sciences, Polish Academy of Sciences

Abstract

Large-scale ore exploration around the world is becoming more and more accessible thanks to high-quality satellite images. The aim of this research was a geological mapping in-situ and comparison with the results of the satellite images analysis of the Sierra Gorda open-pit mine located in the Atacama Desert in Chile. Sierra Gorda belongs to KGHM Polska Miedź S.A., and is one of the largest copper mines in the world. Geological mapping and remote sensing analyses were possible thanks to the lack of vegetation, the arid climate, and the rock outcrops in the mine and adjacent areas. The research focused on satellite images from the Sentinel-2A satellite due to their excellent spatial (10 m/pixel) and time resolution. Due to the lack of vegetation, arid climate, and diversified terrain, Sierra Gorda is treated as an analog for the Moon and Mars research.

In August 2023, we mapped a ~50 x 30 m test area adjacent to the Sierra Gorda mine in Chile, which is rich in rock outcrops with ore mineralization and its weathering products. Geological mapping was performed at regular points grid spaced 3 meters apart. The content of ore minerals in five randomly selected samples was assessed at 64 points. Among the minerals, sulfides (chalcocite, chalcopyrite, pyrite, sphalerite, and galena), oxides (hematite or magnetite), as well as other hydrothermal minerals such as goethite, jarosite, natrojarosite, alunite, copiapite, chrysocolla, atacamite, and nitrate were observed. The location of each measurement was recorded by GPS device with a measurement accuracy of 1–3 m and transformed into a digital map, to compare with remote-sensing data. This research allowed us to verify the remote spectral detection threshold of ore minerals in the field. Bands ratio (mathematical operations on the satellite channels) methods have been used to highlight the interesting geological features remotely: 1) B11/B4 – gossan; 2) B6/B8A – jarosite and hematite; 3) B11/B8A – ferric oxide rich rocks; 4) RGB Composition: R12 G11 B2; 5) Principal component analysis (PCA) –RGB: R1 G2 B3 and R6 G5 B4; 6) Fe silicate. On all resulting maps, the analyzed research area adjacent to the mine (without active mining) coincides in color with the area of the mine itself with active mining. Therefore, the presented method can be used at the stage of preliminary searching for ore minerals of large regions with sparse vegetation on Earth, as well as on the Moon, Mars and perhaps large asteroids, which are characterized by similar conditions.

Geological evidence reveals a staircase pattern in Earth’s rotational deceleration evolution

He HUANG[1]*, Chengdu University of Technology (huanghe@cudt.edu.cn)
Chao Ma[2], Chengdu University of Technology

Abstract

Astronomically forced climate change can be recorded in the sedimentary record. Conversely, such paleorecords can inform past dynamics of solar system and the related history of Earth rotation. Due to tidal dissipation, the Earth’s rotation has been decelerating, but the rates of this process are an ongoing subject of debate. Here we conduct a comprehensive cyclostratigraphic analysis of eight geological datasets to constrain the Earth's rotation history from the late Ediacaran to the early middle Triassic. Our results allow us to test theoretical physical tidal models, and support a suggested staircase pattern in the Earth’s rotation deceleration from 650-280 million-year-ago, thereby increasing the Earth-Moon distance by approximately 20,000 km and the length of solar day by approximately 2.2 hours. A high rate of Earth’s rotation deceleration from 650 to 500 million-year-ago can be attributed to an enhanced tidal resonance. By contrast, unusually low tidal dissipation from 500 to 350 million-year-ago led to a flatter trend in Earth’s rotation deceleration, this was followed by another high rate of Earth’s rotation deceleration from 350 to 280 million-year-ago. These changes in Earth’s rotation are linked to global tectonics and ocean tidal resonance. We speculate on the possible relationship between Earth's rotation and geological processes.

Astrochronology and cyclostratigraphic analysis of Ordovician-Silurian transition —— Case study from JY11-4 borehole in Yangtze Block, Southern China

Shang YUE[1]*, China University of Geosciences, Wuhan (yes@cug.egu.cn)
Chunju Huang[2], China University of Geosciences, Wuhan
Xuebin Du[3], China University of Geosciences, Wuhan
Ke Zhao[4], China University of Geosciences, Wuhan

Abstract

Ordovician-Silurian transition (OST) was an important period in the geological history where many global events happened. Precise astronomical timescale (ATS) provides a foundation for identifying and understanding the key Earth system processes during that period. The cyclostratigraphic analysis for establishing astronomical timescale and improving geological timescale (e.g., GTS2020) has been widely used especially in Cenozoic sedimentation. However, there is a lack of a complete and continuous time scale for the Late Ordovician Early Silurian, despite some scattered studies. Here, we provided a high-resolution grayscale data and gamma-ray logging data from JY11-4 borehole with complete stratigraphic records in Yangtze Block (Sichuan Basin, Southern China) to establish an 8.5 Myr floating ATS from the Late Ordovician to Early Silurian based on the 405-kyr long eccentricity cycle tuning. The results show that the duration of late Katian Wufeng Formation to Aeronian Lower Longmaxi Formation is 8.19 Myr. We further calculated the duration of the Hirnantian glaciation (0.141 Myr, Guanyinqiao Bed) and volcanic activity during OST (5.66 Myr from Wufeng Formation to Lower Longmaxi Formation) in Southern China, and found that the deposition of 42 volcanic ash beds were obviously constrained by orbital cycle. Our result is of great important for improving the timescale of Late Ordovician to Early Silurian and constraining the durations and rates for key geological events during OST.

Iron's Role in Astrobiology: The Significance of Ferrihydrite in Martian Habitability

Adomas VALANTINAS[1]*, Brown University (adomas_valantinas@brown.edu)
John F Mustard[2], Brown University

Abstract

Ferrihydrite, a poorly crystalline iron oxyhydroxide mineral, is found in several types of environments, from freshwater to marine systems, cool aquifers to hydrothermal springs, temperate soils, areas affected by mining, and in iron storage proteins of all living organisms. Multiple lines of evidence as well as our observations suggest that ferrihydrite is also abundant on Mars. This hints to a prevalence of wet and low-temperature weathering environment on ancient Mars.

Beyond the geological implications, the presence of ferrihydrite may be significant due to its potential role as a microbial energy source. During the formation of ferrihydrite from iron chloride salts free hydrogen is released, which could serve as an energy source for microbial life. The redox reactions associated with reduction of iron may also be used by microbes.

Moreover, on Earth ferrihydrite's interaction with microbial life is evidenced by its role in iron permineralization. Studies have shown that microbial mats containing cyanobacteria and other phototrophs can become encrusted and permineralized by ferrihydrite, leading to the preservation of cellular and morphological features. This process not only provides insights into ancient microbial life but also suggests a protective mechanism against harsh surface conditions, such as UV radiation, due to iron's UV-absorbing properties.

In addition, ferrihydrite's irregular structure and nanometer-scale crystal size creates a high surface area, which may be important for prebiotic chemistry. This property makes ferrihydrite a strong adsorbent of organic compounds, potentially concentrating biomolecules crucial for the emergence of life. The presence of adsorbed organics also has been shown to inhibit the transformation of ferrihydrite to more crystalline iron oxides phases, making it metastable.

In conclusion, the identification of ferrihydrite on Mars opens up new avenues for understanding the planet's astrobiological potential. Its potential role as an energy source, its participation in iron biogeochemical cycling, and its possible significance in prebiotic chemistry the necessity of studying iron oxides, alongside clays, to assess Martian habitability. The dust samples to be returned by NASA's Mars Sample Return (MSR) mission may contain ferrihydrite, which could illuminate past environmental conditions conducive to life, offering a deeper understanding of the prerequisites for habitability on rocky planets.

Development of Early Microbial Communities within Newly Emplaced Lava in Iceland: A 3-Year Fixed-site Time-series Study

Nathan Kelly Hadland[1]*, Lunar and Planetary Laboratory, University of Arizona (nkhadland@arizona.edu)
Solange Duhamel[2], Department of Molecular and Cellular Biology, University of Arizona
Christopher W Hamilton[3], Lunar and Planetary Laboratory, University of Arizona

Abstract

Newly emplaced lava flows are initially sterile because of their high temperature upon emplacement. Once cooled, they present microbial colonizers with significant challenges such as low nutrient availability, variable temperatures, oxidative stress, and ultraviolet radiation. Consequently, these lava rocks harbor extremely low biomass, and microorganisms likely require specialized adaptations to survive these environmental conditions.

Mars has abundant evidence of both volcanic and hydrological activity in the past, raising the question if volcanic terrains on Mars were habitable in the past. To explore the potential habitability of Mars-analog systems and life detection in low biomass systems, we investigated ecological dynamics of the 2021 Fagradalsfjall eruption site in Iceland. This site represents a young, low biomass terrain situated within an active aeolian environment. The event was a 6-month subaerial, effusive, basaltic eruption, followed by subsequent episodes in 2022 and 2023. Prior to and during the 2021 Fagradalsfall eruption, we collected soil and (later) lava samples on a ~weekly basis. Additionally, we collected bioaerosol, rain, and hot spring samples to identify microorganisms associated with the newly formed lava flow-field. We also sampled older lava flows nearby (e.g., <8000 years) to compare taxonomic diversity between young and older volcanic substrates.

Samples were fixed for cell counts or frozen at –80oC. Slurries of crushed lava and soil samples were incubated in nutrient-rich and nutrient-poor broths to isolate microorganisms in culture. DNA was extracted from lava using a modified method for low-biomass rock samples and then sequenced. Processing of the sequencing data included the calculation of relative amplicon sequence variant (ASV) abundance, estimates of alpha and beta diversity, dissimilarity patterns, and significance testing. We used the algorithm SourceTracker2 to search for common ASVs between potential source environments (e.g., soil, bioaerosol, rain, hot spring, old lava) and the new lava.

Fourteen strains were isolated in culture, including oligotrophic (Sphingomonas sp.) and thermophilic (Brevibacillus borstelensis) spore formers. Cell counts increased as a function of lava age, except in fumarole sites on the flow, which remained below the detection limit. Alpha diversity generally decreased as a function of lava age. On a Bray–Curtis dissimilarity matrix, lava clustered with aerosols. This trend was confirmed quantitatively with SourceTracker2, with aerosols sourcing up to 73% of sequences. One-year old samples comparatively had more ASVs sourced from old lava samples (up to 97%).

This study reports the establishment of a community, starting from a sterile material and evolving into an inhabited ecosystem. Microbial bioaerosols have been shown to have adaptations such as endospore formation and tolerance to oligotrophic conditions. These selection pressures are also faced by microorganisms in volcanic terrains and may explain why the isolates were endospore formers and could grow on nutrient poor broth. Furthermore, a large proportion of ASVs were sourced from the atmosphere, highlighting the importance of airborne microorganisms in colonizing volcanic substrates. Understanding the succession dynamics in low biomass basaltic rocks is a critical task in astrobiology to constrain the local habitability of such systems on other planets and to optimize life detection strategies.

Profiling the lipidome of microbial communities in Icelandic and Azorean lava tubes

Joleen M CSUKA[1]*, Columbia University (jmc2330@columbia.edu)
Nina Kopacz[2], Utrecht University
Oddur Vilhelmsson[3], University of Akureyri
Brent R Stockwell[4], Columbia University

Abstract

Reliable biosignatures and extra-terrestrial analogue environments on Earth are important in our search for life elsewhere in the universe. Often, however, these environments and the life that thrives in them are not fully understood. One such environment are lava tubes, typical of basaltic pahoehoe volcanic eruptions. Low-lying shield volcanoes can form lava tubes–hollow, cave-like structures that form as the surface of a basaltic lava flow cools and hardens and the lava inside continues to flow. The insides of lava tubes are isolated from the surface environment, leading to light deprived and oligotrophic conditions. Despite this, we find microbial life colonizing these caves.

Images taken by Mars Orbiters show features indicative of lava tubes across Mars. Collapsed lava tube roofs appear on the flanks of Elysium Mons, a shield volcano thought to have formed when Mars had a milder climate and was more hospitable to life. The surface of Mars, now harshly bombarded with ionizing radiation and frigid temperatures, has not yet offered evidence of organic life; however, the subsurface remains a protected environment in which signs of past or extant life may be found. Thus, lava tube environments hold strong potential as a vestige for any life that might exist on Mars.

We hypothesize that lipids may serve as a biosignature for life on other planets, as lipid biosynthesis is generally energetically demanding and lipids are not commonly formed through abiotic processes. Lipids often resist non-biological degradation, provide compartmentalization, and are important regulatory components required for extremophile survival in terrestrial environments. More specifically, we hypothesize that carotenoids are a class of stable lipids that confer protective functions to microbial life and could serve as useful and stable biosignatures.

We have determined the abundance of carotenoids, pigmented lipids, in Martian analog lava tube samples that have been carefully collected from several locations with lava tubes on Earth in effort to elucidate its potential role as a biosignature. Carotenoids are useful reactive oxygen species (ROS) scavengers, help maintain redox homeostasis under extreme conditions, and have been previously demonstrated to be found in a number of extremophiles. In our recently published paper, “A Study in Blue: Secondary Copper-Rich Minerals and Their Associated Bacterial Diversity in Icelandic Lava Tubes”, we measured carotenoid signals using Raman spectroscopy in a blue colored microbial sample. DNA analysis of that sample revealed many bacteria known for high metal resistance, which was expected for a sample containing such high copper concentrations, as well as known metabolic pathways leading to the synthesis of terpenoids and

carotenoids. Here we investigate new lava tube bacterial mat samples from the Azores, Portugal using liquid chromatography mass spectrometry to identify specific lipids and lipid metabolisms present in these extremophile environments.

GEOLOGIC MAPPING OF LUNAR PYROCLASTIC DEPOSITS IN SINUS AESTUUM, RIMA BODE, AND MARE VAPORUM

Catherine Weitz[1]*, Planetary Science Institute (weitz@psi.edu)
Daniel Berman[2], Planetary Science Institute
Scott Mest[3], Planetary Science Institute
Gareth Morgan[4], Planetary Science Institute
Lisa Gaddis[5], Lunar and Planetary Institute

Abstract

Lunar features classified as “dark mantle deposits" (DMDs) were initially identified based on their relatively low albedos, surface smoothness, mantling relationship to underlying terrain, and spectral absorption bands due to the presence of iron- and titanium-bearing volcanic glasses (herein called “pyroclastics”) produced from explosive volcanic eruptions. These pyroclastics vary in color and reflectance owing in part to differences in Fe and Ti content, and to differences in physical properties. Because all pyroclastic glasses were emplaced by volatile-rich explosive eruptions, they provide clues to the nature of the lunar interior and volcanism on the Moon.

To further understand the geologic context and distribution of pyroclastics within the larger DMDs, we are producing a USGS geologic map of the Moon at 1:1M scale from 18.5° W to 9.5° E and 0° N to 16° N on a WAC basemap, which includes the DMDs in Sinus Aestuum, Rima Bode, and Mare Vaporum. Multiple data sets were used to better refine the extent of pyroclastics for these three DMDs, identify and characterize plausible source vents for the DMDs, map and determine the compositions of the mare and highlands within the study region, perform crater counting to establish ages, explore the geologic setting and history of the mapping region, and attempt to characterize the eruption(s) that emplaced each DMD. An improved understanding of the distribution, composition, and eruption conditions that produced the pyroclastic deposits gained through stratigraphic, morphologic and mineralogic characterization has the potential to reveal important information about the thermal and volcanic history of the Moon.

We mapped forty-one different geologic units and divided them into four groups: (1) Crater Units, (2) Dark Mantle Deposit Units, (3) Mare Units, and (4) Highlands Units. All craters >5 km in diameter have been mapped and are identified in age as either Copernican (Cc), Eratosthenian (Ec), Imbrian (Ic), and Nectarian (Nc) based upon the characterization and extent of their rim and ejecta. Larger craters have been mapped into distinct units including their central peaks, smooth floors, rough floors, and crater rims. Crater statistics were used to establish absolute modeled ages of geologic units.

Eleven mare units were mapped based upon location and brightness, which is related to variations in TiO2 and FeO abundance. Units include several smaller dark mare, basin mare, highland mare, intermediate and disrupted mare, bright mare, and mixed brightness mare. Several previously unmapped/unknown small mare units were mapped in the highlands.

Fourteen highlands units were mapped based on roughness, topography, relative brightness, and presence or absence of lineations.

Five DMD units were mapped, including a localized DMD unit at Hyginus crater, a higlands mare DMD unit, a diffuse DMD unit, a thick DMD unit, and a thin DMD unit.
Surface features mapped include secondary craters and crater rays marked by bright ejecta predominantly from Copernicus crater, light-colored ejecta, high Ti+Fe ejecta, high Ti+Fe lavas, high Ti+Fe pyroclastics, and high Ti+Fe+spinel pyroclastics. Many linear features were mapped, such as sinuous volcanic rilles, wrinkle ridges, faults, scarps, volcanic cones, and grabens.

Late Drainage Along Samara Valles, West of Jones Crater, Margaritifer Terra, Mars

John A GRANT[1]*, Smithsonian Institution (grantj@si.edu)
Roodra Manogaran[2], Louisiana State University
Sharon Wilson[3], Smithsonian Institution

Abstract

Relatively pristine valley segments along medial-to-distal Samara Valles in Margaritifer Terra likely originate within the continuous ejecta west of the Late-Hesperian Jones impact crater. Valley expression between a ~46 km3 upper basin and a ~7 km3 lower basin is typically well-incised with smooth walls and a relatively uniform width-to-depth, but elsewhere varies from well-incised to diffuse and some segments appear anastomosing or truncate one another. Many are more than a kilometer across and 100s of meters deep and display interior terraces and depositional forms. More pristine segments continue north and are associated with finely layered, alternating dark- and light-toned deposits well beyond Jones ejecta. Basins are approximately bound by the -1275 m MOLA contour and the upper basin displays benches and partially filled craters near and below that elevation. Lower interior surfaces of the upper basin are not incised, expose relatively light-toned discontinuous deposits, include polygonal fractures, and are locally Mg/Fe phyllosilicate-bearing. We interpret the formation of the relatively pristine segments as the result of water from impact-melted ice in and under the Jones ejecta draining westward, with some filling the upper basin. Water accumulated over a period of months to years before overtopping the divide and draining at rates perhaps on order of 104 m3s-1 before filling and overwhelming the lower basin and breaching two additional local divides. Drainage persisted for a period of years at most and then ceased. If correct, our model indicates a geologically brief interval of transient potentially habitable environments relatively late in Mars history that was likely unrelated to global climate.

Enhanced bedrock weathering on Martian hillslopes with Recurring Slope Lineae (RSL)

Amit MUSHKIN[1]*, University of Washington (mushkin@uw.edu)
Aharon Adam[2], Geological Survey of Israel
Itai Haviv[3], Ben-Gurion University
Shimrit Maman[4], Ben-Gurion University
Dan G Blumberg[5], Ben-Gurion University

Abstract

Recurring Slope Lineae (RSL) are dynamic, low-albedo, slope-parallel surface features on Mars that typically occur on steep (>25°) slopes. RSL often display seasonal dynamics as they appear during late Martian spring, progressively grow during summer, and subsequently fade as summer ends. RSL formation mechanisms remain under debate with proposed mechanisms involving either water/brines ('wet theories') vs. dry granular flows within a surficial dust layer ('dry theories'). In an attempt to distinguish between plausible RSL mechanisms, this study examined morphologic and topographic proxies for rock weathering intensity on adjacent RSL vs. non-RSL hillslopes within three craters: Corozal (39°S, 159°E), Garni (12°S, 290°E) and Rauna (35°N, 328°E). We hypothesize that increased rock weathering intensity on RSL hillslopes would argue against the 'dry' RSL mechanisms as RSL dynamics within a thin dust layer are not expected to significantly impact bedrock weathering. In contrast, the presence of water or brines on RSL hillslopes could conceivably contribute to increased rock weathering rates. To test for variability in rock weathering intensity between RSL vs. non-RSL hillslopes we used HiRISE images to map the fracture characteristics of bedrock outcrops and HiRISE-CTX Digital Elevation Models (DEMs) to measure hillslope-scale variability in topographic attributes, such as slope distribution and curvature commonly examined in terrestrial settings. Our results revealed increased rock weathering intensity for RSL hillslopes at Corozal and Garni and no detectable differences in weathering intensity between RSL and non-RSL hillslopes at Rauna crater. Thus, slope morphologies on Mars appears to support a 'wet' formation mechanism for at least some of the RSL occurrences.

Open mineral identification from CRISM hyperspectral data using an ensemble of Support Vector Machines and Extreme Value Theory

Sandeepan DHOUNDIYAL[1]*, Indian Institute of Technology Bombay (sdhoundiyal@iitb.ac.in)
Alok Porwal[2], Indian Institute of Technology Bombay
Pattathal V. Arun[3], Indian Institute of Information Technology Sri City
Guneshwar Thangjam[4], National Institute of Science Technology and Education, NISER

Abstract

Hyperspectral data from the Compact Reconnaissance Imaging Spectrometer for Mars (CRISM) onboard the Mars Reconnaissance Orbiter (MRO) have been instrumental in advancing our understanding of Mars' geological history and habitability by enabling the identification and mapping of a wide variety of aqueous minerals. However, despite their utility, the CRISM image database (containing over 10,000 images) remains underutilized due to the significant manual intervention necessary in traditional methods of analysis.

Recently, machine learning-based methods have been developed to map minerals from CRISM data. However, these methods are limited by the need for complex pre-processing or manual feature selection. Furthermore, these algorithms are designed for closed-set mineral identification, which assumes that only the classes seen during training would be encountered during testing/mapping. This is a significant limitation, as a classifier needs to accurately detect samples from previously unseen classes ('outliers') to both mitigate false positives and facilitate the detection of previously unreported minerals on a planetary body.

Therefore, a novel method for identifying minerals from publicly available CRISM data under an open-set classification regime is proposed.

The proposed algorithm then uses an ensemble of Support Vector Machine (SVM) classifiers, each trained over a random subset of fifteen CRISM bands, to identify minerals under a closes-set regime. Thereafter, class-wise Weibull distributions (fitted over true positives from the validation set for which the ensemble had the least confidence) are used to predict the probability of an unknown spectrum belonging to an unknown class based on its average distance from the separating hyperplane (the decision boundary learnt by the SVMs).

This algorithm is tested over ~470,000 labelled spectra from the CRISM machine learning toolkit's mineral dataset where it returns an overall accuracy of 0.89, while effectively identifying outliers (F-score=0.74) when combined with a simple pre-processing pipeline.

The pre-processing consists of (i) denoising; (ii) continuum removal; and (iii) l2-normalization. It facilitates mineral identification by eliminating variance in the data due to illumination conditions and physical factors (such as abundance and grain size) while enhancing compositional information.

In its current iteration, the trained model can identify 22 minerals (including but not limited to olivine, pyroxenes, phyllosilicates, carbonates, and sulfates), and can be used to accurately map minerals from CRISM data. It may also be used to classify other hyperspectral datasets.

Terrestrial hot spring systems as repositories for biosignatures on Earth and Mars

Federica BARILARO[1]*, CNR-IGAG (federicabarilaro@gmail.com)
Andrea Di Capua[2], CNR-IGAG

Abstract

Whilst most of the research on the origins of life has essentially focused on submarine hydrothermal vents, terrestrial hot springs have recently designated as the cradle of life on Earth. Terrestrial hot spring water and environments are known for their ability to harbour microbial mat and biofilm of different morphology and pigmentation and fossilized microbial communities. Thus, due to the complex interaction existing between microbes and the environment, hot spring systems represent locations of planetary exploration and exobiological interests. The interpretation of Mars' early history reveals numerous parallels with the early stages of Earth. The Red Planet, in fact, retain clear evidence of terrestrial hydrothermal systems that provide a potential record of microbial life. It has been postulated that during the Noachian and Hesperian time hydrothermal systems on Mars were most massive and attained their maximum hospitable conditions. Therefore, understanding the mechanisms of mineral formation and diagenesis in these fascinating systems will provide important insight concerning the role of microbes in mineral nucleation and growth and their preservation potential in the fossil records. An interdisciplinary investigation on modern hot spring systems (Italy) have been performed. The unique occurrence of authigenic minerals in association with living microbial communities (including viruses) in the study areas, acted as classical natural laboratories providing the opportunity to evaluate bio-geochemical and physicochemical factors that have direct influence in mineral precipitation. Using traditional and new tools from a sedimentary, petrographic, geochemical, mineralogical and geomicrobiological perspective integrated with high resolution techniques, it was possible to unequivocally identify biotic and abiotic components, document the nucleation processes and growth of authigenic precipitates and define their morphological and textural features linked to biotic compounds. This investigation sheds light on a direct correlation between biological activities, the degradation of organic matter, and the precipitation of authigenic minerals within geological systems. Indeed, filamentous bacteria, virus-like particles and extracellular polymeric substances are the main sites where minerals nucleate and grow. The findings of this study have significant implications for the search for biosignatures on early Earth and Mars.

From Jezero Crater to Nili Planum: Tracing the Subsurface Life Potential on Mars

Adomas VALANTINAS[1]*, Brown University (adomas_valantinas@brown.edu)
John F. Mustard[2], Brown University
Valentin T. Bickel[3], University of Bern

Abstract

Jezero Crater, the landing site of the NASA Mars 2020 Perseverance rover, is a promising location for astrobiology research. It contains both a sedimentary record of a past lake and delta system, and its surrounding terrains a potential subsurface record of early Mars. The rover will collect and cache samples from the delta system, which may be returned to Earth in the future. However, these lacustrine samples may not capture the full diversity of possible life forms on Mars, especially if they were anaerobic and subsurface-dwelling. Subsurface life could have originated and survived on Mars before it became a frozen desert, and may have left traces in ancient rocks that are better preserved on Mars than on Earth. To complement the existing sedimentary rock samples and expand the habitable environments sampled, the rover must also explore geologic units in the rim of Jezero and outside the crater in Nili Planum. Fracture zones mineralized in the subsurface are one such promising habitat.

We used a deep learning method to map exhumed ridges on Mars, thought to be mineralized fracture zones, that have analogs on Earth and may indicate ancient hydrothermal activity and biosphere traces. Similar ridges are also found in Nili Planum, a region of old rocks that Perseverance could explore after leaving Jezero crater. We are investigating the mineralogy of the ridges with orbital data to evaluate their astrobiological relevance.

We used a public object detection model (Yolov5x CNN, PyTorch 1.7) to identify polygonal ridges on Mars from various CTX images. We ran the model on the CTX global mosaic, i.e., 86,546 images, using a reliable processing infrastructure and one NVIDIA RTX 3090 GPU (processing time of ~two months). Each detection was checked by a human, in context with the CTX mosaic. Multispectral CaSSIS data in the ridge sites were analyzed using ENVI software.

We detected more than 1,200 ridge clusters on Mars using global mapping, creating the first global and consistent catalog of polygonal ridges. We found several ridge hotspots in Gordii Dorsum, Arsia Mons, Meridiani Planum, Hellas Planitia, Nili Fossae and Nepenthes Mensae. Our detections in Nili Fossae agree with previous studies. The ridges in Nili Planum may be representative of a global process involving subsurface hydrothermal reactions that could have provided hydrogen for anaerobic bacteria.

The boxwork ridges in 3.5 Ga old rocks in the Pilbara Craton (Australia) have been suggested to

have formed in anoxic hot spring settings and may be a good analog for Mars. These ridges inside them include black chert veins that preserve microbialites and isotopic signatures consistent with the presence of life. Silica, the principal component of chert is a good preserver of biosignatures and therefore its presence (if confirmed) in the ridges in Nili Planum would raise significantly the astrobiological potential of the extended mission of Perseverance.

We plan to enhance mineralogical and morphological analyses by integrating CaSSIS, CRISM, and HiRISE data, and obtaining spectral measurements of terrestrial analogs using NASA's RELAB facility.

Abstract

Unraveling the true origin of an impact crater demands meticulous investigation and rigorous verification processes. This summary presentation of a remarkable 17 year journey undertaken by dedicated researchers who embarked on a quest to verify a suspected impact crater known as the Massive Australian Precambrian-Cambrian Impact Structure (MAPCIS), unraveling the fascinating complexities involved in the identification and confirmation of such geologic features. Utilizing a comprehensive approach, combining geological, geophysical, and remote sensing techniques, the research team meticulously examined the purported impact site along with the rigorous laboratory analysis of the rock collected samples. This presentation highlights the diverse methodologies and cutting-edge technologies employed during this extensive investigation. The researchers punctiliously analyzed shock metamorphism related mineralization, and geochemical and petrographic features that are characteristic of large comparable impact events such as Vredefort, Sudbury and Chicxulub. This presentation also discusses the challenges and setbacks faced during the verification process, such as distinguishing impact signatures from common terrestrial geological anomalies. Ultimately, the cumulative efforts of this multi-disciplinary team culminated in a conclusive determination regarding the authenticity of the suspected impact crater known as MAPCIS. Insights gained from this 17 year odyssey provide invaluable guidance to future researchers endeavoring to verify impact events and contribute to our understanding of Earth's history and the broader impact processes shaping the celestial bodies.

Mineralogy and chronology of Ca-phosphates in the lunar meteorite SaU_169

Xiaochao CHE[1]*, Beijing SHRIMP Centre, Institute of Geology, Chinese Academy of Geological Sciences (cxc@bjshrimp.cn)
Alexander Nemchin[2], Department of Applied Geology, Curtin University
Tao Long[3], Beijing SHRIMP Centre, Institute of Geology, Chinese Academy of Geological Sciences
Dunyi Liu[4], Beijing SHRIMP Centre, Institute of Geology, Chinese Academy of Geological Sciences
Wenxiao Peng[5], Beijing SHRIMP Centre, Institute of Geology, Chinese Academy of Geological Sciences
Yiyi Ban[6], Beijing SHRIMP Centre, Institute of Geology, Chinese Academy of Geological Sciences

Abstract

Introduction: Lunar meteorite SaU_169 is an extremely KREEP-rich sample, containing high concentrations of Th in impact melt breccia (32.7ppm) and regolith breccia (8.44ppm), and rich in U-rich minerals such as Zircons and Ca-phosphate. Previous Zircon U-Pb studies have shown identical main age peak, 3909±13, 3920±13 and 3921±3Ma, which can represent Imbrium basin-forming event. This study aims to discuss the Mineralogy and Chronology of the Ca-phosphate grains in SaU_169 to explore its more complex impact event information compared with zircons.
Analytical Methods: Ca-phosphates of SaU_169 were identified in the polished mount by SEM (Zeiss Merlin Compact) and EDS (Oxford X-MaxN150) in Beijing SHRIMP Center (SHRIMP Center), Institute of Geology, Chinese Academy of Geological Sciences, Beijing, with a beam current of 3.0nA and an accelerating voltage of 15kV. Ca-phosphate chemical compositions were analyzed using the Jeol JXA-8230 electron microprobe at the Shandong Institute of Geological Sciences, Jinan, with a beam size of 1-5μm and a current of 10-20nA, The measured elements include Si, Ca, P, Na, Mg, Fe, La, Ce, Pr, Nd, Sm, Gd, Y, S, F, Cl. Raman was analyzed using the Horiba LabRAM HR Evolution Raman spectrometer at the SHRIMP, with a 532 nm laser excitation system (Nd: YAG), ~1 μm laser spot size. The laser power was ~5mW. The spectra were obtained in the 200-1500 cm-1 range, with 1800 grooves/mm and 40 s counting times. The U-Pb ratios of Ca-phosphates were analyzed by the SHRIMP II at the SHRIMP Center. The primary beam spot size was 12-14μm with a current of 1.0-1.5nA. 175Ca2PO4+, 204Pb+, 204.3Background, 206Pb+, 207Pb+, 208Pb+, 238U+, 232ThO+, and 238UO+ were measured sequentially using an electron multiplier positioned on the axis. In this study, we also used the Leap 5000 XR Atom probe at the SHRIMP Center to analyze the element and isotope distribution in the nanoscale of the Ca-Phosphates.
Results: The Ca-phosphates in SaU_169 are composed of apatite and merrillite, ranging in size from 1 to 150 microns. The Raman spectra of apatite and merrillite indicate that their crystal structure was not significantly affected by impact events after 3.92 Ga, as the grains are well-crystallized. The merrillite has a high REE content compared with apatite, up to 1.17wt% La2O3, 2.48wt%, Ce2O3, 0.71wt% Pr2O3, 1.74wt% Nd2O3, 0.60wt% Sm2O3, and 0.74wt% Gd2O3,

3.0wt% Y2O3. The change of content of Fe in both apatite(0.27-2.78wt%) and merrillite(0.62-1.88wt%) is relatively significant, and the results of Atom probe tomography indicate the presence of Fe nano-inclusions in those minerals. Three types of Ca-phosphates exist poikilitic grains, independent mineral clasts, and intergrowths with Fe-Ni metal. Four different age groups can be distinguished, with a weighted mean age of 4010.0Ma from the intergrowths with Fe-Ni for the first group, 3951.1Ma for the second group, and the third and fourth age groups from poikilitic grains coinciding with the majority of data from the previous study. The upper intercept age of 3921.0Ma represents the age of the Imbrium basin, and the lower intercept age of 589±110Ma is associated with the L-type asteroid parent body breakup event.

Light noble gases characteristics in Chang'E-5 lunar soil

Junjie LI[1]*, Beijing Research Institute of Uranium Geology (564484480@163.com)
Ziying Li[2], Beijing Research Institute of Uranium Geology
Zhixin Huang[3], Beijing Research Institute of Uranium Geology
Ting Li[4], Beijing Research Institute of Uranium Geology
Dongfa Guo[5], Beijing Research Institute of Uranium Geology

Abstract

Noble gases in lunar soil have unique advantages to study the solar and cosmic ray interactions with the lunar surface and intensity, as well as the frequency history of impact events affecting regolith turnover and material transport processes. We reported the characteristics of the light noble gases He, Ne, and Ar in Chang'E-5 lunar soil. The relatively high 4He/36Ar and 20Ne/36Ar values not only showed that Chang'E-5 had typical mare terrain characteristics, but also indicated that the soil may not be mixed with the ejecta from highland rocks severely. The integrated exposure times to solar wind of the soil on the lunar surface were close to the upper limit of those of Apollo soils, proving that the Chang'E-5 soil was only minimally contaminated by sputtered material from nearby rocks. Trapped (40Ar/36Ar) tr values of the soil indicated that the soil was likely irradiated by the solar wind relatively late in lunar history, perhaps as late as 10 Ma ago.Trapped (3He/4He) tr and (20Ne/22Ne) tr values were less fractionated than those of Apollo soils, especially for ilmenite mineral which could well preserve He and Ne, the values were very close to those of solar wind, indicating the secondary process endured by the Chang'E-5 soil was not strong.

Mapping the Geology of Venus as an Engagement Tool for Undergraduate Planetary Science Research

Katherine Janet Boggs[1]*, Mount Royal University; Country Committee for IUGS (kboggs@mtroyal.ca)
Melvin Spear Chief[2], Mount Royal University
Jerry Demorcy[3], Mount Royal University
Ember Varga[4], Mount Royal University
Jess Hall[5], Mount Royal University
Holly Bley[6], Mount Royal University
Lara Trnski[7], Mount Royal University
Mercedes Rego[8], Mount Royal University
Lovleen Dhami[9], Mount Royal University
Richard Ernst[10], Carleton University
Hafida El Bilali[11], Carleton University
Jim Head[12], Brown University

Abstract

Mount Royal University (MRU) in Calgary, Canada is an undergraduate university with a Bachelor in Science Geology Major and no planetary geology courses. In Alberta, our geology programs need to include 29 courses from four groups, for students to obtain their professional geologist designation after graduation. There are 7 geology faculty with a maximum of 25 geology major students per year. We are restricted in the number of courses that we can deliver. Yet the MRU Venus Geological Mapping team has 25 undergraduate students (geology, general science, anthropology, environmental sciences majors) actively mapping quadrants within the Henie (V-58) Quadrangle in Southern Venus. This team was formed in response to student interest in planetary geology (e.g. Hall, Rego, Trnski) and thrives today because of our affiliation with the International Venus Research Group (IVRG) led by Ernst, El Bilali, and Head. The MRU team is very grateful for access to the incredibly valuable resources that have been compiled by the IVRG (webinars, papers, conference presentations). Collectively the MRU team has mapped one half of the Henie Quadrangle. Student projects nearing publication include studying the characteristics of lava canali (Demorcy), and confirming if Artemis (bordering the nw corner of Henie) is the largest tectonomagmatic feature in the Solar System (Bley). Projects in progress are constraining the dynamics of wrinkle ridges (Varga), characterizing tesserae (Hall, Tnski) and constraining the dynamics of coronae (Rego). Many students are recruited out of 1st and 2nd year geology courses. During year one (Y1) they learn about the geological features of Venus while mapping their first quadrant using ArcGIS and the NASA Magellan Mission data (e.g. Spear Chief, Rego, Trinka). During Y2/Y3 students refine hypothesis and present a poster usually at the MRU Faculty of Science and Technology research day. By Y3/Y4 the plan is for students to publish a peer-reviewed journal article (which is a work in progress). We plan to expand this to include local junior and high school students. “I (Boggs) find this program incredibly inspirational to coordinate as it brings great pleasure to witness the students learning and applying their skills as they unravel

the geological features in their quadrants." Demorcy joined the team because he is "passionate about planetary geology and believes in the power of education and outreach to inspire other students." Varga sees the importance of mapping the geology of Venus because "other planets provide a pathway towards understanding our own planet better." Five students (Bley, Demorcy, Dhami, Hall, Varga) went to the June 2023 Large Igneous Province Conference in Marrakesh, where Bley, Demorcy, Hall and Varga presented posters and talks. As the only undergraduate students at the conference they did exceptionally well. Bley and Hall mentioned that the Morocco trip was important for building their international networks of "not only colleagues, but friends that share the same passions." Bley also described the importance of these undergraduate research experiences for building confidence, while others spoke of enjoying the mentorship available within the MRU Venus geological mapping team (Trnski).

Platinum Group Element abundances and Re-Os isotopic composition of melt rock/breccia support the impact origin of the Simlipal structure, Singhbhum Craton, India

AJAY Kumar SINGH[1]*, CSIR-National Geophysical Research Institute, Hyderabad -500007 (India) (ajay23india@gmail.com)
Sung Hi Choi[2], Department of Geological Sciences, Chungnam National University, Daejeon 34134, South Korea
Dewashish Upadhyay[3], Department of Geology and Geophysics, Indian Institute of Technology (IIT) Kharagpur, 721302, India

Abstract

The Simlipal complex is a circular/semi-circular structure having a diameter of ca. 50 km at the eastern margin of the Singhbhum Craton in India. The structure coincides with an elliptical region of high gravity. The major rock types in the complex include quartzites, shale/phyllite, basalt/meta-basalt, and ultramafic rocks (dunite, harzburgite, picrite, gabbro). The complex is flanked by several granite-granophyre (Mayurbhanj granite) and ultramafic/gabbro/anorthosite along its periphery. In an earlier study, Singh et al. (2021) identified shock metamorphic features such as two/three sets of decorated/annealed planar deformation features (PDFs), crystallographically-controlled melting/amorphization along two or three planar directions, spall and concussion micro-fractures in quartz clasts, and the presence of coesite in melt breccia/melt rocks which suggests that the Simlipal structure maybe the remnant of an impact crater. In this study, we used highly siderophile element (HSE) and Re-Os isotope systematics to search for meteoritic component in breccia (SMP-77, 95A, 111) and melt rock (SMP-86B) of the complex. The concentration of moderately siderophile elements like Cr (9 ppm), Co (89 ppm), and Ni (2.6 ppm) in the melt rock is lower than those in the breccia (Cr = 610-1350 ppm, Co = 58-70 ppm, and Ni = 300-537 ppm). The Cr/Ni ratio of the impact melt rock (2.0-3.6) is higher than that of CI-chondrite (~0.26) and similar to the Upper Continental Crust (UCC ~2.0). The CI-chondrite-normalized HSE patterns show higher abundance of Ir, Os, Ru, Pt, and Pd in breccia and melt rock compared to the Mayurbhanj granophyre/gabbro and the UCC. The 187Os/188Os ratio of the breccia samples range from 0.3245 to 0.6670, while the melt rock has 187Os/188Os of 0.7647. The Mayurbhanj granophyre has comparatively radiogenic 187Os/188Os ratio of 1.4632, whereas an associated gabbro has exceptionally elevated 187Os/188Os ratio of 57.19. The lower 187Os/188Os ratios, coupled with elevated Os concentrations in the breccia and melt rock samples vis-à-vis the UCC or mafic and felsic lithologies in and around the Simlipal complex is strongly suggestive of the presence of a meteoritic component in these rocks. Two-component mixing calculations using 187Os/188Os composition of CI-chondrite and UCC shows the potential presence of up to 0.02 % impactor component in the breccia.

The application of ilmenite Crystal Size Distributions in experimental charges to understand the cooling rates of Apollo 11 basalts

Vanesa Mary MUÑIZ LLORÉNS[1]*, University of Notre Dame (vmunizll@nd.edu)
Clive R. Neal[2], University of Notre Dame
Cordula Haupt[3], Universität Münster
Stephan Klemme[4], Universität Münster

Abstract

In an attempt to quantify the cooling rates of Apollo 11 high-Ti basalts, we have combined experimental petrology and Crystal Size Distribution (CSD) methods. Based upon whole-rock analyses of the returned basalts, an equivalent Apollo 11 bulk composition was created and melted, then cooled at controlled temperatures (5°C/h, 10°C/h, 20°C/h & 30° C/h). These samples were created in the University of Munster's experimental petrology laboratory, where they were also photographed using a Back Scatter Electron (BSE). Ilmenite CSDs were constructed for each experimental charge. The steeper the slope of the CSD the faster the cooling rate is. The y-intercept of the CSD gives an indication of nucleation density, which depends on bulk composition.

The experimental charges had opposite sides cut and polished and BSE images of both sides were exported to Paintshop Pro, where each ilmenite crystal was traced and filled in. The crystal fills and the outline of the area studied were then exported to ImageJ that counts the number of crystals and that area. The minimum requirement for a statistically relevant ilmenite CSD is 250 crystals; our research far exceeds that with an average of 1000 crystals per charge. The resulting data were then exported to CSDSlice, which gave information about the crystal shape and 3-D habit. Finally, CSDCorrections was employed to convert 3-D data into 2-D graphs of the CSD profiles that contain crystal size (x-axis) and population density (y-axis).

The processing of BSE images results in one CSD profile for each cooling rate. Preliminary results show that CSDs at 5°C/h and 10°C/h exhibit the presence of crystals bigger than 1 mm and a concave up or slightly kinked graph. Charges at 20°C/h and 30°C/h show a high population density of crystals smaller than 0.5 mm and steep concave up graph. According to Marsh (1998), CSDs with concave up profiles indicate a non-linear cooling rate or textural coarsening. Kinked profiles indicate cooling at two distinct rates. Because the charges were cooled in a controlled environment, the steeper part of the profile is a result of the quench-cooling of any residual liquid after the experiment was concluded. As such, the quench-cooled parts of the CSD were omitted from determining CSD slopes and intercepts. These were obtained using >0.5 mm crystals for 5°C/h and 10°C/h and >0.1mm for 20°C/h and 30°C/h. The resulting slopes range from -1.39 to -17.49, while the intercept is less variable ranging from 3.34 to 11.07. As cooling rate increases, the ilmenite CSD profiles become progressively steeper. Comparison with the actual Apollo 11 basalt ilmenite CSDs show four samples cooled at rates of between 10˚C/h and 20˚C/h (cooled in the interior of thin flows or just beneath the top of thicker flows), and three samples cooled at

>30˚C/h indicating these samples were quenched cooled at the top of a lava flow.

Bridging Disciplines: A Feasibility Study on Integrating Mathematics and Geology in Education

Lujia PAN[1]*, Hebei Normal University (peter205834@hebtu.edu.cn)
Lujia PAN[2], Hebei Normal University

Abstract

This paper presents a comprehensive feasibility study on the integration of mathematics and geology within educational frameworks, aiming to explore the interdisciplinary teaching and learning opportunities that such a blend offers. The research is grounded in a multidisciplinary approach, combining qualitative and quantitative methodologies to assess the potential benefits, challenges, and strategies for effective curriculum development that synergizes mathematical theories with geological concepts. Through a systematic literature review, curriculum analysis, and case studies, this study identifies key areas where mathematical skills are essential for understanding and solving geological problems, such as in geochronology, sedimentology, and structural geology. Furthermore, it evaluates existing educational practices and student outcomes to propose a model curriculum that incorporates mathematical modeling, statistical analysis, and computational simulations within geology courses. The study also addresses pedagogical considerations, including teaching methodologies, learning materials development, and assessment techniques tailored to foster an interdisciplinary learning environment. By showcasing successful examples of interdisciplinary education from various institutions and providing guidelines for overcoming common barriers, this paper argues for the viability and necessity of integrating mathematics into geology education. It concludes that such integration not only enhances students' understanding and application of both disciplines but also prepares them for the challenges of modern scientific research and professional practice in geosciences. This work contributes to the ongoing dialogue on interdisciplinary education and offers a blueprint for educators and policymakers aiming to cultivate a more holistic and interconnected scientific curriculum.

Moreover, the research delves into the psychological and educational aspects of learning, examining how students perceive the relevance of mathematics to their geological studies and identifying factors that influence their engagement and motivation. Through surveys and interviews with students and educators, the study highlights the importance of contextual learning and the application of mathematics in real-world geological scenarios to enhance student comprehension and interest. It also considers the implications of such an interdisciplinary approach for educator training, emphasizing the need for professional development programs that equip teachers with the necessary skills to integrate these subjects effectively.

The feasibility study further explores technological advancements and digital tools that can facilitate the integration of mathematics and geology, including virtual reality simulations of geological formations, online databases for mathematical geoscience modeling, and interactive software for data analysis and visualization. These tools not only make the interdisciplinary

learning process more engaging and accessible but also reflect the evolving nature of both disciplines in the digital age.

In conclusion, the integration of mathematics and geology in education is not only feasible but also imperative for advancing our understanding of the Earth and its processes. This study provides a foundation for developing interdisciplinary curricula that bridge the gap between these disciplines, offering students a more comprehensive and applicable education. As the demands of scientific research and industry evolve, fostering such interdisciplinary approaches in education will be crucial for preparing the next generation of geoscientists and mathematicians to tackle the complex challenges of the future.

Magnetic Susceptibility Instrument for Magnetically Inhomogeneous Granular Mixtures

Charles T Pett[1]*, University of Maryland at College Park (pett@umd.edu)
Alexandra Pick-Aluas[2], University of Maryland at College Park
Meyer Taffel[3], University of Maryland at College Park
Cecily M Sunday[4], University of Maryland at College Park
Daniel P Lathrop[5], University of Maryland at College Park
Christine M Hartzell[6], University of Maryland at College Park

Abstract

A plethora of apparatus exist for measuring the magnetic susceptibility of solid, monolithic materials. However, most naturally-occurring terrestrial and extraterrestrial granular samples are polydisperse mixtures composed of different elements with different magnetic properties. Variations in magnetic permeability across granular mixtures make it challenging to understand their bulk magnetic properties, so the range of magnetic susceptibility values for such mixtures are poorly constrained. Inspired by recent asteroid sample return missions, a future close exploration of the metallic asteroid Psyche in 2029, and rejuvenated interest in lunar science, we designed a susceptibility instrument that could accurately probe a diverse catalog of magnetically, geometrically, and elementally irregular granular mixtures. Characterizing the magnetic susceptibility of samples on the Moon will help scientists understand the formation history of and space weathering effects on lunar regolith. Additionally, susceptibility measurements of lunar regolith will aid in the design of granular transport systems for future sample collection, excavation, and ISRU techniques since lunar regolith is magnetic (Oder, 1991; Liu et al., 2007; Kawamoto & Egawa, 2021). In this work, we introduce an electronically simple, affordable, and portable susceptibility instrument that can be made in-house with a lathe and commercial off-the-shelf electronics (Pett et al., Submitted Feb. 2024). The inductor coil (currently at TRL 4) can be submerged in a variety of granular mixtures in the lab or in-situ to quantify bulk inhomogeneous magnetic effects. The relative magnetic permeability of a sample affects the inductance of a coil. To exploit this phenomenon, we relate the permeability of the medium to the inductance of a solenoid coil of a specific radius and length, composed of N turns (Wheeler, 1942). Neither the inductance nor the permeability were known a priori so we obtain a separate value for the coil inductance experimentally. The measured angular frequency at which resonance occurs in the coil is a feature of the inductance and capacitance in an LRC circuit, which varies with material and volume fraction of mixture. We substitute the measured inductance into the equation for a solenoid to solve for the permeability of the medium relative to air. It follows that the permeability of the mixture relative to air less one gives the magnetic susceptibility. To make the coil, we wound motor winding wire on a lathe into a solenoid. We recorded values for the magnetic susceptibility of monodisperse mm-sized steel-brass (51200 Alloy Steel and 260 Brass) mixtures by submerging the coil in mixture. Then we compared our coil measurements to commercial Terraplus Inc. KT-10 meter readings and theoretical approximations (Bai et al., 2018) and report

similar trends, but interesting differences. Our instrument was validated by a measurement of the permeability of air to within 0.045% of the theoretical value and a susceptibility measurement of brass mixture equal to the Terraplus Inc. KT-10 reading. Our coil was then used in experiments by Sunday et al. (Submitted Feb. 2024) to describe the avalanching behavior of magnetic grains. The aim of future work will be to measure the susceptibility of lunar simulants inside a vacuum chamber.

COMPLEX MAGMA CHAMBER PROCESSES IN THE MOROKWENG IMPACT MELT SHEET, SOUTH AFRICA

SUMAN MONDAL[1]*, University of the Witwatersrand, Johannesburg (suman.mondal@wits.ac.za)
ROGER GIBSON[2], University of the Witwatersrand, Johannesburg
GRANT BYBEE[3], University of the Witwatersrand, Johannesburg

Abstract

The ~80 km diameter, 146 Ma, Morokweng Impact Structure (MIS) in northwest South Africa occurs in a region almost entirely covered by post-Cretaceous Kalahari sediments. Current models based on geophysical and borehole core data suggest that the central region of the MIS ~ 15 km from the center of the structure, is underlain by one of the largest impact melt sheets preserved on Earth that is also the only one known to preserve fragments of the original meteorite impactor. The M3 drill core, located approximately 14 km from the center of the structure, intersects 800 m of impact melt rock overlying Neoarchaean granitoid and amphibolitic gneisses. The melt sheet has an overall noritic composition and granophyric texture, with local complexity related to partially digested mineral and lithic clasts derived from granitoid, mafic (amphibolite, dolerite), ultramafic, clastic, and chemical sedimentary rocks, as well as the meteorite. It displays a fine-grained basal chill margin and clast-rich lower zone between 700 m and 872 m depth. The absence of an upper chill margin is attributed to post-impact erosion. Above 700 m depth, previous workers have noted a broad upward coarsening and decrease in mafic mineral content, which has been interpreted as evidence of fractionation processes in the melt sheet; however, apart from basic petrographic and major element geochemical analysis, specific details about the magma chamber processes have not been explored.

In this study, reconnaissance petrographic analysis of 10 samples from the melt sheet spanning depths of between 88 and 587 m have been combined with EPMA and LA-ICP-MS analysis of plagioclase and clinopyroxene crystals to explore crystallization processes in the upper parts of the melt sheet. Plagioclase shows normal zoning from An50-An10 at a depth of 465 meters. However, above 407 meters, plagioclase in all the samples shows oscillatory zoning, with cores from An50-An10 and overgrowth from An22-An2. As a result, simple geochemical modelling by Rayleigh fractionation cannot explain the geochemical variation, even though the core of the analysed grain may retain its primary composition. We incorporate incompatible trace elements in plagioclase and whole-rock geochemical data to understand the geochemical changes in the Morokweng melt sheet by using the trapped liquid shift effect model. By using this model, we can also explain the unusual Cr content in the clinopyroxenes, which shows an initial decrease of 200 meters, then a sharp and gradual increase of 500 meters, and finally, a sudden decrease below 500 meters.

The temperature distribution in the mantle of the Moon based on geophysical data and evolutionary model

Ekaterina KRONROD[1]*, Institute of Geochemistry and Analytical Chemistry (GEOKHI)
(e.kronrod@gmail.com)
Victor Kronrod[2], Institute of Geochemistry and Analytical Chemistry (GEOKHI)
Oleg Kuskov[3], Institute of Geochemistry and Analytical Chemistry (GEOKHI)

Abstract

Temperature distribution is a crucial factor in constructing models of the Moon's composition and internal structure. However, the temperature distribution within the lunar interior remains uncertain.

In this study thermal evolution of the Moon has been computed in this study from 500 million years to the present time. The Moon model is divided into layers according to geophysical constraints: crust, upper and lower mantle, low-velocity/viscosity zone (LVZ), and core. We numerically solved a one-dimensional non-stationary heat conduction equation, accounting for both conductive and convective heat transfer, as well as mantle heating due to radioactive decay. The physical properties of the mantle (density, thermal conductivity, heat generation) were determined using the chondritic model, taking into account the heat generation obtained for the magma ocean model. To enable partial melting within the LVZ, supplementary radioactive heat sources have been introduced, whereas there are no heat sources within the core.

The calculated temperature distribution results are in agreement with geophysical data and previous constraints on lunar temperature [Kuskov, Kronrod, 2009]. The obtained temperature profile is consistent with geophysical data and previous estimations of temperature distribution in the Moon, calculated from seismic data [Kuskov, Kronrod, 2009]. The viscosity value within the LVZ layer is 1.6 × 10^17 Pa s, which corresponds to the conditions of the existence of a low-viscosity layer at the mantle-core boundary, although it slightly exceeds the value of 3 × 10^16 determined by [Tan, Harada, 2021].

Decoding a complex geological record of the Yilgarn Craton using laterite iron crusts enriched with scandium

Daria LONGLEY[1]*, LMC (dasha@longleymining.com)

Abstract

Scandium deposits in lateritic weathering profiles represent an important potential source of scandium. Understanding the geological processes of its formation is crucial. Lateritic duricrusts occupy large areas of the Yilgarn Craton and reflect the global events associated with their occurrence.

It is traditionally believed that scandium deposits within lateritic weathering profiles occur as secondary minerals formed by the weathering of primary scandium-bearing minerals from ultramafic rocks. This implies that the duricrust is an integral part of the weathering profile. However, some scientific facts contradict the established opinion regarding the genetic connection of ferruginous crusts with the saprolite material of the weathering profiles. Firstly, the ages of ancient weathering profiles and ferruginous duricrusts are strikingly different. In Africa, the ages of ancient weathering profiles are Paleogene or Upper Cretaceous, and the ages of ferruginous duricrust are Miocene. Secondly, there are multiple instances of territorial discrepancy between ferruginous duricrusts and saprolites, when cuirasses lie directly on hard rocks and have unconformable relationships to the underlying materials. Thus, ferruginous duricrusts are not constituting the upper zone of the weathering profile, but rather represent later superimposed formations and must be considered as independent geological entities.

It has been observed that the epochs of formation of the iron crusts coincide with the moments when the solar system was in the spiral galactic arms, which also corresponds to the epochs of extinctions and bombardment of the Earth by cometary matter. Iron crusts in Africa appeared 22 million years ago, which coincides with the time of passage through the galactic arm. Iron crusts of the Yilgarn Craton were formed 66 million years ago (palaeomagnetic dating), which also coincides with the time of passage through the arm, and the Cretaceous-Paleogene big mass extinction.

During cometary bombardments a large amount of cosmic matter, enriched with chemical elements synthesized inside of stars, arrived on Earth. The cause of the Cretaceous-Paleogene crisis was most likely the result of a “shower” from cometary asteroids, which caused the initial influx of water, and subsequently, as a result of surface heating due to collision energy, local complete drying of water bodies and the formation of ferro-scandium crusts in their places. In the Yilgarn Craton Sentinel-2 imagery has proved to be a highly effective regolith mapping tool. Sentinel data, when spectrally enhanced, allowed the identification of crater-like structures and iron crusts.

Based on the galactocentric paradigm, a new hypothesis for the origin of iron-scandium crusts has been proposed. Iron-containing sediments (economically viable deposits) are mainly deposited during the epochs when the Sun enters the jet streams of the Galaxy. In addition to its scientific significance in understanding the formation of iron-scandium crusts, this study has a practical value for the methods of exploration and identification of scandium deposits in iron-scandium laterite crusts.

Joshua Ramos[5], GeoZentrum , University of Erlangen (FAU), Schlossgarten 5, Erlangen, Germany

Abstract

The Central Zone (CZ) of the Limpopo Belt in southern Africa is a complex high-grade metamorphic zone, which comprises three major high-grade metamorphic complexes with apparently distinct tectono-metamorphic evolutions: (1) The Beit Bridge Complex, (2) the Phikwe Complex, and (3) the Mahalapye Complex. Three metamorphic events, at 3.22 Ga (M1), 2.72–2.56 Ga (M2), and 2.02 Ga (M3) are recognized in the Beit Bridge Complex, whereby the long-lasting granulite-facies M2 event was interpreted by most authors to reflect the Neoarchean continental collision orogeny. The subsequent granulite-facies M3 event is interpreted to record either an intracontinental Paleoproterozoic transpressional orogeny or just a thermal overprint unrelated to regional deformation.

To better understand the geological evolution and poly-metamorphic history of the Paleoproterozoic Limpopo orogeny we present geological, petrological, and SHRIMP U-Pb zircon age data of high-grade metamorphic rocks from the Baines Drift and Phikwe Complexes. The narrow Baines Drift Complex occurs between the Phikwe and Beit Bridge Complexes. The Baines Drift and Phikwe Complexes constitute the north-western segments of the CZ for which the geology and P-T-t evolution are poorly understood. Detailed geological mapping (1:10.000) of the exposed transitional areas of the Beit Bridge, Phikwe, and Baines Drift Complexes in the area around Baines Drift revealed a N-NE-trending planar fabric and well-developed mineral lineations dipping moderately to the S-SE or N. The dominant deformation displays a large broadly NE-SW striking fold structure, reflecting NW-SE directed shortening, typical of the CZ. Locally NE-SW striking shear zones occur.

High-pressure (HP) granulite facies metamorphism and a clockwise P-T evolution for feldspar-free Grt-Opx-Crd-Oam gneisses of the Baines Drift Complex are constrained by pseudosection modelling, Grt-Opx thermometry, and quartz-in-garnet (QuiG) elastic barometry. The peak-metamorphic garnet-orthopyroxene-rutile-ilmenite-quartz assemblage formed at HP granulite-facies conditions of > 900°C and 14 kbar, followed by significant decompression still under granulite-facies conditions as recorded by conspicuous orthopyroxene-cordierite coronas around garnet. The widespread formation of orthoamphibole documents subsequent near-isobaric cooling

into the amphibolite-facies. Metamorphic zircon in the Grt-Opx-Crd-Oam gneiss yielded a precise SHRIMP U–Pb age of 2014 ± 8 Ma for the HP granulite-facies metamorphism in the Baines Drift Complex. The clockwise P-T path of the Baines Drift Complex resembles the similarly aged granulite-facies 2.02 Ga metamorphism in the Beit Bridge Complex that forms the main segment of the CZ. Thus, based on the zircon data we precisely determined crustal thickening reflected by the HP granulite-facies metamorphism during NW-SE-directed compression at ca. 2.02 Ma, interpreted to reflect the intracontinental Paleoproterozoic transpressional orogeny within the consolidated Kaapvaal-Zimbabwe Craton. SHRIMP U-Pb zircon data further indicate that the granitic magma of a charnockite sample from the Phikwe Complex intruded at 2586 ± 27 Ma, broadly synchronous with major granitoid emplacement in the Beit Bridge Complex. The similar structural-geological characteristics and the P-T evolution of the ca. 2.02 Ga metamorphism, and the comparable voluminous granitoid emplacement at ca. 2.6 Ga indicate a common evolution of the Baines Drift, Phikwe, and Beit Bridge Complexes in the CZ of the Limpopo Belt.

Kyanite trace element zoning as a tool for gaining insights into the petrological evolution of migmatites

Sara Nerone[1]*, University of Torino (sara.nerone@unito.it)
Chiara Groppo[2], University of Torino
Mónica Ágreda-López[3], University of Perugia
Maurizio Petrelli[4], University of Perugia
Franco Rolfo[5], University of Torino

Abstract

The variation in trace element concentration in kyanite has been recently investigated by several studies, highlighting its potentiality as a petrogenetic indicator in metapelites. Kyanite can contain significant amounts of Fe (thousands of ppm), Cr, Ti, V (hundreds of ppm) and other elements, displaying chemical zoning observable under cathodoluminescence (CL) microscopy. Changes in the CL colour intensity are visual indicators of chemical variability and textures that can be related to multiple episodes of growth and/or consumption of kyanite during metamorphism.

The role of kyanite as a petrogenetic indicator is especially important for constraining the evolution of anatectic metapelites, where kyanite can grow through: (i) metamorphic reactions at sub-solidus conditions (i.e., subsolidus Ky1), (ii) muscovite dehydration melting reaction (i.e., peritectic Ky2), and (iii) during cooling and melt crystallisation either through back-reactions between melt and solid phases (e.g., garnet, K-feldspar) or crystallising directly from the melt (i.e., back-reaction overgrowth or magmatic Ky3). A petrochemical study combined with phase equilibrium modelling performed on biotite + kyanite + garnet migmatites from the Lower-Greater Himalayan Sequence exposed in eastern Nepal Himalaya highlights a link between the trace elements chemical zoning of kyanite and the consumption vs. growth of the main minerals acting as reservoirs/sinks for those elements (e.g., muscovite, biotite, garnet), and ultimately to specific growth stages of kyanite (i.e., Ky1, Ky2, Ky3). The combination of petrochemical investigations (CL imaging + trace elements spot analyses and maps) and forward thermodynamic modelling is an indispensable tool for a reliable interpretation of the kyanite behaviour in anatectic rocks from collisional orogens. The complexity of kyanite porphyroblasts textures and their relation to its growth history can shed light on: (i) the prograde sub-solidus evolution of high-grade metamorphic terranes that could be otherwise obscured by partial melting; (ii) the anatectic processes, e.g. melt-producing reactions, melt segregation and extraction, chemical differentiation between melt and restite, melt crystallisation, and (iii) the behaviour of trace elements during anatexis.

H2O content variation in the metamorphic evolution of shear zones: a case from the Dora-Maira Massif (Western Alps)

Sara Nerone[1]*, University of Torino (sara.nerone@unito.it)
Alessandro Petroccia[2], University of Bologna
Fabiola Caso[3], Università degli Studi di Milano
Davide Dana[4], University of Torino
Andrea Maffeis[5], Università degli Studi di Milano-Bicocca

Abstract

When applying thermodynamic modelling to the investigation of metamorphic rocks, the choice between the modelling using H2O-saturated conditions or a fixed amount of H2O. During the prograde path of terranes, rocks are thought to experience only fluid loss, as dehydration reactions occur at increasing temperatures. In contrast, forward thermodynamic modelling of shear zones often considers fluid-present metamorphism to account for fluid availability. In these settings, the interplay between deformation and metamorphism is, in fact, mainly influenced by the access of fluids and fluid/rock interactions.

Here, we discuss the necessity of investigating the H2O evolution within shear zones, as H2O-saturated and -undersaturated conditions may be present at different times during the shear zone development. A thermodynamic modelling approach has been used in a case study, the Mt. Bracco Shear Zone (MBSZ). The MBSZ is an Alpine ductile tectonic contact that marks the boundary between two HP units, the polymetamorphic Ricordone Unit and the monometamorphic Sanfront-Pinerolo Unit, in the Dora-Maira Massif (Western Alps, Italy). The high strain zone of the shear zones displays a polyphase pressure (P) – temperature (T) history related to exhumation and a complex fluid regime evolution and its influence on the shear zone behaviour. After the eclogite-facies peak consistent with previous works, the subsequent mylonitic event is constrained at amphibolite-facies conditions, continuing its evolution at decreasing P and T during rock exhumation. The investigation of H2O content variation using forward thermodynamic modelling highlights the attainment of both H2O-saturated and -undersaturated conditions. After reaching a maximum H2O content during decompression with increasing temperature, a significant fluid gain is modelled before the mylonitic event. Then, the MBSZ evolves toward H2O-undersaturated conditions in a closed system. Furthermore, the difference in behaviour between the considered lithologies suggests that fluid evolution within shear zones could result from both externally and internally derived fluid flux. The MBSZ can be considered as a preferential pathway for fluid fluxes during exhumation but also determines a redistribution of the fluid.

Pre-Himalayan Metamorphism in the Lesser Himachal Himalaya: Insights from P-T pseudosection, U-Pb dating of zircon and monazite, and Sm-Nd garnet isochron

HIFZURRAHMAN -[1]*, WADIA INSTITUTE OF HIMALAYAN GEOLOGY (khan.hifz@gmail.com)
PRITAM NASIPURI[2], INDIAN INSTITUTE OF SCIENCE EDUCATION AND RESEARCH BHOPAL

Abstract

There is substantial evidence for post-collisional geological records associated with the India-Asia collision during the Cenozoic Era. The findings we made from the Wangtu gneissic complex (WGC) in Lesser Himachal Himalaya have revived the discussion over the existence of pre-Himalayan metamorphism. We studied the mineral chemistry and monazite geochronology of two metamorphic gneisses close to the Karcham granite intrusion, as well as the thermal effects of these granites on the adjacent Wangtu gneisses. The dating of zircon by the ID-TIMS method in two granite samples yields ages of 1872 ± 3 Ma and 1861 ± 13 Ma. Karcham granites exhibit similarities to porphyry-type granite, characterized by the presence of feldspar and quartz clasts, which are wrapped around by biotite and mica minerals. Monazite from the two metamorphic gneisses defines U-Th-Pb total chemical ages of 1900–1800 Ma, with partly more reset values down to 1400 Ma. The partial discordance of both zircon and monazite reflects the Cenozoic tectonics affecting the region.

The other pre-Himalayan metamorphic event is from the Jutogh Group of metasediments in WGC, where chlorite-mica schist, garnet-staurolite schist, and sillimanite-schist develop successively. The formation of chemically zoned garnet at 550 °C to 650 °C and 0.8 to 0.9 GPa, which destabilizes low-temperature assemblages, was predicted by phase equilibria modelling. The retrograde segment consists of exhumation and cooling, which results in a clockwise P-T route. Furthermore, textural observations and in-situ U-Th-Pb total chemical ages show that metasedimentary rocks contain Cambrian monazites. These monazites are around 500 Ma old. The ƐNd[1.8Ga] of Jutogh rocks ranges from -1.97 to -8.14, with depleted mantle-model periods between 3.07 and 2.25 Ga. The age of 472 Ma is determined by combining the isotopic composition of the garnet core and its leachates. A combined isotopic analysis of biotite, garnet rim, and garnet rim leachate yields an isochron age of 454 Ma. Phase equilibria modelling, garnet Sm-Nd isochron, U-Th-Pb monazite and zircon dating, and other evidences suggest that the WGC experienced metamorphism during Proterozoic Columbia assembly and Cambro-Ordovician accretion along the northeast margin of Gondwanaland.

Petrogenesis of Maneswar Complex, Rengali Province, India: Implications for tectono-metamorphic evolution along craton-mobile belt margin

PRIYA PACHAURI[1]*, Geological Survey of India (priyapachauri2610@gmail.com)
ABHINAV OM KINKER[2], Geological Survey of India
ASUTOSH KUMAR TRIPATHY[3], Geological Survey of India
FREDRICK RONALD KISPOTTA[4], Geological Survey of India

Abstract

The Rengali Province is a Neoarchean metamorphic terrane in eastern India sandwiched between Singhbhum Craton (SC) in the north, Bastar Craton (BC) in the west and Eastern Ghat Province (EGP) of Eastern Ghats Belt in the east. Maneswar Complex forms a structurally rigid gneiss-granulite complex exposed in the south-west trending arm of Rengali Province sandwiched between BC and EGP. It comprises charnockite, mafic granulite, and intrusive leucogneiss. Charnockite shows acidic to intermediate nature with opdalite-enderbitic composition. Mineralogically, it is composed of orthopyroxene (Wo1.17-3.35 En41.92-42.85 Fs53.81-56.70) ± clinopyroxene (Wo45.96-47.42 En28.66-31.45 Fs21.93-24.41), k-feldspar (Ab8.3-27.2 An0.1-0.6 Or72.1-91.6), plagioclase (Ab19.4-47.9 An50.9-80.1 Or0.3-1.1), ± garnet, ± biotite, hornblende, quartz, opaque, and zircon. It is metaluminous with calc-alkaline affinity. It shows ferron-magnesian character indicative of rift related environment setting. Coronal garnet formed at the interface between plagioclase and pyroxene denotes isobaric cooling after attainment of peak metamorphism. Mafic granulite is metaluminous and conforms to gabbroic composition. Mineralogically, it is composed of clinopyroxene (Wo31.217-47.68 En29.067-37.35 Fs15.86-32.39) + orthopyroxene (Wo0.814-1.5 En36.02-55.72 Fs43.46-62.91) + hornblende (XMg: 0.33-0.54) + plagioclase (Ab41.9-61.1 An36.8-57.1 Or1-1.8) + garnet (Alm60.35-67.71 Grs18.30-23.43 Py8.68-9.76) + biotite and quartz with apatite, zircon, and ilmenite as accessory mineral constituents. On field, mafic granulite show evidence of incipient melt generation in the form of small, irregular and disconnected patches and anastomosing veinlets of quartzo-feldspathic composition. In tectonic discrimination diagrams, it shows alkali basalt affinity and plot in Ocean Island Arc Tholeiites field. Leucogneiss is intrusive into both charnockite and mafic granulite. It comprises quartz, k-feldspar, and plagioclase with occasional biotite and garnet. It is sheared forming protomylonite to mylonite with strong down dip stretching lineations. It is acidic in composition and conforms to true granitic composition. It is metaluminous with calc-alkaline affinity. In tectonic discrimination diagrams, leucogneiss indicates emplacement in a syn-collision to post orogenic tectonic setting.

The high grade rocks comprising Maneswar Complex suggest a counter clockwise P-T path in metamorphic evolution of the terrain. This is depicted by peak granulite facies metamorphism followed by isobaric cooling. The rocks were then re-equilibrated to amphibolite facies of metamorphism represented by retrogradation of pyroxene to hornblende and biotite. The presence of garnet corona in mafic granulite and charnockite along with presence of decompression related

melt generation forming quartzo-feldspathic bands in mafic granulite suggest rapid upliftment/ exhumation of lower crustal portion. Our field, geochemical and petrological findings will thus help in understanding geo-dynamic processes occurring along craton-mobile belt margin and in comprehending tectonic evolution of Bastar craton.

Abstract

The ice free Larsemann Hills and adjacent areas in southern Prydz Bay have been recognized as an important juncture of the early Palaeozoic Pan-African (550–500 *Ma*) *high-grade tectonic mobile belt* (*the Prydz Belt*) *in East Antarctica. The geological expedition carried out for constraining tectono-metamorphic evolution of major Peninsulas from Larsemann Hills were mainly Grovnes Peninsula, Brattnevet Peninsula, Fisher island and Stinear Peninsula which represents signature of both Grenvillian and Pan-African orogeny. Grovnes Peninsula preserves low to medium pressure high temperature granulite facies metamorphism during early Palaeozoic* (~515 *Ma to* 530 *Ma*) *exposed in a* 900-490 *Ma deep crustal section. Prograde dehydration melting reactions inferred by inclusion assemblage of sillimanite in garnet and cordierite*; *amphibole in pyroxene, coronal orthopyroxene and clinopyroxene around amphibole and biotite which indicates prograde condition was well within sillimanite stability field. Peak condition estimated to be* 830±25*oC at* ~6.5 *kb for garnet pyroxene granulite and relatively lower P-T range of* 730±25*oC at* 5.5*kb for sillimanite-garnet-cordierite-spinel bearing gneiss. Retrogression defined by isothermal decompression* (*ITD*) *due to exhumation* (*uplift*) *after reaching peak* (*granulite facies*) *followed by isobaric cooling* (*IBC*) *to lower amphibolite facies conditions. Clock-wise evolution path is constrained. CHIME dating reveals prograde isobaric heating might have triggered at waning stage of Grenvillian Orogeny* (~850-900*Ma*), *where heat budget provided by process of crustal thinning. Process might continue up to* 600-550 *Ma to reach peak condition with high P-T sustained by crustal rejuvenation related to collision tectonics during Pan-African Orogeny. Post peak retrogression represented by ITD commenced at* 550 *Ma culminate at* ~490 *Ma through IBC. North* & *South Grovnes belongs to single cratonic block forming two limbs of plunging non-cylindrical fold. Adjacent Brattenevet Peninsula experienced M*1 *metamorphism* (*which is associated with D*1-*D*2) *around* 920 *Ma whereas M*2-*M*3 *occurred between* 530-480 *Ma. In Brattenevet M*2 *event represents peak metamorphism and M*3 *event is a decompression episode of Pan African orogeny* (*rapid uplift and development of*

decompression textures) and a clockwise a P-T path is inferred. There are only Pan-African ages which is obtained from Monazites from orthogneiss and that represents melt from the earlier granulite event (Grenvillian) then metamorphosed and deformed during Pan-African orogeny. The relict ages/older ages estimated in the inclusion monazite indicate Grenvillian metamorphic event. The older (637 Ma) core in monazite present in matrix indicate reset of older event (probably Grenvillian or ca.750 Ma). Similarly, adjascent Fisher island, experiences peak M2 metamorphism in garnetiferous gneiss is 835oC with a reference pressure of 6.5 Kb. For the pyroxene granulites peak P-T condition at M2 can be estimated as 870oC at reference 6.2 Kb whereas Opx-granite attained 865oC at 6.5 Kb and comparatively lower P-T range for the metapelite is estimated as 727oC at 6.0 Kb. The retrograde path is defined by the isothermal decompression due to exhumation (uplift) after reaching the peak (granulite facies) followed by isobaric cooling to lower amphibolite facies metamorphic conditions. Preliminarily, it can be assessed that evidences of Grenvillian and Pan-African ages obtained from in-situ monazites of Larsemann Hills can be constrained

[Keynote] Phase equilibria computations in Metamorphic Petrology- Applications and limitations

Somnath Dasgupta[1]*, Indian Statistical Institute Kolkata (somnathdasg@gmail.com)

Abstract

Readily available software packages for computing phase diagrams have been extensively used in Metamorphic Petrology for the last three decades. These software packages are regularly updated and have a robust scientific basis. They address major problems related to the stability of mineral assemblages, thermobaric computations, pressure-temperature (P-T) trajectory, prograde and retrograde paths of evolution, change in bulk composition due to fractionation of phases, mass transport, and others. P-T pseudosections are perhaps the most commonly used technique to decipher the P-T evolution of a specific bulk composition. All other properties of the system, such as equilibrium compositions and modal abundance of the phases at different P-T conditions and stability limits of varying mineral phases, are computed from the pseudosection. Therefore, the pseudosection calculation must be robust, and it is necessary to understand the uncertainty limits of the various inferences drawn from it. Several factors contribute to the uncertainties. These are:(a) choice of representative sample volume to compute bulk composition ;(b) estimation of volatile content if volatile-bearing phases are considered; (c¬) choice of thermodynamic database; and, (d) activity-compositional relationships for both the solid and fluid phases. All these factors should be carefully evaluated before constructing a pseudosection. We will demonstrate how these uncertainties may change the interpretations derived from pseudosection analysis. It is suggested that careful petrographic analysis, mineral chemical data, and conventional thermobarometry calculations should precede pseudosection analysis to obtain the relevant boundary conditions.

Comparing qualitative and quantitative isopleth thermobarometry based on garnet composition

Sara Nerone[1]*, University of Torino (sara.nerone@unito.it)
Pierre Lanari[2], University of Bern
Jacob Benedict Forshaw[3], University of Bern
Chiara Groppo[4], University of Torino
Franco Rolfo[5], University of Torino

Abstract

In modern metamorphic petrology, forward thermodynamic modelling is a common tool for determining the pressure (P) and temperature (T) conditions of mineral formations based on a given bulk composition (X). Mineral compositional isopleths can be used to further refine P–T conditions, known as isopleth thermobarometry. For example, the molar amount of Fe, Mg, Mn, and Ca in garnet is P–T–X dependent; therefore, the observed composition of garnet can be compared to modelled garnet compositional isopleths in order to aid P–T determination. Traditionally, isopleth thermobarometry involves manually tracing the field of maximum isopleth overlap, which can be considered a qualitative method. However, in the last decade, several software solutions have provided more quantitative approaches to calculate the 'optimal' P–T conditions from a statistical point of view, resulting in a more accurate interpretation of forward model results.

This study compares the P–T conditions of garnet formation constrained by the traditional qualitative isopleth thermobarometry approach with those obtained by quantitative methods. Garnet-bearing two-mica schists from the Lesser Himalayan Sequence (LHS) of the Nepal Himalaya are used as a case study. Three different quantitative approaches were tested: (i) a least squares approach, which minimises the difference between the observed and modelled values, referred to as the residue; (ii) a weighted least squares approach, which adds a weighting factor based on the analytical uncertainty; and (iii) a quality factor approach, which assesses the quality of fit between the modelled and the observed compositions. The contents of Fe, Mg, Mn, and Ca in garnet were all considered in the calculation. The results show that using quantitative techniques allows the relative uncertainties in P–T estimates to be considered, especially when the uncertainties in mineral compositions are propagated. Further investigation tests the influence of variations in the calculated bulk rock composition on the model prediction and, hence, on both qualitatively and quantitatively determined P–T conditions.

Phase equilibria and advanced thermobarometric modellings of Paleoproterozoic metapelites of NW Himalaya, India: Implication for its linkage with the Aravalli Supergroup

BIRAJA PRASAD DAS[1]*, DHARANIDHAR UNIVERSITY (birajageology@gmail.com)
Mallickarjun Joshi[2], Banaras Hindu University
Shubham Patel[3], Banaras Hindu University

Abstract

We present here the outputs of petrochemistry, conventional thermobarometry along with Perple_X phase section modelling, and advanced MATLAB based High-resolution garnet P-T path results to the metapelites of Askot Klippe particularly to look for their textural and mineralogical characteristics along with P-T conditions of metamorphism. Askot Klippe in the northwestern Himalaya is one among many detached erosional remnants of an extensive thrust sheet that was extruded from the Higher Himalaya in response to the Cenozoic continental collision. The klippe comprises granitic gneisses of the Ramgarh Group overlain by the metapelitic Almora Group. The Almora Group comprises garnet-cordierite- sillimanite-K-feldspar bearing metapelitic gneisses that are exposed in central parts of the Klippe in a south-verging overturned antiform flanked by successively lower grade schists. We employ multiple pressure-temperature (P-T) path modellings to deduce the tectono-thermal conditions of the klippe. High resolution garnet-based PT path modelling using Theriak-Domino and classical conventional thermobarometric approach are used for the metapelitic schists and gneisses to compare the results. Our results suggest that the metamorphism in rocks of the Askot Klippe exceeded upper amphibolite facies conditions (770oC/6.5 kbar). Comparable litho-tectonic set up, metamorphism, structure, and available dates of ~1830 Ma for the metapelitic gneisses of the Askot Klippe and Almora Nappe suggest that both are Paleoproterozoic and overstepped amphibolite facies P-T conditions. Similarities in metamorphic grades and the dates of metamorphic rocks of Kumaun to the Aravalli rocks together with the relict Aravalli trends in Kumaun Himalaya indicate the metamorphic rocks of Kumaun to be the possible reworked northernmost extensions of the Aravalli rocks.

Abstract

The study area is in the eastern segment of the Benin-Nigerian Shield and underlain by the Nigerian Precambrian basement complex rocks. This metamorphic basement serves as the eastern demarcation of the Trans-Saharan Orogenic Belt (TSOB) within the broader Benin-Nigerian Shield. It consist of migmatitic gneisses and schists, granitoids, metagabbros, metadolerites, meta ultramafic rocks and meta quartz diorites. We present new petrological data and P-T conditions of regional metamorphism in the framework of the evolution of the Trans Saharan Orogenic belt. The migmatized pelitic schist exhibits prominent peak mineral assemblage, comprising plagioclase + quartz + K-feldpar + biotite + garnet + sillimanite + rutile and liquid. Through geochemistry and phase equilibria modelling, the peak metamorphic conditions have been constrained between 900 and 940 °C at a pressure of 7–10 kbar. Furthermore, retrograde conditions have been deduced based on an assemblage of plagioclase, quartz, muscovite, biotite, cordierite, rutile, and sillimanite, with pressure-temperature estimates ranging from 2.2 kbar/642 °C to 3.8 kbar/800 °C. The findings of this research represent the initial substantiation of granulite-facies metamorphism in the southeastern part of the Benin-Nigerian Shield. The identified P-T path implies a geological context characterized by continent-continent collision, indicative of the region's evolution in connection with the subsequent development of the Trans-Saharan Orogenic Belt.

Metamorphic P-T paths and timing of garnet-mica schists from the Mianlüe Tectonic Zone: Insight into the early Mesozoic collisional thickening of the South Qinling orogen, Central China

Sang Wan PAK[1]*, Northwest University (flyingwing44@icloud.com)
Xiao Ying Liao[2], Northwest University
liang liu[3], Northwest University

Abstract

The Mianlüe Tectonic Zone (MTZ), marking the boundary between the South and North Qinling, is a pivotal area for understanding the tectonic evolution of the Qinling orogenic belt. This study, through detailed petrography, mineral chemistry, phase equilibria modeling, and zircon U-Pb dating, aims to investigate the metamorphic P-T-t path of two metapelites within the MTZ. Results show that, before reaching the peak stage, temperatures ranged from 510°C to 530°C with pressures between 4.0 and 6.1 kbar, displaying a peak pressure metamorphic mineral assemblage indicative of amphibolite facies conditions with temperatures from 580°C to 595°C and pressures from 9.2 kbar to over 10.1 kbar. Peak temperature conditions ranged from 625°C to 660°C with pressures between 6.0 and 6.8 kbar. Retrograde metamorphism was observed, with temperatures and pressures measured at 575°C to 600°C and 2.0 kbar to 5.0 kbar, respectively. These stages form a clockwise P-T evolutionary trajectory, reflecting an initial increase in temperature followed by a subsequent decrease in both temperature and pressure. Zircon U-Pb ages indicate that the protolith ages fall between 700~950 Ma and 1051 ± 120 Ma, with peak metamorphism occurring at 236 ± 20 Ma and retrograde metamorphism at 208 ± 18 Ma and 208 ± 5.3 Ma, aligning with the late Triassic continental collision processes in the MTZ. Furthermore, the discovery of Neoproterozoic ages for the protoliths of high-pressure rocks challenges previous interpretations that the Mianlüe tectonic belt was primarily associated with oceanic crust subduction, suggesting instead a complex zone of plate-shaped ophiolite and tectonic mixed rocks. It has been determined that the Mianlüe Ocean opened in the Middle Devonian, reached its expansion peak during the Carboniferous-Permian period, and finally closed in the early to middle Triassic. However, recent years have yielded a significant amount of Neoproterozoic age data from representative ophiolite sections in this structural belt, indicating earlier subduction events and underscoring the role of the MTZ in the broader tectonic evolution of the South Qinling belt. This study offers critical insights into the formation and evolution of collisional orogens, emphasizing the significance of high-grade metamorphism as a record of orogenic processes.

P-T pseudosection and garnet diffusion modeling of phengite eclogite from Yuka terrane, North Qaidam

Rong-Guo Hu[1]*, College of Earth Sciences,Guilin University of Technology (hurongguo@glut.edu.cn)
Zhong-Tian Hu[2], College of Earth Sciences,Guilin University of Technology
Xi-Jun Liu[3], College of Earth Sciences, Guilin University of Technology

Abstract

Eclogitic facies meta-mafic and -pelitic rocks are widespread crop out in the Yuka terrane, the north Qaidam Orogen, NW China. In order to evaluate their P–T metamorphic evolution and uplift/exhumation rates and mechanisms, detailed petrographic observation, mineral chemistry, P–T pseudosections and garnet diffusion modeling are performed on a phengite eclogite from this terrane. The phengite eclogite consists mainly of garnet, clinopyroxene, amphibole, phengite, quartz, and minor rutile, titanite, apatite, epidote, plagioclase and biotite. Based on microstructural observations, mineral relationships and different garnet domains, five metamorphic stages and related mineral assemblages have been recognized: M0) GrtC + Omp0 + Amp0 + Ph0 + Rt + Qz; M1) GrtM + Omp0 + Amp0 + Ph0 +Ttn + Qz; M2) GrtIR + Omp1 + Ph1-1 + Rt + Qz/Ceo; M3) GrtOR + Omp2 + Ph1-2 + Rt + Qz; M4) Cpx1/2 + Pl1/2 ± Amp1/2 ± Qz. The prograde stages of M0 and M1 conditions are recorded by garnet core and mantle domains, as well as minerals inclusions preserved in these domains, which are constrained at P–T conditions of ~575°C and 24.6~25.4 kbar, ~585°C and 22.5~23.1 kbar, respectively. The peak eclogite-facies metamorphic condition (M2) is represented by garnet inner rim domain and phengite core domain, which can be constrained at P–T conditions of ~600°C and ~28.6 kbar. The initial retrograde metamorphic condition (M3) at ~615°C and 25.1~25.5 kbar is marked by garnet outer rim domain and phengite mantle domain. During the subsequent exhumation, the eclogite underwent variable developed amphibolite-facies retrogression and experienced significant cooling to nearly 580°C, recorded by the breakdown of garnet and omphacite and the appearance of Cpx1/2 + Pl1/2 ± Amp1/2 ± Qz (M4) symplectite. The P-T path suggests that the phengite eclogite underwent at least two burial-exhumation cycles. The forward diffusion modeling further reveals the second exhumation process from ca. 92 km to ca. 81 km lasted only ca. 3 Myr, revealing an exhumation rate of ca. 4 mm/yr. We posit that the convective flow in the subduction channel is probably the most reasonable incentive for the first pressure reversal and uplift scenario. In contrast, the second pressure decompression and relatively fast exhumation process after the peak metamorphism could most likely be triggered by buoyancy forces with the assistance of channel flow due to slab rollback or oceanic crust breakdown.

The contribution of serpentinite to crust-mantle interaction and arc magma formation in subduction zones

Yi-Xiang CHEN[1]*, School of Earth and Space Sciences, University of Science and Technology of China, Hefei, 230026, China (yxchen07@ustc.edu.cn)

Abstract

Serpentinites play an important role in crust-mantle interaction and arc magma formation in subduction zones. However, it is usually difficult to trace the serpentinite signature in deeply subducted crustal rocks or in arc magmas. Therefore, we need to develop effective geochemical tracers to address this issue. Boron and Mg isotope compositions have increasingly used to track the effect of serpentinite derived fluids in crust-mantle interaction. This is because serpentinite derived fluids have been documented to show high Mg-B contents and heavy Mg-B isotope compositions even at subarc depths, which are distinct from fluids released from AOC and sediments. In this talk, I will introduce our work on Mg-B isotope studies of fluid-metasomatized rocks from the western and eastern Alps, as well as the South Sandwich island arc magmas. We show that the greatly elevated Mg and B isotope compositions in the fluid metasomatized rocks formed at forearc to subarc depths of Alps can be unambiguously ascribed to the infiltration of fluids derived from serpentinites. In addition, by integrated Mg-B isotope analyses of South Sandwich island arc magmas, we find that they show the heaviest Mg and B isotope compositions among worldwide arc magmas. This unique signature can be attributed to a serpentinite component. However, by combined Mg-B isotope compositions, we propose that the traditional model, i.e., fluid-flux melting of mantle wedge cannot explain simultaneously the Mg and B isotope composition of the arc magma. Instead, the origin of the unique geochemical composition of the arc magma can be explained well by partial melting of serpentinite mélange in subduction zones.

Magnesium isotope constraints on the role of recycled carbonate-rich sediments in the formation of ultrapotassic magmatic rocks at a continental arc setting

chen yu[1]*, University of Science and Technology of China (chenyu123@mail.ustc.edu.cn)
Chen yi xiang[2], University of Science and Technology of China

Abstract

The formation process of orogenic ultrapotassic magmatic rocks, especially the role of carbonate metasomatism in the mantle source at an oceanic subduction setting, is still unclear. To address this problem, whole-rock Mg-Sr-Nd isotope compositions were measured for ultrapotassic magmatic rocks from the Central Pontides arc, northern Turkey. These ultrapotassic rocks have relatively low (87Sr/86Sr)i of 0.70461-0.70687 and εNd(t) values mostly of 0.3 to 2.6. Such rocks display δ26Mg values, much lower than the normal mantle values. The petrological and geochemical results indicate that the low δ26Mg values do not result from surficial weathering, diffusion or magmatic differentiation, but instead reflect the distinct Mg isotope compositions of the mantle source. The geochemistry features suggest that the low δ26Mg values cannot originate from the recycled carbonated eclogites. Instead, such a signature is probably induced by the contribution of carbonate-rich sediments to the mantle source. Using two end-member mixing of Mg-Sr isotope compositions, the mantle source of the ultrapotassic rocks is constrained to contain various proportions of carbonates, mostly dolomite. Based on the carbonate stability field and trace element compositions, the ultrapotassic rocks were possibly produced at depths of 100~150 km. In this regard, the enrichment of K and other large ion lithophile elements in the ultrapotassic rocks can be induced by the contribution of silicic sediments. Meanwhile, carbonatitic melts can be formed through partial melting of carbonate-rich sediments in the subducting oceanic slab, which then react with the overlying mantle to form carbonated peridotite that serves as the source of ultrapotassic rocks with low-δ26Mg, low-silica, and high-LREEs. This study reports for the first time the Mg isotope data of ultrapotassic rocks formed in a continental arc setting and documents that carbonate-rich sediments play an important role in the formation of such rocks. Future work is needed to test if this process is common at both oceanic arc and continental arc settings.

Supercritical fluids in subduction zones and their geochemical effects

Ren-Xu Chen[1]*, University of Science and Technology of China (chenrx@ustc.edu.cn)
Tie-Nan Chen[2], University of Science and Technology of China

Abstract

Supercritical fluids are ideal media for mass transfer from the subducting slab into the mantle wedge because of their high solubility of elements but low viscosity. Studying supercritical fluids is important for understanding the processes and mechanisms of crust–mantle interactions, the compositions of arc magmas, and the recycling of crustal material at convergent plate boundaries. We carried out geochronology, petrology, and geochemistry on a coesite-bearing eclogitic vein and its surrounding eclogites from the Dabie orogen. The results are used to reveal the composition and source of supercritical fluids, the P–T conditions and timing of their formation and their geochemical effects in subduction zones. The eclogitic vein is composed of garnet, omphacite, quartz, amphibole, rutile and apatite, with minor amounts of epidote, plagioclase and zircon. Coesite was identified in omphacite in the vein, demonstrating its formation under ultrahigh-pressure (UHP) metamorphic conditions that correspond to subarc depths in oceanic subduction zones. Zircon and rutile U–Pb dating yields ages of ca. 220 Ma, consistent with their crystallization at the UHP eclogite facies. Multiphase crystal inclusions (such as omphacite, quartz, epidote, apatite, amphibole, plagioclase, mica, rutile, calcite, and anhydrite) as well as liquid and gas phases of H2O were observed in the vein. The mineral element and isotope compositions of the vein and its host eclogites suggest that the vein was formed by supercritical fluids derived from dehydration of the eclogite. The fluid was recovered to have a composition of 31 wt.% SiO2, 20 wt.% CaO, 10 wt.% (SO4)2-, 8 wt.% (CO3)2-, 8 wt.% FeO, 7 wt.% Al2O3, and 9 wt.% H2O, with traces of Na2O, K2O and TiO2. The dehydration of subducting eclogites at subarc depths can produce supercritical fluids with suprachondritic Nb/Ta ratios. The UHP eclogites and mantle wedge peridotites metasomatized by supercritical fluids can acquire suprachondritic Nb/Ta ratios and thus provide a complementary reservoir to balance subchondritic reservoirs on Earth. The supercritical fluids are oxidizing and can oxidize the metasomatized rocks. The supercritical fluids are thus efficient carriers of oxidized components from the slab to the mantle wedge, eventually contributing to the oxidization of the arc magma source. The vein has heavier Fe-Mg isotopic compositions compared to the eclogites. The metasomatism of supercritical fluid causes the elevation of δ56Fe and δ26Mg values in garnet and omphacite in eclogites, suggesting that the supercritical fluids have higher δ56Fe (0.34-049‰) and δ26Mg (0.30-037‰) values than aqueous solutions and hydrous melts. Theoretical modeling suggests that supercritical fluid canstrongly influences the Fe isotopic composition of mantle wedge peridotite and thus can explain the Fe isotope variation in some arc magmatic rocks.

The processes of serpentinization in subduction zones: Reaction rates and hydrogen (H2) generation

Ruifang HUANG[1]*, South China Sea Institute of Oceanology, Chinese Academy of Sciences (ruifanghuang_geo@163.com)
Weidong Sun[2], Institute of Oceanology, Chinese Academy of Sciences
Xing Ding[3], Guangzhou Insitute of Geochemistry, Chinese Academy of Sciences
Xiuqi Shang[4], Institute of Oceanology, Chinese Academy of Sciences

Abstract

Serpentinization is a low-temperature (≤500 °C) hydrothermal alteration of ultramafic rocks (commonly komatiite and peridotite). During serpentinization, olivine and pyroxene are reacted with aqueous fluids, producing serpentine, (±) talc, (±) brucite, and (±) magnetite. Serpentinization greatly influences geodynamics and the recycling of volatiles (such as H2O, carbon, and sulfur) in subduction zones. Serpentinites contain abundant H2O, up to 13.5 wt%, and they are also enriched in carbon and sulfur. High-pressure experiments have suggested that serpentine remain stable at a depth of >150 km. Therefore, serpentinization plays an important role for the recycling of volatiles. In particular, serpentinization produces hydrogen (H2), and the formation of H2-bearing fluids may greatly influence oxygen fugacity of fluids in subduction zones.

In spite of the significance of serpentinization, the mechanisms that control the rates of reaction and H2 generation remain poorly constrained. Experiments about the kinetics of serpentinization have been performed mostly using olivine and pure H2O as starting reactants, at temperatures of ≤300 °C and pressures of ≤2.0 kbar. Compared to synthetic forsterite, natural olivine has much slower rates of serpentinization, around 2-3 orders of magnitude slower. We have carried out serpentinization experiments at 300 °C and 3.0 kbar using natural peridotite, and found that peridotite has much faster rates of serpentinization compared to natural olivine, resulting from the influence of pyroxene and spinel (Huang et al., 2017, 2023). Hydrothermal experiments were also performed at 400-500 °C and 3.0-20 kbar, and the kinetics of peridotite serpentinization are around 1-2 orders of magnitude faster compared to the rates of olivine hydrothermal alteration. The pH and salinity of fluids strongly influence the kinetics of serpentinization (Huang et al., 2023).

Hydrogen generation during serpentinization can be greatly influenced by temperature, pyroxene and spinel, and fluid salinity (Huang et al., 2023). Compared to olivine, peridotite serpentinization produces larger amounts of H2, which reflects the effect of pyroxene and spinel. Spinel, aluminum, and chromium significantly enhance H2 generation. In contrast, pyroxene inhibits H2 production by around 1-2 orders of magnitude (Huang et al., 2021). Serpentinization of olivine produces ultra-reducing fluids, with oxygen fugacities down to FMQ-4.5, where FMQ represents

fayalite-magnetite-quartz buffer assemblage. This suggests that serpentinization greatly decrease oxygen fugacities of fluids in subduction zones.

Hydrogen solubility of stishovite provides insights into water transportation to the deep Earth

Lei Kang[1]*, State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University (kanglei@nwu.edu.cn)
Mengdan Chen[2], State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University
Liang Liu[3], State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University
Danling Chen[4], State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University
Changxin Yin[5], State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University

Abstract

Water plays a crucial role not only in the origin and evolution of life but also in various Earth processes, including slab subduction, crust–mantle reaction, and recycling. During slab subduction, water is transported from the Earth's surface to its interior through subduction zones, and a significant amount of water returns to the surface mainly through magmatism, thus forming a large-scale water cycle. In subducting slabs, hydrogen exists in melts, fluids, fluid inclusions, hydrous minerals (e.g., amphibole and mica), and nominally anhydrous minerals (NAMs). Stishovite, a prominent mineral present in subducting slabs, remains stable at mantle pressures of 9–50 GPa and can incorporate various amounts of water (H^+, OH^-, and H_2O) in its crystal structure. Consequently, stishovite can play a crucial role in transporting water into the deep Earth through subducting slabs.

This study provides a comprehensive review and exploration of water solubility in stishovite, hydrogen incorporation mechanisms, and governing factors. Also, we have constructed a new model for water solubility in Al-bearing stishovite and delved into stishovite's role in transporting water through a subducting slab and implications for water distribution in the deep Earth. The key conclusions can be summarized as follows:

1. Water solubility in stishovite exhibits a positive correlation with Al content, which increases water concentrations via coupled substitution $Al^{3+} + H^+ \rightarrow Si^{4+}$ and enhances the incorporation of interstitial H_2O by Al substitution-induced expansion of the stishovite structure.
2. The calculation results based on our new model demonstrate that Al-bearing stishovite's water solubility strongly depends on pressure, exhibiting a positive correlation below 22–32 GPa and a negative correlation above, indicating a peak solubility range at 22–32 GPa, while temperature dependence is weakly negative up to 30 GPa and weakly positive beyond.
3. Following a cold subduction slab geotherm, Al-bearing stishovite's water solubility increases from 998 wt ppm at 14 GPa to 1317 wt ppm at 22 GPa. This suggests that stishovite can potentially accommodate water released from the breakdown of hydrous minerals, contributing to the water-rich transition zone.

However, several crucial unanswered questions persist in research on the water solubility of stishovite: (1) the solubility of Al and its impact on water solubility across varying pressure–temperature conditions require clarification; (2) the roles of minor elements like Fe and Ti, as well as oxygen fugacity, remain unclear; (3) partitioning coefficients governing water distribution between stishovite and other major phases (e.g., Cpx, Grt, and melts) during slab subduction are not yet understood; and (4) the new model for water solubility in Al-bearing stishovite proposed in this paper needs refinement through systematic experiments conducted under controlled conditions. These issues are essential for understanding how water is transported into the deep Earth during subduction and require further detailed experimental and simulation-based investigations to address.

Valentina BATANOVA[3], Univ. Grenoble Alpes, Univ. Savoie Mont Blanc, CNRS, IRD, IFSTTAR, ISTerre, Grenoble, France

Abstract

The North Balkhash ophiolite zone (NBOZ) situated in the Central part of the Kazakhstan orocline, comprises serpentinite mélange with large blocks of igneous, metamorphic and metasomatic rocks along with varisized slivers of volcanogenic-sedimentary strata. The latter mostly include Middle-to-Upper Ordovician silicic-basaltic or volcanoclastic lithologies. Plutonic ophiolitic suites are attributed to residual dunite-harzburgite and layered dunite-wehrlite-pyroxenite-gabbro-plagiogranite complexes of 530–520 Ma in age. Separated blocks of plagiogranites aged 500-480 Ma distributed in the mélange, are assigned to derivatives of subducted basaltic oceanic crust and record the latest Cambrian-Early Ordovician stage of intraoceanic island-arc magmatism within the NBOZ.

Metamorphic formations hosted by serpentinite mélange, constitute varisized blocks up to several meters long, and include variously retrograded phengite-bearing epidote-glaucophane eclogites and garnet blueschists, which are immediately associated with the lower-grade metavolcanoclastic and albite-rich schists with various modal proportions of sodium-rich amphibole. The high-pressure rocks follow a clockwise ‘subduction-type’ evolution with the estimated near–peak stage parameters at ca. 1.6–1.9 GPa and 500–560°C beyond lawsonite stability field. 40Ar-39Ar phengite ages of ~491 Ma and ~465 Ma obtained for the eclogites and garnet blueschists, respectively, are interpreted to reflect the near-peak to early retrograde stages of rock evolution and mark two diachronous episodes of high-pressure re-equilibration within the NBOZ.

The epidote-glaucophane eclogites possess banded structure; the least retrograded micro-layers comprise near-peak assemblage of garnet porphyroblasts associated with oriented crystals of omphacite (Jd35-42Ae12-18), Sr-rich epidote (up to 0.86 wt.% of SrO), apatite aggregates up to several mm in size, Fe-Mg chlorite, minor kataphorite rimmed by glaucophane, rutile surrounded by titanite, and minor quartz. Eclogitic garnets contain occasional inclusions of aegirine-rich clinopyroxene (Jd21-31Ae43-55), apparently corresponding to relics of significantly oxidized prograde assemblage entrapped during early garnet growth. Intensively amphibolised bands intercalating with omphacite-rich layers, are composed of idioblastic garnet, ubiquitously developed Ca-Na amphiboles, epidote (SrO of ~0.1 wt.%) with Ba-rich phengite and chlorite, which frequently form veins or replace garnet, and subordinate omphacite (Jd31-37Ae8-11). Fine-grained titanite and zircon (~30-50 μm) are widespread in the rock matrix. Both amphiboles and epidotes demonstrate notable contents of LREE and U (up to 27 ppm in epidote), whereas

omphacites are enriched in transition metals (46-84 ppm of Sc; 411-628 ppm of V). Retention and enrichment in LILEs (particularly Ba, U, LREE, and Sr) by the peak eclogitic assemblage may have therefore record the interaction with sediment-derived fluids through devolatilization of downgoing slab during high-pressure re-equilibration at ca. 491 Ma, whereas serpentinite-derived fluids could contribute to selective enrichment in transition metals. Fluid-assisted recrystallization is proposed for the garnet blueschists and associated albite-rich schists, which is reflected by high total contents of LREE, LILEs, U, and variable modal amounts of barite and apatite. It has been proposed that tectonic slices comprised by fluid-modified metamorphic formations of various grades were tectonically juxtaposed at different levels in the subduction channel at ca. 465 Ma, and were subsequently exhumed in the Late Ordovician.

The research has been carried out following the plans of the scientific research of the GIN RAS (FMMG-2023-0009).

Abstract

Carbonated serpentinites, ophicarbonates, are exposed in ophiolites that can be remnants of oceanic lithosphere. Multiple generations of fluid for carbonation are recorded in fluid inclusions of ophicarbonates in the Oman and the Chenailet and the Lago Nero ophiolites on the Franco-Italian border in the Western Alps. The Oman ophiolite records oceanic lithosphere in fast-spreading ridges, whereas the Chenailet and the Lago Nero ophiolites in slow-spreading ridges. The fluid inclusions of ophicarbonates are studied with Raman microscopy and microthermometry, revealing saline fluid inclusions commonly found in the carbonates. Their homogenization temperature ranges from 100 to 220 °C, suggesting they are hydrothermal origins. Three types of fluid inclusions are observed in the ophicarbonates studied in the Oman and the Western Alps: (1) fluid inclusions show a wide range of salinities from 0-11 wt. % NaCl eq., suggesting seawater boiling and subsequent variable mixing of brine and steam in the ophicarbonate of the Chenaillet and Lago Nero ophiolites, (2) fluid inclusions with an average of 5 wt. % NaCl eq., a little higher than seawater, which may circulate beyond the Moho and form veins into the oceanic mantle harzburgite of the Oman ophiolite, (3) meteoric water during obduction processes in the Oman ophiolite with low salinities of 0–1 wt.% NaCl eq. The role of slab-derived fluids in ophicarbonates can be understood by studying meta-ophicarbonates in the Queyras (France) and Monviso (Italy) regions of the Western Alps.

Carbonate ions are more soluble in saline fluids than in fresh water. It is reasonable to observe the saline fluids in carbonate minerals, though the fluid inclusions with low salinities are also found as seen in the third type mentioned above. Not only salinity, but pH may have great effects on the carbonate solubility especially in shallow levels. To understand the conditions for carbonation of these serpentinites, experiments have been conducted in which mantle rocks have been reacted with H2O-CO2 fluids using hydrothermal apparatus under 300–400 °C at 180 MPa with NNO oxygen buffer. The starting materials (olivine, antigorite with/without diopside) are used. In addition to magnesite and talc, quartz is also found. Experiments with magnesium-end components are largely consistent with previous work in the MgO-SiO2-H2O-CO2 system [Johannes (1969) American Journal of Science, 267, 1083-1104]. Various reactions have been

observed in the olivine-diopside and serpentine-diopside systems. The experimental results show that the carbonation of serpentine is accompanied by a dehydration reaction. Under all experimental conditions, the volume of the solid phase increases during reactions. The addition of a carbon dioxide-containing fluids to serpentine causes both dehydration and an increase in solid volume. Carbonate veins are commonly found in serpentinite in nature. In most cases, calcite veins are formed, but in the present experiments, only magnesite or dolomite is formed, at least at temperatures above 300°C. We conclude that natural carbonation reaction in ophicarbonates occur at low temperatures below 300°C or the fluids carry Ca, which may come from sedimentary or mafic rocks.

Halogen cycling at the slab-mantle interface: constraints from metabasites from SW Tianshan, China

Zheng-Hua Pan[1]*, University of Science and Technology of China (zhpan0@mail.ustc.edu.cn)
Ren-Xu Chen[2], University of Science and Technology of China

Abstract

Halogens play an important role in fluid activity and mass transfer in the Earth's interior. Halogens are enriched in surface reservoirs but depleted in the mantle. Subduction processes can transfer halogens to the deep Earth, leading to the formation of enriched components. A systematic study of whole-rock and mineral F and Cl concentrations was carried out for a series of blueschists, high-pressure (HP) eclogites and ultrahigh-pressure (UHP) eclogites from the Chinese southwestern Tianshan. In combination with whole-rock and mineral element compositions, phase equilibrium modeling and apatite U–Pb dating and element data, the results are used to constrain the halogen storage and transport in the subducting oceanic crust. Fluorine contents decrease from the blueschists to the UHP eclogites, whereas Cl contents increase from the blueschists and HP eclogites to the UHP eclogites. Combined with the halogen compositions of their possible protoliths, it is inferred that most of the Cl was lost, whereas F was retained during subduction of the oceanic crust to blueschist facies. Minerals in the UHP eclogites exhibit elevated Cr and Co contents and Ba/Th ratios, indicating that the infiltration of serpentinite-derived fluids resulted in Cl enrichment in the UHP eclogites. Reconstruction of whole-rock F and Cl contents from mineral models and halogen concentrations indicates continuous F and Cl loss from subducting oceanic crust during prograde metamorphism from the blueschist to UHP eclogite facies. The F loss from the subducting oceanic crust is consistent with the decreases in F contents in glaucophane, phengite and apatite. Apatite hosts 73-77% of the F in the rock and thus is the main F-host mineral in the subducting oceanic crust. Due to the different behaviors of F and Cl, the fluids released from the subducting oceanic crust had low F/Cl ratios before blueschist facies but high F/Cl ratios during prograde metamorphism from blueschist- to UHP eclogite-facies. The UHP eclogites metasomatized by serpentinite-derived fluids exhibit significantly higher Cl contents and comparable F contents relative to UHP serpentinites. This difference suggests that halogen-enriched UHP eclogites are important carriers of volatiles to subarc depths and beyond. Changes in the halogen composition of the subducting oceanic crust and halogen flux between different lithologies in the subduction channel significantly affect the element solubility in metamorphic fluids and thus the mass transfer from the subducting slab to the overlying mantle wedge.

Fluid-mediated Cu and Zn isotopic fractionation in subduction zones: Constraints from high pressure veins within eclogites in the Dabie Orogen

Jian HUANG[1]*, University of Science and Technology of China (jianhuang@ustc.edu.cn)
Shu Bin Fang[2], University of Science and Technology of China
Shun Guo[3], Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

Fluids released by subducted slab is an important medium of material and energy exchange in subduction zones. High-pressure (HP) veins in eclogites are the products of fluid-rock interaction and provide insight into the composition and evolution of fluids in subduction zones. We here present the Cu and Zn isotopic data for different types of HP veins and their host eclogites from Ganghe and Hualiangting in the Dabie Orogen to reveal the behavior of Cu and Zn isotopes during fluid-rock interaction and fluid evolution. The HP veins include omphacite-epidote (Omp-Ep), epidote-quartz (Ep-Qtz), and kyanite-epidote-quartz (Ky-Ep-Qtz) veins. The Omp-Ep veins first crystallized from eclogite-derived, solute-rich fluids with the Ep-Qtz and Ky-Ep-Qtz veins successively crystallizing from the residual fluids after the Omp-Ep vein formation. The early Omp-Ep veins have variably lower δ65Cu (−1.32 to −1.12‰ at Ganghe, -0.70 to -0.66‰ at Hualiangting) but higher δ66Zn (0.36 to 0.38‰ at Ganghe, 0.40 to 0.41‰ at Hualiangting) relative to the host eclogites (δ65Cu: -0.71 vs. 1.84‰, δ66Zn: 0.22 vs. 0.33‰), indicating Cu-Zn isotope fractionation during slab dehydration in subduction zones with the lighter Cu and heavier Zn isotopes preferentially entering the vein-forming fluids from the eclogites. Systematic increase of δ65Cu from the Omp-Ep (−0.70 to −0.66‰) through Ep-Qtz (0.01‰) to Ky-Ep-Qtz veins (0.46 to 0.95‰) can be attributed to isotope fractionation induced by redox changes during the evolution of metamorphic fluids, as revealed by the negative correlations of δ65Cu with $Fe^{3+}/\Sigma Fe$ and $(Eu/Eu^*)_N$ in these veins. Additionally, the higher δ66Zn of the Omp-Ep veins relative to the Ky-Ep-Qtz veins can be explained by equilibrium isotope fractionation between crystallized minerals and evolved metamorphic fluids. Our results thus demonstrate that Cu-Zn isotopic fractionation occurred during the evolution of slab-derived metamorphic fluids in subduction zones. Incorporation of such fluids to the mantle can cause Cu-Zn isotopic heterogeneity observed in mantle rocks and their derivative melts. Thus, Cu-Zn isotopes can be used as sensitive tracers of element migration and oxygen fugacity variation during crust-mantle interaction.

"Detrital" zircons in eclogite: their origin and implications for mass transfer

Taehwan KIM[1]*, Korea National University of Education (taehwan.kim@knue.ac.kr)

Abstract

Theoretically, the crystallization and preservation of zircon in mafic magma is unlikely because of its high solubility. Zircons appear, however, in basalts/gabbros, peridotites and kimberlites. The origin of zircon in (ultra)mafic rocks has been accounted for by igneous processes such as the incorporation of xenocrysts during magma emplacement and magmatic growth from late-stage melts. Post-magmatic processes include metasomatism and even fluid-mediated migration. In this study, on the basis of age, isotopic composition and REE pattern of eclogite zircons, we demonstrate the incorporation of “detrital” zircon xenocrysts and discuss implications on their origin and mass transfer in arc-related settings.

Zircon separates of a coarse-grained eclogite sample from the Antarctic Ross orogen are overwhelmingly rich, and as abundant as being comparable with those of common siliciclastic sedimentary rocks. Zircons vary in size and shape, and primarily consist of an inner zone with heterogeneous CL intensity and texture surrounded by outer zone. The zircon inner zone encloses non-HP minerals such as chlorite, biotite, feldspars, and titanite, while the outer zone captures eclogitic minerals such as omphacite, phengite, and rutile. The inner zones widely vary in both age (n = 70) and REE pattern, the former spanning the Paleoproterozoic (c. 2.29 Ga) to the Early Cambrian (c. 530 Ma). The Cambrian ages of the zircon outer zones record the timing of subduction-zone metamorphism as early as c. 528 Ma, based upon the absence of prominent negative Eu anomaly and the flattening of HREE. The age distribution pattern of the zircon inner zone is characterized by bimodal peaks of the Pacific-Gondwanan (c. 700-500 Ma) and Grenvillean (c. 1200-900 Ma) groups, consistent with that of detrital zircons from the Ross-orogen clastic (meta)sedimentary rocks. Ten youngest exotic or “detrital” zircon ages yielded the weighted mean of 546 ± 4 Ma.

We suggest that: (1) the “detrital” zircons in the coarse-grained eclogite sample are not inherited cores indicative of the assimilation process, but likely have been introduced from the surrounding (meta)sedimentary or basement rocks after the solidification of the basaltic igneous protolith; (2) the mechanism responsible for the incorporation of the “detrital” zircon-bearing sediments was likely a solid-state mixing with the eclogite protolith at a subduction front near trench; (3) the zircon xenocryst mixing has taken place not earlier than c. 546 Ma; and finally (4) a material recycling at subduction zone was rapid within <18 Myr duration, encompassing from the emplacement of continental arc granitoids, their exposure to surface and erosion, sediment deposition in an arc-related setting, burial and mixing with the eclogite protolith, and subduction to mantle depth (~60 km) with an average burial rate of >3 mm/yr.

The fate of methane in subduction zone fluids

Lijuan ZHANG[1]*, Peking University (lijuanzhang@pku.edu.cn)

Abstract

Methane (CH4) is a critical but overlooked component in the study of the deep carbon cycle. Abiotic CH4 produced by serpentinization of ultramafic rocks has received extensive attention, but its formation and evolution in mafic rocks in subduction zone are poorly understood. Massive CH4-rich fluid inclusions are commonly found in ultrahigh-pressure (UHP) eclogites from the Western Tianshan, China. The combination of the petrological observations and thermodynamic models leads to a complete P–T–fO2- fluid evolution trajectory for the CH4-bearing eclogites. During the prograde metamorphism from the blueschist facies at ~50 km to UHP eclogite facies at ~120 km, the carbon species in the aqueous fluids were dominated by reduced CH4. During the exhumation with heating and decompression,the fluid evolved into a CH4-CO2-bearing aqueous fluid and the oxygen fugacity increased to FMQ-1. The reaction CH4 + CO2= 2C + 2H2O could occur, which demonstrates by the Deep Earth Water (DEW) model, and lead to the precipitation of solid graphite. With the progression of decompression and an increase in oxygen fugacity, the carbon species in the fluids completely changed into CO2, which persisted through the epidote-amphibole facies to even shallower depths during exhumation. Therefore, the fluids released by subducted slabs can be initially reduced, but continuously evolves to oxidized during decompression and exhumation, which provides a novel perspective for understanding the redox of arc magma.

[Keynote] Formation of abiotic H2 and CH4 in subduction zones

Renbiao TAO[1]*, Center for High Pressure Science & Technology Advanced Research (renbiao.tao@hpstar.ac.cn)
Chao Wang[2], Center for High Pressure Science & Technology Advanced Research
Lifei Zhang[3], School of Earth and Space Sciences, Peking University

Abstract

Subducting slabs could carry large amounts of H2O and CO2 on Earth's surface into the deep mantle (Tao et al., 2018a). Various water-mineral interactions occur in subducting rock systems at high-pressure and high-temperature conditions. At the same time, the redox condition of the slabs will generally decrease along with the subducting processes (Tao et al., 2020). When the redox conditions are low enough, the recycled H2O and CO2 in subducting slabs will be reduced to abiotic H2 and CH4, which may be an important source of deep Energy. In this talk, we will summarize geological observations and experimental simulations of abiotic H2 and CH4 in subduction zones. For example, based on a comparative study between CH4-bearing ultrahigh- and CO2-bearing high-pressure eclogite from the Chinese S.W. Tianshan subduction zone, we proposed the favorable P–T– fO2 conditions for the formation of abiotic CH4 in subducted oceanic crusts (Tao et al., 2018b; Wang et al., 2022). On the other hand, we also carried out a series of high-pressure experiments to investigate the formation mechanism of abiotic H2 and CH4 in FeCO3 + H2O systems at subduction zone conditions (Wang et al., in preparation). Finally, combining petrological observation and high-pressure experimental simulation, we concluded that the subduction zone is a factory for producing abiotic H2 and CH4 at deep mantle conditions.

Jie Li[5], State Key Laboratory of Isotope Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences
Yu Wang[6], State Key Laboratory of Isotope Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences

Abstract

The petrogenesis of basaltic arc lavas with heavy Mo isotopic compositions is controversial. Given that oceanic crust preferentially loses isotopically heavy Mo during subduction at forearc depth and the remaining Mo is isotopically light and locked in rutile, fluids derived from such crust at subarc depth cannot account for the heavy Mo isotopic compositions of basaltic arc lavas. Serpentinites can contain substantial Mo and volatiles and are a potential source of isotopically heavy Mo in basaltic arc lavas. However, the Mo isotopic composition of serpentinites and the Mo isotope behavior during serpentinite dehydration are poorly constrained. Here, we present Mo contents and isotope data for serpentinites from the South Sandwich Trench-Fracture Zone intersection, and deserpentinized peridotites and high-pressure meta-serpentinite veins from the western-central Alps and Betic Cordillera, Spain. Most of these samples have heavy Mo isotopic compositions (δ98/95MoNIST 3134, ranging from -0.26‰ to 1.84‰) with low Ce/Mo (0.10-23.98) and Ce/Pb (0.17-3.59) ratios, which are distinct from the compositions of eclogite-facies metabasalts and metapelites. In addition, no systematic variations in Mo contents and Mo isotopic compositions occur for the studied samples, indicating limited Mo isotope fractionation during serpentinite dehydration. The above results suggest that serpentinites and their derived fluids at subarc depths can serve as the main isotopically heavy Mo sources for basaltic arc lavas. The Mo isotope data with Ce/Mo and Ce/Pb systematics suggest that serpentinite-derived fluids or melting of serpentinite diapirs at subarc depths can explain the heavy Mo isotopic compositions of basaltic arc lavas. Furthermore, recycled oceanic slab (oceanic crust + serpentinized mantle) would has limited influence on the Mo systematics of the mantle, which explains why the mantle has maintained a nearly constant Mo isotopic composition since 3.5 Ga.

Deciphering the relative timing of deformation, recrystallization and fluid infiltration in the Dalrymple Amphibolite: Implications to the slab-mantle wedge interface

Gabriel Theophilus Vinalay VALERA[1]*, University of the Philippines National Institute of Geological Sciences (gvvalera@up.edu.ph)
John Daniel Laurente[2], University of the Philippines National Institute of Geological Sciences
Dominique Anne Operania[3], University of the Philippines National Institute of Geological Sciences

Abstract

Megathrust faults separating the subducting slab from the overriding plate is a site of complex overlapping processes including mechanical mixing of components derived from the hanging and foot wall, shear stress-related deformation, and fluid infiltration and associated fluid-rock interaction. These processes are thought to ultimately control the petrological and geochemical characteristics of rocks comprising this interface. Understanding the complex interplay between these processes, their relative timing, and their effects require detailed studies of the rocks which may have once represented fossil slab-mantle wedge interfaces. One locality of such rocks is the Dalrymple Amphibolite located at the base of the central Palawan Ophiolite (CPO).

The clockwise pressure-temperature-deformation (P-T-D) path followed by the Dalrymple Amphibolite is subdivided in a prograde and retrograde metamorphic stage preserved in the amphibolite blocks and surrounding matrix. The prograde stage involves deformation of the subducting slab and its transformation into a block-in-matrix complex. Fluid infiltration during the prograde stage resulted to leaching of components away from the blocks and matrix. Retrograde metamorphic stage on the other hand coincided with the infiltration of another set of fluids preserved as quartz veins. These later fluids added highly mobile components and promoted the growth of low T minerals such as actinolite, chlorite, and muscovite in some retrogressed samples.

In this study, a relatively coherent epidote amphibolite block of the Dalrymple Amphibolite with notable finer and coarser-grained domains was investigated. The coexistence of fine and coarser grained epidote amphibolite blocks with similar mineral assemblage hints on the interplay between recrystallization and deformation in this high T, high shear stress environment. Zr-in-rutile geothermometry revealed a significant difference between the Zr concentrations of rutile between the two texturally different samples. Fine-grained Ep amphibolites have a mean-max Zr concentration in rutile of ~411 ppm, corresponding to a crystallization temperature of ~681°C. In contrast, the coarse-grained Ep amphibolites have a mean-max Zr concentration of ~217 ppm (~631°C). The marked difference in equilibration temperatures suggests that subsequent localized shearing and recrystallization at higher T transformed the coarser-grained sections into finer-grained epidote amphibolite. Another epidote amphibolite sample transected by multiple discordant quartz vein was also analyzed to determine the timing this fluid infiltration event and

the likely fluid source. Detailed mineral chemistry of zones proximal and distal from the vein revealed increasing actinolite component towards the quartz vein likely as a result of ion-exchange between the fluid and the epidote amphibolite. Elemental mapping of the epidote amphibolite reveals increasing Si, Ca, and Mg and decreasing Al, Na, and K towards the vein. These signatures indicate that the formation of the quartz vein is due to late-stage fluid infiltration in the Dalrymple Amphibolite linked to the retrograde metamorphism which affected the mélange.

Contributions of serpentinizing fluids to the low δ^{26}Mg isotopes of subduction zone fluids: Evidence from jadeitites and jadeite-rich rocks from the Rio San Juan complex, the Northern Dominican Republic

KUN CHEN[1]*, CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei (Kun_Chen@mail.ustc.edu.cn)
YI-XIANG CHEN[2], CAS Key Laboratory of Crust-Mantle Materials and Environments, School of Earth and Space Sciences, University of Science and Technology of China, Hefei
HANS-PETER SCHERTL[3], Institute of Geology, Mineralogy and Geophysics, Ruhr-University Bochum

Abstract

Jadeitites are the products of direct precipitation through Na-Al-Si rich fluids (P-type) or replacement of magmatic protoliths by fluids (R-type) in subduction zones. Therefore, they are unique targets for investigating the chemical composition of subduction zone fluids. However, the genesis of jadeitites and the Mg isotopic compositions of subduction zone fluids are poorly constrained. Jadeitites and jadeite-rich rocks from the Rio San Juan complex (RSJC) of the northern Dominican Republic were of P- or R-type origins, which are ideal samples for addressing the above issues. Here, we present trace element and Mg-O isotopic studies for RSJC jadeitites and jadeite-rich rocks. The studied samples are divided into matrix-quartz-free suite and matrix-quartz-bearing suite based on the presence of quartz in the matrix. Most of the studied samples are characterized by enriched LREEs, flat HREEs patterns as well as enriched FMEs (Ba, Sr, Pb, U), Sb, Zr, Hf, Cr and Ni, which are similar to those of R-type jadeite-rich rocks and plagiogranites, but quite different from those of P-type jadeitites, indicating that R-type origin jadeitites are dominant in RSJC.

The matrix-quartz-free suite has a wide range of δ^{26}Mg values from −0.94‰ to −0.32‰, and the matrix-quartz-bearing suite has δ^{26}Mg values −0.48‰ to −0.22‰. The δ^{26}Mg values of R-type jadeitites are from −0.67‰ to −0.43‰, slightly higher than those of P-type (−0.94‰ ~ −0.47‰). Although all the studied samples have similarly lighter Mg isotopes to those of the Myanmar jadeitites, there are no correlations between δ^{26}Mg and CaO/TiO_2, CaO/Al_2O_3 and Sr/Nd. In addition, the studied samples (5.41–10.27‰) and estimated jadeite-forming fluids (4.71–6.42‰) have low δ^{18}O values. These signatures indicate that the light Mg isotopes of the RSJC jadeitites and jadeite-rich rocks were not derived from carbonate-fluid metasomatism. In contrast, the negative correlation between δ^{26}Mg and Na_2O in the studied samples indicates that the light Mg isotopes of jadeitites were caused by jadeitite-forming fluids. Besides, RSJC jadeite-rich rocks have higher Ni, Cr, As and Sb contents as well as lower δ^{26}Mg values than plagiogranite protoliths. The compiled results for global jadeitites show positive correlations between MgO, Cr and Ni. These evidences imply that serpentinizing fluids may have contributed to the light Mg isotope of the studied jadeitites and jadeite-rich rocks. Combined with the results of the binary

mixing model and Rayleigh fractionation model, we conclude that replacement of plagiogranites by serpentinizing fluids or direct precipitation of jadeitite from serpentinizing fluids at forearc depths could produce light Mg isotopic signatures of RSJC jadeitites and jadeite-rich rocks. Considering that fluid-metasomatized rocks, such as rodingites and jadeitites, are isotopically and genetically related to serpentinizing fluids, metasomatic processes associated with serpentinization are possible to contribute to Mg isotope heterogeneity in the mantle and to the formation of arc magmas with light Mg isotopes.

Yuji Ichiyama[2], Chiba University
Tomoaki Morishita[3], Kanazawa University
Akihiro Tamura[4], Kanazawa University

Abstract

Fluid mobile elements are fixed in the mantle wedges as hydrous minerals formed by the influx of slab-derived fluids and consequent metasomatism. Particularly, phlogopite and amphibole possibly play important roles in elemental migrations and recycles in subduction zones, because they are involved in compositional changes in island arc magmas as the reservoirs of alkali elements (Tatsumi, 1989).

The Kurosegawa belt distributed in southwestern Japan is a tectonic serpentinite mélange zone, which preserves tectonic records of an Early Paleozoic subduction zone (Osanai et al., 2014). A small-scale ultramafic complex (Jikkoku Pass complex) and tectonic mélanges (Kiroko–Naguri mélange zones) distributed in the Kanto Mountains, central Japan, are interpreted as part of the Kurosegawa belt. The serpentinized harzburgite of the Jikkoku Pass complex contains pyroxene pseudomorphs composed of richterite + phlogopite + clinopyroxene + olivine + antigorite ± monticellite. The formation temperatures of the pseudomorphs are estimated at <500–600 ℃, based on the coexistence of Fe-rich olivine and antigorite. Early Paleozoic amphibolites in the Kiroko–Naguri mélange zones contain katophorite and rutile, indicating that they experienced high-pressure metamorphism. The Jikkoku Pass ultramafic complex and amphibolites in the Kiroko–Naguri mélange zones probably represent the mantle wedge and subducted oceanic crust of an Early Paleozoic subduction zone, respectively. The bulk compositions of the pyroxene pseudomorphs calculated from elemental mapping images indicate that K2O, Na2O, and CaO contents are 10–100 times more than primary orthopyroxene. Their trace element compositions are enriched in LREE, Cs, Rb, and Ba. These facts indicate that slab fluids given off by the dehydration of amphibolite facies pelitic rocks may have infiltrated into the overlying mantle wedge, and fluid mobile elements, especially alkaline elements, may have been fixed in the mantle wedge as pyroxene pseudomorphs.

Similar pyroxene pseudomorphic textures are also found in mantle wedge-origin serpentinized harzburgites from an Early Paleozoic supra-subduction zone ophiolite (Miyamori ophiolite) and a Cretaceous serpentinite mélange (Kamuikotan belt) in northeast Japan and the serpentinite seamount of the Mariana forearc. The constituent mineral assemblages of pyroxene pseudomorphs from the above three localities are clinopyroxene + antigorite, richterite + clinopyroxene + olivine + antigorite ± phlogopite, and (K-rich) richterite + tremolite + talc + antigorite, respectively. The pseudomorphs observed in the Kamuikotan belt and Mariana serpentinite seamount indicate the

formation at similar temperatures to those of the Jikkoku Pass complex, but those of the Miyamori ophiolite are estimated to have been formed at <450–500 ℃, based on the coexistence of clinopyroxene and antigorite. The calculated bulk compositions of the pyroxene pseudomorphs are characterized as follows; those of the Miyamori ophiolite are poorer in K_2O and Na_2O and are richer in CaO, whereas those of the Kamuikotan belt and Mariana serpentinite seamount are poorer in CaO and K_2O, compared with the Jikkoku Pass complex. These petrological and geochemical diversities of pyroxene pseudomorphs may have been due to the infiltration of slab-derived fluids with different geochemical characteristics, which were caused by the different lithology of slabs and the different thermal gradients of the mantle wedges.

The genesis of metabasic rocks in the Yadong region of the Himalayan orogenic belt

XIN DONG[1]*, Institute of Geology, Chinese Academy of Geological Sciences
(dongxin5811935@163.com)

Abstract

The Greater Himalayan Sequence (GHS), in the core of the Himalayan belt, records information about the subduction and thickening of the Indian continental crust to the lower crust and its exhumation. The sporadically exposed ultrahigh-temperature (UHT) overprinted eclogites in the upper part of the GHS have drawn extensive attention from international scholars. However, there is still controversy surrounding whether the metabasic rocks distributed widely in other layers of GHS have undergone similar metamorphic processes, and there is debate over their genesis and exhumation mechanism.

The Yadong region, situated in the upper-middle part of GHS, has reported the presence of UHT overprinted eclogites in the upper layers. These rocks experienced peak-pressure eclogite-facies metamorphism (2.1 GPa and 750-770 °C) at ca. 17 Ma, followed by an exhumation process involving decompression heating, reaching peak temperatures of the UHT granulite-facies conditions (0.8 GPa and 950-1000 °C), and then cooled to the amphibolite-facies conditions (Wu et al., 2022). The protolith of the eclogites and the metamorphism of their surrounding rocks have not been reported. Our study shows that the metabasic rocks and their surrounding rocks in the upper and lower layers at the exposure of the eclogite underwent high-pressure (HP) granulite-facies metamorphism. Their protoliths formed in the Neoproterozoic and Ordovician. In the upper layers of the eclogite, the metabasic rocks experienced peak granulite-facies metamorphism (0.9-1 GPa and 800-845°C) and medium-pressure granulite-facies (0.6-0.7 GPa and 825-840 °C) isothermal decompression processes (occurring between 21-17 Ma). The protoliths of the metabasic rocks in these layers formed at ca. 800 Ma, with geochemical characteristics of E-MORB type rocks. In the lower layers of the eclogite, the metabasic rocks and their surrounding rocks underwent similar metamorphic processes (with similar P-T trajectory as the metabasic rocks in the upper layers), but with higher peak metamorphic pressures conditions (1.4-1.5 GPa and 880-915 °C). The peak metamorphism and retrogression occurred at ca. 36-18 Ma and 16 Ma respectively, with the protoliths being basic and granodiorite rocks formed at ca. 450 Ma.

In summary, the metabasic rocks and their surrounding rocks in the Yadong region of the GHS mostly underwent HP granulite-facies metamorphism, with the variety of protoliths and peak metamorphic time of predating ~20 Ma. We suggest that these HP rocks underwent prolonged burial processes, differing from the retrogression history of the reported eclogites in the same study area. Therefore, it is speculated that eclogites may not represent the overall metamorphic degree of exposed rock layers. Further research is needed on the exhumation mechanisms of different types of metabasic rocks.

Serpentinization and deserpentinization of the mantle wedge at a convergent plate margin

ZHUANGZHUANG YIN[1]*, University of Science and Technology of China (zzyin@ustc.edu.cn)
Renxu CHEN[2], University of Science and Technology of China

Abstract

Plate subduction is an important mechanism for energy and mass transfer between the mantle and the crust and is a key factor in maintaining the habitability of the Earth. The relationship between the genesis of serpentinite at convergent plate margins and the composition of metasomatic mantle wedge fluid represents the forefront of geochemical research on subduction zone fluids. Previous studies have made many assumptions and inferences about slab serpentinites but have ignored the geochemical effects of dehydration of mantle wedge serpentinite. An integrated study of petrography, whole-rock and mineral major-trace elements and oxygen isotopes as well as zircon U-Pb ages, trace elements and Hf-O isotopes was carried out on serpentinites from the Hong'an orogen to constrain the protolith nature, metamorphic evolution and multiple episodes of crustal metasomatism of the serpentinites. These serpentinties are mainly composed of Ol+Atg+Liz+Mag±Bru±Mgs and have high Mg# and MgO/SiO2 ratios but low Al2O3/SiO2 ratios are well as low Ti contents, resembling those from the mantle wedge rather than the subducting oceanic slab. The enrichments of Th, U, LREE and HFSE in the whole-rock and the finding of zircon indicate that these rocks formed through metasomatism of mantle wedge peridotites by subducted crust-derived fluids. The ca. 310 Ma zircon domains exhibit positive εHf(t) values of 4.5-19.1, variable δ18O values and high Th/U ratios similar to those of oceanic eclogites in the Hong'an orogen but different trace element compositions, indicating their formation through metasomatism by fluids from the subducting Paleo-Tethyan oceanic crust. The ca. 430 Ma zircons exhibit U-Pb ages, trace elements and Hf-O isotopes similar to those of the protolith magmatic zircons in the oceanic-type eclogites. The older zircon domains also exhibit similar element and isotope compositions to those of inherited zircons from high- to ultrahigh-pressure metamorphic rocks in the Hong'an orogen. The ca. 220 Ma zircon domains show negative εHf(t) values of -16.0 to -2.7, indicating their formation through metasomatic overprinting by deeply subducting continental crust-derived fluids in the continental subduction channel during Triassic continental collision. In this context, mantle wedge peridotites were first metasomatized in the Carboniferous by subducted oceanic crust-derived fluids. Afterwards, part of the metasomatized peridotites were off-scrapped into the oceanic subduction channel, where they were hydrated by further subducting oceanic crust-derived fluids to form antigorite serpentinite at forearc depths. The antigorite serpentinite was carried to deeper depths during subsequent continental subduction and underwent dehydration there. This gave rise to metamorphic olivine with extremely high Fo values of 96.7 to 97.6 and higher MnO but lower NiO contents than common mantle olivine. Therefore, the present observations and interpretations of orogenic serpentinites provide insights into multistage fluid metasomatism at different depths during the

tectonic transition from oceanic subduction to continental collision.

Hydration of the deep mantle by slab-derived fluids: insights from arc-type hornblendites of eastern Arunachal Himalaya, NE India

Amrita DUTT[1]*, Physical Research Laboratory (amritadutt6@gmail.com)
Anil Dutt Shukla[2], Physical Research Laboratory
Sanjeev Kumar[3], Physical Research Laboratory

Abstract

Hornblendites are amphibole-rich rocks typically observed in arc settings. Thus, their chemistry can reveal significant information on the processes occurring in the sub-arc mantle and yield information on the nature of fluids and their probable source. In this study, we present the whole-rock major, trace, and isotopic chemistry along with mineral chemistry of the hornblendite dykes occurring in the Neotethyan ophiolites of eastern Himalaya, NE India to decipher their origin, and shed light on the source of fluids occurring in the mantle wedge of an intraoceanic subduction zone. The hornblendites contain >90 modal % amphibole with pargasite being the most dominant end member. They have high whole-rock MgO (~12–20 wt.%) contents with overall deplete LREE [(La/Yb)N = 0.22–0.47] indicative of their refractory nature. Geothermobarometric calculations reveal that the pargasites formed under a high P-T regime (~950°C; 1.6–1.7 GPa) and high fO2 conditions (ΔNNO+2). The-Sr-Nd isotopic ratios of these rocks, calculated at 127 Ma, are also indicative of their depleted mantle origin [(87Sr/86Sr)i = 0.703775–0.7042779; (143Nd/144Nd)i = 0.512733–0.512827), falling near the high-μ compositions. The elemental carbon concentration of these rocks is very low, with a total carbon of ~112 ppm and light δ13C isotopic ratios (~-25.4‰), indicative of an organic origin of the carbon. The whole-rock geochemistry, P-T conditions, and fO2 values of the hornblendites suggest formation from a depleted mantle in an island arc setting. The correlation of the Sr-Nd isotopic ratios of the samples with the high-μ mantle reservoir however, suggest inputs from a recycled subducted oceanic slab in the deep mantle. The isotopically light carbon ratios for the bulk carbon of the hornblendites further support the input of organic sediments from an oceanic slab in their formation. Thus, we propose that the hornblendites were sourced from a hydrated refractory mantle that underwent preferred crystallization of amphiboles instead of clinopyroxenes under high P-T and fO2 conditions at the root of an island arc. Based on the carbon isotopic ratios of the hornblendites, we further comment that the residence time of the 13C-depleted crustal component was too short to re-equilibrate with the mantle carbon isotopic ratios. This study opens further questions on the isotopic re-equilibration of carbon in the deep mantle, which may be studied in future.

Fluid flow and isotopic inheritance in the subducted eclogitic crust recorded by in-situ Rb-Sr isotopes (North Balkhash ophiolite zone, Central Kazakhstan)

Sergei SKUZOVATOV[1]*, Vinogradov Institute of Geochemistry, Russian Academy of Sciences, Siberian Branch (skuzovatov@igc.irk.ru)
Anfisa Skoblenko[2], Geological Institute, Russian Academy of Sciences

Abstract

Metamorphic white micas are known to multiply grow and recrystallize as a response to distinct thermal events, deformations and fluxes of hydrous fluids in the evolving subduction-related complexes. Progressive recrystallization and preservation of prograde, non-recrystallized (early metamorphic) populations, as well as variable elemental/isotopic uptake in response to external fluid precipitation may produce ambiguous 40Ar-39Ar and Rb-Sr dates, which are crucial for constraining dynamics of subduction zones and tectonic reconstructions, as the recrystallization-induced dates may span over up to ~30–40 Myr. Using the in-situ, texturally linked (LA)-MC-ICP-MS Rb-Sr isotope data, here we constrain the P–T conditions of rehydration and its impact onto Sr isotopic disequilibrium and Rb-Sr geochronology of phengite-bearing assemblages produced by combined pervasive and channelized fluid overprint of HP rocks from the Kenterlau-Itmurundy paleo-oceanic HP complex (North Balkhash ophiolitic mélange, Central Kazakhstan). The eclogites are mostly hydrous rocks, which have amphibole, epidote and phengite evenly spread in the matrix, with only minor to no primary omphacite preserved due to retrogression. Some samples are macroscopically heterogeneous, with relatively dry (omphacite-dominated) and moderately to completely hydrated (with amphibole-dominated matrix exhibiting enlarged phengite flakes) sections/domains. Strongly hydrated domains are commonly crosscut by veins showing no orientation regularities and rich in enlarged amphibole and phengite crystals. Same coarse-grained phengite commonly associated with chlorite is observed in cracks, which cut garnet porphyroblasts.

Omphacite exhibits nearly homogeneous 87Sr/86Sr ratios at measured 87Rb/86Sr normally below 0.01, with a slight difference between “dry” (0.70521±0.00010) and moderately hydrated (0.70565±0.00037) domains. Amphibole has a uniquely uniform (87Sr/86Sr)0, which were recalculated to 500 Ma due to increased 87Rb/86Sr (0.02–0.11) ratios relative to Rb-poor omphacite and epidote. The 87Sr/86Sr ratios throughout both moderately and strongly hydrated zones are averaged at 0.70591±0.00018, which is higher than that of primary omphacites. Individual epidote grains have the weighted average 87Sr/86Sr of 0.70519±0.00004. The apparent effect of amphibolization and phengite growth is consistent with bulk-rock Rb-Sr systematics of omphacite-dominated, “dry” domains and their hydrous counterparts. The total Rb-Sr isochron using all phengite analyses yields an age of 482±16 Ma (MSWD = 3.3), which is equal within the error to the earlier reported 40Ar-39Ar age of phengite separates. However, the potential effect of progressive LILE uptake is evident by distinct isochrones of phengite with high 87Rb/86Sr ratios (486±17 Ma, MSWD = 4.5, 87Sr/86Sr of 0.7037±0.0034) and low (<10) 87Rb/86Sr (530±18 Ma,

MSWD = 1.5, 87Sr/86Sr of 0.7014±0.0020). The textural and isotopic data emphasize that phengite growth was mainly linked to post-peak, combined focused (veining) and pervasive (induced by inter-grain fluid migration) rehydration of eclogites. Isotopically depleted (with low 87Sr/86Sr) phengite thus represents the inherited prograde-to-peak population that did not approach the equilibrium with other prograde-to-peak phases (exemplified by omphacite) on a sample scale. In contrast, more radiogenic Sr in “younger” phengite may reflect progressive Sr isotopic re-equilibration with a contribution from high-Rb/Sr (e.g., metasedimentary) source.

The research has been supported by the Russian Science Foundation (grant 21-77-10038).

Mineral assemblage and temperature estimates of continent-derived metapelites and metapsammites in Sibuyan Island, Romblon, Philippines

John Kenneth Beran BADILLO[1]*, University of the Philippines Diliman (jbbadillo@up.edu.ph)
Gabriel Theophilus Vinalay Valera[2], University of the Philippines Diliman
Andrew Exequiel Sanchez Tabilog[3], University of the Philippines Diliman
Betchaida Duetes Payot[4], University of the Philippines Diliman

Abstract

The metamorphic rocks exposed in Sibuyan Island form part of the Romblon Metamorphic Complex (RMC), which are metamorphosed pelitic and psammitic rocks that occur along with the mafic-ultramafic units of the suprasubduction zone type Sibuyan Ophiolite Complex (SOC). The metapelites and metapsammites are observed in the western and eastern portions of the island, while SOC gabbros and peridotites occur at the center of the island. The occurrence of these metamorphic rocks is attributed to the arc-continent collision of the Palawan Microcontinental Block (PCB) and the Philippine Mobile Belt (PMB). This work presents novel field and petrological data from the metapelites and metapsammites in Sibuyan to provide insights into their metamorphic pressure-temperature-deformation (P-T-D) history.

In eastern Sibuyan, alternating metapelites and metapsammites that exhibit schistose texture are observed. The metapelites are composed of biotite (Bt) + muscovite (Ms) + quartz (Qz) + plagioclase (Pl) + orthoclase (Or) + aluminosilicate (Als) + rutile (Rt) + zircon (Zrn), whereas the metapsammites consist of Qz + Pl + Or + Ms + Als. In Barangay Mabini, an exposure of metapelites was documented near the coast. It is composed of dark-colored schists and is cut by leucocratic dikes that show foliation subparallel to those of the schists. Petrographic analysis and back-scattered electron (BSE) imaging of the metapelite schist and dike samples revealed similar mineral assemblage of Qz + Pl + Bt + Or + apatite (Ap) (± Ms ± chlorite (Chl) ± pyrite (Py) ± oxides) in varying abundances. Qz, Pl, and Or are more abundant in the dike, while Bt and Pl are more dominant in the schist. Pl and Bt are the common porphyroblasts, whereas Qz typically occurs in the matrix of both the schist and dike. The Pl grains in the dike exhibit oscillatory zoning, which is absent in the Pl grains of the schist. Most of the Qz grains in the matrix of both the schist and dike exhibit a sigmoidal structure.

Using the two-feldspar geothermometry of Whitney and Stormer (1977), the equilibrium temperatures for coexisting plagioclase and alkali felspar pairs in the schists and dike in Brgy. Mabini were calculated. Results show that the metamorphic temperature preserved in the feldspar pairs in the schists ranges from ~530 to 549°C and ~509 to 631°C, at 2.0 to 3.2 kbars in the rims of the dike, whereas the igneous temperature recorded in the cores of the feldspar pairs in the dike is within ~753 to 885°C, at 2.0 to 3.2 kbars. These temperatures and the subparallel foliations present in the dike and schist imply that the intrusion happened earlier than the deformation event

that possibly caused the metamorphism in the area. Also, the presence of mica, Or and Qz suggests a continental sandstone-mudstone protolith likely related to the PCB. Further petrological and geochemical analyses will be done to interpret the P-T-D history and petrogenesis of these metamorphic rocks in Sibuyan Island.

Betchaida Duetes Payot[4], Rushurgent Working Group, National Institute of Geological Sciences, College of Science, University of the Philippines, Diliman 1101, Quezon City, Philippines

Abstract

Metamorphism of mafic crustal materials can commence right after their formation and proceeds in response to changing pressures, temperatures, and fluid infiltration events. The resulting metamorphic textures and mineral assemblages reflect these conditions and can serve as records of events that affected the crustal rocks. In Tablas Island where evidences of arc-continent collision between the Philippine Mobile Belt and Palawan Microcontinental block can be observed, metamafic rocks are found in contact or proximal to the intrusive units of Sibuyan Ophiolite Complex. However, the metamorphic events that led to their formation remain unclear.

In northern Tablas, metamafic rocks such as amphibolites are inferred to be thrusted onto metapelitic schists along northeast striking, northwest dipping thrust faults. They are overlain by gabbros which are cut by plagiogranite veins emanating from the amphibolite. These lithologies are then crosscut by diabase dikes. In Calaton Hill, southern Tablas, amphibolites are inferred to be thrusted onto metapelitic schists along northwest striking, northeast dipping fault and are overlain by hornblende pyroxenite. The presence of sillimanite fibrolites overprinting the andalusite clasts in pelitic schists may imply that the deformation event affecting their protoliths are accompanied by heating. Recrystallized grains in amphibolites suggest that their protoliths have undergone amphibolite-to-granulite facies metamorphism. These observations may indicate that the amphibolites in Tablas could provide further insights on the tectonic events that occurred during the arc-continent collision in west central Philippines.

Abstract

Recently, the researches of metamorphic complexes of western and central Mongolia belonging to the eastern part of the Central Asian Orogenic Belt has been widely reported. We conducted a collaboration work to understand the origin of the metamorphic complexes in Tarvagatai, Baidrag and Zavkhan terranes and to determine the age intervals of metamorphism in detail.

In the eastern part of the of the Central Asian Orogenic Belt, as the remnants of the Precambrian ancient craton, the Neoarchaean Bombogeer metacomplex of Baidrag terrane was intruded by the Paleoproterozoic Olonkhudug massif. Also, the migmatized gneiss of the Neoarchaean Ider metacomplex of the Tarvagatai terrane was cut by Paleoproterozoic Khunjliin Gol anorthosite massif. This might indicate that several cycles of tectonic-metamorphism are distinguished within these cratonic terranes.

Recently, geological and geochronological studies have been intensively carried out in the Zavkhan terrane, and a crystalline complex containing boudinage of the Urgamal eclogite was firstly discovered near the southeast end of the Zavkhan terrane. The Urgamal eclogite is mainly composed of garnet coexisting with omphacite, rutile, epidote, barroisite, white mica, and quartz, which have been retrogressed into a symplectite of hornblende, albite, and biotite. We measured zircon U–Th–Pb ages in a barroisite–rich sample of the Urgamal eclogite using an electron probe microanalyzer, which yielded an age of 1113 +31/ −52 Ma.

Geochemical evidence from coesite-bearing jadeite quartzites for large-scale flow of metamorphic fluids in a continental subduction channel

Xiao-Ying GAO[1]*, University of Science and Technology of China (gaoying@ustc.edu.cn)

Abstract

Metamorphic fluids produced by dehydration of subducting crust transport mass and energy at the slab-mantle interface in subduction channels. It is commonly assumed that fluid flow is significant in oceanic subduction channels but insignificant in continental subduction channels. This assumption is challenged by a combined study of whole-rock geochemistry, Mg and O isotopes, zircon U-Pb ages and trace elements in coesite-bearing jadeite quartzites from the Dabie orogen, China. Although the target samples were collected from different outcrops in an area of ~50 km2, zircon U-Pb dating yields similar discordia lines with not only consistent upper intercept ages of 1.9-2.0 Ga but also consistent lower intercept ages of 224-235 Ma. This indicates the same Paleoproterozoic protolith and the same Triassic metamorphism for these jadeite quartzites. The O isotope analysis of mineral separates and whole-rock yields variable δ18O values from 6.3 to 9.4‰, indicating involvement of supracrustal components. Except for one outlier at -0.43‰, all the other rocks give variable δ26Mg values from -0.16 to 0.61‰, much higher than normal mantle values. The whole-rock Mg isotopes show significant positive correlations not only with MgO contents but also with Rb/La, Rb/Gd and Rb/Nb ratios, but a negative correlation with Na2O contents. These observations indicate that the middle Paleoproterozoic protolith of jadeite quartzites was weathered to produce a kind of sedimentary rocks in a passive continental margin and then underwent significant metasomatism by metamorphic fluids with high δ26Mg values during the continental subduction in the Triassic. The metamorphic fluids were produced by the breakdown of biotite in the metasedimentary rocks during their subduction to subarc depths for ultrahigh-pressure metamorphism. They would have acquired their geochemical compositions not only from the biotite breakdown but also through leaching reaction with the TTG provenance. In view of the spatial occurrences of the target samples, the metamorphic fluids would have flowed inside the continental subduction channel on a large scale. This is the first report of the large-scale fluid flow in the continental subduction zone and therefore demonstrates that fluid flow can be significant in continental subduction channels.

The effect of argillization and opalization on the properties of andesites and basaltic andesites on the thermal fields of the Kamchatka Peninsula

Ilya BOLSHAKOV[1]*, Lomonosov Moscow State University (bolshakov.ilya.210@yandex.ru)

Abstract

Within the areas of active volcanism, there are specific areas where the natural discharge of heated thermal waters and steam to the daytime surface takes place and that is where hydrothermal-metasomatic rocks appear. In the global diversity of hydrothermal-metasomatic rocks, two varieties can be distinguished that are most common in the near–surface zone - argillized and opalized rocks.

One of the simplest definitions of argillization is: argillization is a metasomatic process consisting in the replacement of the initial minerals of igneous rocks with clay. Most often, this process takes place in thermal fields characterized by medium acidic to slightly alkaline thermal waters (pH ~ 4-8.5). The final product of argillization is hydrothermal clay.

As a result of argillization on igneous rocks, a radical change in their properties occurs. In particular, in massive andesites undergoing argillization on the East Pauzhetka thermal field, porosity increases approximately by 7 times (from 2.6% to 18.1%) and density decreases by 15% (from 2.71 g/cm3 to 2.28 g/cm3), the velocity of longitudinal waves by almost 2 times (from 5.6 km/s to 3.0 km/s), the dynamic modulus of elasticity by 3.5 times (from 62.7 GPa to 17.0 GPa), uniaxial compressive strength in the air-dry state by about 7 times (from 142.3 MPa to 20.7 MPa) and magnetic susceptibility by 40% (from 31.1 SI*10-3 to 18.8 SI*10-3)

Opalization can be defined in the most rational way as follows: opalization is a near–surface hydrothermal-metasomatic process occurring under conditions of discharge of strongly and ultraacid thermal waters (pH < 4), consisting in leaching of primary components of effusive rocks and their replacement with opal.

Opalization begins with the leaching of volcanic glass of effusive rocks and individual sections of crystals. In particular, the inclusions represented by plagioclases first undergo acid leaching in the central parts, which usually have a more anorthitic composition due to its higher crystallization temperature, and some of the inclusions.

As a result of the impact of the opalization process on igneous rocks, the indicators of their properties also undergo significant changes. At the same time, in most cases, opalization negatively affects the properties of modified rocks, with the exception of especially weak differences in volcanogenic sedimentary rocks, the impact of opalization on which can lead to their hardening. In case of opalization of massive basaltic andesites composing the thermal fields of the Bolshoy Semyachik massif, the density can decrease by almost 3 times (from 2.90 g/cm3 to 1.07 g/cm3, and in individual samples the density value turned out to be 0.80 g/cm3), the dynamic modulus of elasticity decreases by more than 40 times (from 54.4 GPa in unaltered basaltic andesites up to 1.3 GPa in collomorphic opalites), uniaxial compressive strength is more than 45 times (from 157.4 MPa to 3.3 MPa), at the same time porosity increases from 3.5% to 51.4%, and

in individual samples exceeds the value of 60%.

Tracing the incipient melting P-T-t conditions of felsic gneiss in South Altyn Tagh: implications on the exhumation of deep subducted slabs

Yongsheng GAI[1]*, Northwest University (gaiysh@nwu.edu.cn)
Liang Liu[2], Northwest University
Tuo Ma[3], Northwest University
Xiaoying Liao[4], Northwest University
Lei Kang[5], Northwest University

Abstract

The partial melting of HP–UHP rocks is impotant in facilitating the exhumation of deep subducted rocks, but in natural studies, this facilitation process is seldum quantificated due to the difficulties in precisely distinguish the incipient partial melting P–T–t conditions. In eastern South Altyn Tagh(SAT), NW China, (U)HP felsic gneiss have been studied to experence deep subduction process. In this study, a series of partial melting evidences in the felisc gneiss, including multi-phase solidus inclusions in garnet mantle and rootless granitic veins in the felsic gneiss have been discovered. Based on geochemical studies, we suggest the granitic veins are originated by the muscovite-dehydration melting of felsic gneiss, based on the high K2O (5.01–9.95 wt%), Rb (182–586 ppm) and low Sr (48.1–241 ppm) content, negative correlations between Rb/Sr and Ba (Sr) of the granitc veins, and the consistent whole-rock Sr–Nd–Pb isotopse between the veins and felsic gneiss. By pseudosection modelling, the initial decompression melting conditions of the felsic gneiss, which just above the solidus, are restricted around 2.2–2.6 GPa and 900–1100 °C, based on the compositions of garnet mantle with titanite and multiphase solid inclusions. The calculated compositions of initial melts by modelling under this restricted partial melting conditions show consistent K2O, Na2O compositions and K2O/Na2O (2.11–4.13) with the granitic veins, further support that incipient partial melting take place during this eclogite facies conditions. Insitu U–Pb dating of titanite preserved in garnet mantle of felsic gneiss show a intersection age of 485 Ma. Based on all the studies above, we suggest the incipient melting of the felsic gneiss in SAT was taken place under 2.2–2.6 GPa and 900–1100 °C, at c. 485 Ma. Besides, based on Ti-in-zircon thermometry, 176Lu/177Hf-in-zircon pressure proxy and zircon U–Pb dating, the crystallization P–T–t conditions of granitic veins were restricted around 0.16–0.82 GPa and 647–872 °C, at 484–488 Ma.

With all the studies above, we suggest the (U)HP felsic gneiss in South Altyn Tagh experienced incipient partial melting process at 2.2–2.6 GPa and 900–1100 °C, then fast exhumed from 2.2–2.6 GPa to ~0.8 GPa within 1–2 Ma. These results not only provide direct evidence that partial melting can facilitate the exhumation of deep subducted slabs, with maximum exhumation rate over 30–60 mm/a, but also provide further insights into the intracrustal differentiation and the generation of potassic granitoids in subduction zones.

The structure and transport properties of diopside supercritical fluid from machine learning potential

Dong WANG[1]*, University of Science and Technology of China (wangdong01@mail.ustc.edu.cn)

Abstract

In deep subduction zones with high temperatures and pressures, the miscibility gap between silicate melt and aqueous fluid diminishes, leading to the formation of a single phase with an intermediate composition, known as supercritical fluid. Supercritical fluids play a crucial role in mass transfer in the subduction zone due to their low viscosity and their ability to carry large amounts of elements. However, the structures and transport properties of supercritical fluids are poorly constrained. Conducting in-situ experiments at high temperatures is still challenging. First-principles calculations can only provide results at extremely high temperatures, since the computational cost required to make the results converge increases significantly as the temperature decreases. Machine learning potentials trained from first-principles data combine the computational efficiency of classical potentials with the accuracy of first-principles, providing a promising way to calculate the properties of supercritical fluids at relatively low temperatures.

Here, we constructed a representative train set for diopside supercritical fluid with 0 ~ 78 wt.% water ($CaMgSi_2O_6$-xH_2O) through a combination of concurrent learning, enhanced sampling, and principal component analysis. The train set was then used to train a machine learning potential for the diopside supercritical fluid. At high temperatures, the melt structure and transport properties calculated by the machine learning potential perfectly match the results from first-principles calculations. By using the efficient machine learning potential, we were able to obtain the structure and transport properties of diopside supercritical fluid down to 1000 K, building a bridge between experiments and theoretical calculations.

Subducted metasedimentary veneer impedes slab–arc carbon recycling

Jilei Li[1]*, Institute of Geology and Geophysics, Chinese Academy of Sciences

Jun Gao[4], Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

The subduction zone carbon cycle plays a crucial role in regulating the global carbon cycle, controlling Earth's climate, and maintaining its habitability. The discrepancy between the amount of carbon released from subducting slabs at sub-arc depths and the carbon output from volcanic arcs suggests the existence of hidden carbon reservoirs within the slab-to-arc pathways. However, the precise location of these reservoirs remains enigmatic. Slab fluid serves as the primary medium for carbon transport in subduction zones, necessitating a comprehensive understanding of the fluid-rock interaction during migration to unravel the carbon flux imbalance between the slab and the arc. In this study, we investigate a high-pressure (HP) metasediment–selvage–vein system from the Southwestern Tianshan HP metamorphic belt (northwest China) to explore rock carbonation along the fluid conduit. Field evidence and petrological observations reveal that, compared to the carbonate-free metasedimentary host rock, the immediate wallrock adjacent to the garnet-bearing calcite-dominated vein (representing carbonic fluid under HP conditions) has undergone significant carbonation, resulting in rapid thinning of the vein structure. We find that substantial rock carbonation (involving dolomite-calcite-magnesite precipitation) occurs when slab-derived carbonic fluids migrate through the metasedimentary sequence at approximately 80 km depths. Furthermore, modeling demonstrates that the metasedimentary layer atop the slab has the capacity to sequester 20%–50% of the fluid carbon from the ascending slab dehydration flux. We propose that the metasedimentary veneer at the plate interface functions as a carbon filter, hindering the transfer of carbon from the slab to the arc. This mechanism mediates the carbon flux imbalance between the amount released by the slab and that emitted by the arc. This study also provides insights into decarbonation efficiency and mechanisms, carbon-transferring pathways, and the temporal aspects of the subduction zone carbon cycle.

Vein-induced carbonatitic metasomatism of eclogites in subduction zones: implications for carbon cycling and mantle isotopic heterogeneity

Weihao Yan[1], Nanjing University
Weiqiang LI[2]*, Nanjing University (liweiqiang@nju.edu.cn)
Qin Wang[3], Nanjing University

Abstract

Ample evidence has shown that carbonates or carbonated eclogites can be subducted to the upper mantle or even the transition zone, facilitating deep carbon cycle. However, carbonates are geophysically buoyant and rheologically weak, how their chemical and isotopic signatures are transported in subduction zones remains elusive. Here we try to address this problem by a detailed Mg and Fe isotope study of a retrograded eclogite boudin and the surrounding marbles in the Dabie ultrahigh-pressure metamorphic belt, China. The studied objects resemble fossil reaction fronts of carbonation of silicate rocks in subduction zone. Both the main bodies of eclogite and marble preserve unaltered Mg isotope signatures, resulting in a sharp Mg isotopic gradient, with δ26Mg values increasing from –1.39‰ in eclogites to –0.23‰ in marbles across the lithologic boundary. However, carbonate veins within the eclogite boudin show remarkably low δ26Mg values (–0.74‰ on average), suggesting extensive diffusive bands during vein injection. The Mg-Fe isotope patterns reveal that the efficiency of carbonatitic metasomatism is low by mechanical mixing of eclogites and marbles at lithologic boundary, but high by injection of carbonatitic veins into eclogites. Thus, vein injection is the key mechanism for carbonatitic metasomatism of eclogites for driving in the deep carbon cycle and geochemical heterogeneity in the upper mantle and transition zone

The mechanism for heavy Cr isotopes in some serpentinites and its implications

Ji SHEN[1]*, CAS Key Laboratory of Crust-Mantle Materials and Environment, University of Science and Technology of China (sjlcwqqq@ustc.edu.cn)

Abstract

Serpentinite is one of the most important water reservoir in subduction zones. The highly variable and heavy Cr isotope compositions of serpentinites have been observed, while its mechanism remains to be highly debated. Here, we have conducted Cr isotope composition analyses for whole-rock and individual mineral separates of serpentinites and associated peridotites and rodingites from Tibet and Fuchuan from China, Cyprus, and Tonga trench. We found that residual hydrothermal fluids after serpentinization reaction exhibit light Cr isotope characteristics, which is evidenced by obviously lighter Cr isotope compositions of the rodingites relative to those of MORB and OIB. However, in consideration of the high Cr content of ultramafic rocks, the released fluids have limited influence on the Cr isotope composition of serpentinites. Combining with the analysis of the primary minerals in serpentinite (serpentine and magnetite), we found that serpentine is always Cr isotopically heavier than magnetite ($\Delta 53Cr_{serp-mag}$=0.02 ‰~0.36 ‰), suggesting a complex Cr migration and redistribution process during or after serpentinization. Based on previous observations of Cr content and Cr isotope trends in serpentinite, we propose that the trend of enrichment of heavy Cr isotopes in serpentinite with low Cr content reflects the leaching effect of magnetite. This found highlights Cr isotope could be a potential monitor to Fe-Cr deposits at ophiolite complex settings.

Origin of fluid beneath the Noto peninsula, Central Japan: Stability of Lawsonite eclogite

Kazuaki OKAMOTO[1]*, Saitama university (kokamoto@mail.saitama-u.ac.jp)

Abstract

Crustal structure beneath earthquake swarm in the Noto peninsula, was already analyzed in detail (e.g. Nakajima et al., 2022), and concluded that large volume of fluids accumulated below the seismogenic zone beneath the Noto peninsula, in Central Japan. Fluid injection into the intra-continent (intra-arc) seismogenic zone is a trigger to slip active fault in back arc region. The fluid has been supplied from the uppermost mantle (50 to 150km) to the lower crust over a geological time scale. Origin of the fluid is considered that water has been transported from subducting Pacific plate to the upper mantle beneath the central Japan. Subducting plate can transport water down to deep mantle because hydrous minerals can be stable. Stability of hydrous minerals are dependent on P, T, and chemical composition of the rock. Lawsonite is major hydrous mineral stable in subducting oceanic crust in deep mantle. It is considered that temperature condition of the subducting Pacific plate beneath the central Japan is cold enough to stabilize lawsonite in the oceanic crust portion of the plate. Slab surface beneath the Noto peninsula is greater than 250 km depths. Ultrahigh pressure experiment in the water-bearing MORB system (e.g. Okamoto and Maruyama, 1999) reveals that 1wt% H2O can be stored in the depth (250 km depth) of the subducting oceanic crust. Further deep (down to 300 km depth), the lawsonite is decomposed to release fluid by dehydration reaction.

Four alkaline shifts of metasomatic reactions by a texture analysis for a garnet amphibolite at 1GPa and ~700°C in Oeyama Ophiolite, Japan

Riichi AKAI[1]*, a post-research student at the University of Tsukuba (r1.akai@gmail.com)

Abstract

Metamorphic minerals have regarded as products of open system in grain scale, and some replaced minerals will also raise a question about metasomatism in thin-section scale. With regard to the analysis of metasomatism, linear algebraic methods constrain a steady state of element mobilities based on numerical conservation theorem in limited observed volume [1] that will be a opposite approach of verification for closed system [2]. Then, a metamorphic stage concretes an image of fluid mediated reactions.

The deformed garnet amphibolite at Wakasa region in Oeyama ophiolitic mélange has several replaced products on the rim of relic amphibole (ex. hornblende to tschermakite, zoisite-epidote, and plagioclase) which result in unexpected imbalance with exchange reactions of coexisted minerals, such as mass of Mg2+. These petrographic characters are common in Oeyama Ophiolite [3]. And, this Wakasa region has reported the oldest 477Ma K-Ar cooling age of Oeyama ophiolite for more coarse altered amphibolite. Relatively high-pressure condition 11kbar, ~670°C was derived by THERMOCALC with effective bulk composition assuming the metasomatic equilibrium. These temperature conditions lays on a temperature interval between plastic stage of peridotite and metasomatic hydration of Oeyama serpentinite [4].

Five reaction modelings by a thinsection's texture analysis result in volumetric increase (1-15%) and high inlet of AlO- and H+ with minor Na+. SiO2 also predicted as inlet in one reaction. These behaviors concordant with the exhumation model in recent pH model for high pressure fluid/rock interaction [5]. Furthermore, Fe2+, Mg2+ and H2O are expelled, probably in correspond to surrounding serpentine or chlorite unit. The garnet bearing reaction in five follows unique phase rule for total 14 phases in 12 components. Other reactions have one lesser 13 phases that assumes to be p=c+1 (p: number of phases, c: number of components) that allowed fully mobile based on Korzhinskii's phase rule [1, 6]. Three of five reactions which differ from Ti-phase has similar volume increase (ΔV=2%), and it's whole view suggests a kind of steady state of external controlled metasomatic fluid and/or some supercritical fluid state having some extinction for phases (ex. by lost of a lithostatic pressure and/or extensive variables). The main compositional changes by these replacements of amphibole can be assumed as "NaAl(Si)H absorbing filter" together with a metasomatic dehydration. The result of numeric modeling is concordant with the other petrography of metasomatised amphibolites and serpentinites in Oeyama ophiolite [3, 4]. This basic mathematical verification and open experiences will help to examine each geochemical research and environmental matters and take our efficient traditional approaches or invisible matters/empirical new modelings for some crustal fluid research or metasomatic analysis.

Abstract

The Nigerian Basement Complex, a high-grade terrain, has undergone a protracted crustal evolution from the Paleoarchean era (3.6-3.5 Ga) and continuing through multiple reworking episodes in the Neoarchean and Paleoproterozoic. This evolutionary trajectory climaxed during the Neoproterozoic with a tectono-magmatic overprint, primarily between 640 and 580 Ma. Isotopic evidence suggests that, except for the Late Archean accretion event during the Eburnean orogeny (2.1-1.9 Ga), juvenile crustal accretion was predominantly confined to the early Archean. Intra-crustal reworking, on the other hand, played a dominant role thereafter. Neoproterozoic plate tectonics fostered the emplacement of diverse granitoids and transformed the intensely reworked basement into a bimodal crust comprising metatexites and diatexites. These processes also obliterated and overprinted earlier structural fabrics. Despite all these pervasive modifications, trace element geochemistry and zircon typology reveal that the old basement has preserved its igneous origins and associations with Paleoproterozoic supracrustal rocks. The protolith sources exhibit near-chondritic rare-earth element distribution patterns and time-integrated 147Sm/144Nd ratios, hinting at the isolation of several segments of the Nigerian lithosphere from the convective upper mantle during the early Archean. In contrast, the vestigial eastern terrains consist of paragneiss and migmatite gneiss derived from probable continental sources and exhibiting granulite facies petrographic modal characteristics.

Abstract

High-pressure metamorphic rocks such as eclogites are primarily formed during oceanic or continental subduction. The exposure of eclogite in ancient subduction zones provides a metamorphic petrological record of the operation of modern-style plate tectonics. In general, the age of potential Precambrian eclogites is mainly defined by accessory phases such as zircon, which cannot be directly matched with the temperature and pressure conditions due to the complex metamorphism process it has undergone. In situ Lu-Hf and U-Pb geochronology techniques have recently been developed to date garnet, the primary mineral phase used for P-T determinations, with aims to overcome the abovementioned shortcomings. Here we reported a detailed in situ garnet Lu-Hf/U-Pb geochronological study on eclogites and associated gneisses exposed in the northern North China Craton (NCC), which has been considered by some scholars to be one of the four key locations with metamorphic petrological evidence supporting the operation of modern-style plate tectonics during the Paleoproterozoic. Garnets from two eclogite and two paragneiss samples yielded consistent in situ Lu-Hf ages of 343 ± 69 Ma to 350 ± 97 Ma and in situ U-Pb ages of 322 ± 34 Ma to 353 ± 37 Ma, which indicate that the eclogites in the northern margin of the NCC were formed during the Late Paleozoic rather than the Paleoproterozoic. The metamorphic zircons within the four studied samples contain eclogite-facies mineral inclusions of garnet, rutile, and phengite. They gave U-Pb ages of 310-325 Ma, which were consistent with those recorded by garnet within analytical errors but have much higher analytical precision. Accordingly, we take the zircon U-Pb ages of 310-325 Ma as the age of eclogite facies metamorphism in the northern NCC. The Paleoproterozoic zircons identified by previous investigations and this study may be derived from the Trans-North China Orogen as detrital or inherited zircons. This study underscores the potential of in situ Lu-Hf and in situ U-Pb

dating of garnet in differentiating between various metamorphic periods and refining the episodic metamorphism of Precambrian eclogite facies, and also advocates for the reexamination of reported Precambrian eclogites worldwide.

Low-pressure, high-temperature metamorphism in the central Mary Kathleen Fold Belt, north-eastern Australia: Tracking an anticlockwise P-T-t path by linking phase equilibrium modelling, microstructures, and in situ geochronology

Juergen REINHARDT[1]*, Department of Earth Sciences, University of the Western Cape, Bellville, 7535, South Africa (jreinhardt257@gmail.com)
Péter Horváth[2], Earth, Environmental, and Sustainability Sciences, Furman University, Greenville, SC 29613, USA
Armin Zeh[3], Institute for Applied Geosciences, Karlsruhe Institute of Technology (KIT), 76131 Karlsruhe, Germany
Michael J. Rubenach[4], School of Earth & Environmental Science, James Cook University, Townsville, 4011, Australia

Abstract

The Mary Kathleen Fold Belt, being part of the Mid-Proterozoic Mount Isa Inlier, NE Australia, experienced prograde low-pressure, high-temperature metamorphism with peak P-T conditions of 600-630°C at 3.8 to 4.8 kbar in its central part. This regional-scale prograde metamorphism correlates with major crustal shortening and resulted in the formation of a pervasive subvertical foliation (S2) and lineation (L2) in which the peak-metamorphic minerals are aligned.

Quantitative phase equilibrium modelling of a variety of metapelitic rock types ranging from Al-rich (aluminosilicate-bearing) to magnesian, low-Al (cordierite-orthoamphibole-dominated) compositions constrains a prograde pressure-temperature path with reaction sequences through the andalusite into the sillimanite stability field that are in line with the observed pre-peak and peak reaction textures and early- to late-syndeformational microstructures.

Incipient to pervasive retrograde overprinting of peak assemblages triggered by episodic H2O infiltration produced random mineral orientations, eliminating the S2-L2 structures. Critical retrograde assemblages and reaction textures that impose constraints on the cooling and decompression path are observed in cordierite-rich rocks. The sequential growth of late-formed aluminosilicates traces a P-T path from the sillimanite into the kyanite and andalusite fields, and eventually into the pyrophyllite stability field. Thus, the prograde-retrograde P-T path is distinctly anticlockwise as documented by the sequential, multi-stage growth of aluminosilicates.

Multiple dating methods have been applied to establish a geochronological framework for prograde and retrograde metamorphism in this area. Analyses of matrix monazites and monazite inclusions in andalusite and cordierite provided a unimodal age peak of 1581±5 Ma (method of Montel et al., 1996). LA-SF-ICP-MS analysis of a set of accessory minerals from both prograde and retrograde samples added further critical geochronological constraints. S2-aligned monazite in pristine prograde samples yielded U/Pb ages of 1580±4 Ma, confirming the monazite age from

microprobe data.

Newly crystallised retrograde monazite and xenotime in pervasively hydrated samples provide coincident U/Pb ages of 1572±5 Ma and 1573±3.5 Ma, respectively, which are close to (and hardly distinguishable from) the age of peak metamorphism. Prograde and retrograde rutile, distinguished microstructurally as well as by their Zr contents, yield both U/Pb cooling ages of 1570-1571 Ma, when the rocks would have reached a temperature of about 500°C. Combining the various U/Pb ages with thermobarometric constraints indicates that initial cooling from peak temperatures to 500°C was relatively rapid, in the order of 10-15°C per million years. This in turn argues for a distinct heating episode triggering prograde metamorphism.

Abstract

Despite half a century of extensive research, the timing and diachroneity of the initial India-Asia collision remains intense debated due to different definitions of the initial collision and the different methods adopted. In the western and central Himalayas, the timing of initial India-Asia collision has been well constrained at ~57 Ma and ~63-60 Ma, respectively, based on metamorphic ages of ultrahigh-pressure eclogites and high-pressure blueschists. In this study, the high-pressure pelitic granulites in the Eastern Himalayan Syntaxis are studied to elucidate their metamorphic evolution and provide new constraints for the onset of India-Asia collision. Petrological examination suggests that the high-pressure pelitic granulite has experienced four metamorphic stages (M1-M4). The prograde stage (M1) is characterized by the garnet core and its mineral inclusions of biotite + muscovite + plagioclase + ilmenite + quartz ± kyanite ± K-feldspar ± rutile, the peak stage (M2) assemblages of garnet + biotite ± plagioclase + K-feldspar + kyanite ± rutile + ilmenite + quartz, followed by the post-peak stage (M3) represented by the transformation of kyanite into sillimanite and rutile into ilmenite and later retrograde stage (M4) marked by the presence of andalusite. Phase equilibria modeling defined a clockwise P-T path involving a near-isothermal decompression process, with peak P-T conditions of 12.4-15.6 kbar/790-850 °C. The P-T path indicates a typical continent- continent collision, during which the pelitic rocks were subducted to a depth of ~50-55 km where they underwent high-pressure metamorphism. Our zircon and monazite dating results indicate that the metamorphic age of pelitic granulites is 60-15 Ma, with the oldest ages clustered at 60-58 Ma. The oldest metamorphic age of north Himalaya high- and ultrahigh-pressure metamorphic rocks may provide an upper limit for the timing of initial collision. Thus, the onset of the India-Asia collision must have occurred before 60-58 Ma in the Eastern Himalayan Syntaxis, roughly consistent with that in the western and central Himalayas. In summary, the northern margin of India and the southern margin of Asia collided synchronously along the entire Yarlung-Tsangpo suture zone at ~60 Ma.

Exsolution textures of Antiperthite and Mesoperthite in the Zhengjiapo BIF, Changyi Metallogenic Belt, North China Craton: evidence of UHT Metamorphic Overprint

Yanrong rong CHEN[1]*, CHINA UNIVERSITY OF PETROLEUM
(chenyanrong272371@163.com)
Xu Ping Li[2], Shandong University of Science and Technology
Yao Qi Zhou[3], China University of Petroleum

Abstract

Paleoproterozoic banded iron formation (BIF) in Zhengjiapo area of Changyi metallogenic belt, Eastern block of North China Craton contains contains abundant coexisting antiperthite and mesoperthite textures. The peak-temperature metamorphic conditions can be derived from this texture. The antiperthite and mesoperthite occur in felsic domains of the Zhengjiapo BIF ore and enable derivation of peak temperature metamorphic conditions. Thermodynamic phase modeling shows that equilibrium conditions of corresponding textures, considering the related mineral assemblage of Pl + Qz + Kfs + Mag + Opx + L, are in the range of 870-940 °C and 5.0-6.8 kbar. Ternary feldspar thermometry using reintegrated compositions of antiperthite and mesoperthite in the felsic domain of the studied BIF iron ore reveals even higher peak metamorphic temperatures of 1045–1080 °C. The ultra-high temperature and low-pressure conditions of the Precambrian BIF have been rarely reported from the North China Craton. Very few studies worldwide have also shown that BlFs and/or their wall rocks experienced UHT metamorphism, which mostly occurred in Archean and Paleoproterozoic. The result of this study documents important details of the metamorphic conditions of the BIF iron ore in the JLJB and sheds new light on the metamorphic development of the North China Craton with respect to the derived HT to UHT granulite facies conditions. The granulite facies BIF ore of the Zhengjiapo iron mine indicates that the BIF was involved in the collision-related tectonic process during Paleoproterozoic to have occurred in the Jiao-Liao-Ji orogenic belt. The current study was supported by the National Natural Science Foundation of China (U2244206) and(U1906207).

Giun HAN[2], Chungbuk National University
Taehwan KIM[3], Korea National University of Education
Taehoon KIM[4], Korea Institute of Geoscience and Mineral Resources
Yuyoung LEE[5], Korea Basic Science Institute

Abstract

The low-pressure/high-temperature metamorphic field gradient has been reported from meta-sedimentary rocks and migmatites in the Wilson Terrane, northern Victoria Land (NVL), Antarctica, but the timing and potential heat source for the low-pressure metamorphism are still controversial. To tackle the issues, the metamorphic and intrusion ages of 2 meta-sedimentary rocks and 5 associated granitoid rocks, respectively, around O'Kane Glacier in the Wilson Terrane were examined. Sedimentary protolith in the study area consists primarily of sandstone, carbonate and pelite, and underwent the Buchan-type metamorphism up to migmatization (700–750 ℃ and 4–5 kbar). Zircon crystals from a meta-carbonate sample yielded the weighted mean 206Pb/238U age of 492.3±3.4 Ma (tσ, MSWD=1.17) with relatively high δ18O values (13.2–15.3 ‰). The age is reproduced in that of metamorphic monazite (491.3±3.7 Ma; tσ, MSWD=2.67) from a migmatitic gneiss sample. Granitoid samples were collected from boudinaged/folded patches in the sedimentary layers, and show a variety of deformation microstructures. The weighted mean 206Pb/238U ages of zircon from 5 granitoid samples are in the range of ~497–500 Ma, except for ~489 Ma from least-deformed one. The earlier ages are coeval with high-P metamorphism in the Lanterman Range (~498 Ma), NVL, and together with their arc-magmatic geochemical affinity such as negative Nb, Ta and Ti anomalies in the spidergram, are interpreted as the final stage of arc magmatism in the Ross orogen. On the other hand, the younger age is considered as syn- to post-orogenic magmatism during or subsequent to the regional metamorphism (~491 Ma). Thus, the emplacement of basaltic magma at ~495 Ma (e.g., gabbroic rocks in the Tiger Gabbro Complex) is the most likely heat source for the Buchan-type metamorphism in the region.

Pressure calibration of natural-quartz Raman spectra variation under hydrostatic condition

Ryusei Harada[1], Saitama University
Shu Miura[2], Saitama University
Kazuaki OKAMOTO[3]*, Saitama university (kokamoto@mail.saitama-u.ac.jp)

Abstract

Pressure dependence of Quartz-Raman shift have been used for conventional geobarometers in metamorphic rocks (e.g. Enami et al., 2007). However, there is obvious discrepancy of estimated metamorphic pressures between the quartz-in garnet (QuiG) elastic geobarometry and equilibrium-based pressure modeling based on thermodynamics (e.g. Mulligan et al., 2002). Several researchers have suspected that pressure difference might be caused by lithological differences in deviatoric stress. Another possible reason is from reference experimental data about the quartz-Raman shift at various pressures. The present study reports systematic pressure calibrations of natural quartz-Raman spectra under hydrostatic conditions. Experiments were done using diamond-anvil cells. Based on our experimental data, equation for quartz-Raman geobarometry for P< 1 GPa is modified as: P(MPa)=0.2696[(ΔνP)206]2 + 30.43[(ΔνP)206]P(MPa)= 0.194[(ΔνP)464]2 + 90.79[(ΔνP)464]. Compared with previous study, estimated pressure becomes approximately 2 GPa lower. It is concluded that previous synthetic quartz-in garnet geobarometry over-estimated metamorphic pressures.

We also analyzed the Raman shift of quartz in garnet to research the effect of garnet host at various pressures. The quartz inclusions used in the present experiments, are from the garnet amphibolite, Hokkaido, Japan. Metamorphic conditions were estimated at 640-670℃ and 1.1 GPa (Ueda et al., 2013). In the present study, metamorphic pressure was calculated as 1.095 G at 660℃. On the other hand, that calculated using inclusion pressure from Schmidt & Ziemann (2000) as 1.174 GPa.

From the in-situ laser-Raman analysis under high pressures, the quartz inclusion in garnet was affected by the garnet shield effect. The peak shift was lower than that of bare quartz. There is residual pressure in the quartz inclusion. However, once it was exposed to the surface of the garnet, it is not affected by the shielding effect. If the quartz was completely included in the garnet, there was no correlation between distance from the garnet surface and Raman peak shift in quartz inclusions.

Fluid-fluxed anatexis of Paleoproterozoic granitic gneiss in the Yeongnam Massif, Korea

Yuyoung LEE[1]*, Korea Basic Science Institute (yuyoung2@kbsi.re.kr)
Moonsup Cho[2], Seoul National University
Jeongmin Kim[3], Korea Basic Science Institute

Abstract

The fluid-fluxed melting of igneous protoliths provides an opportunity to assess the role of fluid for the formation and modification of continental crust during high-temperature metamorphism. In order to investigate such an anatexis in the Buncheon granitic gneiss, Yeongnam Massif, we combined field, microstructural, and geochemical studies with the U–Pb and oxygen isotopic analyses of zircon and monazite. The granitic gneisses comprise metatexitic migmatites containing leucosomes, although neither melanosomes nor peritectic phases are associated with neosomes. These migmatites underwent syn-kinematic wet melting in the presence of ca. 0.9–1.4 wt.% H2O (estimated from the pseudosection modeling) via the reaction, plagioclase + K-feldspar + quartz + H2O = melt, that took place at ~650–750 °C and 4–6 kbar. The leucosomes differ in the degree of Eu anomalies and have variable amounts of rare earth elements, Zr, Y, and Th. Such variations are attributed to the segregation and migration of melts as well as the entrainment of residual phases. Sensitive high-resolution ion microprobe (SHRIMP) U–Pb ages of zircon and monazite were determined from two granitic gneisses and three leucosomes together with an adjacent, undeformed Hongjesa granite. Zircon grains are oscillatory-zoned, except for homogeneous overgrowth rims rarely present in two leucosomes. Both zircon domains were dated at ca. 1.98–1.97 Ga and ca. 1.86 Ga, respectively, suggesting that igneous protoliths were partly recrystallized during the late Orosirian. Monazites from two gneiss samples contain submicroscopic polycrystalline inclusions of K-feldspar + quartz + apatite, reflecting the presence of former melts, and yielded a pooled 207Pb/206Pb age of 1859 ±6 Ma (n= 30). In contrast, monazites from a leucosome are inclusion-free, and yielded the youngest age of 1840 ±16 Ma (n= 6). This result is interpreted to represent the melt crystallization at ca. 1.84 Ga following the ca. 1.86 Ga anatexis. On the other hand, monazite from the Hongjesa granite, yielded a weighted mean 207Pb/206Pb age of 1878 ±5 Ma (n= 11), most likely reflecting a prograde metamorphic growth. The δ18O values of ca. 1.98–1.97 Ga igneous zircon in granitic gneisses are 7.1–7.2 ‰, but those from the leucosome are reduced at 5.9–6.7 ‰. The latter is largely identical to 5.7–6.7 ‰ estimated from ca. 1.86 Ga domains of zircon in the leucosome and monazite in the granitic gneiss; in contrast, a slightly lower δ18O value of 5.46 ± 0.61 ‰ is recorded in the ca. 1.84 Ga monazite of leucosome. The relatively low δ18O values are most likely accounted for by an influx of fluid that has apparently triggered partial melting in the granitic gneiss, and the fluid itself is possibly linked to the crystallization of mafic magmas in an arc complex. Taken together, in contrast to the majority of zircons preserving the crystallization age of igneous protoliths, monazites are more susceptible to recrystallization during the fluid-present melting and permit us

to decode a protracted (~20 m.yr.) episode from partial melting to melt crystallization in the Yeongnam Massif. Such a longevity of melt-present system typifies the prolonged crustal reworking of Paleoproterozoic Korean arc situated

Middle Permian high-pressure rocks preserved in the Southern Beishan Orogenic Belt, NW China: metamorphic evolution and tectonic implication

Wenxuan Li[1]*, University of Waterloo (w54li@uwaterloo.ca)
Shoufa Lin[2], University of Waterloo

Abstract

The Beishan Orogenic Belt, located between the southern Tianshan suture to the west and the Solonker suture to the east, is a typical accretionary orogen formed as a result of subduction and closure of the Paleo-Asian Ocean. The timing of the final closure of the Paleo-Asian Ocean in the orogenic belt remains controversial. We present here preliminary results of geochronology, petrography, mineral chemistry, thermodynamic modelling, and P-T path construction on tonalitic gneisses from the Shiyao Complex. Petrological examination reveals that the tonalitic gneisses experienced three metamorphic stages (M1-M3). The M1 is characterized by with epidote, garnet, hornblende, muscovite, plagioclase, quartz, rutile. The M2 assemblage is marked by the growth of garnet, ilmenite, plagioclase, hornblende on the consumption of muscovite and epidote, and the transformation of rutile to ilmenite and/or sphene. The M3 stage is represented by the development of chlorite, muscovite in the matrix. Thermodynamic phase equilibrium modeling defined a clockwise P-T path involving a decompressional heating process from P-peak eclogite-facies (M1) of 13.8-14.2 kbar/580-588 °C to T-peak amphibole-facies (M2) of 8.2-8.8kbar/630-650°C, with low- to medium-thermobaric ratios of 414-420°C/Gpa. This indicates a typical cold subduction, during which these rocks were subducted to a depth of 40-50 km where they underwent low temperature eclogite-facies metamorphism and then exhumated to a shallow depth of 20 km along the subduction channel. Zircon SHRIMP dating yielded a metamorphic age of 275.9±6.1 Ma, interpreted to be the age of the amphibole-facies metamorphism. In summary, our results, combined with available data, suggest that subduction leading to the closure of the Paleo-Asian Ocean in the Beishan Orogenic Belt was continuing in the middle Permian.

Experimental evidence for the exsolution of kyanite from Al-bearing stishovite: Implications for ultra-deep subduction/exhumation of continental crust

Liang Liu[1]*, NORTHWEST UNIVERSITY (liuliang@nwu.edu.cn)

Abstract

Based on experimental studies on the solubility (dissolution) of specific components (or exsolved minerals) in host minerals, exsolution microstructures identified in minerals, such as pyroxene/sodic amphibole in garnets, Fe-Ti oxides in olivine, K-feldspar in pyroxene, coesite in sphene, kyanite + spinel in former stishovite, from ultra-deep mantle xenoliths within kimberlites or lamproites, and from ultra-high-pressure (UHP) metamorphic rocks within subduction zones, is an important mineralogical probe to investigate the original depth as well as the mantle processes and slab subduction/exhumation dynamics. However, due to the complexity or multiplicity of the formation mechanisms of exsolution, especially the reversed experiments (compared to dissolution experiments) reproducing the exsolution microstructures, have rarely been reported, which make the interpretation of the genesis of the exsolution microstructures in minerals still controversial or even doubtful. In addition, with the intensive studies on UHP metamorphism and deep subduction of continental crust, mineralogical evidence of ultra-deep subduction to or near the depth of the stability field of stishovite (SFS) and subsequent exhumation to surface has been recognized in a number of typical UHP metamorphic terranes represented by South Altyn, NW China. However, since those evidences are mainly specific mineral exsolution microstructures or quartz paramorphs after stishovite, which in turn leads to the ultra-deep subduction to SFS is not widely recognized by the geoscience community. Therefore, in order to address these issues, this study attempts to further investigate the geological significance of exsolution microstructures and their implications based on exsolution experiments of kyanite in synthesized Al-bearing stishovite.

Our results show that the Al dissolved into stishovite exsolved completely in two stages. Firstly, ~69% of Al exsolved in the form of kyanite lamella as a decompression from 17 to 9 GPa (SFS). Then, the remaining ~31% of Al exsolved in the same form during the transformation from stishovite to coesite with continuous decompression to the stability field of coesite. As further decompression to the stability field of coesite/quartz + kyanite, the host stishovite transformed to coesite/quartz which correspondingly inherited kyanite lamellae exsolved from precursor stishovite. As decompression to the stability field of quartz + sillimanite, not only the host stishovite transformed to quartz, but also the former exsolved kyanite lamellae transformed to sillimanite.

Consequently, our results suggest that exsolution microstructures constrained by dissolution and exsolution experiments can indicate the subduction depth of UHP metamorphic rocks as well as UHP index minerals (e.g. coesite, diamond and stishovite). Therefore, the quartz associated with exsoleved lamella of kyanite + spinel in pelitic gneisses from South Altyn, China could be reasonably attributed to the decomposition of a precursor stishvotite, indicating continental crust experienced ultra-deep (SFS) subduction/exhumation. Moreover, the transformation of both

precursor host UHP minerals and exsolved minerals to low-pressure phases during retrograde metamorphism implies that lamella of sillimanite in quartz could not be excluded the possibility of a product of former kyanite in stishovite.

TIN ORE FORMATIONS OF ZIRABULAK-ZIAETDIN REGION OF UZBEKISTAN

Farrux Raxmatullayev RAXMATULLAYEV[1]*, Institute of mineral resources
(farruxraxmatullayev6868@gmail.com)

Abstract

Zirabulak-Ziaetdin ore region in Uzbekistan, which is located in the southwestern part of the Central Kyzylkum, is gold-rare metal. In the pre-Mesozoic basement of the region there are the Ingichke tungsten deposit, the Karakutan, Kyzbibi, Yangi Davon gold deposits, the small tin deposits of Karnab, Lapas, Semizkuduk, Kyzkurgan, Kochkaraly Changalli, etc. Sandstone-type uranium deposits are located in the sedimentary cover. .Insufficiently studied, but promising are the tin-ore objects of the region, located within two tin-ore fields: Karnabsky and Lapasssky.

The tin deposit Karnab ore field are confined to the southwestern endocontact of the C3-P1 biotite granite intrusion, which breaks through the core of a large anticline fold, on the wings of which marbled Devonian limestones and Ordovician terrigenous rocks are exposed. The Karnab intrusion hosting the mineralization is a C3-P1 granitoid complex. Contacts of an intrusion with a folded structure are secant. The northern contact is steep, the southern one is more gentle, complicated by a series of ruptures of the Karnab-Lapas deep fault. Dikes and stock-like bodies of leucocratic granites, aplites, and, to a lesser extent, pegmatites, are widespread in the exocontact zone.

Tin deposits of the Lapassky ore field are located in the zone of the southern exocontact of the Chirakdzhurinsky intrusive in carbonate-terrigenous sediments O2-3-D2.

The metamorphic events registered in the Santander Massif (Colombia)

Luis C. MANTILLA F. [1]*, UIS (lcmantil@uis.edu.co)
Carlos A. GARCIA R.[2], UIS

Abstract

The Santander Massif (SM) is an igneous-metamorphic basement, outcropping in the Colombian eastern cordillera, composed mainly by high and low-grade metamorphic rocks (Precambrian and early Paleozoic in age), along with igneous lithologies formed during different subduction events that took place during the late Paleozoic, Mesozoic and Cenozoic time.

The metamorphic rocks from the SM are traditionally grouped in the following stratigraphic units[1]: Bucaramanga Gneiss (its zircon crystals, analyzed by SHRIMP method, shows an U-Pb age between ~1550 and ~900 Ma[2]), Silgara Schist (its U-Pb detrital zircon geochronology shows an age ranging from 1624 to 451 Ma; [3]) and Orthogneis (a sin-tectonic igneous plutons emplaced then at 477 Ma;[4]). A more recent study in the Floresta Formation rocks, a sedimentary unit affected by low-grade-metamorphic event, shows a prominent U-Pb detrital zircons age pick at 410 Ma [5]; and a garnet and whole rock Lu/Hf geochronology from a sample collected in the SW area of the SM (affected by amphibolite facies and traditionally related to Silgara Unit), yielded an age of 271.11.5 Ma. Biotites and amphiboles from the Bucaramanga gneissic rocks has exhibited completely reset Ar/Ar spectra, with well-defined plateau ages in the 190-200 Ma [2,6].

The before mentioned data suggest a complex metamorphic history for the SM. At least two main regional metamorphic events have been recognized, related to the Grenville and Fammatinian orogenic events; but other metamorphic events, more local in their effect on the rocks (late Paleozoic and Mesozoic in age), have also been recognized in the MS, mainly related to contact, dynamo-thermal, hydrothermal and probably a burial metamorphism as well.

METAMORPHIC EVOLUTION OF THE UBENDIAN BELT IN NORTHERN MALAWI

Ruth MUMBA[1]*, Geological Survey Department (ruthmumba89@gmail.com)
Joseph Chirwa[2], Mines Department

Abstract

The Ubendian belt is a northwest-southeast trending metamorphic belt that borders the Tanzania craton on the southwest and separates the craton from the Bangweulu Block and Irumide belt on the Southwest and extends into the northern part of Malawi. It has eight tectonic blocks of different lithologies three of which namely the Ufipa, Mbozi and Nyika extend into Malawi. The belt has experienced several periods of reactivation since the Palaeoproterozoic era. Some of these activities obliterated the earliest metamorphic history of the rocks. This study was undertaken in part of northern Malawi in the Chitipa district using selected lithologies to constrain further the metamorphic evolution of the Ubendian Belt. The methods used in this study included geologic mapping, petrography and pressure-temperature analysis. The study investigated the structural geology of paragneisses, phyllites , granitic gneisses; and the pressure-temperature conditions of cordierite gneisses which are some of the oldest rocks in the area dated 1815±260 m.y. BP by Rb-Sr whole-rock isochron method from the previous work (Ray 1974).This information, coupled with previous data, gave us more information on the area's metamorphic evolution. It was observed that the earliest metamorphic event has been erased from the rocks. What is prominent are the effects of the Irumide and Mozambique orogeny. On pressure-temperature conditions, amphibolite facies were calculated and the possibility of a retrograde path as the mineral chlorite was observed.

Crustal Thermal transitions and the Rise of the Tibetan Plateau: From Amphibolite to Ultrahigh-Temperature Granulite Facies Crust since the Miocene

XIU-ZHENG ZHANG[1]*, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences (zhangxz@gig.ac.cn)
QIANG WANG[2], Guangzhou Institute of Geochemistry, Chinese Academy of Sciences
WEI DAN[3], Guangzhou Institute of Geochemistry, Chinese Academy of Sciences

Abstract

Numerical models have highlighted the critical role of the thermal state transition (TST) from a cold to a warm mid-to-lower crust in dictating the morphological fate of orogens—shaping them into either linear mountain ranges, akin to the Alps, or expansive hot orogens with flat plateaus, reminiscent of Tibet. The Tibetan Plateau's rapid ascent, the most prominent topographic anomaly on Earth, is generally attributed to thermal mechanisms involving either the mantle, such as lithospheric delamination, or the crust, through processes like crustal flow. Yet, the precise timing and mechanisms underlying the shift from a cold to a warm state in the lithospheric mantle or deep crust remain elusive. This study presents findings from unique mid-to-lower crust xenoliths embedded in igneous rocks dated at 28, 3.8, and 2.3 Ma from central Tibet, shedding light on this transition. Our data reveal a cold, H2O-rich deep crust at 28 Ma, transitioning to a hotter, drier granulite crust by ~23 Ma, driven by an increasing geothermal gradient. These findings mark the first concrete temporal constraints on the TST, delineating the duration of this pivotal transition. The marked shift observed between 28 and 23 Ma aligns with the hypothesis of lithospheric mantle delamination induced by hot asthenosphere upwelling. Rising geothermal gradients likely transformed the once H2O-abundant mid-lower crust, generating substantial melt volumes until 2.3 Ma, when conditions evolved to ultra-hot (>1100 ℃) and arid states. Correlated with paleoelevation data, our results imply a nearly concurrent cold-to-hot thermal transition in the mid-lower crust with the topographic transformation from rugged mountains to a level plateau during the early Miocene. This supports the theory of crustal flow as the predominant mechanism for landscape leveling across central-northern Tibet.

Abstract

The Kerguelen large igneous province (LIP) is linked with the opening of the eastern Indian Ocean. During the Early Cretaceous, widespread volcanism coincided with the rifting to breakup between Greater India and Australia-Antarctica (East Gondwana). Subsequent to the breakup, a series of massive volcanic eruptions formed the basalts of the southern Kerguelen Plateau and other microcontinents in the proto-Indian Ocean. However, the role of the Kerguelen LIP in the opening and evolution of the Indian Ocean remains a contentious subject. A primary point of debate is the poorly constrained age and characteristics of early magmatic products and their uncertain relationships with the Kerguelen LIP. The International Ocean Discovery Program (IODP) Expedition 369 recovered Early Cretaceous volcanic and sedimentary sequences at Site U1513 on the Naturaliste Plateau, southeastern Indian Ocean. The Naturaliste Plateau, a large submarine continental block on the southwest Australian rifted margin, situated near the projected position of the Kerguelen plume during the opening of the eastern Indian Ocean. Recent investigations into the volcanic sequences have revealed new critical evidence supporting the involvement of the Kerguelen LIP in the East Gondwana breakup. Our study delves into the intricate relationships between the Kerguelen LIP and the post-breakup evolution of the proto-Indian Ocean and the southwest Australian rifted margin. Re-analyses of core-sections and samples discriminated an early Aptian interval, potentially synchronous with the southern Kerguelen Plateau volcanism. The interval reveals distinctive signatures of volcanic influence, including tuffaceous sediments and a high Hg content, even though the volcanism on the Naturaliste Plateau had already ceased during the early Barremian. These findings suggest that the

early Aptian deposits contain volcanic ash transported from the Southern Kerguelen Plateau. Additionally, this interval exhibits an abrupt transition from shallow and restricted marine to deep and open marine environments, signifying the initiation of post-rift thermal subsidence. Contrary to substantial post-rift subsidence experienced elsewhere following the final breakup, the Naturaliste Plateau displayed limited subsidence after the final breakup during the Barremian, likely attributed to the proximity or elevated temperature of the Kerguelen mantle plume. Consequently, we infer that the early Aptian activity of the Kerguelen LIP influenced the thermal condition of the lithosphere, which resulted in the rapid subsidence of the Naturaliste Plateau and associated environmental changes in the proto-Indian Ocean.

Neoproterozoic (ca. 830 Ma) carbonatite dykes from Qianlishan in the western North China Craton and their tectonic and metallogenic implications

Shuan-Hong ZHANG[1]*, Institute of Geomechanics, Chinese Academy of Geological Sciences (tozhangshuanhong@163.com)
Hong-Yu WANG[2], Institute of Geomechanics, Chinese Academy of Geological Sciences

Abstract

Carbonatite and the associated alkaline intrusive complexes are the primary sources of light rare earth element (REEs). Our field investigations in the western margin of the North China Craton (NCC) have firstly identified over 20 carbonatite dykes and minor coeval carbonate-rich lamprophyre dykes intruding into the Paleoproterozoic Qianlishan Group in the southern Qianlishan area. Zircon LA-ICP-MS U-Pb dating on six carbonatite samples yielded crystallization ages ranging from 835.2+/-3.7 Ma to 828.9+/-3.8 Ma, indicating emplacement of the carbonatite dykes at ca. 830 Ma during the Neoproterozoic. Geochemical data show that most of the carbonatite dykes are rich in light REEs with total light REEs >600 ppm to 4932 ppm, and the carbonate-rich lamprophyre dykes are characterized by high Cr (1219–1267 ppm) and Ni concentrations (857–1076 ppm). Petrological and scanning electron microprobe (SEM) analytical results show that the dominant REE-bearing minerals in the carbonatites are monazite, and other REE-bearing minerals are parisite and bastnäsite. Geochemical and carbon-oxygen isotopic results indicate that the ca. 830 Ma carbonatite dykes were produced by low-degree partial melting of a previously metasomatised subcontinental lithospheric mantle with assimilation of crustal material. Emplacement of the ca. 830 Ma carbonatite and carbonate-rich lamprophyre dykes in the southern Qianlishan area and the previously reported ca. 810 Ma mafic dykes in the middle Qianlishan area occurred in a continental rift environment. Simultaneous development of the Neoproterozoic (830–810 Ma) continental rifting events in the western margin of the NCC and the eastern margin of the Alxa Block as previously suggested may indicate a connection between the eastern Alxa Block and the western NCC during and before the middle Neoproterozoic.

Deciphering the Emplacement Mechanism of Paleoproterozoic Mafic Dyke Swarms in the Dharwar Craton: Insights from AMS and Fracture Analyses

SRINJOY DATTA[1]*, BANARAS HINDU UNIVERSITY, VARANASI
(dattasrinjoy94@gmail.com)
AMIYA KUMAR SAMAL[2], BANARAS HINDU UNIVERSITY, VARANASI
SAYANDEEP BANERJEE[3], BANARAS HINDU UNIVERSITY, VARANASI
RAJESH KUMAR SRIVASTAVA[4], BANARAS HINDU UNIVERSITY, VARANASI

Abstract

The Dharwar craton hosts several Paleoproterozoic mafic dyke swarms ranging in age from ca. 2.37 Ga to ca. 1.79 Ga. These dyke swarms, which are extensively exposed throughout the craton, have been studied in detail for their geochemistry, geochronology, and paleomagnetism. However, there remains a lack of understanding regarding their emplacement dynamics and magma flow patterns. Anisotropy of magnetic susceptibility (AMS) offers a straightforward method to investigate magma flow dynamics within dyke fractures. When combined with fracture data analyses, AMS data can yield valuable insights into dyke emplacement mechanisms.

In this study, samples from four distinct Paleoproterozoic dyke swarms, viz. ca. 2.37 Ga Bangalore-Karimnagar dyke swarm, ca. 2.25 Ga Ippagudda-Dhiburahalli dyke swarm, ca. 2.21 Ga Anantapur-Kunigal dyke swarm, and ca. 2.08 Ga Devarabanda dyke swarm have been studied considering their wide-ranging spatial and temporal distribution. The magnetic fabric data of the mafic dykes are compared to those of the associated host granites, as well as fracture geometry data, in order to explore potential relationships between magmatic stress regimes and pre-existing strain fabrics. The results indicate that, with the exception of the ca. 2.08 Ga Devarabanda dyke swarm, most dyke swarms exhibit lateral magma injection from distant plumes suggesting no plume centre is located below the cratonic lithosphere of the Dharwar craton. In contrast, the ca. 2.08 Ga dyke swarm displays a combination of lateral and vertical magma injection from a proximal plume center. By analysing the imbrication of magnetic minerals within the dyke planes, potential location of plume centers for the studied dyke swarms have been identified. Furthermore, by comparing the magnetic fabrics of the dykes with those of the host rocks and examining fracture geometry, emplacement models have been proposed for each dyke swarm. Overall, the study highlights significant influence of pre-existing strain fabrics and regional stress regimes on the emplacement of dyke swarms within the craton. Given that dyke swarms are often associated with supercontinent breakup or assembly, and considering the Dharwar craton's position in several major supercontinents, this research enhances our understanding of the Dharwar craton's tectonic architecture, with potential implications for the broader Precambrian tectonic framework.

Abstract

Silicic Large Igneous Province (SLIP) represent a distinct class within the Large Igneous Provinces (LIPs), predominantly characterized by silicic magmatic rocks with subordinate proportions of basalt and/or mafic/ultramafic intrusive equivalents, originating without any subduction influence. Based on an in-situ LA-ICPMS U-Pb zircon date of 2480 ± 17 Ma obtained for a granophyre dyke emplaced in the Pakhanjore area, central-west Bastar craton and earlier reported coeval Bijli rhyolite, Pitepani basalts, Khallari ultramafic-mafic complex, Nuapada syenite, and several granitic intrusions, we identified a new ca. 2.49-2.46 Ga Dongergarh SLIP event in the Bastar craton, the second SLIP event discovered in the Indian Shield. The other SLIP event known in the Indian Shield is the ca. 750 Ma Malani SLIP, which is consisting of basaltic eruptions transitioning to massive silicic lava flows, granitic plutonism, and terminal dyke-swarm activity. Geochemical composition of the studied granophyre dyke aligns closely with Kotri and Bijli rhyolites, suggesting its eruption within an intraplate tectonic setting through crustal anatexis. The coeval magmatic rocks collectively constitute a comprehensive assemblage, displaying close spatiotemporal relationships clearly indicate the presence of a SLIP event. Although, no matching SLIP event known from other part of the world, however, there are coeval LIP events are known from the Superior, Wyoming, Hearne, Karelia, and Zimbabwe cratons, particularly the Matachewan LIP in the Superior craton, which consists of multiple pulses of mafic dykes emplaced between 2490-2450 Ma.

Abstract

A systematic study of intracratonic regional mafic dyke swarms, within shield areas provide crucial insights on short-lived, mantle-generated large igneous province (LIP) events through space and time. More importantly, mafic dyke swarms record the pulse of the Earth and rhythm of intraplate mantle melting events through time. Significantly, if it is precisely dated, it may deliver incredible information on continental rifting and supercontinent break-up, secular evolution of the mantle, location of plume centres and their frequency, key paleomagnetic poles, mantle sources, and many more. In addition, dyke swarms and their LIP events are also drivers of catastrophic environmental change, regional uplift, regional basin formation, Ni-Cu-PGE and other types of ore deposits, and fluctuations in the reversal frequency of the Earth's magnetic field. One of the most important characteristics of the regional dyke swarms identified in any shield area represents part of the plumbing system of Large Igneous Provinces (LIPs). This is crucial as the young Mesozoice-Cenozoic record LIPs are expressed as continental flood basalts or oceanic plateaus, whereas, in the case of older LIPs of Precambrian age, the flood basalts have typically been removed by erosion, thus exposing the plumbing system component, which consists of regional dyke swarms, sill provinces and associated mafic-ultramafic intrusions; also, silicic magmatism and carbonatites and kimberlites can also be associated.

Like the other shield areas of the globe, the Indian Shield too hosts a spectacular record of dyke swarm emplacements in space and time. Based on several proxies that include mapping with the help of Google™ Earth images and ArcGIS™, field-data, trend and patterns of dyke swarms, geochronology, and geochemistry, more than 25 distinct dyke swarms are identified in different Archean cratonic blocks of the Indian Shield. On the basis of these dyke swarms, together with other magmatic intrusions, more than 15 very well-preserved LIP events are characterized. The geochemical attributes of many of these dyke swarms, by inference LIPs, indicate the assimilation of crustal material prior to their emplacement. This assimilation process establishes a probable connection to the formation of Cu-Ni-Co-PGE deposits. Some identified LIP events also show association with carbonatite, kimberlite and lamproite and related economic potentials, particularly rare-earth elements and diamonds. The age bar-code record of these magmatic units has a good match with magmatic records of other regions globally that provide a basis for a robust evaluation of the position of the various Indian cratons within the known supercontinents, viz., Kenorland, Columbia, Rodinia, and Gondwana.

The Midcontinent Rift System LIP initiated passively — Evidence from diverse mantle source contributions during early rift development

Pete HOLLINGS[1]*, Lakehead University (Peter.Hollings@lakeheadu.ca)
Matthew Brzozowski,[2], Lakehead University
Jing-jing Zhu[3], Chang'an University
Robert Creaser[4], University of Alberta

Abstract

The magmatism associated with the Midcontinent Rift System (MRS) of Canada has generally been suggested to result from the impingement and melting of the Keweenaw Plume beneath the crust ca. 1.1 Ga. However, the long duration of MRS magmatism combined with paleomagnetic evidence consistent with rapid plate motion during that time suggests that plume melting may not have been the main source of the magmatism. This has raised questions regarding the nature of the mantle sources that fed the MRS and the processes that initiated rift development. Although important for understating early MRS development and associated critical mineral resources, addressing these uncertainties has remained challenging given that many of earliest MRS magmas were variably contaminated by crustal material, masking primary geochemical signatures. To overcome this, we integrated new Os isotope data of Initiation (>1,109 Ma), Early (1,109–1,104 Ma), and Hiatus (1,104–1,098 Ma) stage rocks with variations in their bulk-rock Nd isotope geochemistry. The MRS rock suite is characterized by highly variable γOsi values of -10 to 3857, with Early Stage melts exhibiting the greatest variability (-10 to 3857) and Initiation Stage melts exhibiting the smallest variability (4 to 50). This variability could not have resulted from different degrees of partial melting, retention of garnet in the mantle, or fractional crystallization because γOsi values do not correlate with La/Sm, Gd/Yb, and MgO, respectively. Based on mixing simulations, the radiogenic εNdi–γOsi values of the early mafic–ultramafic intrusions and sills suggest crystallization from melts derived largely from enriched Subcontinental Lithospheric Mantle (SCLM), which assimilated limited (<10%) crustal material during emplacement. In contrast, the variably negative to positive γOsi values of late diabase sills and subaerial lavas suggest crystallization from melts that originated from depleted portions of the Keweenaw Plume, which were subsequently contaminated during emplacement in the crust. Although contamination can explain the range of εNdi values exhibited by the rock suites, it cannot independently account for the range of γOsi values as i) this would require geologically unreasonable degrees of contamination and ii) not all of the rock suites were contaminated. It is likely that fractionation of sulfide liquid and/or Os-bearing platinum-group minerals also contributed to this variability. These results have two critical implications for magma sources and rift development. First, not all of the rock suites in the MRS crystallized from plume-derived melts as traditionally thought, with melt contributions from the SCLM being greatest during the early stages of rift formation. Second, the MRS likely initiated passively, with later plume impingement providing the energy and material necessary for voluminous magmatism.

Links between plume-generated LIPs and new ocean formation through time

Hafida EL BILALI[1]*, Carleton University, Canada (hafidaelbilali@cunet.carleton.ca)
Richard Ernst[2], Carleton University, Canada

Abstract

It is clear from the Phanerozoic geological record that plume-generated Large Igneous Provinces (LIPs) can be associated with major continental breakup and formation of new oceans. Prominent examples include the 62-55 Ma North Atlantic LIP, the 201 Ma Central Atlantic LIP, and the 132 Ma South Atlantic LIPs (including the Parana-Etendeka LIP), which are associated with formation of the North Atlantic, Central Atlantic and South Atlantic, respectively. In each case ocean opening began within a few million years after the arrival of the plume-generated LIP.

It is equally clear that some major plume-generated LIPs are not associated with breakup, such as the 251 Ma Siberian Traps LIP, which caused rifting (but no breakup) between Asia and Europe. A Proterozoic example is the 1106-1090 Ma Keweenawan LIP associated with the 2000 km long Mid-Continent Rift system in the Great Lakes region, but which failed to separate 'Canada' from the 'United States'. In both cases, coeval compressional stresses prevented ocean opening: assembly of Pangea in the case of the Siberian Traps LIP and the Grenville Orogeny in the case of the Keweenawan LIP.

We propose that formation of new oceans requires both a mantle plume and favourable extensional stresses in the plate at the time. It is further hypothesized that formation of every major ocean through geological history required the presence of a plume-generated LIP. In this present study, we provide an initial catalogue of plume-generated LIPs through time which can be linked with new ocean formation.

LIP events can be extensive (covering up to 10,000,000 km2) and for demonstrating a link with ocean opening it is key that the plume centre be located approximately along the new ocean boundary. We review criteria for locating plume centres of LIPs. The strongest constraint is giant mafic radiating dyke swarms which focus on the plume centre. Giant circumferential dyke swarm can also be important. Triple junction rifting can focus approximately on the plume centre, in some cases with offset of a few hundred km. Another criterion is variation in the thicknesses of flood basalts (as an indicator of proximity to the plume centre).

The effective elastic thickness of lithosphere for continental large igneous provinces

Qin WANG[1]*, School of Earth Sciences and Engineering, Nanjing University (qwang@nju.edu.cn)
Yao Yao[2], Nanjing University
Richard Ernst[3], Carleton University
Hafida El Bilali[4], Carleton University

Abstract

The effective elastic thickness of the lithosphere (Te) provides a proxy to reflect the overall long-term (>106 years) rheological strength of the lithosphere. So far there are only a few studies on Te of large igneous provinces (LIPs) and lack comparison of Te of different LIPs. In order to clarify the influence of thermal and loading effects of LIPs on rheology of the lithosphere, we used the admittance method, the coherence method and the joint inversion method to calculate Te distribution and loading ratios (F) of the Emeishan LIP and surrounding area with topography data from ETOPO1, gravity data from WGM2012 and the CRUST1.0 model. The results indicate that the joint inversion method is more robust than the other methods. We then used the joint inversion method to estimate Te and loading ratios (F) of the Deccan Traps LIP (~66 Ma), the Central Atlantic magmatic province (CAMP) (201-202 Ma), the Siberian Traps LIP (~252 Ma), and the Kalkarindji LIP in Australia (~511 Ma). The results indicate that Te of the continental LIPs is independent of the crustal thickness (Tc) but has a positive correlation with Te/Tc. The eruption center (i.e., the area with thickest basalt lavas) has smaller Te/Tc values than the surrounding cratonic regions, but higher than tectonically active regions. Te/Tc values increase with the age of LIPs.

Development of LIPs is associated with surface loading by massive continental flood basalt and subsurface loading by mafic intrusions and magma underplating at the crust-mantle boundary. The loading ratio F in the eruption center of the Deccan Traps LIP, the CAMP and the Siberian Traps LIP is negatively correlated with Te. Compared with other LIPs, the Emeishan LIP shows the higher heat flow, lower F, lower Te and lower Te/Tc, which can be attributed to the enhanced tectonic activity during the eastward growth of the Tibetan plateau in the Cenozoic. The subsurface loading is dominant in the Emeishan LIP, the Decan Traps LIP and the CAMP, whereas the surface loading is dominant in the Siberian Traps LIP and the Kalkarindji LIP. In addition, the influence of LIPs on the lithospheric strength varies with space and time. During formation of LIPs, the mantle upwelling and magma underplating increase the lithosphere temperature and decrease the crust-mantle coupling, resulting in smaller Te values. The subsequent cooling will gradually increase the crust-mantle coupling and the overall strength of the lithosphere. However, the Te values in the eruption center will decrease because the surface loads from flood basalts and crustal intrusions produce high stress. Finally, the surface loads gradually decrease due to surface processes with time, the induced stress in the eruption center reduce simultaneously and the strength of the lithosphere gradually recovers. For the Kalkarindji

LIP in ~511 Ma, the influence of LIP on the strength of the continental lithosphere can be ignored.

Record of Archean Large Igneous Provinces (LIPs) and their mafic dyke swarms

Richard Everett ERNST[1]*, Carleton University, Canada (richardernst@cunet.carleton.ca)
Hafida El Bilali[2], Carleton University, Canada
Kenneth L. Buchan[3], 273 Fifth Ave., Ottawa, Ontario, Canada
Kevin R. Chamberlain[4], Wyoming University, USA
Rajesh Srivastava[5], Banaras Hindu University, India

Abstract

Over the past two decades, there has been a significant expansion of the Archean Large Igneous Province (LIP) record through precise U-Pb dating, new approaches to geochemical characterization, improved reconstruction constraints (based on paleomagnetism and age matching of magmatic events), and a better understanding of LIP plumbing system architecture. Key criteria for the recognition of Archean LIPs are volcanic sequences with associated komatiites (indicating a high temperature mantle source), geochemistry consistent with intraplate origin (with potential modification by lithospheric mantle or crust), large inferred magmatic volume, and the presence of large mafic dyke swarms. Based on such criteria, there are a minimum of 70 Archean LIP-fragments (on different crustal blocks) from the 3.8 to 2.5 Ga period, which fall into a minimum of 30 age groups spanning different crustal blocks that could potentially represent single reconstructed LIPs/plumes. This represents an average of one LIP fragment every 20 myr and a minimum of one (potential) reconstructed LIP event every 40 myr. These values are remarkably similar to the post-Archean continental record of one LIP fragment per 20 myr, and age groups (representing potentially reconstructed LIPs) of about one per 30 myr. In both time periods (Archean and post-Archean) there is certainly incomplete information, In the post-Archean time (except for the past 200 myr) the oceanic LIP record is only preserved as fragments in collisional belt. While the Archean LIP record may include oceanic LIPs, a full understanding of this aspect of the geological record is hindered by a more extensive history of metamorphism, deformation and crustal fragmentation.

Archean dyke swarms are particularly valuable in recognizing and characterizing mantle plumes. We currently recognize nearly 40 dyke swarms from the 3.51-2.5 Ga period, which can be grouped by age across different crustal blocks and represent a minimum of 17 different events (2510-2500, 2550, 2575, 2620, 2660, 2700-2680, 2720-2710, 2725, 2750-2740, 2780-2770, 2860, 2920, 2960, 3265, 3320, 3470, 3510 Ma), each likely linked to a mantle plume. At least two Archean plume centres have been identified based on radiating swarms, both are in the Kaapvaal craton (at ca. 2.96 Ga and at 2.70-2.68 Ga). Additional candidates are being assessed.

A comprehensive geochemical study on mafic dyke swarms from the central-western Bastar craton, India, and their link with different Paleoproterozoic large igneous provinces of the Indian Shield

Ankur ASHUTOSH[1]*, Banaras Hindu University (ankurashutoshsingh@gmail.com)
Amiya Kumar Samal[2], Banaras Hindu University
Gulab Chand Gautam[3], Banaras Hindu University
Rajesh Kumar Srivastava[4], Banaras Hindu University

Abstract

The Archean Bastar craton of the Indian Shield is transected by several Mesoproterozoic-Neoarchean mafic dyke swarms of different trends and compositions. Among them, at least three distinct mafic dyke swarms have been documented in the central-western part of the craton, particularly around the Bhanupratappur and Pakhanjore regions. These include NW-trending ca. 2.36 Ga Bhanupratappur, ENE-trending ca. 2.25 Ga Chhura, and NNW-trending ca. 1.88 Ga Bastanar mafic dyke swarms. This study reports a comprehensive geochemical study on these distinct mafic dykes to understand their petrogenetic evolution. Geochemically, samples of all three swarms show basaltic to basaltic-andesite composition and exhibit fractionation of olivine, clinopyroxene, plagioclase, and Cr-spinel, however, a slight difference in the petrogenesis of these swarms is perceived. The ca. 2.36 Ga and ca. 2.25 Ga dykes show enriched LREE and flat HREE patterns, however, LREE enrichment is more pronounced in the ca. 2.25 Ga samples which may be due to variable degrees of mantle melting and crustal contamination. REE-patterns of the ca. 1.88 Ga dykes vary uniquely and are categorized into two groups; the Group 1 possesses an almost flat to slightly enriched pattern and the Group 2 follows an overall inclined pattern; each hinting at different degrees of mantle melting and derivation from a mixed spinel-garnet lherzolite source from variable depths. Furthermore, the melts of two older swarms, i.e., ca. 2.36 Ga and ca. 2.25 Ga, are from shallower depths originating from spinel-rich lithospheric mantle. Field setting, trends of dykes, and geochemical characteristics, together with available geochronological data, these distinct mafic dyke swarms can be linked with the three LIP events, viz. ca. 2.37-2.36 Ga Bangalore, the ca. 2.26-2.25 Ga Ippaguda, and ca. 1.89-1.88 Ga Bastanar LIPs of the Indian Shield.

The Late Mesozoic Volcanic Events and Metallogenic Basin Dynamics Mechanism in Eastern Shandong and Adjacent Seas

Yan ZHANG[1]*, China University of Petroleum (East China) (3255338266@qq.com)

Abstract

The northern part of the Large Igneous Province along the eastern coast of China is a narrow and north-south oriented Large Igneous Province. The Late Mesozoic volcanic events were mainly generated by the interaction between magma from the mantle and the crust. A transcrustal magmatic system was formed within the crust of the Jiaodong Peninsula and adjacent areas. There is a unified and coupled relationship between the magmatic process and the mineralization process of the basin mountain process. With the occurrence of intense mineralization in eastern Shandong during the Late Mesozoic era, the mineralization dynamics background has gained important understanding, but further refinement and explanation are needed.This paper intends to use body wave, surface wave, receiver function, and gravity data to jointly invert and obtains high-precision three-dimensional velocity and longitudinal and transverse wave velocity ratio models to establish the mechanism of Cretaceous major volcanic events and deep fault system structural inversion. Based on the unified geodynamic model of "magma structure mineralization basin formation", a new model of cross crustal magma system basin mountain coupling mineralization is constructed. We Analyze the transformation process of deep thermal systems, explore the inherent relationship and laws between the rheological structure of the lithosphere and large-scale concentrated mineralization under the background of major volcanic events, and enrich the theory of mineralization in eastern Shandong.

Revealing 2.4 LIP in the Belomorian province, Fennoscandian Shield: U-Pb ID-TIMS studies of baddeleyite and baddeleyite-zircon aggregates

Maria Alexandrovna SUKHANOVA[1]*, Institute of Precambrian Geology and Geochronology RAS, St.Petersburg (mariia.sukhanova.01@mail.ru)
Ekaterina Borisovna Salnikova[2], Institute of Precambrian Geology and Geochronology RAS, St.Petersburg
Alexandra Vladimirovna Stepanova[3], Institute of Geology, Karelian Research Centre, Russian Academy of Sciences, Petrozavodsk
Svetlana Valerievna Egorova[4], Institute of Geology, Karelian Research Centre, Russian Academy of Sciences, Petrozavodsk

Abstract

The Belomorian province, eastern Fennoscandian Shield, is an Archean crustal block that expired a tectono-metamorphic reworking in the Paleoproterozoic (1.8 – 1.9 Ga) being involved in Lapland-Kola collision orogeny (Balagansky et al., 2016). In the early and middle Paleoproterozoic Belomorian province was affected by several mantle plumes resulted in mafic intrusions and dykes of ages 2.5, 2.45, 2.4, 2.3, 2.2 and 2.12 Ga (Stepanova et al., 2022).

Olivine gabbronorites are widespread in the Belomorian province and often occur as tectonic fragments of larger intrusive bodies or dykes. Metamorphic alteration caused the formation of corona reaction rims around mafic minerals. These rocks also contain baddeleyite-zircon aggregates morphologically similar to corona reaction rims. The central part of the aggregates consists of igneous baddeleyite surrounded by a zircon rim that forms a parallel columnar aggregate. The rim contains fluid inclusions suggesting its metamorphic origin.

The Ambarny intrusion is characterized by a significantly lower degree of preservation of primary igneous minerals and corona reaction rims are developed everywhere. Unaltered baddeleyite is scarce in these rocks but baddeleyite-zircon aggregates are widespread. Structural relationships of baddeleyite-zircon aggregates and corona reaction rims indicate the synchronicity of zircon rims of corona mineral reaction rims. Zircon in aggregates forms 35-90% of the crystal volume, which has a significant impact on the baddeleyite U-Pb isotope system. Discrete chemical abrasion technique (modified M. Rioux's (2010) technique) was applied to separate both baddeleyite and zircon phases. The procedure consists of high temperature annealing, pre-treatment with HCl (baddeleyite dissolves) and final decomposition with HF (zircon dissolves) and separate ID TIMS analysis of each phase. The age of baddeleyite is 2411±6 Ma, the age of zircon is 1911±35 Ma. This allows us to yield the age of the Ambarny intrusion at 2.4 Ga and determine the age of the formation of corona reaction rims in olivine gabbronorites (Salnikova et al., 2022).

The Kamennoe intrusion is characterized by the best preservation. Here, coronas around olivine are poorly developed, and well-preserved igneous baddeleyite is recognized. U-Pb ID TIMS single grain geochronological studies of baddeleyite yield an emplacement age of 2404±11 Ma.

The Kondostrov dyke comprise well-preserved olivine gabbronorites. Metamorphic alteration here are confined to tectonic zones; primary igneous minerals are preserved in undeformed parts of the

dyke. Baddeleyite here is also well-preserved with rare thin shells of zircon. However, the shells have little effect on the isotope system of baddeleyite, which made it possible to carry out geochronological studies using standard techniques. The age of baddeleyite is 2418±8 Ma.
These data indicate that ca. 2.4 Ga mafic igneous rocks in the Belomorian province belongs to a distinct igneous event and support the existence of ca. 2.4 Ga LIP.
The study was supported by grant No. 22-17-00211 from the Russian Science Foundation.

The Karoo large igneous province contains diamondiferous lamproites

Sebastian TAPPE[1]*, UiT The Arctic University of Norway (sebastian.tappe@uit.no)
Ntando S Ngwenya[2], University of Johannesburg

Abstract

Both lithospheric and sublithospheric mantle sources contribute to the vast volumes of primitive magmas in continental flood basalt provinces. Several large igneous provinces (LIPs) on cratons have been directly associated with rapid climatic and biotic change on a global scale. The outgassed volcanic CO2 and SO2 (and other volatiles) responsible for the observed environmental impact have been suggested to be sourced from either recycled crustal components in deep-seated mantle plumes or from volatile-rich components within ancient continental lithospheric mantle. These scenarios compete with models in which greenhouse and other gases are primarily released from sedimentary rock units intruded by LIPs. Distinguishing between these options has implications for modeling potential links between deep volatile cycles, volcanic activity, and environmental change. Many basalt and picrite units of the ca. 180 Ma Karoo LIP in Africa–Antarctica show trace element and isotopic features that are best explained by melt contributions from incompatible element enriched components within the lithospheric mantle of former Gondwanaland. This implies that thick continental roots took actively part in magma formation. However, the exact nature of these strongly incompatible element enriched components remains elusive. We identified a ca. 180 Ma old lamproite magmatic event in south-central Africa, sourced from within the diamond stability field. The ultrapotassic lavas provide first constraints on the origin and evolution of ‘pure’ K-rich components within the mantle source regions of a continental flood basalt province. Non-traditional stable isotope data do not support an origin of the K-rich component by subduction recycling of continental or oceanic crust. Rather, radiogenic isotope systematics suggest that such ultrapotassic components accumulated within a cratonic mantle root during episodic percolation of low-degree alkaline silicate melts since ca. 1 Ga. Such K-rich metasomes have relatively low melting points and, thus, are readily remobilized as the dominant enriched component of continental LIPs, which are sourced mainly from below the lithosphere. The most enriched Karoo picrites may contain up to 10% mass fraction from such K-rich cratonic mantle components. The carbon and sulfur budgets of these metasomes are, however, too small to cause significant environmental impact.

Dyke swarms map of the Indian Shield on 1:25,00,000 scale

Amiya Kumar Kumar SAMAL[1]*, Banaras Hindu University (amiyasamal007@gmail.com)
Rajesh Kumar Srivastava[2], Banaras Hindu University
Richard E Ernst[3], Carleton University
Gulab Chand Gautam[4], Banaras Hindu University

Abstract

The Indian Shield consists of several Archean cratonic blocks, viz. Aravalli, Bundelkhand, Bastar, Singhbhum, Dharwar, and Southern Granulite Terrain (SGT) and Meso- to Neoproterozoic mobile belts with Archean protoliths. The different crustal blocks are separated from each other by thrust zones and/or rifts. These major structural features likely to be active at ca. 1500 Ma or possibly earlier. The entire Indian Shield is transected by a number of distinct dyke swarms, which range in age from ca. 2800 Ma (Singhbhum craton) to ca. 65 Ma (Deccan Volcanic Province). These spectacular records of mafic dykes (together with sills, volcanic rocks, and other associated magmatic units) are meticulously mapped with the help of Google™ Earth images and ArcGIS™. The mapping process involved the integration of field data, incorporating observations from cross-cutting relationships between the distinct dykes and with country rocks, available geochronology, in some cases, geochemistry, and earlier published dyke maps on the Indian dykes. Dyke trends and geometry played a crucial role in the identification of different generations of dyke swarms. Through this comprehensive approach, more than 25 distinct well-dated dyke swarms and several unclassified dyke swarms are identified from the Indian Shield, mostly emplaced within the Archean cratons.

The Dharwar craton consists of 12 dyke swarms; the Bastar craton comprises 11 dyke swarms; Singhbhum Granite Complex (southern part of the Singhbhum craton) craton is transected by 10 dyke swarms; Chhota Nagpur Gneissic Terrane (northern part of the Singhbhum craton) consists of 3 dyke swarms; Bundelkhand craton comprises 2 dyke swarms; Aravalli craton contains 2 dyke swarms; Southern Granulite Terrane, mostly in Kerala, comprises 2 dyke swarms. Besides these dyke swarms, a huge number of mafic dykes are emplaced within the Deccan Volcanic Province. This comprehensive mapping of the Indian Shield also encompasses various other magmatic units, such as mafic sills, and volcanic rocks. This includes the Panjal Traps in the Himalayan Mountain Range, occurrences of komatiite-tholeiite in Archean cratons, as well as kimberlite-lamproite-lamprophyre dykes and plugs, along with carbonatites.

Petrological study of the Agulhas Plateau in the Southwest Indian Ocean: Results from core samples drilled during IODP Expedition 392

Kouki MORI[1]*, Chiba University (23wm1119@chiba-u.jp)
Yuji Ichiyama[2], Chiba University
Osamu Ishizuka[3], Geological Survey of Japan, AIST
Jörg Geldmacher[4], GEOMAR
Peter Cameron Davidson[5], GEOMAR
Jia Liu[6], Zhejiang University

Abstract

According to the plate tectonic reconstructions, large igneous provinces (LIPs) distributed in the Southwest Indian Ocean were formed during the breakup of the Gondwana (Parsiegla et al., 2008). After the antecedent formation of the Mozambique Ridge (MOZR) in ~125–130 Ma, the Agulhas Plateau (AGP) was constructed together with the Maud Rise (MR) and Northeast Georgia Rise (NGR) in 80–100 Ma (Gohl and Uenzelmann, 2001). The production by a mantle upwelling is expected for the formation of the MOZR (Jacques et al., 2019), but the origin and petrological relationships of the AGP with the MOZR and related oceanic edifices are poorly understood. Scientific drilling was operated in the AGP during IODP Expedition 392, and the mafic rocks comprising the AGP were successfully recovered. In this study, we investigate the emplacement processes and geochemical characteristics of the AGP mafic rocks and compare them with the related oceanic edifices in the South Indian Ocean.

Mafic lavas and intrusive rocks were collected from Sites U1579 and U1580 in the central part and Site U1582 in the northern tip of the plateau. Several mafic sills intruding into sediments were recovered at Site U1579 and Site U1580. These sills are composed of basaltic rocks in the margins of the sills and doleritic to gabbroic rocks in the interior of the sills. The basaltic rocks have olivine (altered) and plagioclase phenocrysts with variable sizes of vesicles and groundmass of plagioclase, clinopyroxene, Fe-Ti oxides, and altered glass. The doleritic to gabbroic rocks with ophitic to sub-ophitic textures are composed of coarse-grained olivine (altered), plagioclase, and clinopyroxene. Apatite, Fe-Ti oxides, and quartz are also included as accessory minerals. Pillow lavas recovered at Site U1582 have fresh grassy rinds as chilled margins and olivine (altered) and plagioclase phenocrysts with a glassy groundmass.

Based on the whole rock compositions, the collected rocks make a tholeiite series in a SiO2-FeOtotal/MgO space. The rocks of Sites U1579 and U1582 are almost homogeneous in composition, but the rocks of the largest sill of U1580 show heterogeneous composition, which might have been caused by the effect of crystal accumulation and fractionation. Incompatible trace element ratios (e.g., Nb/Y and Zr/Y) of the sills at Site U1580 gradually decrease with the increase of depth, indicating the various magma compositions that formed the sills. The trace element ratios of Site U1579 and U1580 are more enriched than those of normal type MORB, and the compositional ranges are similar to those of the MOZR. On the other hand, they are discriminated from those of the MR and NGR, which are significantly enriched in incompatible trace elements.

The samples of Site U1582 show highly depleted geochemical characteristics compared with Site U1579 and U1580, indicating that they were formed by the higher degree of partial melting of the mantle.

Gurmeet Kaur[6], Department of Geology, Panjab University, Chandigarh 160014, India

Abstract

Antecrysts, which are not mantle xenocrysts, are produced from earlier generation(s) of magma, incorporated into younger pulses of genetically-related magma. Unlike kimberlites and lamproites, antecrysts are not typically present in carbonatites. This work describes the first occurrence of carbonate antecrysts in Newania carbonatite and discusses its relevance to carbonatite petrogenesis.

The Proterozoic Newania carbonatite complex (24°39'02"N, 74°03'40"E) is located NE of the village of Newania (Udaipur district of Rajasthan, India). It is an approximately 3 km in length and 1 km in width, NW–SE trending plutonic body, emplaced within the Untala granite of the Banded Gneissic Complex. Genetically-related alkaline silicate rock(s) are not present in and around the complex. Two types of carbonatite are recognized: (1) coarse to medium grained, grey, massive to banded ferroan dolomite carbonatite; composed dominantly of ferroan dolomite and accessory apatite, amphibole, phlogopite–biotite, magnesian siderite, pyrochlore, columbite-(Fe), monazite and graphite; (2) medium grained, maroon, dominantly massive ferroan magnesite carbonatite; ferroan magnesite is the dominant phase with subordinate dolomite, Fe-bearing dolomite and ferroan dolomite; apatite and mica are accessory phases. Antecrysts are found only in the ferroan magnesite carbonatite. These occur as very coarse (up to 1 cm), oval crystals of dolomite and Fe-bearing dolomite. Inclusions of ferroan magnesite occurs as re-absorbed euhedral crystals in antecrysts.

Dolomite–ferroan dolomite carbonates display an evolutionary trend of increasing Fe and decreasing Mg contents from antecrysts to subordinate carbonates in ferroan magnesite carbonatite to dominant carbonate in ferroan dolomite carbonatite. The ferroan magnesite occurring as inclusions in antecrysts and as the dominant mineral in ferroan magnesite carbonatite have similar compositions. Both display Fe-enrichment towards accessory magnesian siderite in ferroan dolomite carbonatite.

The compositional evolution of the carbonates in the Newania carbonatites together with data from experimentally-derived phase diagrams for carbonates suggest that the ferroan magnesite

carbonatite is crystallized prior to the ferroan dolomite carbonatite. Ferroan magnesite is the earliest crystallizing carbonate mineral and is separated from the magma as a consequence of crystal setting or by rheological processes. A few crystals which remained suspended in the magma subsequently became unstable in the evolving magma and were partially re-absorbed as dolomite to Fe-bearing dolomite antecrysts at a peritectic reaction point. This was followed by the crystallization of relatively evolved subordinate dolomite–ferroan dolomite carbonates and subsequent incorporation, together with antecrysts into the ferroan magnesite carbonatite.
The occurrence of either ferroan magnesite or ferroan dolomite as dominant phases in the Newania carbonatites indicate the magnesian composition of the parent carbonatite-forming magma. The parent magma, capable of generating ferroan magnesite carbonatite, followed by ferroan dolomite carbonatite is considered to be of F–silica–alkali-rich magnesian composition, generated at pressures exceeding 3.2 GPa from the partial melting of phlogopite-amphibole-magnesite lherzolite.

The areal extent of the Qiangtang-Panjal large igneous province

Wei Dan[1]*, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences (danwei@gig.ac.cn)
Qiang Wang[2], Guangzhou Institute of Geochemistry, Chinese Academy of Sciences
Gong-Jian Tang[3], Guangzhou Institute of Geochemistry, Chinese Academy of Sciences
Xiu-Zheng Zhang[4], Guangzhou Institute of Geochemistry, Chinese Academy of Sciences

Abstract

The Qiangtang-Panjal large igneous province (QP-LIP), which occurred between 290 and 285 Ma in NE Gondwana, is one of the three Permian LIPs. It. The occurrence of the PQ-LIP coincides with the rifting and breakup of the eastern Cimmerian continent and the birth of the Neo-Tethys Ocean. Thus, it is generally accepted that this LIP played an important role in the breakup of the Cimmerian continent. However, the geodynamic mechanism for the generation of the QP-LIP is highly controversial. In this study, we report 285 Ma mafic dykes occurred in the South Pamir, suggesting that the PQ-LIP extends westward into the Pamir syntax. Combined with regional data, the QP-LIP is limited to occurred in the eastern Cimmerian continent from the South Pamir, Southern Qiangtang, Lhasa, to Sibumasu terranes, and northern India-Australia plate. In contrast, no such event was found in the western Cimmerian continent (west of the Pamir syntax) and the northern Arabian-African plate, except for minor ~298 Ma bimodal magmatism found in Oman. The areal distribution characteristics suggest that the eastern Neo-Tethys is characterized by a magma-rich rifted margin, whereas the western Neo-Tethys by a magma-poor rifted margin. As the north drift of the Cimmerian continent was counterclockwise around the rotation pole at the western end of the Neo-Tethys, it may suggest the strong extension in the eastern Cimmerian continent caused by slab-pull forces responsible for the generation of the QP-LIP. However, similar scenarios also occur in many other rifted margins, such as in the East African Rift and the Red Sea, but the mantle plume-related LIP is confined to the south Rea Sea area. It is argued that the mantle plume may be coincidentally located in the northern India-Australia plate. Alternatively, it is more likely that different lithospheric structures control the areal distribution of the LIP and the type of the rifted margin.

Permian-Triassic silicic volcanic province of the West Siberian basin: Evidence for the temporal and genetic relationship with the Siberian Traps

Anton LATYSHEV[1]*, Individual Researcher (anton.latyshev@gmail.com)
Ivan Panchenko[2], Closed Joint Stock Company “Modeling and Monitoring of Geological Objects”
Maria Smirnova[3], Closed Joint Stock Company “Modeling and Monitoring of Geological Objects”
Peter Kulikov[4], Closed Joint Stock Company “Modeling and Monitoring of Geological Objects”

Abstract

Permian-Triassic Traps of the Siberian platform and coeval mafic volcanic rocks in the West Siberian basin constitute probably the most voluminous continental Large Igneous Province. The contribution of felsic volcanic rocks to this huge province has been underestimated until recently. We present the detailed results of the first comprehensive study of silicic rocks from the central part of West Siberia. Permian-Triassic volcanics in this area are buried under the thick (2.5–3.5 km) sedimentary cover and are available only as drill cores. They fill many rift structures, including the large Rogozhnikov-Nazym graben.

Lavas of rhyolitic-dacitic composition predominate among the volcanics, while volcaniclastic rocks are rare. Silicic lavas from all studied areas demonstrate both supra-subduction and within-plate geochemical signatures. A complex of structural and geochemical features of silicic rocks corresponds to the tectonic setting of post-collisional rifting. Basalts are subordinate in the studied area and resemble the Nadezhdinsky Formation from the Noril’sk region (the Siberian platform, the middle part of the volcanic sequence). Geochemical peculiarities confirm the genetic relationship between the West Siberian silicic and mafic rocks, and the Siberian Traps, and indicate the origin of the former from the interaction of the continental crust with a mantle source similar to that of the upper part of the Noril’sk volcanic sequence.

Nine new U-Pb ages constrain the timing of silicic volcanic activity in West Siberia as ~5-10 Myr near the Permian-Triassic boundary (253.69 – 248.21 Ma). Thus, silicic rocks in West Siberia are nearly coeval to the main phase of Siberian Traps emplacement.

Silicic rocks occupy about 105 km2 within the West Siberian basin and can be considered as a Silicic Large Igneous Province, coeval and genetically related to the mafic Siberian Traps LIP. The silicic volcanics distribution area in West Siberia coincides with zones of young continental crust, reworked in the Late Paleozoic by the subduction and collision processes, and associated episodes of magmatic activity and metamorphism.

Multiple mantle components for alkaline lavas of the Tuli basin, Karoo LIP

Osvaldo González-Maurel[1]*, Universidad de Concepción (osvgonzalez@udec.cl)
Geoffrey Howarth[2], University of Cape Town
Julian Marsh[3], Rhodes University
Andy Duncan[4], University of Cape Town
Petrus le Roux[5], University of Cape Town

Abstract

The Tuli basin in Zimbabwe and Botswana is one of the largest and best-preserved remnants of rift-related sequences associated with the Karoo Large Igneous Province (LIP) of southern Africa. Early Jurassic tholeiitic high-Ti picrites and basalts mostly represent the continental LIP volcanism in Tuli, but rare alkaline rocks are also found in the volcanic sequence. Here we present new whole-rock major and trace element and Sr-Nd-Pb isotope data for the alkaline volcanic rocks from the Tuli basin. We have identified three distinctly different groups of alkaline rocks: nephelinites (K2O/Na2O < 0.5), potassic (K2O/Na2O = 0.5 to 2), and ultrapotassic rocks (K2O/Na2O > 2).

Nephelinites are characterised by an incompatible trace element enrichment, low Zr/Nb ratios, positive Nb-Ta anomalies, and radiogenic 87Sr/86Sri (0.705 – 0.707), low εNdi values (-7.0 to -6.7) and radiogenic Pb isotope ratios (208Pb/204Pb = 37.83 – 38.07; 207Pb/204Pb = 15.49 – 15.52; 206Pb/204Pb = 17.55 – 17.61). Potassic rocks have similar low Zr/Nb ratios, positive Nb-Ta anomalies, radiogenic 87Sr/86Sri (0.705 – 0.706), unradiogenic εNdi (-8.3 to -4.5) and highly radiogenic Pb isotope ratios (208Pb/204Pb = 38.89 – 39.54; 207Pb/204Pb = 15.59 – 15.65; 206Pb/204Pb = 17.75 – 18.31), however, they differ from nephelinites in recording higher K contents (and lower Na contents) and higher incompatible and rare-earth element concentrations. Lastly, ultrapotassic rocks show very pronounced positive K anomaly, negative Nb-Ta anomalies and BSE-like Sr, Nd and Pb isotope ratios (87Sr/86Sri = 0.704 – 0.705; εNdi = -1.7 – -1.1; 208Pb/204Pb = 38.10 – 38.20; 207Pb/204Pb = 15.51 – 15.55; 206Pb/204Pb = 17.60 – 17.78).

The high initial Sr and Pb isotope ratios and low εNdi together with high incompatible trace element concentrations from the nephelinites and potassic rocks, and the marked depletion of Nb and Ta from the ultrapotassic rocks, are consistent with a metasomatised SCLM source. However, such a source alone cannot consistently explain some signatures of the Tuli alkaline rocks. Nephelinites and potassic rocks differ from other Tuli magmas including picrites, basalts and ultrapotassic rocks in recording low Zr/Nb ratios and positive Nb-Ta anomalies, which are typically associated with plume-derived OIB lavas. Ultrapotassic rocks, in turn, are characterised by 87Sr/86Sri ratios and εNdi values roughly similar to BSE, which has been interpreted to be derived either from asthenospheric MORB sources or OIB-type mantle sources. This implies that there may have been some contribution from a sub-lithospheric (MORB- or OIB-like) component

in the nephelinite, potassic and ultrapotassic source.

Therefore, the mantle source is interpreted to be highly heterogeneous for the Tuli alkaline rocks, and each alkaline rock type represents a distinct source component. These source components resemble the more geographically dominant SCLM signature, but the high alkali compositions support incorporation of sub-lithospheric fluids/melts into the SCLM source. We thus suggest that the Tuli alkaline rocks were derived from a mixed mantle source, which differs from the broadly accepted origin for other alkaline rocks in the Karoo LIP that were interpreted to be sourced only from enriched mantle components.

Late Permian basalts in the eastern part of the Emeishan Large Igneous Province, SW China: Implications for plume–lithosphere interaction

Wenmin HUANG[1]*, League member (459717413@qq.com)
Xijun LIU[2], members of Chinese Communist Party
Zhenglin LI[3], members of Chinese Communist Party
Xiao LIU[4], members of Chinese Communist Party

Abstract

The Emeishan Large Igneous Province (ELIP) is situated along the western margin of the Yangtze Craton, adjoining the southeastern edge of the Tibetan Plateau, SW China. Predominantly composed of basalts, the ELIP features two primary lava types: high-Ti and low-Ti basalts (using TiO2 content of 2.5 wt.% and Ti/Y ratio of 500). Spatially, the ELIP is segmented into inner, intermediate and outer zones based on biostratigraphy, sedimentology, and geochemical characteristics. The inner zone is characterized by thick sequences (2000–5000 m) of predominantly low-Ti volcanic rocks, interspersed with high-Ti basalts and occasional picrites. In contrast, the peripheral zone contains much thinner sequences (500 m) of high-Ti volcanic rocks, including lavas with extremely high Ti/Y ratios, all linked to mantle plume activity in the late Permian (~260 Ma). However, the basalts in the ELIP's outer zone display notable compositional diversity, leading to varied theories regarding their petrogenesis. This study provides a comprehensive examination, including detailed zircon U-Pb dating and Hf isotopic analysis, alongside whole-rock geochemical and Sr-Nd-Hf-Pb isotopic assessments of the basalts from Napo area in western Guangxi, within the ELIP's outer zone. The zircon 206Pb/238U weighted mean ages of these basalts are pinpointed at 258–257 Ma, aligning with the ELIP's main magmatic phase. They are alkaline basalts and show moderate Ti characteristic with the moderate TiO2 contents (1.82–2.09 wt.%) and Ti/Y ratios (473–568). They are characterized by moderate 86Sr/87Sr(t) ratios (0.70500 to 0.70532), slightly negative εNd(t) values (-1.95 to -1.38), positive whole-rock εHf(t) values (0.25 to 0.81), high zircon εHf(t) values (1.60 to 11.6) and distinctive "extreme DUPAL" Pb isotopic compositions, marked by high 208Pb/204Pb(t) ratios (37.9 to 38.7) and pronounced positive Δ8/4 values (54.8 to 91.2). These geochemical and isotopic features suggest that an oceanic island basalt (OIB)-like affinity for the Napo basalts and most likely involved subcontinental lithospheric mantle, indicative an interaction between the Emeishan plume and the lithosphere through decompression melting in a continental rift setting. The slightly varied Nd and Hf isotopic compositions in the whole rock samples imply the addition of a minor crustal component (<5%) to the Emeishan plume-lithosphere mantle source. Melt composition reconstructions estimate the magma generation pressure at 1.71–2.32GPa and mantle melting temperatures between 1400–1460℃, exceeding typical asthenospheric mantle temperatures (1280–1350℃). Our findings suggest that the substantial compositional variability in the ELIP's outer zone basalts resulted from interactions between the Emeishan plume and the lithosphere.

Abstract

Systematic investigations into the spatiotemporal evolution of Gondwana megacontinents is always an appealing topic amongst geologists. Gondwana, comprising of East Gondwana (Madagascar, Greater India, Australia, and Antarctica) and West Gondwana (Africa and South America), is thought to be fragmented at ca. 180 Ma and coinciding with the separation of the Greater Indian plate (together with Madagascar and Seychelles) from the African plate. It is suggested that the separation of the Madagascar from the Greater India started ~90 (92-88) Ma and the Marion mantle plume played a pivotal role. However, a strong debate persists on the existence of the Marion mantle plume before ca. 92-88 Ma. This is crucial as track of Marion hot-spot was closely following the rifted eastern margin of Madagascar between 120 and 88 Ma (cf. Storey et al., 1995, Science, 267, 852-855). In the present work, we studied carbonatite xenoliths from the carbonatite breccia exposed at the Saidivasan, an integral part of the Ambadungar-Saidivasan alkaline carbonatite complex (ASACC), western India. Although it is documented that the ASACC, which intrude the Deccan basalts, has been emplaced at ca. 65 Ma and product of the Réunion plume, however, a new 40Ar/39Ar plateau age, which yields 97 ± 2.2 Ma, of a carbonatite xenolith extracted from the carbonatite breccia suggest its link with the Marion plume. This finding likely represents one of the early magmatic pulses associated with the Marion plume. This is probably the first report of a carbonatite magmatism of this age belonging to the Ambadungar-Saidivasan alkaline carbonatite complex. Available dates on different magmatic rocks, which are thought to be associated to the Marion hot-spot, range in ages from ca. 123 Ma to 80 Ma in the Indian Shield and ca. 98 Ma to 84 Ma in the Madagscar. While the major Marion plume induced magmatic activities were recorded ca. 92-88 Ma during the break-up of the India-Madagascar continents, the observed age range strongly suggests a prolonged magmatic pulse linked to the Marion plume. This comprehensive investigation provides a better constraint on initiation and spatiotemporal extent of the Marion mantle plume induced large igneous province.

Paleoenvironmental Constraints on Pleistocene Ice Sheets Informed by Glacio-Volcanic Deposits in Northeast Iceland

Cameron Essex[1]*, University of Wisconsin-Milwaukee (cdessex@uwm.edu)
Barry Cameron[2], University of Wisconsin-Milwaukee
Ben Edwards[3], Dickinson College
Magnús Guðmundsson[4], University of Iceland

Abstract

A growing body of research suggests that deglaciation can lead to increased eruption rates by destabilizing existing magma bodies and even prompting new magma generation. Given its high rate of magma production and periodic glaciations through the Pleistocene, Iceland is the ideal locality on Earth to study volcano-ice interactions as much of its landscape is dominated by glacio-volcanic landforms such as tuyas and tindars. One of the main products from magma-ice interactions is volcanic glass, which locally contains dissolved volatiles such as water, carbon dioxide, and sulfur. The pressure dependence of volatile solubility in magmas allows estimation of the ice thickness at the time of eruption by measuring the volatile content of glassy eruption products such as pillow lavas rims and hyaloclastite. Here we use volatile estimates from samples of three tuyas (Gæsafjöll [65.77], Bláfjall [65.55], Búrfell [65.44]) to test the hypothesis that in northeastern Iceland the Pleistocene ice sheets thickened southwards towards the present-day location of the Vatnajökull ice cap. Major element and sulfur concentrations of the glasses were analyzed by electron microprobe (EPMA) at the University of Wisconsin-Madison, and major element concentrations are basaltic for all three tuyas (SiO2=46.99–51.22 wt. %; MgO=4.11–9.06 wt. %; CaO 8.90–13.88 wt. %; FeO=9.40–16.48 wt. %). Gæsafjöll and Bláfjall have similar major element concentrations, whereas Búrfell contains a component enriched in FeO and depleted in MgO and CaO. Glass (n=102) sulfur contents, which are proxies for water, range between 100 ppm and 3,100 ppm for all three edifices with sulfur contents generally increasing towards the south (Gæsafjöll=199.1 ppm–1,864.9 ppm; Bláfjall=130.4 ppm–2,356.3 ppm; Búrfell=163.3 ppm–3,001.8 ppm). Thus, our preliminary data support the idea that the Pleistocene ice bodies through which these three volcanoes erupted thickened to the south. Future work will include FTIR measurements of water and carbon dioxide to further test this hypothesis.

Recognition of Hidden Effusive Centers from the Emanating Pattern of Lava Tube and Channels in Deccan Volcanic Province of Western India

ANSHUMAN MISRA[1]*, Doon University, Dehradun (anshumanmisra22@gmail.com)
K S MISRA[2], University of Petroleum and Energy Studies

Abstract

Non-recognition of volcanic cones, craters and effusive zones in large Deccan volcanic region of Western India, has intrigued the geologists for over a century. It was assumed that the effusive source existed somewhere in the west and presently submerged in the Arabian Sea and the lava has flowed to several hundred kilometres. This has led geologists to establish unified lava stratigraphy and supported it by inconsistence geochemical signatures. Contrary to this misconception, it is a common observation that lava cools and solidifies without long distance movement. Our mapping in western part of volcanic province, illustrates not only transportation through arterial system of lava tubes, channels and tunnels, from common centers but also a new emanating parameter for recognition of effusive centers. Multi-central as well as multi-level out-pouring has given rise to local lava stratigraphy around the effusive centers. In approximately 90% area, the centres are covered by the younger flows, 8% are deeply eroded and are difficult to recognize and only in remaining 2%, where they are exposed in recent times, are the best locations to study the physical volcanic features. Interpretation of remote sensing data sets, followed by verification in field has emerged as extremely useful method for mapping the thermally baked, indurated, hardened and reddened remnants of lava channels, tubes and tunnels. Channels are identified by unique sinuous shapes of levee portions; tubes in vertical sections by upward converging columnar jointing, slowly cooled nodular basalt in the core portions and tunnels by cylindrical hollowness. Weathering and erosion of more than sixty five million years, has dissected the Deccan plateau into several small plateaus and later into innumerable mesa hills. Innumerable remnants are mapped radiating out from these plateaus and mesa hills at different elevations. This disposition of remnants along with emanating pattern establishes the presence of large hidden multi-central volcanic fields, at different levels.

Neoarchean volcanism in the Western Dharwar Craton, India: Petrology, Geochemistry and Tectonic Significance of BADR volcanics from Shimoga basin

Arpita KARMAKAR[1]*, Geological Survey of India, Bangalore (arpita.karmakar@gsi.gov.in)
Nirmal Kumar T[2], Geological Survey of India, Bangalore
Anindya Bhattacharya[3], Geological Survey of India, Jaipur

Abstract

The extensive exposure of volcano-sedimentary sequence in Shimoga schist belt, Western Dharwar Craton, India, makes it an important window into tectonic evolution of early earth. Here we provide a comprehensive study on petrological and geochemical analysis of basalt, andesite, dacite, rhyolite (BADR) suit of Neoarchean Shimoga greenstone belt. The sequence comprises 20% volcanic rocks and 80% pyroclastics. The metabasalts are high Mg tholeiite and Komatiitic basalt, with intergranular texture defined by clinopyroxene and plagioclase as essential minerals and chlorite, actinolite as accessory phases. The rhyolite contains more than 90% quartz and shows flow banding. Pyroclastics are mostly basaltic andesite, andesite and dacite in composition. These rocks contain unusual shaped quartz grains such as rod shaped, spindle shaped, bi-pyramoidal, flame quartz, indicating possible volcanic source. Presence of K-feldspar also suggests volcanic input. Flattening and rugged termination of grains along grain boundary, the eutaxitic texture, strong compaction and welding, especially near the edges of crystal again confirms pyroclastic origin. According to the geochemical plots of Zr/TiO2 – SiO2, Nb/Y – Zr/TiO2 and Nb/Y – Zr/Ti, the volcanic suit is composed of mafic to intermediate to felsic volcanics starting from basalt, basaltic andesite, trachy-andesite, dacite, rhyodacite to rhyolite (BADR suit). Among the different volcanics, the metabasalt generally falls under tholeiite field, in contrast to dacite and rhyolite, which falls under calc alkaline series. The intermediate rocks particularly andesite and dacite show affinity towards both tholeiite and calc-alkaline magma series. The concentrations of major oxides are plotted against those of SiO2. Positive correlation indicated by Al2O3, Na2O and K2O whereas negative trend is seen in CaO, TiO2, P2O5, MgO and FeO. As the parental magma differentiates SiO2, Na2O and K2O increases (Positive slope) while MgO, FeO, TiO2, P2O5 & CaO decreases (Negative slope). Since these plots show a clear trend or correlation, hence all these volcanics are probably related or co-magmatic. On a primitive mantle- normalized diagram the basaltic andesite and basalt are characterized by enriched light rare earth elements (LREE) patterns relative to heavy rare earth elements (HREE) [(La/Yb) N =1.95 –15.03], with weak to negligible Eu anomalies (Eu/Eu* = 0.63–0.89). The intermediate and acidic rocks are characterized by enriched light rare earth elements (LREE) patterns relative to heavy rare earth elements (HREE) [(La/Yb) N = 3.12 –31.51], with negative Eu anomalies (Eu/Eu* = 0.2–0.89). High Mg basalts are likely reflecting melting of hotter ambient mantle in Archean. Ternary plot of FeOT-MgO-Al2O3 suggests basalts and basaltic andesites were formed in ocean ridge and floor settings, whereas the andesite, dacite and rhyolites were formed in

convergent margin settings. The Ti Vs Zr binary plot indicates island arc setting for these volcanics. The ThN-NbN binary diagram indicates continental margin volcanic arc.

Development of New Concepts in Cretaceous Volcanism during Last Fifty Years in Peninsular India

K S MISRA[1]*, University of Petroleum and Energy Studies (drksmisra@gmail.com)

Abstract

The author enumerates several new concepts developed in the study of Cretaceous Volcanism during last fifty years. In early years from 1973, emphasis was on mapping the physical volcanic, tectonic and structural details. This was supported by interpretation of aerial photographs and satellite images. It has emerged that major igneous complexes are located along lineaments associated with major rift and grabens. Dipping felsic units in otherwise horizontal disposition, explosive volcanism, alkaline rocks and Carbonatite dyke were reported, suggesting continuation of Narmada-Tapti Tectonic Zone of continental dimension in Saurashtra. Later large-scale mapping of entire Saurashtra and Kutch was conducted to include tectonic disposition, major E-W trending dyke swarm, with parallel effusive zones and large felsic complexes, suggesting that the Cretaceous volcanism was initially felsic followed by dominant tholeiite units. Aeromagnetic data along with vertical gradient component showed that near surface felsic complexes have deeper strong magnetic anomalies, leading to the concept of decompression melting of successive lithospheric zones. Volcanic fields with a number of plugs, vents, craters and effusive centers were identified in Kutch region.

Non-recognition of effusive centres in large Deccan Volcanic Province has intrigued geologists for over a century. Earlier it was believed that the effusive source existed somewhere in the west and is presently submerged in the Arabian Sea. This assumption led to establish unified lava stratigraphy, contrary to the observation that soon after eruption; lava cools and solidifies without long distance movement. Mapping of thermally baked, indurated, hardened and reddened remnants of lava channels, tubes and tunnels, has brought out an integrated arterial system and radially emanating pattern. This has helped in identification of innumerable effusive centres, both in exposed as well as in areas covered by younger flows. Multi-central and multi-tier volcanic fields, with local lava stratigraphy have been identified in different parts of volcanic province.

Information about volcanic units was extracted from innumerable litho-logs and seismic profiles generated for hydrocarbon exploration. Nearly a dozen producing as well as perspective pull-apart, off-shore and oceanic basins associated with rift and grabens, transecting volcanic regions, are having unique interlayered volcano-sedimentary sequence ranging in age from beginning to the end of Cretaceous. This disposition also suggests repeated decompression volcanism along nearly vertical faults, subsidence and sedimentation continued for nearly eighty million years. Furthermore, high resolution seismic profiles, acquired by long offset configuration, pre-stacking time and depth migration processing techniques, have provided geological and thickness details of both basalt as well as sub-basalt sedimentary succession. It illustrates the tectonic controls on basin formation, subsidence, magma generation and effusion. This does not support the idea of hot spot below the northerly moving Indian plate. It was detrimental to exploration as a hot spot

would have vaporized the hydrocarbons. On the contrary the tectonic controls distilled the sediments by the upwelling heat and hydrocarbon seals were created by the effusion of volcanic units. Quest for understanding the Cretaceous volcanic units has increased many folds, as they are reservoir rocks for prolific production of natural gas.

Recent Evidence of the Evolution of Pleistocene Volcanism in the Northwestern End of the Central Volcanic Cordillera of Costa Rica, Central America.

Ana Sofia Sofia HUAPAYA R.P.[1]*, Dirección de Geología y Minas, MINAE
(sofia.huapayar@gmail.com)
Evelyn Rodriguez C.[2], Dirección de Geología y Minas, MINAE

Abstract

Recent studies conducted in the northwestern sector of the Central Volcanic Coordillera (CVC) of Costa Rica, located at a latitude of 10°30'00'' and longitude of 84°30'00'', have allowed the identification of volcanic debris deposit, the Ron Ron Unit, which exceed more than 50 km3. These deposits from the Lower Pleistocene (Proto-Platanar) whit a calc-alkaline composition are presumed to be the product of the collapse of a primitive volcanic structure, prior to the already known volcanic structure, the Bajos del Toro Unit, from the Middle Pleistocene (Paleo-Platanar). The petrographic characteristics of debris deposit, the estructural pattern - system of NW-SE strike-slip dextral faults with normal component system and the hydrothermal alteration are the evidence of the collapse of this primitive structure. The migration of the magmatic chamber to the east may have resulted in the emergence of a new volcano with the same magmatic composition, collapsing during the Middle Pleistocene and with episodes of calderic activity during the Upper Pleistocene (Alto Palomo Formation) to Early Holocene, forming the current Chocosuela-Palmira calderic complex, and whose most recent volcanic expression are resurgent structures such as the stratovolcano composed of the Platanar and Porvenir cones (Neo-Platanar). This studies provides new data that shows that the calderic processes in the Central American region were highly active during the Pleistocene, a product of the intensive tectonic deformation promoted by the closure of the Central American Isthmus.

The Ages of the lithological units is defined by K-Ar analyses, the lithological units whit petrography studies, XRD, scanning electron microscopy (SEM), and chemical analyses. For the morphotectonic intrepretation was used information of radar image from the Alos Palsar sensor (whit resolution of 12.5 m), Carta and Terra aerial photographs, a spectral image from Landsat 7ETM, and the Models SRTM and Aster elevation (DEM) models.

Integration of the field information and the mentioned analyses, can be reinterpreted the calderic complex known as Chocosuela-Palmira, dividing into three constructive and destructive temporal phases of Pleistocene volcanism in the NO extreme of the CVC: Proto-Platanar, Paleo-Platanar and Neo-Platanar.

The outputs of this study include a geological map at a scale of 1:50,000 of Quesada and Aguas Zarcas sheets, a tectonic map at a scale of 1:50,000 and a model of Pleistocen volcanic complex including the three constructive and destructive stages.

Block-and-ash flows deposit from 2015 at Volcán de Colima (Mexico): Textural and granulometric characterization as a tool in determining the dynamics and interaction with topography

Laura Fabiola Fabiola HERNANDEZ DIAZ[1]*, Universidad Nacional Autónoma de México (lfabiolahd@geociencias.unam.mx)
Lucia Capra Pedol[2], Universidad Nacional Autónoma de México

Abstract

On July 10 and 11, 2015, Volcán de Colima, one of the most active Mexican volcanoes, underwent its largest eruption since the 1913 Plinian event. Highly mobile block-and-ash flows (BAF) originated from the dome collapse and subsequent extrusion of bubble-gas-rich magma from the conduit. This event is extraordinary as it surpassed the displacement of previous eruptions, approaching towns close to the volcano. Over the last eight years deep lahar erosion has exposed excellent outcrops of the eruptive sequence.

This study aim is to determine the textural and granulometric characteristics of the entire sequence to better understand the transport and sedimentation mechanisms in response to abrupt morphological changes. Along the Montegrande ravine, 50 stratigraphic sections were analyzed and sampled; granulometric analysis was conducted for the ranges of -11 to +4 phi with Rosiwal intersections and dry sieving methods and from +4 phi to 9 phi with a laser sedimentograph. The statistical parameters were calculated, and component analysis and shape analysis were performed.

Preliminary findings indicate that massive and stratified depositional units respond to abrupt changes in topography; their granulometry shows a general bimodal distribution and poor sorting. The results are related to factors such as distance from the source, channel geometry, and flow depth.

Post-2008 Eruption Volcanic Activities of Cerro Azul Volcano in the Galápagos Archipelago Estimated Using Time-series InSAR

Seohyeon Kim[1]*, Kangwon National University (rlatjgus514@kangwon.ac.kr)
Hyangsun Han[2], Kangwon National University

Abstract

The Cerro Azul volcano, located on southern part of Isabela Island in the Galapagos Archipelago, stands as one of the most active volcanoes globally, having erupted 11 times since 1932. Its most recent eruption occurred in 2008, followed by a period of unrest in March 2017 with no eruption. In this study, we applied the Small BAseline Subset Interferometric Synthetic Aperture Radar (SBAS InSAR) technique to 22 Envisat ASAR images (July 2008–September 2010) and 156 Sentinel-1 SAR images (April 2017–June 2022) to monitor the post-eruptive volcanic activities of Cerro Azul associated with the 2008 eruption. Cerro Azul volcano underwent gradual uplift during the observation period, with variations in uplift rates observed. The uplift rate of summit caldera was approximately 0.019 m/yr from July 2008 to September 2010 and approximately 0.033 m/yr from April 2017 to June 2022. For the two periods of distinctive uplift rate, we performed inversions of the time-series surface displacements to estimate changes in magmatic activity. Inversion results, based on the Mogi model, indicated that the depth of the magma source remained consistent at ~4 km below the caldera floor for both periods. The volume change of the magma source was ~4.40×10^6 m^3 from July 2008 to September 2010 and ~20.97×10^6 m^3 from April 2017 to June 2022. The annual average volume change of magma source in the two years immediately after the 2008 eruption was ~1.8×10^6 m^3/yr. However, this rate dramatically increased to ~3.9×10^6 m^3/yr from 2017 onwards. This suggests that the magma supply rate significantly increased after 2017 compared to the period from 2008 to 2010.

Numerical Model of High-temperature Geothermal Based on Trans-crustal Magmatic System in Eastern Shandong Province

Jie LIU[1]*, China University of Petroleum(East China) (13964771227@126.com)
Yaoqi Zhou[2], China University of Petroleum(East China)

Abstract

The Yishu fault in eastern Shandong Province has experienced multiple periods of intense tectonic movement, which provides abundant geothermal resources. However, due to the multiple and complex evolutions here, little research focus on the formation mechanism of deep geothermal. Combined numerical modeling with trans-crustal magma, we analyzed the geophysical models to predict the distribution trend and depth of shallow lithosphere structure, the target depth of geothermal reservoir is over 6 km. Estimated the spatial modeling features, such as strata, structure, and fluids, explained the response of magma reservoir to the lithosphere structural anomaly, and further elaborated the theoretical model of deep geothermal reservoir formation in eastern Shandong. As such, this research reveals the deep structure and power mechanism of the trans-crustal magma in eastern Shandong. During the late Mesozoic, due to intense deep tectonic activity, and the trans-crustal magma upwelled to the surface along the large-scale fractures, accompanied by the thermo-upwelling and assimilation-contamination. The lithospheric mantle was dismantled and replaced, meanwhile the thickness of the lithosphere was thinned. Afterwards, the mantle was activated again and upwelled to the upper and middle crust, the crustal rocks there were melted, and the incompatible radioactive elements in the crustal rocks were transported with the magma. It increased the radioactive elements content in the shallow. With the heat generated by the elements rising, the thermal and rheological structure of the lithosphere changed. This study predicts the collective scale of geothermal reservoirs in the target area, and provides a basis for the evaluation of deep high-temperature geothermal resources and the study of thermal reservoir evolution.

Mahesh Mopkar[2], Savitribai Phule Pune University
SATISH SANGODE[3], Savitribai Phule Pune University
Ashish Dongre[4], Savitribai Phule Pune University
Amarjit Bhagat[5], Savitribai Phule Pune University

Abstract

The plagioclage feldspar represents the most common and universal constituent of the Deccan lava flow sequence occurring as groundmass, porphyry to phenocrysts such as the varieties of giant plagioclase feldspars (GPB) as stratigraphic markers. We present petro-mineralogic, textural and magnetic fabrics documentation for a complete lava flow sequence (~1200m) encountered in the borehole core KBH 07 from the Koyna drilling program. Modal percentage indicate 50-55% feldspar grains, 40-45% Clinopyroxene, 10-15% Opaques and 4-5% Olivine. Further, we produced semiquantitative estimates by developing the parameters based on the grain width and length ratios of feldspar groundmass, phenocrysts, olivine and opaque minerals largely comprising ophitic to sub-ophitic and porphyritic to glomeroporphyritic textures as a result of various cooling modes and rates of nucleation. The Ist order variability indicate general trend towards top marked by: a) decrease in the volumes (sizes) of the plagioclase feldspar, olivine and clinopyroxene crystals, b) decrease in clustering of the plagioclase phenocrysts towards and c) decrease in abundance of glomeroporphiritic textures. The parameters based on the counts of Feldspar groundmass (Fg) and phenocryst (Fp), their width and length (WxL), width:length (W/L) ratio, groundmass to phenocryst ratios (Fg/Fp) and the degree of preferred orientation. Similar ratios were also calculated for the for the opaque, olivine and pyroxene grains that are less abundant to study their association with feldspar. The opaques are generally evenly distributed when their size decreases; and they show inverse size relation with that of the feldspar grains. The IInd and IIIrd order variability is derived by comparing these parameters with our previously published magnetic fabric and rock density results on the same samples. Overall the higher order episodic variation reflects framework and modal distribution governed by magmatic compositional history, effusive mixing, fractionation, rates of nucleation and the cooling history.

Plio-Pleistocene rear-arc magmatic belt in the Southern Central Andes: the Varvarco Volcanic Field

Sofía Iannelli[1]*, National Scientific and Technical Research Council - Buenos Aires University (sofia.iannelli@hotmail.com.ar)
Vanesa LITVAK[2], Universidad de Buenos Aires-CONICET
Carina GRECO[3], Universidad de Buenos Aires-CONICET
Andrés FOLGUERA[4], Universidad de Buenos Aires-CONICET

Abstract

Plio-Pleistocene magmatic evolution in the Southern Central Andes between 34 and 37.5°S, has been influenced by changes in plate kinematics associated with the subduction of the Nazca plate beneath the South American plate. Between Early to Middle Miocene times, a shallow subduction regime developed which provoked the eastward migration of arc-like magmatism towards the east. Afterwards, by Pliocene times, the Nazca plate re-steepened and in consequence arc-like magmatism retreated towards the west reaching its present-day position and developing in three coetaneous magmatic belts between the back-arc and the Chilean-Argentinean present day arc-front. Furthermore, during the Nazca plate steepening, a tearing took place at ~38°S which triggered the upwelling of an asthenospheric anomaly responsible for the emplacement of alkaline magmatism in the back-arc area. The steepening of Nazca plate provoked an extensional regime that controlled the emplacement of Plio-Pleistocene magmatism. In this context, between the back-arc and the active volcanic front, a Plio-Pleistocene N-S magmatic belt was emplaced in an anomalous rear-arc position.

Rear-arc magmatism comprised collapsed calderas, stratovolcanoes, and monogenetic cones along large volcanic fields. Between 34 and 38ºS, most of these volcanic fields developed along the Las Loicas Trough, a NW-SE oriented Plio-Pleistocene extensional collapsed structure. Along this belt, different magmatic fields were installed as the Puelche and Laguna del Maule volcanic fields. Particularly, in the middle part of the Las Loicas Trough developed the Pleistocene Varvarco Volcanic Field (VVF), one of the largest rear-arc magmatic districts emplaced near the surface projection of the Nazca plate tearing. The VVF is characterized by subhorizontal basaltic lava flows interbedded with pyroclastic flows, and intruded by dacitic to rhyolitic subvolcanic bodies and mafic dykes. Geochemically, the basal lava flows are calc-alkaline rocks while the upper lava flows are tholeiitic. Trace elements composition indicates that both groups came from the same magmatic source, although fractional crystallization (FC) degrees decreased towards the latest magmatic pulses. Overall, the VVF lavas show slab-fluid signal and no influence from the asthenospheric plume-like structure nearby. The VVF geochemical evolution would be mainly associated with different degrees of FC process, and to a lesser extent with variable sediment or crustal influence. The transition from calc-alkaline to more primitive and tholeiitic magmas would evidence the progressively steepening of the Nazca plate by Pliocene times. The associated extensional regime would have allowed the rapid ascent of magmas and would have favoured decreasing degrees of fractional crystallization.

The study of this rear-arc magmatic sequence allow us to understand the relation between its magmatic genesis and the subducting slab steepening, the westward migration of the asthenospheric wedge, and the development of a tearing. Moreover, this work enables to understand if the upwelling of the asthenospheric anomaly had an impact on the VVF magmas and, regionally, on the rear-arc magmatic belt, as intraplate-like geochemical features are described in the Payún Matrú volcanic field, east of the studied area.

Geochemistry of the Volcanic Rocks of the Central Northeast Foothills of the Tilarán Volcanic Arc, Costa Rica

Martin Rojas Barrantes[1]*, Directorate of Geology and Mines, Costa Rica (martinr@minae.go.cr)

Abstract

The geochemistry of the volcanic rocks is analyzed (Upper Miocene to Quaternary) from the northeast of the Cordillera de Tilarán, Costa Rica. The volcanism that originates the volcanic rocks in this area of the Tilarán Volcanic Arc has been considered essentially calc-alkaline; however, differentiation is remarkable as a consequence of the magmatic evolution of the internal volcanic arc of northern Costa Rica, as shown from the analyzed samples. The objective was to analyze the geochemistry of a variety of samples in a relatively small area of 650 km2 to analyze the local volcanic evolution of the study area. The method consisted of several fieldwork campaigns as part of the geological mapping of the area and the sample collection from the best outcrops. Twenty-nine samples were analyzed (18 igneous and 11 pyroclastic rocks) under the total whole rock method according to the AQ200 standard. The results and analysis were processed with the GCDkit software. Since the volcanism is mostly mafic to intermediate in composition, the MgO content is used to analyze the differentiation processes. Also, the contents of TiO2, Fe2O3, Na2O, K2O, the trace elements Ni, Zr, Sr, Nb, Co, Sc, and Rb, the ratios Ba/La, Zr/Nb, U/Th, La/Yb, Th/Nb, and La/Nb, the REE normalized to chondrites, and the normalization to the primitive mantle to analyze the source of the magmas, the degrees and mechanisms of partial fusion, and the contribution of sediments and fluids to the metasomatism of the mantle. The Upper Miocene volcanism is sub-alkaline with marked tholeiitic and calc-alkaline affinity and transitions to both series, varying from basalts to dacites. The geochemical analysis suggests a strong differentiation of these magmas from OIB-type sources (calc-alkaline and alkaline rocks) to MORB-type sources (tholeiitic basalts) modified by the subduction processes. The Plio-Pleistocene pyroclastic volcanism is associated with ignimbrites of calc-alkaline dacitic-andesitic composition. Related to primary magmas, the analysis suggests greater or higher degrades of partial melting with an input of fluids and carbonate pelagic sediments from the subducting slab to the mantle metasomatism. The Monteverde Formation of the lower Pleistocene covers most of the area, forming transitional and sedentary soils mainly of andesite composition, associated also with pyroclastic and volcaniclastic volcanism. The Buena Vista Formation conforms to the subsequent volcanism of the Monteverde Formation and is composed of volcaniclastic deposits (lahars) of very indurate volcanic breccia. The pyroclastic Holocene deposits of Arenal volcano (Tephras) are calc-alkaline in andesitic-basaltic andesite composition. The primitive mantle normalization shows LILE enrichments and HFSE depletions associated with the input of marine fluids and sediment dehydration of the subducted slab to the mantle metasomatism, typical of arc volcanism with an alkaline component that may be more related to the back-arc than the intra-arc volcanism of northern Costa Rica.

Records of lava-ice interactions during the Pleistocene in the Chiles volcano, Colombia-Ecuador border

CAMILA MARTINEZ[1]*, Universidad Nacional de Colombia (cmartinezar@unal.edu.co)
JOHN JAIRO SANCHEZ[2], Universidad Nacional de Colombia

Abstract

Chiles volcano is an active stratovolcano with a maximum altitude of 4748 m a.s.l., located on the border between Colombia and Ecuador, and which was covered by glaciers until 1950. During its evolution it has presented mainly two periods of effusive activity during the Chibanian (~572-271.4 ka) and Upper Pleistocene (~57.5-42 ka), respectively. They generated dacitic to andesitic lava flows that make up the current volcanic edifice. There is evidence of the direct interaction between volcanic activity and past glaciers in this area.

Studying lava-ice interactions and their products is essential to understand the eruptive history of this and other volcanoes around the world, to make paleoclimatic reconstructions of past glacial extents and to identify threats associated with eruptions that involve ice in their dynamics. Therefore, this study focuses on the reconstruction of the glaciovolcanic evolution of Chiles volcano and the recognition of its records such as geoforms and fracture patterns in lavas and it constitutes a pioneering study in Colombia on this topic.

This research is based on the analysis of aerial photographs, satellite images, slope and shadow maps and field observations. Additionally, it is supported by the temporal correlation with glacial stages defined from the altitude of moraine systems in other areas of Colombia and Ecuador, and with the Marine Isotopic Stages (MIS) defined globally.

According to the observations, nine glacial stages are defined for the Chiles volcano from the Chibanian to the present (numbered from one to nine, from oldest to youngest age). Stages two, three and four (Chibanian) show a temporal relationship with the first period of effusive activity, and stage six (Upper Pleistocene) shows a direct interaction which generated geoforms of glaciovolcanic origin classified as ridge-forming flows, and pseudopillow joints, kubbaberg or blocky joints, platy joints, and column-forming joints in andesitic and dacitic lavas. These ones can be recognized mainly the southern and southeastern flank of the volcano.

The most recent glacial stages (<35 ka) show geomorphological records like U-shaped valleys, terminal, lateral and ground moraines, kettle lakes and tarns, and till deposits that indicate an erosion process after volcanic activity, and which possibly removed the typical fractures of the most superficial areas of lava flows.

Overall, most of the evidence of glaciovolcanic interactions was observed on the southeastern and

southern flank of the Chiles volcano, especially due to the fracture patterns that predominate in lavas from its second period of activity, which confirms the ice-lava interactions in this region and helps to understand the evolution of the activity of this volcano and the extinct glaciers that covered it.

2 University of Geneva, Department of Earth Sciences

3 RMG Rich Metals Group Company

The Bolnisi district is a part of the Lesser Caucasus and is located at its northern extremity. To the west, this ore district continues into the Eastern Pontides, Turkey. The Late Cretaceous (~87–71 Ma) bimodal volcanism in this region resulted in mafic and felsic rock types, the latter being a major host of the ore deposits and prospects, and being defined locally as the felsic Mashavera and Gasandami suites. The existence of caldera structures in this region has been mentioned by various scientists, which was primarily associated with the strong exposure of ignimbrites, cross-cutting extrusions, and lava domes. although this criterion alone is not sufficient, since the system is Cretaceous and a large mass of sediments has been washed away.

Different types of ignimbrites are described by the author in this region: welded, mon-welded, slightly welded, and crystal-rich ignimbrites. Thickness varies from several m up to 400-500 m maximum. At the Sakdrisi deposit, the transition from unwelded ignimbrites to welded ignimbrites can be seen, as well as the frontal part of this pyroclastic flow is outcropping, which is built of different compositions and sizes rounded to well-rounded lithic fragments and large blocks of rhyolite/rhyodacite composition; Gas- escape pipes and accretionary lapilli horizons are observed in this thick ignimbrite. Pumice tuff with different sizes of pumice and sometimes with transition zones to fine ash material, ash fall, and accretionary lapilli thick (up to several meters) horizons is outcropping in this region; different types of breccias including the phreatomagmatic, phreatic, volcanic and sedimentary is observed and mostly connecting with explosive character.

Ore deposits in Bolnisi district are connected to the Upper Cretaceous explosive volcanic event in different stratigraphic levels and there is lithological structural control on mineralization. Explosive breccia and pumice-bearing rocks (including different types of ignimbrites and pumice tuffs) are good permeable rocks for fluid, where mineralization is mostly localized. Even non-mineralized explosive breccia in the system creates a fracture system sometimes together with the regional faults where gold/copper gold-bearing quartz and quartz-sulfide veins and stockworks are developing [1].

Geochemical and geochronological evolution of mafic-felsic volcanic rocks prior to the collision of India and Eurasia: Evidence from the northwestern Ladakh Himalaya, India.

Abstract

Contributions to geology, geochemistry and geochronology of the Ladakh Himalaya have impacted the understanding of the development of suture zones and pre- and post-collisional magmatism. The Shyok suture zone is sandwiched between the Ladakh block in the south and the Karakoram block in the north. There are pockets of magmatic rocks having different geochemical evolutionary histories, formed at different geological time scales in the Shyok suture zone. One of the most widespread volcanic suites exposed in the northwest Ladakh Himalaya is the Khardung volcanic suite that sits on the northern tip of the northwestern Ladakh block. This volcanic suite comprises basalt, basaltic andesite, andesite, dacite and rhyolite. These closely associated volcanic rocks exhibit calc-alkaline affinity, with the felsic rocks forming the voluminous bulk. Their chemistry shows enrichment in large ion lithophile elements (Rb, Sr, Ba, U, Pb) and depletion in high field strength elements (Nb, Ta, Hf, Ti) with increasing Eu negative anomaly from mafic to felsic rocks. Bulk-rock liquid line of descent (LLD) modelling showed fractional crystallisation as a predominant mechanism in their petrogenesis. The calculated zircon saturation temperature (TZr) in mafic magmas (745oC) is higher than the felsic magmas (682oC). Zircon age of 69 Ma-68 Ma for the mafic rocks, and a younger 59 Ma-64 Ma age for the more evolved dacite and rhyolite are consistent with their generation in the late stage of magmatism in an active continental marginal setting. This event occurred during the Late Cretaceous and the Paleocene Epoch due to the subduction of the Neo-Tethyan oceanic slab underneath the Eurasian plate boundary prior to the main collision between India and Eurasia.

Radiogenic Sr, Nd, Hf and Pb isotope characteristics of Pumice from the Andaman Sea

Prabala Bhaskara RAMA MURTY[1]*, CSIR-NGRI (pbrmurty@gmail.com)
Neethu Sukumaran[2], CSIR-National Geophysical Research Institute
Miriyala Pavan[3], CSIR-National Geophysical Research Institute
Teeda Vijaya Kumar[4], CSIR-National Geophysical Research Institute
G Balu[5], CSIR-National Geophysical Research Institute

Abstract

During a survey of multibeam swath bathymetry in the Nicobar swarm region onboard RV Sonne, seabed sampling with a TV-guided grab recovered pumice clasts from the offaxial high of Andaman Sea. These pumice clasts had ferromanganese oxide coatings either partly or fully. We have sampled the fresh portion from the inner side and measured Sr-Nd-Hf-Pb isotopic ratios and major element abundances for three representative pumice of fully coated, partly coated and uncoated with ferromanganese oxides.

Prior to the isotope analysis, all samples were leached by an intense multi-step leaching with 6N HCl to remove the oxide coatings carefully and finally cleaned with Milli Q water. Analysis of major elements reveals contents of SiO2 ranging from 69 to 72wt% and total alkali from 6% to 9wt% suggesting that all pumice analyzed are rhyolytic in nature. Measured 87Sr/86Sr, 143Nd/144Nd,176Hf/177Hf, 206Pb/204Pb, 207Pb/204Pb, 208Pb/204Pb isotopic ratios are in the range of 0.70447-0.70454, 0.512765-0.512763 (2.68-2.81 Nd), 0.28305-0.28315 (10.02-13.05 Hf) 18.424-18.426, 15.608-15.619, 38.648-38.706 respectively. Very narrow variations in the Sr, Nd, Hf and 206Pb/204Pb isotopic ratios suggest that despite variable ferromanganese oxide coatings, analyzed pumice samples were essentially from a similar source.

Relatively large ranges observed in 207Pb/204Pb and 208Pb/204Pb ratios indicate the involvement of a DUPAL - like MORB source. Our results though preliminary with a limited number of samples, suggest more likely a source mixing between an EM2 component and Dupal-like MORB source. Comparison of the measured pumice compositions in all isotope space with the known volcanoes of regional Toba and Krakatau and local Barren Island and Narcondam suggests an unlikely scenario for a localized source, but a drifted one from Krakatau eruption. More geochemical and isotope data with the increased number of samples can resolve the source and origin of the pumices from the Andaman Sea.

Tertiary and quaternary volcanism of the western part of Senegal: State of research and prospects

Raymond SAGNA[1]*, Service Géologique National du Sénégal (SGNS)
(raymond.sagna@sgns.gouv.sn)
Rokhaya SAMBA[2], Organisation of African Geological Survey (OAGS)
Alla DIAW[3], Service Géologique National du Sénégal (SGNS)

Abstract

Located at the western end of the African continent, the geology of Senegal is composed mainly of old formations of birimian and pan-African and sedimentary formations of the Meso-Cenozoic Senegalese-Mauritanian or «Senegalese-Mauritano-Guinean Basin». This basin formed after the opening of the Atlantic Ocean in the Middle Jurassic is filled with sediments of Trias-Lias to Quaternary age and covers ¾ of the area of the country. The basin has a monoclinal structure and is characterized by a rarity of outcrops with the exception of the horst of Diass. Deep knowledge of the basin is made possible by oil drilling and geophysical data.

This basin has experienced two volcanic episodes namely that of the tertiary including Upper Eocene – Oligocene – Miocene in the region of Thiès and Cape Verde and that of the ancient quaternary of Dakar.

Tertiary lavas are composed of alkaline basic rocks with porphyry nephelinite, melalitis nephelinite, fine basanite and doleritic basanites. These rocks are associated with clusters or veins of pegmatitoids and their outcrops are scattered over 7000 km2 between Dakar and Thiès and divided into 4 sets namely that are the volcanic ensemble of the Thiès region, the volcanic ensemble of the Dome of Diass, The peninsula of Cape Verde composed of four volcanic ensembles and the oceanic margin of the basin.

Thus, the geology of tertiary and quaternary volcanism seems to be well described. However, understanding magma from source magma remains a topic of discussion. Hence the realization of a set of Master's thesis and Theses. This work, which in addition to petrography involves isotopic and geochemical analyses and gas analyses, is gradually providing an answer to the origin of magma.

It is in this context that we have chosen to make a contribution to the

understanding of tertiary and quaternary volcanism including the characterization of the source of magma using isotopes but also a rare gas, Neon.

Thus, after having made the economy of the work carried out, we will decline in turn the methodological approach used and the expected results.

volcanism IIIaire and IVaire, magma, isotopes, Neon

Monitoring magma chamber processes at silicic volcanoes through single zircon mineral chemistry and U-Pb ages in the Sabga Volcanic Complex, Cameroon Volcanic Line

Edith Etakah Bate TIBANG[1]*, University of Bamenda (edithbate@yahoo.com)
Cheo Emmanuel Suh[2], University of Bamenda

Abstract

In order to constrain the petrogenesis of silicic magma along the Cameroon Volcanic Line (CVL), zircon chemistry combined with U-Pb ages from two rhyolite samples obtained from two lithostratigraphic strata separated by a basaltic unit in the Sabga area are presented. Previously dated zircon grains with crystallization ages of 21.4 – 33.2 Ma from two rhyolite samples were analyzed for trace element contents and Lu-Hf isotopic compositions using Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICP-MS). Ti in zircon temperature for both rhyolites vary from 636 – 886 0C, and very low oxygen fugacities below the quartz-fayalite-magnetite buffer (0.08 - (-19.9)) were also obtained. This low oxidation state suggests that the rhyolites evolved as part of the anorogenic setting of the early Tertiary plutonism along the CVL which are associated with tin mineralization. Zircon REE patterns and slight negative and positive correlation trends between hafnium and trace element ratios (e.g., Hf vs Th/U, Hf vs Sm/Yb and Hf vs U), are indicative of magma evolution through an open system fractional crystallization, with coeval growth of other REE-rich accessory minerals. The Epsilon hafnium values for Tertiary zircons from both rhyolites vary from -10.6 to 6.8 and yielded Neoproterozoic mantle model ages (TDM(Ma)) between 440- 1144 Ma. The Lu-Hf data discloses mixing of materials from a juvenile mantle source and reworked crustal contribution from the Neoproterozoic and a possible Paleoproterozoic basement (TDM (2511-2407 Ma).

Preliminary Study of Magma Mixing/Mingling in Pleistocene Volcanic Rocks of the Rakiraki Area, Viti Levu, Fiji

Kamal R REGMI[1]*, Nazarbayev University (kamal.regmi@nu.edu.kz)

Abstract

The most recent volcanism on the island of Viti Levu, Fiji, is represented by Pliocene and younger mafic-intermediate rocks found in the areas of Sabeto, Tavua, Rakiraki, and Vatia, including Cainozoic shoshonites in the Vatukoula area. Some post-subduction (Pleistocene?) rocks are best exposed in the Rakiraki area, particularly along the Nakauvadra River and in the cones of the Narewa Plug complex. The rocks along the river are mainly andesites and basaltic-andesites with sporadic breccia horizons and dykes. In contrast, the rocks exposed in the Plug are Hbl-andesites. These rocks belong to the Mba Basaltic Group. Porphyritic basaltic andesites from the River are predominantly composed of microlites of Pl, Cpx, Fe-Ti oxides, Opx, and Ol with phenocrysts of altered and serpentinized Ol and subhedral to euhedral lath-shaped to tabular Pl (sometimes showing resorbed cores with mantled overgrowth) and sporadic Cpx. Rarely, Opx and Pl are found as inclusions in Cpx. Fine-grained basalts are composed mainly of microlites of Pl and Cpx with groundmass rich in Pl and Cpx.

Phenocrysts in the porphyritic Hbl-andesites from the plug complex are represented mostly by euhedral, zoned, and twinned Pl and Hbl with lesser amounts of euhedral Cpx. In contrast, Pl, Hbl, Cpx, and Fe-Ti oxides are found in the groundmass. There are zeolites (wairakites) that seem to have originated at the expense of Pl, indicating a hydrothermal activity.

Field studies at both of these sites show preliminary evidence for mixing/mingling between magmas, i.e.: a) chilled margins around MME and FME in the basaltic-andesites in the River b) cm-scale quenched enclaves of basaltic composition, finer in grain size (made up of microlites of Pl and Cpx) and coarser-grained mafic enclaves with chilled margins in andesites of the Plug. In addition, in the River section, coeval masses of basalts and andesites indicate a genetic link and fragments of sedimentary rocks are present in the basaltic andesites, confirming phreatomagmatic eruption. Although previous studies indicated that andesites from the Plug were the products of fractional crystallization of gabbroic magma, the present study suggests stronger support for magma mingling. However, a supporting geochemical investigation is needed.

Denton Ebel[6], American Museum of Natural History, Department of Earth and Planetary Sciences

Abstract

The isotopic fractionation of carbon between gas and silicate melts is a crucial parameter to understanding the carbon cycle at the planetary scale that requires accurate quantification. This experiment measured the carbon isotope fractionation factor between CO2 gas and carbon dissolved in silicate melt across a range of melt compositions at 350-420 MPa and 1160-1225°C. Integrating data from previous literature experiments and this study, a linear relationship was established between the fractionation coefficient and the depolymerization degree of the melt (NBO/T; non-bridging oxygens per tetrahedral cation). The fractionation coefficient increases for depolymerized melts (e.g., basalt) and decreases for polymerized melts (e.g., rhyolite). These relationships enable the calculation of carbon fractionation factors in silicate melts, providing a means to interpret δ13C measurements in natural volcanic gases and melts through forward and backward modeling of degassing paths from mantle to surface. The relationship is calibrated from NBO/T = 0 to 1, covering most major melt compositions. However, it is expected to stabilize and remain constant at NBO/T > 1. We hypothesize that the ratio of CO32-/CO2 dissolved in the melt is the key parameter behind this relationship. Carbon dissolved as CO2 molecule transfers to the gas phase with a fractionation factor of 0‰ whilst carbon dissolved as CO32- transfers with a fractionation factor of 3.5 ‰. Carbon isotopic fractionation might hence offer a window into carbon speciation in natural melts.

GEOLOGIC MAP OF THE PLEISTOCENE VOLCANO OF MONTE AMIATA (SOUTHERN TUSCANY, ITALY)

Claudia Principe[1]*, Istituto di Geoscienze e Georisorse - CNR, Pisa (c.principe@igg.cnr.it)
Luigina Vezzoli[2], Istituto di Geoscienze e Georisorse - CNR, Pisa
Sonia La Felice[3], Istituto di Geoscienze e Georisorse - CNR, Pisa

Abstract

Monte Amiata (305–231 ka; Italy) is an uncommon example of a completely effusive silicic (mainly trachytic) composite volcano. A detailed geological map (1:25,000 scale) based on Unconformity Bounded Stratigraphic Unit criteria is presented accompanied by volcano-tectonic, stratigraphic relationship, and volcano evolution schemes. The volcanic facies analysis and structural analysis criteria have been applied to decipher Monte Amiata's geological evolution and structure, and to infer the relations between volcanism and regional tectonics. The performed stratigraphic reconstruction is based on the recognition of a large number of lithostratigraphic units (Formation, Fm). Many of which are composed of various lithosomes. These lithostratigraphic units were grouped into the appropriate Unconformity Bounded Stratigraphic Units (UBSU) based on the recognition in the field of geological discontinuities. Based on the occurrence of a first-order geological unconformity representing a paleo-weathering surface of paleoclimatic significance, two major volcanic stratigraphic units and seven phases of activity are recognized. Petrographic descriptions of the rocks in the map legend are made at the scale of the hand sample to facilitate the identification of the various units in the field, based on the characteristics of volcanic textures, groundmass, grain size, and relative abundance of phenocrysts and mega-phenocrysts, and the presence of glomerophyres, magmatic enclaves, metasedimentary xenoliths, magmatic enclaves, and metasedimentary xenoliths.

Updated post 3 ka BP volcano-stratigraphy of Ulleungdo volcano, South Korea: insights into the Holocene post-caldera eruptions

Ho-Jun AHN[1]*, Division of Earth Environmental System, Pusan National University (ahnhj@pusan.ac.kr)
Chang Woo KWON[2], Geologic Hazards Division, Korea Institute of Geoscience and Mineral Resources
Gi-Bom KIM[3], Department of Geological Science,Pusan National University

Abstract

This study focuses on reporting a newly found silicic volcaniclastic unit deposited at ca. 3 ka BP, and suggests an updated volcano-stratigraphy of the Ulleungdo since the past 3,000 years. A newly found phonolitic volcaniclastic deposits, named unit N-0, is exposed along the wall of the incised valley that extends from the Albong to Chusan coast. Eruption age of the unit N-0 is constrained at ca. 3 ka BP, based on the radiocarbon dating of the charred woods (3,051±117 yr cal BP) and peat (3,056±99 yr cal BP) collected in and below of the unit N-0, respectively. These are the youngest absolute ages reported in the Ulleungdo, suggesting that the volcanism of Ulleungdo was active even in the historical period of Korea. The Albong, considered as the youngest trachyandesitic–trachytic volcanic edifice of the Ulleungdo, unconformably overlies the unit N-0, indicating that eruptive quiescence exists between the unit N-0 and the Albong, and that the Albong eruption occurred at least after 3 ka BP. The Chusan breccias, directly overlying the unit N-0 on the Chusan coast, is strongly suspected to originate from the Songgotbong phonolitic lava dome considering that whole-rock and phenocryst compositions of the Chusan breccia are similar to those analyzed from the Songgotbong lava. The stratigraphic relationships among the unit N-0, Chusan breccias, and Songgotbong lava dome suggest that the Songgotbong lava dome is also younger than 3 ka BP. All lines of evidence we presented here propose that the explosive and effusive eruptions by compositionally distinct silicic magmas occurred at least three times since 3 ka BP, of which the eruptive centers are spatially separated. In order to fully understand eruptive history and assess the geohazard potential for future eruptions in the Ulleungdo, additional studies are required to constrain the eruption ages of the Albong and Songgotbong whose ages still remain uncertain.

Abstract

The island of Pantelleria (Italy) is a volcanic complex that lies along the continenal rift system of the Sicily Channel. It has been the site of intensive volcanic, tectonic and volcano-tectonic activity older than 300 Ka.

The most evident morphological elements comprise two different aged calderas situated in the south-central part of the island and a resurgent block inside the younger caldera. If the presence of two calderas is accepted by a large number of authors, the relationships of two are still disputed. The oldest caldera, Cinque Denti Caldera, occupies the central-southern part of the island and is related to four explosive eruptions associated to the emplacement of PDCs, dated between 175-106 and 114 ka. The youngest caldera, named Monastero Caldera, is related to the Green Tuff eruption at about 50 Ka. This formation represents the best-known pyroclastic product of this volcano, zoned from pantellerite to trachyte and represents the main stratigraphic marker in the island. After Green Tuff caldera forming eruption, volcanic activity continues associated with an important resurgent phase, forming Montagna Grande relief and carrying high the Green Tuff from sea level deposition to more than 800 m in altitude.

The results of geological and structural survey as well some morphological observation on detailed DEM allow us to depict an updated volcano-tectonic evolution of Pantelleria Island.

Nino Popkhadze[4], Al. Janelidze Institute of Geology of Tbilisi State University. Tbilisi, Georgia

Abstract

As is known, resurgent calderas are formed after especially large volcanic eruptions by ground collapse, the diameters of which can reach many of kms. Post-caldera andesitic domes are typical for these types of calderas. Here we describe a special type of probably resurgent caldera complex, whose domes are currently up to 3000 m. a. s. l., which is not typical for these types of calderas. This is a late Miocene volcanic formation in the Georgian Lesser Caucasus, known as the Goderdzi Volcanic Complex. The complex, forms a volcanic highland, the thickness of which exceeds 1200 meters and occupies more than 4500 km2 in Georgia. It is divided into three parts, near the rock-cut city of Vardzia, in the Mtkvari canyon: The lower part is composed by a thick of 200–250 m
of pyroclastic material, predominantly andesitic-dacitic composition. This part is overlain by a 60–90 m thick andesitic-dacitic ignimbrite. On top of the ignimbrites, another thick layer of coarse-grained lithic breccia andesitic-dacitic composition is observed (700-900 m thick). Presumed, total volume of the Goderdzi Volcanic Complex within the territory of Georgia exceeds 500 km3. The SiO2 content of this complex changes from 58% to 65%, εNd values vary between +2 and +4, and 87Sr/88Sr ratios vary between 0.7034 – and 0.7045, which indicate a mantle orgin [1].

The volcanic center of this complex is located on the state border between Türkiye and Georgia. Part of this center is located on the territory of Georgia within the Niala caldera (~7x8 km) and the Gumbati andesitic dome (2996 m e.s.l.). The caldera also extends to the territory of Türkiye (NE part of the Kars Plateau), where the Keltepe Andesitic Complex (3032 m e.s.l) is located. The zircon U-Pb geochronology indicates, that the age of the Mtkvari Ignimbrites (flows from the Nyala caldera and extends more 35 km) is ~7.5 Ma and the Gumbati andesitic dome is ~ 6.5 Ma [2].

The analysis of the structural and compositional data of the Goderdzi Volcanic Complex indicates that it may be linked to the eruption from a large resurgent caldera. The only objection to this assumption is the high altitude of andesitic volcanic domes (~ 3000 m. a.s.l.), which does not seem to be consistent with typical resurgent caldera structures. We suggest that this can be attributed to the regional uplift caused by the active continental collision between the Arabian and Eurasian over the last ~7 Ma.

During this period, the caldera structure appears to have experienced intense deformation and erosion, bat the andesitic domes have been more resistant to these processes as a solid, hard

igneous bodies.

Correlation of proximal and distal deposits of a caldera-forming eruption based on the variation of juvenile materials: A case study of Toya Volcano, southwestern Hokkaido, Japan

Mitsuhiro Nakagawa[1]*, Hokkaido University (mnakagawa@sci.hokudai.ac.jp)
Mizuho MIYASAKA-ANMA[2], Hokkaido University
Akiko MATSUMOTO[3], Hokkaido University

Abstract

We correlate eruptive deposits of the caldera-forming eruption (106 ka) of Toya volcano from proximal to distal areas, by focusing on the temporal changes in the diversity of juvenile materials. The proximal deposits are divided into six units, from unit 1 to 6 in ascending order. Of these, Unit 2 and Units 5 and 6 are large PDCs. The juvenile material can be divided into three types, crystal-poor type pumice (CP), crystal-rich type pumice (CR), and gray banded pumice (GRY). These can be distinguished not only by lithofacies but also by phenocryst assemblages, mineral compositions, and whole-rock and matrix glass chemistry. Although units 1 to 3 only contain CP, small amounts of CR and GRY are also recognized in Unit 4. Then, the proportion of CP decreases to about 90% in Unit 5, and that of CR becomes particularly high. In addition, CP decreases to about 50% in Unit 6, and GRY increases in addition to CR. We compare the proportions of types of juveniles in PDC deposits from proximal to distal areas. When the juvenile material becomes fine-grained, the classification is confirmed by the matrix glass chemistry. Then, it is revealed that Unit 2 and 6 are not distributed more than 30 km from the caldera, whereas Unit 5 has reached more than 50 km far from the caldera. Moreover, the co-ignimbrite ash, which are distributed at the area more than 400 km in the distance from the caldera, can also be correlated based on the difference in matrix glass chemistry between the earlier (Unit 2) and later (Units 5 and 6) PDC. In areas up to about 120 km far from the caldera, the lower part of the ash correlates with Unit 2, and the upper part with Units 5 and 6. However, in areas further than 100 – 150 km, the ash layers are composed only of units 5 to 6. According to the above procedure, the correlation of the eruptive deposits from proximal to distal areas has been successfully completed. Considering the time interval and the temporal change of the erupted magma types, the eruption can be divided into two main stages: Stage I (Units 1 to 3) and II (Units 4 to 6). The estimated eruptive volumes are 39 km3 DRE in stage 1, 133 km3 DRE in stage 2, and the maximum in unit 5 with 106 km3 DRE. Stage II is the main stage of the eruption and erupted various types of magmas, such as CR and GRY magmas in addition to CP. The catastrophic phases of the eruption were Units 5 and 6, in which obvious lag breccia layers occurred, indicating that collapse and enlargement of the caldera had occurred.

Morphological analysis of volcanic cones and its implication to Quaternary tectonics of the Jeju Island (South Korea)

Francois HATEGEKIMANA[1]*, Pukyong National University, Department of Earth and Environmental Sciences, Geological and Geo-Hazard Research Lab (francoishate@pukyong.ac.kr)
Sambit Prasanajit NAIK[2], Active Fault and Earthquake Hazard Mitigation Research Institute, Pukyong National University, Korea
Young-Seog KIM[3], Active Fault and Earthquake Hazard Mitigation Research Institute, Pukyong National University, Korea

Abstract

The morphological characteristics and distribution of volcanic cones of Jeju Island in Korea could be controlled by several factors, including stress field in the substrate and subsurface fractures. Controlling fractures, however, might not be visible on the outcrop in volcanically active areas like Jeju Island, because of the layer of volcanic rocks covering them. Furthermore, inferring the paleostress is much more difficult. Hence, it is essential to identify the concealed feeding fractures through an indirect approach based on a morphometric analysis. Thus, Jeju Island is one of the best places to study this issue. Measurements of ellipticity, maximum crater diameter, breaching azimuth, coeval cone alignment, and the line connecting depressed points on 152 Quaternary volcanic craters, were taken to identify magma-feeding fractures. Jeju Island in SW Korea comprises Quaternary volcanic rocks overlying the Tertiary ~ Quaternary sediments of the Seogwipo Formation, Tertiary unconsolidated sediments (U Formation), and Cretaceous granite. This study identified two dominant types of Pre-Pleistocene magma-feeding fractures including E-W and NE/ENE-trending fractures consistent with previously identified Pre-Neogene E-W and Miocene NE-trending fractures around Jeju Island. These fractures might be associated with the rotation of maximum horizontal stress direction (σHmax). Identifying subsurface structures is critical for seismic hazard assessment because their reactivation could result in destructive earthquakes.

[Keynote] Hydrovolcanic activity in relation to Quaternary sea levels in Jeju Island, Korea

Young Kwan Sohn[1]*, Gyeongsang National University (yksohn@gnu.ac.kr)

Abstract

Jeju Island is a basaltic shield volcano built mainly by monogenetic volcanic activity on the Yellow Sea continental shelf under the influence of fluctuating Quaternary sea levels. Early eruptive activity was hydrovolcanic (either Surtseyan or Taalian), and volcaniclastic sedimentation occurred in either submarine or subaerial settings, depending on the sea levels. The hydrovolcanic activity lasted for over a million years and resulted in the deposition of the ca. 100 m-thick Seoguipo Formation. As the volcano grew above the fluctuating Quaternary sea levels, lava effusion became dominant in the middle to late Pleistocene, forming the current shield morphology of the volcano. In the late Pleistocene and Holocene, tuff rings and cones of Suwolbong, Udo, Ilchulbong, and Songaksan were produced by hydrovolcanic activity near the present coastlines. Suwolbong and Udo, which are pre-Holocene in age, were produced by phreatomagmatic explosions in the subsurface without any trace of marine processes. On the other hand, Holocene volcanoes (Ilchulbong and Songaksan) were produced by very wet Surtseyan to phreatomagmatic activity and preserve the records of paleo-sea-level at the time of eruption. Songaksan even contains the records of a paleo-storm event, i.e., storm wave-worked volcaniclastic deposits, up to an altitude of ~4.6 m above high tide level, implying that coastal volcanoes can preserve the records of extreme events in coastal areas, such as storms and tsunamis. The volcaniclastic materials of Songaksan were reworked by marine processes to form a marine sedimentary formation up to an altitude of a few m above present sea level, suggesting a period of higher sea levels during the middle to late Holocene. Footprints of humans, deer, birds, and marine benthic animals in the formation suggest that volcaniclastic sedimentation on Jeju Island continued until just before the historical era. Jeju Island thus shows that Quaternary sea-level fluctuations were a major control of volcanic activity and sedimentation on the island.

Triggering of rapid ascent of magma and explosive eruption: The case for the Cretaceous Sinsudo Tuff in the Gyeongsang Basin, Korea

Yong-Un CHAE[1]*, Pukyong National University (chae@pusan.ac.kr)
Youn-Joong Jeong[2], Korea Basic Science Institute
Jong-Sun Kim[3], Korea National Park Service

Abstract

In the East Asian region, including the Korean Peninsula, many sedimentary basins were formed due to the subduction of the paleo-Pacific plate under the Eurasian plate during the Cretaceous, and subduction-related volcanic activity occurred frequently around the area adjacent to the plate boundary. The Cretaceous Gyeongsang Basin (ca. 128 Ma~), the largest basin on the Korean Peninsula, was also accompanied by siliciclastic and pyroclastic sedimentation. The Sinsu and Changseon islands located in the southern part of the basin contain the Sinsudo Tuff, which is one of the representative tuff with ca. 2.5 m thick. The tuff has overall characteristics of being pumice-free and crystal-rich. Due to its stratigraphic and volcano-sedimentological importance, many studies have been conducted on its petrology, eruptional condition, and depositional process. As a result, it was revealed that the Sinsudo Tuff was deposited by surge (basal layered division) and current (upper massive division) of pyroclastic materials that underwent full fragmentation at shallow depth with a rapid magma rise. However, there is no information about the evolutionary history of the magma reservoir before the eruption that caused the rapid magma ascent interpreted based on its characteristics. Here we simultaneously determine changes of magma environment and crystallization ages from zircon crystals in the Sinsudo Tuff, which allows us to decipher the evolution history causing rapid ascent of magma and explosive eruption. U-Pb dating and elemental analysis of zircons were performed using LA-ICP-MS instruments installed at the Korea Basic Science Institute. As a result, zircons showing about 99 Ma, which indicate the eruption age, are divided into two characteristic domains with large differences in brightness in cathodoluminescence (CL) images. In general, dark domains have much higher (about 10-100 times) uranium content. Based on the combination of two domains in the CL image, individual zircons show dark overall, dark in the core with bright rims (reverse zoning), and only bright oscillatory zoning. And some boundary of the dark domains in the cores had dissolved and overgrown by bright ones. There is no reverse case, and this means an environmental change caused by the inflow/recharge of magma that formed bright domains into the magma reservoir that formed dark domains. The dark domains of zircons were formed in relatively highly evolved and cooler magma (ca. 770℃), while the bright domains of zircons were formed in less evolved and hotter magma (ca. 819℃). Similar U-Pb ages indicate that the cores of reverse zoning zircons are most likely not xenocrysts or inherited zircons, but are autocrysts and/or antecrysts. Dark domains of zircons crystallized first in more evolved magma reservoir, and then domains with bright and

distinct oscillatory zoning were formed with the recharge of less evolved magma from deeper sources. At the same time, bright domains grew on the rims of existing dark zircons due to the magma mixing in the reservoir. During ca. 99 Ma, rapid pre-eruptive rejuvenation in magma reservoir caused internal overpressure, which ultimately might trigger the rapid ascent of silicic magma through volcanic vent.

Abstract

The Suwolbong tuff ring is a basaltic monogenetic volcano in the quaternary intraplate volcanic field of Jeju Island, Korea. The tuff ring was previously interpreted as having a congested magma plumbing system consisting of multiple dike complexes based on graded and mixed chemical trends of alkaline to sub-alkaline glassy pyroclasts. Microscopic observations, petrological analysis, and componentry analysis of the glassy pyroclasts show that the glassy pyroclasts in the tuff ring have alkaline to subalkaline compositions but also found that they have contrastingly different textural characteristics. We could confirm that some of the glassy pyroclasts in the tuff ring are accidental and inappropriate for interpreting magmatic processes. Juvenile particles are vesicular, alkaline in composition, volumetrically abundant (avg. 35 vol.%), and show a correlation between the vesicularity change and the lithofacies change in the outcrop. In contrast, accidental particles are non-vesicular, alkaline to subalkaline in composition, less abundant (avg. 8 vol.%) in deposits, and show alteration rims. The accidental particles are interpreted to have been derived from the hyaloclastite layers deposited before the eruption of the Suwolbong tuff ring. When considering only the geochemical characteristics of the newly defined juvenile particles, the Suwolbong tuff ring is interpreted to have had a rather simple magma plumbing system in contrast to a previous model. This study shows that a clear distinction between juvenile and accidental particles, based on rigorous microscopic analysis, is essential for accurately understanding the properties of the source magma and the magma plumbing system in monogenetic volcanoes, which commonly contain considerable amounts of accidental materials.

Abstract

In East Asia, including Korea, widespread intraplate volcanism has appeared during the late Cenozoic. The origin of magmatism has been suggested by various hypotheses such as stagnant Pacific plate or mantle corner flow beneath East Asia. Here we provide a new perspective on the Cenozoic East Asian magmatism using geochemistry of volatiles. In order for this, 3He/4He (1 Ra = 1.38 x 10-6) ratios and δ13C-CO2 (vs. VPDB) values of Korean Cenozoic basalts and spring gas samples were measured. The maximum 3He/4He ratio (7.3 Ra) of the basalts appears within the range of the depleted MORB mantle (8 ± 1 Ra). In addition, the spring gases have the maximum 3He/4He ratio (6.8 Ra) corresponding to the lithospheric mantle range (6.1 ± 0.9 Ra). Moreover, spring gases show high carbon dioxide concentrations (up to 99 vol.%), and the δ13C-CO2 values mainly indicate the mantle origin (-6.5±2.5‰). Overall, gases containing mantle-derived volatiles are discharged to the surface adjacent to the Cenozoic volcanic rocks, which shows that it is largely consistent with the recently reported distribution of low velocity zones beneath the Korean Peninsula. Therefore, we propose that the asthenospheric mantle upwelling can explain the Cenozoic intraplate magmatism in Korea, releasing volatiles of the mantle origin.

Dualistic Bubble Formation in Explosive Silicic Volcanism of Baekdusan

Gi-Bom KIM[1]*, Pusan National University (kimgb@pusan.ac.kr)
Young-Kwan SOHN[2], Gyeongsang National University
Jongok JEONG[3], Gyeongsang National University

Abstract

Volatile exsolution and consequent gas bubble formation in subvolcanic magmatic liquid induce explosive volcanic eruptions. The liquid fraction of ascending magma bodies progressively loses volatile contents in response to ambient pressure drop. Exceptionally, some trapped in phenocrysts as melt inclusions preserve volatiles as long as their crystal traps remain undamaged. The difference in volatile preservation potential between the two mechanically separated magmatic liquid domains infers that the path of syn-eruptive magma degassing is fundamentally dualistic. Hitherto, the duality has been neither properly evidenced nor conceptualized. Here, we present direct evidence showing the dualistic nature of magma degassing in explosive silicic volcanism. Investigation of pumice deriving from the A.D. 940s Millennium eruption at Baekdusan (Changbaishan in Chinese) reveals that a considerable volume of gas bubbles has originated from melt inclusions in spatial and temporal separation from the host domain of magma. Common near-spherical bubble pockets containing jigsaw-fit crystal fragments therein indicate instantaneous and simultaneous total decrepitation of melt inclusions in response to drastic decompression shortly before or coincidently with magma fragmentation. The distinctive compositional zonation of Millennium pumice coupled with bubble pockets evince a magma mixing event, possibly the trigger of the Millennium eruption as well as the inducer of mass entrapment of melt inclusions.

Abstract

Mount Bakedu/Paektu (also known as Changbaishan) located on the border of China and the Democratic People's Republic of Korea (DPRK) is famous for intense volcanism in Cenozoic. Many studies show evidence for partial melt beneath the volcano, but details on the structure of the magmatic system are lacking due to a lack of data in the region. In this study, using ambient noise tomography and receiver functions at a new dense seismic array, we obtained a high-resolution crust and upper mantle shear wave velocity (Vs) model beneath the volcano. The absence of velocity anomalies beneath nearby Wangtian'e and Namphothe volcanoes suggest a lack of magma within the crust. However our models show two low velocity anomalies coinciding with the location of TCV in the upper crust. The shallow one (<4km depth) overlaps with petrological estimates for the rhyolite magma reservoir, involved in recent eruptions and also depth inferred for hydrothermal reservoir from recently MT study. This may be associated with saline fluids and/or a magma reservoir. The deeper anomaly is located at depths between 7 and 14 km with a lateral extent of ~30 km. This low velocity anomaly is interpreted to be the main magma reservoir with an estimated melt fraction of ~4%-12% that could feed the surface volcanism and hydrothermal activities. This double layered low velocity anomalies is in agreement with the observations of volcanic seismicity, ground deformation and volcanic gas geochemistry in 2002-2006 volcanic unrest. Underlying the deeper low velocity zone in the lower crust is a region of faster velocity compared to the surrounding region. In the bottom of lower crust and uppermost mantle, our Vs model shows low velocities close to the Moho beneath TCV. This is likely the source of partial melt that supplies the volcano. We proposed that magma from the mantle continues to intrude into the lower crust, where through reactive transport it migrates to form a basaltic magma reservoirs beneath CBVF, leaving behind a chemically differentiated crust with faster seismic velocities.

Wei Wei[4], China Earthquake Administration

Abstract

The westward subduction of the Pacific plate has led to widespread intraplate volcanism across the Korean Peninsula and NE China. However, the causes of these intraplate volcanoes and how the asthenospheric upwelling interacts with the lithosphere remain poorly constrained. In this study, we use data from across northeast China and the Democratic People's Republic of Korea. We apply a number of different seismological methods to reveal the mantle structure and dynamics beneath the region. We use teleseismic data to measure the phase and group velocities of Rayleigh and Love waves, and invert for the shear wave velocity and radial anisotropy within the crust and uppermost mantle. We also analyze shear wave splitting in converted P to S-waves at the Moho (Pms), S-waves from the subducted slab interface (local S), and SKS phases. Our results show that there are significant low-velocity anomalies and negative radial anisotropy to the northeast of Changbaishan. This suggests aligned partial melt is present within the asthenospheric mantle, underlain by a region consistent with vertical flow. The presence of many null SKS splitting phases, together with scattered local S anisotropy across a wide range of incidence angles further confirms a localized region of vertical flow. The flow is localized, suggesting it is not linked to a wider regional flow likely dominated by the Pacific subduction. Rather, it is more likely linked to an anomalous feature of the underlying subduction zone, such as a gap in the slab or deep dewatering linked to deep earthquakes. This mantle upwelling is deflected to the SW beneath Changbaishan and spreads asym-metrically at the base of the lithosphere, possibly because of the long history of volcanism in the region.

Eruptive and Emplacement Processes of the Namseongri Tuff, southern Jeju Island, Korea

Sunghyun KIM[1]*, Gyeongsang National University (kimsh1148@gnu.ac.kr)
Young Kwan Sohn[2], Gyeongsang National University

Abstract

Jeju Island is a volcanic island produced by intraplate volcanic activity during the Quaternary. In the southern coast of the island, the oldest rock formations, i.e., a basaltic volcaniclastic rock named the Namseongri Tuff and the shallow-marine sedimentary strata named the Seoguipo Formation, are exposed, preserving the records of volcanic and sedimentary processes during the early stage of Jeju Island formation. The Namseongri Tuff is composed of disorganized tuff breccia (dTB), massive lapilli tuff (mLT), inversely graded lapilli tuff (iLT), stratified tuff (sT), massive tuff (mT), and thinly stratified lapilli tuff of openwork lapilli (sLT), which commonly contain cauliflower and bread-crust bombs/blocks and are disrupted by later intrusions and faults. They are interpreted to have resulted from near-vent pyroclastic density currents and fall in an intra-crater or upper diatreme setting. The cauliflower and bread-crust bombs/blocks suggest that the magma was semi-solidified and fragmented by partly magmatic and partly phreatomagmatic processes, involving interactions with moisture-containing sediments. Accidental clasts in the tuff, derived from the volcaniclastic Seoguipo Formation and a lava beneath the tuff, suggest that the magma intruded the Seoguipo Formation and stayed underground for a while and became semi-solidified. The semi-solidified magma was fragmented by mixed magmatic-phreatomagmatic explosions most probably in a diatreme. At about 0.4 Ma, trachyandesitic magma intruded and erupted into the surface, cross-cutting the Namseongri Tuff and overlying the Seoguipo Formation. The Namseongri Tuff suggests that there was a peculiar style of phreatomagmatic activity during the early stage of Jeju volcanism.

Abstract

Ulleung Island, an oceanic intraplate volcano located in the East Sea of Korea (Sea of Japan), has a caldera structure called the Nari Caldera, which was formed by the most explosive eruption of the latest volcanic activity. To understand the characteristics of the latest volcanic activity, it is necessary to identify the caldera structures. In this study, we perform the three-dimensional (3-D) inversion of audio-magnetotelluric (AMT) data and interpret the electrical resistivity structure of the Nari Caldera area on Ulleung Island. To consider the topographic and ocean effects, detailed land and ocean terrain models were used, and a finer, non-uniform grid was generated in the caldera area. Subsequently, 3-D inversion and imaging were conducted on AMT data collected at 25 stations. The 3-D resistivity model of the Nari Caldera area is divided into two bodies: a high resistivity body located to the south and a low resistivity body located to the north. The high resistivity body has a bowl-shaped distribution in the subsurface. According to geological studies, the Nari Caldera is a complex of at least two calderas located in the north and south. Therefore, the high resistivity body in the south is interpreted as an old caldera, specifically the Seongin Caldera. The Seongin Caldera fill is inferred to be the trachytic lavas from the stratigraphy of Ulleung Island and physical properties. The low resistivity body in the north of the Nari Caldera, based on the high geothermal gradient of Ulleung Island and the borehole stratigraphy, could be interpreted as trachytic rocks with hydrothermal alteration and highly porous and/or weathered rock. We expect that the results will contribute to preparations for any potential volcanic hazards.

Sun Young GO[2], Korea Institute of Geoscience and Mineral Resources
Chang Woo KWON[3], Korea Institute of Geoscience and Mineral Resources

Abstract

Understanding volcanic and volcanogenic processes and their timescales in detail is essential for volcanic hazards and risks analyses. It requires multidisciplinary studies regarding volcanoes. Paleomagnetic and rock-magnetic analyses have been applied worldwide to resolve diverse volcanological research topics. However, paleo- and rock-magnetic techniques remain underutilized or unadvertised in the Korean geoscience community. This presentation introduces a representative suite of available paleo- and rock-magnetic applications for Korean volcanological research topics, with the current status of use in Korea. The addressed topics in terms of volcanic processes are [1] to detect (crypto)tephra in a sedimentary succession through magnetic susceptibility, [2] to determine the (lava or pyroclastic) flow directions and processes, and source vents through anisotropy of magnetic susceptibility, [3] to estimate emplacement temperatures of pyroclastic density currents using natural remanent magnetization, [4] to estimate the heating of substrates beneath the ‘hot temperature’ emplacement of volcanic products, and [5] other cases of rock-magnetic applications. The addressed topics in terms of ‘age constraining’ (timescale) are [1] correlation/differentiation of volcanic units, [2] chronostratigraphic analysis using the recording features of geomagnetic reversals and excursions, [3] a numerical dating technique using paleo-secular variation of the geomagnetic field, and [4] a numerical dating using viscous remanent magnetization. We expect that future paleo- and rock-magnetic analyses introduced in this presentation will contribute to a better understanding of volcanic and other volcanogenic processes during eruption, transport, emplacement, and even post-emplacement, their ages and durations, and the spatiotemporal correlations of volcanic and volcanogenic units in the Korean Peninsula.

Abstract

The geochemical composition of basalt which was formed from primordial magma of mantle origin provides valuable basic information to understand the magma differentiation process and the Earth's evolution process. And the isotopic composition provides geochemical information about the formation age or environment of primordial magma. Recent reports suggested that Eu isotope fractionation and magma differentiation may have a close relationship (Lee and Tanaka, 2021; Lee et al., 2023).

In addition, Hu et al. (2023) and Schauble (2023) predicted that Eu isotope fractionation can occur through the fractionation of hydrothermal solution or feldspar. These research results indicates that the isotope fractionation of Eu can be an important indicator in understanding evolution process of the Earth as well as the differentiation process of magma.

In this work, we determined Eu isotope ratio of various kinds of basaltic rocks from Jeju Island, Ulleung Island, Baekdu Mountain in Korean Peninsula in order to understand geochemical significance of Eu isotope ratio in the geological rocks derived from primitive magma, and discuss variation of Eu isotope ratio of various kinds of basaltic rocks because it serves as a cornerstone for deriving the geochemical significance of Eu isotope fractionation.

Abstract

The residence timescales of antecrystic minerals contribute a key piece of information regarding the petrologic evolution of transcrustal magmatic systems and may be inferred using a combination of observations derived from microanalytical chemistry and diffusion modelling. Here, we present state-of-the-art stacked CMOS-type active pixel sensor (SCAPS) isotopographic images of tephra-hosted plagioclase microantecrysts from Tongariro Volcanic Centre in the southern Taupo Volcanic Zone, New Zealand. These crystals exhibit high-frequency Sr and anorthite zonation at sub-micron spatial resolution. We also find that all crystals display high-frequency intracrystalline Sr chemical potential variations, indicating that they have not resided at magmatic temperature for diffusive relaxation to advance significantly. To quantify crystal residence times at the well-constrained magmatic temperatures of these tephras, we first forward-modeled intracrystalline Sr diffusion over time using numerical methods. Results were then analyzed using novel spatial Fourier-transform techniques developed to understand the systematics the diffusive decay of Sr disequilibria in the spatial frequency domain. This ultimately permitted the estimation of Sr concentration profiles at crystal formation, prior to uptake into the carrier melt at the onset of eruption. Our data imply residence times of hours to days for the studied microantecrysts. This is inconsistent with long antecryst residence times in magmatic mushes at elevated temperatures, pointing instead to a cool plutonic nature of the magmatic plumbing system beneath the southern Taupo Volcanic Zone.

Abstract

Traditionally, CSDs are determined by outlining crystals in 2D images that are not representative of the natural tridimensionality of the particles, requiring the measurement of a large number of crystals in order to obtain reliable results. Instead, the use of 3D data sets where the crystals can be measured directly provides more robust CSDs and is thus preferable.

In the case of lava flows with high density in microlites, crystals frequently overlap in 2D sections, which may cause significant errors on the CSD results obtained. Hence, the use of 3D images obtained through high resolution equipment such as synchrotron radiation micro-computational axial tomography (SR-XCT) are key for the direct measurement of the parameters in the crystals.

Sixteen lava samples belonging to the Mangawhero Formation of Mount Ruapehu were analysed through Scanning electron microscopy (SEM) at Academia Sinica (Taiwan) and through SR-XCT at the BL47XU of the SPring-8 synchrotron facility (Japan), to compare the similarities and differences between CSDs obtained through the analysis of both 2D and 3D data. For this, equant magnetite crystals were used since the measurements are expected to be similar in both 2D and 3D and thus can be compared using the transformation from 2D data to 3D data.

Additionally, using the 3D data, the CSDs slopes for pyroxenes were calculated and used in combination with a well-constrained orthopyroxene growth rates to determine magma residence times, which are estimated between 1 to 6 days. These timescales are similar to those found for tephra deposits from the last 10kyr of the Tongariro volcanic centre in the STVZ, in which the magma rises through the upper crust in 2 to 4 days as dykes controlled by the regional tectonic setting and triggering explosive eruptions.

We will discuss the similarities and differences between explosive and effusive eruptions from the STVZ in terms of CSDs, using additional petrographic and mineral chemistry data to elucidate which factors control explosive versus effusive volcanic activity in this area.

Intense fractional crystallization dominated by amphibole in continental arc: A highly efficient way to generate felsic continental crust

JING RAN[1]*, Institute of Geology and Geophysics, Chinese Academy of sciences, Beijing, China (ranjing2711828803@163.com)

Abstract

The continental arc is an important site for the production of continental crust, but there is still much debate about how primitive basaltic arc magmas are transformed into the felsic continental upper crust. A suite of mid-lower crustal rocks (exceeding 8 kbar) has been exposed in the Boluonuo region, northern North China Craton, including clinopyroxene gabbro, cumulate hornblendite, hornblende gabbro, diorite, tonalite, and quartz-rich granite, with silica contents ranging from 38 wt.% to 75 wt.%. These rocks exhibit arc-like elemental characteristics, including enrichment in light rare earth elements and large ion lithophile elements, depletion in heavy rare earth elements and high field strength elements (Nb, Ta). Moreover, the presence of large hornblende crystals (up to 40 cm long) in the cumulate hornblendites reveals its extremely water-rich arc magmatic nature, making it an excellent place to study the formation and evolution of continental crust in the continental arc. These rocks have consistent zircon U-Pb ages of ca. 280 Ma, enriched ISr (0.705 to 0.706) and negative εNd (t) (−9.6 to −7.3), implying that they are derived from the continuous differentiation of the same parental magma. The plagioclases in gabbro have high An contents up to 86, indicating that they crystalized in water-rich magma. The continuous growth of magnetite from clinopyroxene gabbro to diorite also indicates the high water contents of their parental magma. Additionally, the continuous crystallization of magnetite may be responsible for the iron depletion of the calc-alkaline magmas of the continental arc. Through a simple simulation, a basaltic magma with 50 wt.% silica can produce felsic magma by the 60% accumulation of hornblendite and gabbro. This ratio is much lower than the traditional belief that 80-90% differentiation is needed to produce granite, so the amphibole accumulation of arc magma is an efficient way to produce the continental crust. This ratio matches the proportions of rocks exposed in the Boluonuo region. This kind of accumulation process inevitably leads to the absence of intermediate rocks. In fact, intermediate rocks were relatively rare in the Boluonuo region. The accumulation of hornblende and its resulting loss of intermediate rocks are alternative explanations for the lack of amphibolite phenocrysts and “Daly Gap” in arc volcanic rocks, respectively. Furthermore, the high silica content of up to 75 wt.% in the trapped melts (quartz-rich granite) of cumulate hornblendite, also attests that amphibole-dominated intense fractional crystallization is an efficient way to produce felsic continental upper crust.

Current understanding of lithospheric mantle evolution beneath Peninsular India

AZHAR M. SHAIKH[1], IISER Berhampur
Partha Sarathi Swain[2], IISER Berhampur
S. Ravi[3], Geological Survey of India
Sebastian Tappe[4]*, 3UiT The Arctic University of Norway (sebastian.tappe@uit.no)

Abstract

Extensive exploitation of relatively abundant mantle-derived xenocrysts such as olivine, clinopyroxene, and garnet entrained by xenolith-deficient 1.1 Ga Wajrakarur kimberlites has significantly advanced our understanding of the continental lithospheric mantle (CLM) beneath Peninsular India (Griffin et al., 2009; Patel et al., 2010; Shaikh et al., 2023 and references therein). Two distinct populations of olivine xenocrysts have been identified in these kimberlites: one associated with mantle-derived peridotites and the second one with metasomatized mantle wall rocks. Independent thermobarometric calculations utilizing peridotitic olivine and clinopyroxene xenocrysts have revealed a moderately warm geotherm of 40 mW/m2, consistent with previously reported pressure-temperature conditions for rare mantle-derived xenoliths from this region of India. The compositions of garnet, olivine and clinopyroxene xenocrysts were used to reconstruct the structure of the lithospheric mantle column at 1.1 Ga, which indicates around 190 km thick CLM with an extensively metasomatized bottom. The compositions of metasomatic olivine and garnet xenocrysts indicate a kimberlitic to carbonatitic nature of the metasomatizing agent. Two layers were identified: a fairly depleted shallow layer (<145 km) and a metasomatized deeper layer (160-190 km), with an intervening garnet paucity zone (145-160 km). The garnet paucity zone is recognized as a mid-lithospheric discontinuity comprising structurally weaker lithologies. It now coincides with the current thickness of the lithosphere, suggesting its role as a detachment plane, contributing to the destabilization of the once thick and diamond-bearing cratonic keel. A further utilization of garnet xenocrysts and eclogite xenoliths to assess Fe3+/ΣFe ratios has enabled us to constrain the redox state of the CLM at 1.1 Ga. Oxybarometric calculations yielded ΔlogfO2 values indicating a wide range between FMQ-4.5 and FMQ-2.6 for garnet xenocrysts and FMQ-3.9 and FMQ-0.9 for eclogites. This broad range of ΔlogfO2 values correlates well with concentrations of Ti-Y-Zr-V in garnet, suggesting a metasomatic control on mantle redox state. This control may have facilitated the stabilization of various metasomatic phases in the CLM, which could have acted as compositionally contrasting metasomes required for the formation of 1.1 Ga kimberlites and lamproites in Peninsular India. In our latest quest for mantle cargo in the Wajrakarur kimberlites, we have exploited mantle-derived oxide minerals, an aspect that has been neglected in previous studies. In this contribution, we report major and trace element data for oxide minerals, which provide new insights into the evolution of the CLM.

The role of lithospheric mantle in the formation of Earth's crust, gold and REE mineralization

Shanshan Li[1]*, China University of Geosciences Beijing (lishanshan199811@163.com)
Kun-Feng Qiu[2], China University of Geosciences Beijing

Abstract

Earth's enriched lithospheric mantle is postulated to be a natural repository of gold and rare earth element (REE) concentration. Shandong Province in eastern China hosts voluminous Archean TTG gneiss, and Early Cretaceous alkaline and granodioritic complexes that are associated with the Weishan REE deposit, the third largest known REE deposit in China, as well as the world's third largest Jiaodong gold province. However, whether their mantle source and partial melting pressure are different that caused diverse metallogeny remains ambiguous.

For the TTGs, zircon U–Pb data reveal magma emplacement during three major pulses at ca. 2.9 Ga, 2.7 Ga and 2.5 Ga in the Jiaobei Terrane, whereas magmatism in the Luxi Terrane was largely concentrated from ca. 2.7 to 2.5 Ga. Whole-rock geochemical and zircon Hf isotopic data show that the tectonic regime was initially dominated by a mantle plume, influenced by partial melting of a hydrous thickened oceanic crust or plateau. Subsequently, dripping or delamination of the lower crust and sub-continental lithospheric mantle (SCLM) that induced upwelling of the asthenosphere. The SCLM was gradually metasomatized by slab–derived fluids in the Jiaobei Terrane during ca. 2.7–2.5 Ga, and by additional melts from sedimentary protoliths in the Luxi Terrane during ca. 2.6–2.5 Ga. The spatial distribution of isotopic and geochemical patterns reveal the presence of a heterogeneous enriched lithospheric mantle beneath the Jiaobei and Luxi terranes, formed by variable degrees of metasomatism and partial melting.

For the Early Cretaceous intrusions, whole-rock geochemical and Nd isotopic data and zircon Hf-O isotopic data show that the alkaline magmas that formed in the Luxi Terrane had A- and I-type affinities, were oxidized, were fluorine-, sulfur-, and copper-rich, were H2O poor, and were generated by low-pressure partial melting of a source region containing enriched lithospheric mantle material and minor amounts of Paleoproterozoic A-type granitic crust. In comparison, the granodioritic magmas within the Jiaobei Terrane had I-type affinities, were relatively reduced, were sulfur-rich, contained low concentrations of Cu, were hydrous, and were formed by high-pressure partial melting of a source region containing enriched mantle material and large volumes of Archean to Paleoproterozoic crustal material. The A- and I-type magmas within the Luxi terrane also have higher HFSE (e.g., Th, Nb, Ta), ΣLREE concentrations and ΣLREE/ΣHREE ratios than the I-type magmas enriched in LILEs (e.g., Ba, Sr) in the Jiaobei terrane.

We suggest that the diversity of REE and gold mineralization was the result of interaction between the lithospheric mantle and hybrid sediment-derived melts and aqueous fluids within the Luxi terrane and with aqueous fluids within the Jiaobei terrane. Our study strongly suggests that the interaction between the lithospheric mantle and sediment-derived melts, the presence of coexisting REE- and fluorine-rich magmas, and low-pressure partial melting were all crucial factors in the

formation of REE deposits, whereas high-pressure partial melting and contemporaneous sulfur and chalcophile element enrichment were critical processes in the formation of gold mineralization.

Using mineral records to unravel magmatic roots beneath sibling volcanoes: A case study at Middle Sister and South Sister volcanoes, Oregon Cascades, USA

May Sas[1]*, Western Washington University (sasm@wwu.edu)
Sean Halstead[2], Western Washington University
Emma Calvert[3], Western Washington University
James Peale[4], Western Washington University
Alex Newsom[5], Western Washington University
Madelyn Cook[6], Western Washington University
Nathan L Andersen[7], Cascades Volcano Observatory, United States Geological Survey

Abstract

To understand how a given magmatic system has evolved, and how it may continue to evolve and behave in the future, it is essential to develop a schematic model of magma storage parameters (e.g., pressures and temperatures) and magmatic conditions. A primary way to begin developing these schematics is by turning to mineral textures and compositions, which may record changing magma storage conditions and can discriminate among magmatic components derived from different reservoirs within a transcrustal magma system (TCMS). This project utilizes mineral textures in concert with compositional zones of major mineral phases to begin developing a TCMS model for Middle Sister (MS) and South Sister (SS) stratovolcanoes in central Oregon, western USA. This work also sets to establish an improved understanding of magma origins and processes at this locus, the Three Sisters Volcanic Complex (TSVC), as it is situated on the confluence of the Cascade volcanic arc and the Basin and Range extensional province, both of which likely contribute to the high compositional variability observed at this center. Units selected target a range of compositions—basaltic andesite to rhyolite— to shed light on mantle compositions and deep crust processes, as well as storage conditions and variability throughout the crust. An array of unit ages (ca. 47-14 ka) was targeted to note any changes or differences, or lack thereof, during the most active eruptive period at both MS and SS. Results indicate a peridotite mantle source for basaltic andesites at both systems, with contribution of lower crust material beneath MS (MS-type magmas) based on elevated Ni contents in MS olivine that are too enriched to originate from a fractionated, pyroxenite-derived melt. A peridotite mantle with variable crustal contributions is consistent with petrogenesis models for the older, MS-adjacent North Sister stratovolcano, where previous workers call on high degrees of mantle partial melting due to extension, with resultant incorporation of mafic lower crust. In contrast, compositions of olivine found in the only basaltic andesite affiliated with SS suggest minimal incorporation of crustal material (SS-type magmas). These differences in Ni contents allow for the distinction of olivine-bearing components (e.g., enclaves, crystal clots) as MS-type vs. SS-type and have revealed that both mafic magma types have interacted with SS silicic lavas, and potentially catalyzed their eruption. Pyroxene trace element contents in mafic-intermediate lavas at both volcanoes exhibit subtle differences, some of which require origins from distinct magma batches and others that could potentially be related via cycles of recharge and fractionation. On the other hand, a pair of

SS flows with identical pyroxene compositional populations erupted ca. 5 ky apart, implying the mobilization of the same crystal cargo from a long-lived mush system beneath SS. Together, these findings suggest that the shallow TSVC magma system is dominated by discrete crystalline reservoirs, some of which may have been tapped by multiple eruptions. The mafic roots of the magma systems beneath SS and MS likewise appear to be largely distinct, but both have contributed recharge magma to silicic reservoirs associated with SS volcano.

Multi-component Magmas of Middle Sister and South Sister in the Three Sisters (Klah Klahnee) Volcanic Complex, Oregon Cascades, USA

Alex Newsom[1], Western Washington University
Madelyn Cook[2], Western Washington University
May Sas[3]*, Western Washington University (sasm@wwu.edu)
Nathan L Andersen[4], Cascades Volcano Observatory, United States Geological Survey

Abstract

The Three Sisters (Klah Klahnee) Volcanic Complex (TSVC) in central Oregon is located at the confluence of several geologic regimes in the Pacific Northwest of the United States, including the Cascade Arc and the Basin and Range extensional province. The overlap between the two regimes results in a high volume of diverse eruptive products (basalt to rhyolite), especially in Oregon, which hosts >1,000 Quaternary vents. Such complex geologic settings assist in the development of more silicic melts and complicated transcrustal magmatic systems (TCMS). The TSVC includes a mafic periphery and three main stratocones: North, Middle, and South Sister. Middle Sister (MS; primarily mafic-intermediate) and South Sister (SS; primarily intermediate-felsic) are adjacent to one another, recently active (50–2 ka), currently experiencing inflation west of SS, and considered very high threat volcanoes by the United States Geological Survey. MS and SS experienced alternating periods of heightened activity whereby one volcano was mainly quiescent while the other was frequently active, leading to questions concerning underlying reservoir interactions. This study focuses on two lavas, a MS-affiliated dacite (dacite of Linton Creek, dlc, ~37 ka) and a SS-affiliated rhyolite (rhyolite of Separation Creek, rsc, ~25 ka), that contain a diverse assortment of magmatic components. Unit rsc erupted in the saddle between MS and SS during a transitional period when SS activity was decreasing and MS activity was increasing. Unit dlc, the oldest known TSVC dacite, is located southwest of MS. Both lavas are porphyritic and contain individual phenocrysts, glomerocrysts, and evidence for more silicic components interacting with more mafic components. These various components provide clues about the structure of the TCMS underlying the TSVC and how new magmatic intrusions contribute to the differentiation and eruption of shallow reservoirs. This study presents compositions and textural observations of major mineral phases to identify distinct mineral populations in these magmatic components and the host lavas. In rsc, olivine compositions from mafic enclaves and glomerocrysts overlap with those of olivine found in MS basaltic andesites, while dlc olivine compositions overlap with olivine from the only known SS basaltic andesite. The presence of amphibole in rsc and amphibole pseudomorphs in dlc supports a SS magmatic affinity, as amphibole in the TSVC is almost exclusively found within SS silicic eruptions. While dlc lacks the abundance of mafic enclaves found in rsc, magma recharge and reheating are preserved by the presence of amphibole pseudomorphs, multiple plagioclase and pyroxene populations, ubiquitous resorption textures, and pyroxene crystals with extensive reaction rims. These mineral compositions indicate that the MS-associated dlc is dominated by SS-type magmatic components, whereas the SS-associated rsc

records the recharge of a SS-type rhyolitic reservoir by MS-type mafic magma. This study improves the currently poorly constrained TCMS model of the TSVC and the understanding of silicic magma generation in the Cascade Arc.

Petrologic study of the youngest stage lavas of Zao Volcano, NE Japan

Kanako OKI[1]*, Yamagata University (o.kanako.sci@gmail.com)
Masao Ban[2], Yamagata University

Abstract

Zao Volcano is an active stratovolcano in central part of the volcanic front of NE Japan arc. The volcanic activity is divided into six stages and the newest stage started at about 35 ka. The eruption products of the newest stage consist of pyroclastics and subsequent amounts of lavas. Petrological and geological studies of the pyroclastics have already performed, but those of lavas were not sufficient. Here, the petrological and geochemical characteristics were examined in this study.

The lava units are Nigorigawa lava (Ngl) (ca. 35 ka), Nigorigawa-upstream lava (Nul) and Goshikidake-east lavas (Gel) (ca. 30 to 10 ka), and Furikodaki lava (Fkl) and Goshikidake-south lava (Gsl) (younger than ca. 10 ka). The rocks are olivine bearing cpx-opx basaltic andesite to andesite, except for Gel, which lacks olivine phenocryst. Modal percentages of plagioclase and cpx phenocrysts are similar among units. Those of opx in Nul and Gel are slightly higher than the other units. Olivine phenocrysts were relatively abundant in Ngl. Plagioclase phenocrysts having dusty zone and patchy or honeycomb core are observed in all lavas, and the amounts of each type of the phenocrysts are various among lavas. Opx phenocrysts are divided into five types by chemical zoning; homogeneous (H), broad high-Mg band (B), moderate width high-Mg band (M), thin high-Mg band (T), and compositionally oscillatory zoning (Os) types. H-type phenocrysts and the cores of B, M, T-types are usually low-Mg in composition. Cores of Os-type are either low or high-Mg. Os-type is dominant in Ngl, H-type is representative in Nul and Gel, and M and B-types are dominated in Fkl and Gsl.

All rocks belong to medium-K calk-alkaline series. The compositional trend slightly changed temporally. The youngest lava units (Fkl, Gsl) are higher (57–58.5 wt. %) than the others (54–57 wt. %) in SiO2 range. The oldest unit (Ngl) rocks plot on higher trend than the middle age units (Nul, Gel) in K2O, and Zr vs. SiO2 diagrams. In addition, the youngest units trend crosscuts the trends of the other age units in FeOt, TiO2 vs. SiO2 diagrams.

Dissolution texture, such as patchy and dusty zone of plagioclase phenocrysts, and the wide compositional range of opx phenocrysts observed in most of the rocks suggest these suffered magma mixing. Coexistence of low and high-Mg opx phenocrysts in most of the rocks indicates that magma plumbing system is basically composed of shallow felsic magma reservoir which receives the injections of mafic to intermediate magmas. The whole rock compositional trends are different by different age units, that implies the compositions of shallow reservoir and/or the injected magmas differ temporally. Furthermore, the zoning features of opx phenocrysts differ by different age units, that suggests the injection processes were different by different age units.

Maturation of continental arc crust via mush remobilization during magmatic flare-up

Long CHEN[1]*, Ocean University of China (chenlong@ouc.edu.cn)
Shengyao Yu[2], Ocean University of China
Dongyong Li[3], Ocean University of China
Sanzhong Li[4], Ocean University of China
Huahua Cao[5], Ocean University of China

Abstract

In volcanic arcs, magma originating from the mantle initially exhibits a basaltic composition, which then undergoes a transformation into intermediate to felsic rocks, a phenomenon known as volcanic arc maturation. Nevertheless, the exact role that magma mushes played in this process and whether the efficiency of this maturation process increases during magma flare-ups remain to be investigated. This study elucidated a three-stage transition in the composition of plutonic rocks from mafic to felsic during a Cretaceous magma flare-up event in the Gangdese arc of southern Tibet. This lithological evolution, coinciding with a gradual enrichment in radiogenic isotope compositions, suggests the influence of mixing processes. Apatite in both the first-stage mafic rocks and the third-stage felsic rocks reached Nd isotope equilibrium with their host rocks. However, the apatite in the second-stage intermediate rocks consistently exhibited a depletion in Nd isotopes compared to their host rocks, but similar to those found in the first-stage mafic rocks. The distinct covariation relationships between SiO2 and apatite-compatible elements, as well as apatite-incompatible elements in all three stages of rocks, confirm the incorporation of apatite-rich mushes into the mixing process. Structural mapping and trace element analysis indicated varying degrees of influence of mafic rock compositions by accumulation. These findings suggest that the mafic rocks represent a solidified apatite-rich mush formed through the crystallization of mafic melts, which later undergo remobilization and are incorporated into felsic magmas to form intermediate rocks. The latest felsic rocks represent the end member of the felsic magmas, formed through crustal anatexis or mafic magma differentiation. These rock suites provide evidence of continental arc crust maturation during a Cretaceous magma flare-up in the Gangdese arc. Similar evolution patterns are also observed in the Andean Cordillera, highlighting a common occurrence in continental volcanic arcs.

Genesis and Evolution of Zoned Magmatic Enclaves in Cretaceous Granitoid: A Case Study from Taejongdae, Busan

Mohammed S. M. Adam[1]*, Pukyong National University (mosaif74@gmail.com)
Young-Seog Kim[2], Pukyong National University

Abstract

This study conducted a thorough investigation of zoned magmatic enclaves (zoned MEs), reported in the Cretaceous granitoid in Busan, known for their complex orbicular rock zones. We studied the evolution of these zoned MEs through a comprehensive examination of the petrological, mineralogical, and geochemical characteristics of the zones, the utilization of SHRIMP U-Pb zircon dating, and the interpretation of Lu-Hf isotope data. The major findings offered a thorough comprehension of the concealed mechanism by which zoned MEs are created. The genesis of these zoned MEs can be attributed to two distinct phases of mixing and mingling within two different magmas. The initial phase took place within a deep dioritic magma, situated at depths ranging between approximately 7.1 and 7.7 km. The second phase occurred in a relatively shallow granitic magma located approximately 1.7–2.4 km below the surface. The dioritic magma was generated through amphibole-dominated fractional crystallization under relatively high pressure and temperature (PT) conditions. Meanwhile, the host granite magma was formed by fractionation of magma generated through partial melting of the continental crust in significantly lower PT conditions than the dioritic magma. Later on, the two magmas were mingled and mixed to produce the zoned MEs in the study area. The zoned MEs observed in the granitoids provide valuable insights into the hidden magmatic processes that occurred before the intrusion of granitic plutons.

This research was supported by a grant (2022-MOIS62-001(RS-2022-ND640011)) of National Disaster Risk Analysis and Management Technology in Earthquakes funded by the Ministry of Interior and Safety (MOIS, Korea).

[Keynote] Petrogenesis of episodic volcanic-intrusive rocks in SE China: crystal-melt segregation and magma mixing

Xisheng XU[1]*, Nanjing University (xsxu@nju.edu.cn)
Changhong Liang[2], Nanjing University
Xueying Wang[3], Nanjing University

Abstract

Intensive episodic magmatism occurred in SE China during the Cretaceous, produced a series of volcanic-intrusive rocks at different stages of magmatic activities in chain-like calderas. We conducted comprehensive petrological, geochemical, isotopic and zircon trace element analyses for several representative calderas (Yunshan, Shiniushan, Kuocangshan, Yandangshan and Xiaoxiong calderas) to reveal the crystal-melt segregation and magma mixing during the magmatism, which provided further insight into the evolutionary process of the calderas and the driving force of paleo-Pacific plate subduction.

Our results show that the magmatism produced multistage volcanic rocks and equivalent intrusive rocks regarding their crystallization ages and Nd-Hf isotopic compositions. The volcanic and intrusive rocks can be connected by fractional crystallization.

In general, the erupted silicic rhyolitic rocks are characterized by distinctly negative Eu anomalies and depletions of Ba, Sr, P, and Ti, while the coexisted intrusive rocks (i.e., porphyritic quartz monzonite, granite porphyry or porphyritic quartz syenite) show complementary geochemical signatures, such as positive Ba anomalies and neglectable Eu anomalies. Micropetrographic observation and back-scattered electron imaging for the intrusive rocks reveal textural indicators of crystal accumulation, such as imbrication and synneusis of plagioclase phenocrysts.

A fractional crystallization modeling and K isotope analysis for whole rock and their K-bearing minerals show the fractional crystallization of feldspar plays an important role in crystal-melt segregation. Mafic microgranular enclaves found in the volcanic-intrusive rocks indicating that magma recharge events occurred in the magma reservoir, which promote crystal-melt segregation processes.

Magmatic evolution and geochronology of Mesoproterozoic A-type Darsi granite pluton from Nellore Schist Belt, Southeast India

NARSHIMHA CHINTHAPALLY[1]*, Department of Geology, Centre of Advanced Study, Kumaun University, Nainital, India (drsimhaou@gmail.com)
Santosh Kumar[2], Department of Geology, Centre of Advanced Study, Kumaun University, Nainital, India
Keewook Yi[3], Korea Basic Science Institute, Ochang Campus, Chungbuk, Republic of Korea
Youn-Joong Jeong[4], Korea Basic Science Institute, Ochang Campus, Chungbuk, Republic of Korea

Abstract

The felsic magmatism in the Darsi area, referred to as Darsi granite (DG), constitutes an NNE-SSW trending ellipsoidal pluton as an integral part of several Mesoproterozoic anorogenic (A-type) plutons of Nellore Schist Belt (NSB), Southeast India. Field relation, mineral and whole rock elemental geochemistry, and SHRIMP U-Pb zircon geochronology have been carried out to reveal the origin and evolution of DG pluton and its implication on crustal evolution through time. The DG comprises quartz, K-feldspar, plagioclase, minor amphibole, zircon, apatite, fluorite, titanite and opaques. DG biotites are primary, siderophyllite to annite, buffered between QFM and NNO, syn-crystallizing with other mafics in water-undersaturated (H2O ≈ 3.35wt.%) alkaline (A-type) magma. Ti-in-biotite thermometer yields 585°C-607°C (av. 600°C) of biotite stability. The DG is peraluminous (molar Al2O3/CaO+Na2O+K2O=1.27) with SiO2 (≥72 wt.%), FeO*/FeO*+MgO (0.87 wt.%), K2O (5.04 wt.%), Ba (320 ppm), Zr (925ppm), Nb (129 ppm), Y (147 ppm) and low MgO (0.04 wt.%), Na2O (3.45 wt.%), TiO2 (0.20 wt.%), P205 (0.01 wt.%), and ΣREE, similar to ferroan A-type granite formed from crustal sources. The Y/Nb ratio (1.13 ppm) of DG corresponds to the granites of oceanic islands and continental rift (A1 type) affinity. The SHRIMP zircon U-Pb isotopes from DG yields an upper intercept age of 1298.9±6.9 Ma (MSWD = 1.05) with a weighted mean 207Pb/206Pb age of 1302 ± 54 Ma (MSWD=0.019), as zircon crystallization age or age of DG magma emplacement. The DG pluton (1298.9±6.9 Ma) seems to represent the early pulse of granite magmatism compared to other A1 type Punugodu (1257±6Ma) and Kanigiri (1284.5 ± 3.9 Ma) plutons of the NSB. The DG zircon records 576±5 Ma tectonothermal event more akin to the Gondwana supercontinent. The arc-related mafic magmatism (1315±11 Ma) in the NSB is represented by the Purimetla, Kanigiri and Pedda Cherlo Palle gabbroids formed in the subduction zone setting. Based on available petrochronological and geochemical records, it is suggested that the mafic-felsic magmatism in the northern part of the NSB is related to the Mesoproterozoic subduction-collision-accretionary orogens followed Rodinia supercontinent assembly, which later experienced Pan-African tectono-thermal event.

Mafic magmatic enclaves in Zao Volcano Stage III products, NE Japan: Evidence of conversion of magma feeding system

Masao Ban[1]*, Yamagata University (ban@sci.kj.yamagata-u.ac.jp)
Shin Sato[2], Chi-ken Sogo Consultants Co., Ltd.

Abstract

Mafic magmatic enclaves are frequently observed in calc-alkaline volcanoes in Japan and possess useful information of the magma feeding system beneath the volcanoes. Here we present an example of the enclaves in Zao Volcano, NE Japan, which have key evidence of a conversion of the feeding system.

The activity of Zao Volcano is divided into six stages. In this study, the stage three eruption products were examined. These are divided into lower, middle, and upper units, mainly composed of lava flows. Rocks are quartz bearing two pyroxene andesite, two pyroxene andesite, and two pyroxene basaltic andesite, respectively. All rocks are medium-K calc-alkaline mixed rock. Mafic magmatic enclaves as well as troctolitic inclusions are observed in the middle unit. The whole rock compositional trends of lower and middle units are similar except for some elements and are linear. The compositions of mafic magmatic enclaves in middle unit are plot on silica poorer extension of the middle unit trend, and the compositions of the upper unit are very similar to that of the mafic magmatic enclaves.

The peak Mg# compositions of opx and cpx phenocryst cores are lower in the lower unit (opx, 62~63; cpx, 67~68) than in the upper unit (opx, 70~74; cpx, 70~72). The compositions in the middle unit span both values of the upper and the lower units. Pyroxene thermometer calculations applied on peak compositions of the lower and the upper units gave ca. 960 and 1030 degrees C, respectively. Bimodal distribution of An contents of plagioclase is observed in all units. The richer one is ca. An90 regardless the unit. On the other hand, the poor ones are around An55 in the lower unit and around An72 in the upper unit. Both ones coexist in the middle unit.

These data indicate that the felsic magmas of the lower and upper units were different, whereas the mafic magmas were similar. In the middle unit, both of the felsic magmas involved in the eruption. Repeated injections of the new mafic magma would convert the lower temperature felsic end-member of the lower unit to higher temperature one in the shallow reservoir. In the period of the middle unit, both of lower and higher felsic magmas were involved in the mixing, afterwards the former was no longer active. The mafic magma that stored beneath the shallow reservoir would precipitate An rich plagioclase and olivine and become the source of the troctolitic inclusions.

Variscan magmatism with linkage to slab-breakoff? Implication from age data and mineralogy in the Western Carpathians granitic rocks

igor Broska[1]*, Earth Science Institute Slovak Academy of Sciences (igor.broska@savba.sk)
Yi Keewook [2], Korea Basic Science Institute
Sergii Kurylo[3], Earth Science Institute Slovak Academy of Sciences
Igor Petrík[4], Earth Science Institute Slovak Academy of Sciences
Marian Janák[5], Earth Science Institute Slovak Academy of Sciences
Maria Maraszewska[6], Earth Science Institute Slovak Academy of Sciences
Martin Ondrejka[7], Comenius University

Abstract

The mineralogy and geochemistry of the Variscan Western Carpathian granitic rocks is derived from protolith character and level of mixing mantle and lower crustal material. High Sr/Y and La/Yb ratios giving them “adakitic” s.l. signature indicate their formation in deep lower crustal conditions by partial melting in the stability field of garnet, in disequilibrium with plagioclase at reduced water contents indicating association with slab break-off process during subduction. Such geodynamic conditions should be an important factor in triggering large granite formation because it opened the way for increased heat and fluid flow from the asthenosphere and it could have happened during the Devonian period after the collision. The slab break-off had been followed by exhumation and crust melting and forming diatexites during decompression. The dated diatexites show age a span of 362 and 360 myr. To summarize SHRIMP age determination performed at Korean SHRIMP laboratory, the principal formation of calc-alkaline granitic rocks in the Western Carpathians occurred in the time range 359 – 342 Ma and in this sense they emplaced as (post)-collisional granites. The data indicate several magmatic peaks estimated on (1) 358-359 myr, which is a phase with formation of tonalite-granodiorite suites with more I-type affinity, (2) 355-353 myr is culmination of granite flare up, and (3) 347-342 myr, is an era of gradual evolution from tonalite to granite formation or formation of mixed granotonalites documented by micro-XRF mapping. The episodic granite formation can be connected with episodic more pronounced rising of asthenosphere as a main heat source for partial melting. The hot granite character allowed effective mixing indicated by missing of larger presence of mafic microgranular enclaves within the Western Carpathian granite massifs, therefore these granites can be considered also as H-type. Former dissolved mafic melt phase in crustal felsic system was detected in the Visean Kriváň massif by preserved plagioclase cores with high basicity of An56. In general mixing within felsic melt is indicated by common multistage formation of plagioclase formed from at least two compound chemically contrasting parts, the occasional occurrence of quartz "ocelli", and also irregular ilmenite, apatite, monazite segregations. In addition, the local presence of antiperthite in granitic rocks indicates very high primary temperatures of parental magmas. Thus, we can assume the formation of granites from a very hot melt in the deep crustal conditions with a high level of mixing in MASH zone resulted in low amount of enclave persisting. The places within granite plutons where the enclave were dissolved is possible to detect by magnetic measurement because

such sites show high magnetic susceptibility inherited from high amount of dissolved Fe-Ti minerals from mafic and intermediate melts into host felsic melt.

Origin and evolution of Fe-Ti oxides in leucogranites of Muglib and Pangong regions of Ladakh Trans-Himalaya, India: Insights from textural and chemical features of manganoan-ilmenite and re-equilibrated biotite

Ravi Ranjan Kumar[1]*, North- Eastern Hill University, Shillong, Meghalaya (raviranjan.bhu.5679@gmail.com)
Santosh Kumar[2], Department of Geology, Centre of Advanced Study, Kumaun University, Nainital, India

Abstract

The Shyok Suture Zone (SSZ) is bounded by the Ladakh Batholith in the south and the Karakoram block in the north of Ladakh Trans-Himalaya. The granite magmatism in this region is represented by the Karakoram Cretaceous granite (106–95 Ma) derived from the Karakoram Proterozoic basement, the Karakoram Cenozoic granite (76–56 Ma) from the juvenile crust, and the Karakoram Miocene granite (26–9 Ma) significantly contributed from the Indian crust. The Fe-Ti oxides (ilmenite-magnetite) are common accessory minerals in many felsic volcano-plutonic rocks. The leucogranites from Muglib and Pangong regions display medium to coarse-grained to massive porphyritic textures with biotite±chlorite–plagioclase–K-feldspar–quartz–ilmenite–magnetite assemblage. These leucogranites are calc-alkaline metaluminous to peraluminous and magnetite to ilmenite series granites. Ilmenite from these leucogranites has a low Cr2O3 (0.11–0.17 wt.%) and high MnO (4.34–5.07 wt.%), whereas magnetite is depleted in MnO (0.34–0.52 wt.%) and TiO2 (0.19–0.29 wt.%). The magnetic susceptibility (MS) values of leucogranites range from 17.8×10-3 to 42.2 × 10-3 SI unit, corresponding to magnetite (oxidized) series granite (> 3×10-3 SI unit). The manganoan-ilmenites are found to be associated with biotite, magnetite, and plagioclase. The Muglib and Pangong regions are bounded by the Shyok Metamorphic Complex (SMC) in the north and the Tangtse Metamorphic Complex (TMC) in the south, and it is further bounded by the Pangong Metamorphic Complex (PMC) in the south-eastern part. Therefore, the study area represents a highly deformed and tectonically active region. Since the SSZ rocks experienced greenschist to amphibolite-facies metamorphism, leucogranites might likely have recorded some tectono-metamorphic imprints. The observed textural and mineral geochemical features of the magnetite-ilmenite assemblage reveal magmatic crystallization and deformation-induced recrystallization during metamorphism and diffusion-induced re-equilibration with co-existing silicate minerals. Biotite is a predominant mafic mineral in these granites, which has re-equilibrated during metamorphism. The Ti-in-biotite geothermometer shows crystallization of primary biotite crystallized between 700ºC and 745ºC, which re-equilibrated during 600–660ºC. The elevated oxidizing conditions induced the Mn diffusion from biotite into ilmenite, forming the manganoan-ilmenite. This also implies short-range equilibrium conditions during metamorphism, as the ilmenite-magnetite geothermometer depicts ~550ºC, which is nearly close to the temperature at which the primary biotite re-equilibrated.

Mafic-felsic magma interaction of granitoids and microgranular enclaves in Lohit Plutonic Complex, Arunachal Trans-Himalaya, Northeast India: constraint from field, petrography, mineralogy, geochemistry and U-Pb SHRIMP chronology.

DIEZENEINO MEYASE[1]*, NAGALAND UNIVERSITY (diezenzets05@gmail.com)
Vikoleno Rino[2], NAGALAND UNIVERSITY
Rokozono Nagi[3], NAGALAND UNIVERSITY

Abstract

The Andean type calc alkaline Lohit Plutonic Complex (LPC) of Arunachal Pradesh in eastern Himalaya, is an integral part of the Trans-Himalaya magmatic arc formed by subduction of the Neo-Tethys oceanic lithosphere beneath the Tibetan continental plate. The felsic magmatic rocks of LPC referred as Lohit Plutonic Granitoids (LPG) hosts mafic (hybrid) microgranular enclaves (ME). ME are a common feature in calc alkaline granitoids and it is generally accepted that ME can offer significant insight on the nature of crust-mantle interactions and processes involved during magma evolution. Previous studies reported the occurrence of enclaves in LPG however there is no systematic study of the petrogenesis of ME in LPG, which limits our understanding of the evolution of Late Cretaceous-Eocene magmatic system in the region. Thus, we present an integrated field-based petrography, mineralogy, whole rock geochemistry and zircon U-Pb geochronology of the ME and host LPG with an aim to unravel the processes responsible for the generation and evolution of the ME and host granitoids. The ME are mostly lenticular, ovoid to sub-rounded dark coloured fine grained with varying sizes ranging from ca. 3 to 20cm exhibiting sharp, crenulated or diffused boundaries with host LPG indicated of mafic (hybrid)-felsic magma mixing. The LPG and ME have a common assemblage of pl-qtz-bt-kfs-hbl-ap-ep-ttn-zr-Fe-Ti oxides but in different proportion and sizes. The ME exhibit higher contents of ferromagnesian minerals (biotite ±amphibole) and plagioclase and lower contents of quartz and k-feldspar as compared to host LPG. Textural features such as ubiquitous needle-shaped apatite, bladed biotite, quartz aggregates rimmed by biotite and/or hornblende, corroded feldspar, feldspar phenocryst with inclusions of biotite, apatite and quartz, zoned plagioclase, and mafic clots recorded from ME strongly reflect the evolution of LPG through mixing and mingling. The amphiboles of host LPG and ME are classified as magnesio-hornblende. The biotites of ME and host granitoids are transitional between siderophyllite and eastonite end-members. Composition of plagioclase of ME and host LPG mostly range from oligoclase to andesine while few ME belongs to labradorite. The presence of amphibole-plagioclase-titanite-apatite is characteristic of their crystallization from a hydrous magma under enhanced fO2 conditions. Both ME and host LPC granitoids are strongly metaluminous. Primitive mantle-normalized trace element patterns of the ME and host granites are broadly similar with enriched Sr, Pb, Nd and Sm and depleted in Rb, Nb, Ti and possess moderately fractionated rare earth element patterns (La/Yb)N ratios ≤ 10.53, and strong to moderately negative Eu anomalies typical of continental arc-related igneous rocks. Zircon U-Pb

dating on zircon grains from ME and host granodiorite yield concordia ages of 49.93 ± 0.92Ma (MSWD = 0.62) and 50.39 ± 0.91 Ma (MSWD = 0.91), respectively. The comparable mineralogical and geochemical compositions and similar zircon crystallization age of ca 50±0.7 Ma for ME and host LPG suggests that tectonothermal event in the Himalayan-Tibetan collision zone is responsible for delamination and the uprise of enriched lithospheric mantle-derived melts to shallow crustal levels followed by crustal-mantle interactions to generate mafic and felsic (hybrid) magma in the Lohit Plutonic Complex.

Petrogenesis of Precambrian granitic suites around Ropp Complex: Constraints from zircon U-Pb-Lu-Hf Isotopes, mineral chemistry, and whole-rock geochemistry

Kayode Abdulgafar AMUDA[1]*, Bayero University Kano, Kano, Nigeria
(akamuda.geo@buk.edu.ng)
Musa Bala GIREI[2], Bayero University Kano, Kano, Nigeria
Safiyanu Muhammad ELATIKPO[3], Ahmadu Bello University, Zaria, Nigeria

Abstract

The Precambrian granite plutons along the western margin of the anorogenic Ropp complex epitomize a pivotal locale bearing imprints of multiple orogenies, namely Eburnean, Kibaran, and Pan-African events, thereby offering insights into the prevailing geodynamic regime during the genesis of the I- type granitic rocks within the west-eastern Nigeria terrane (ENT). Zircon LA-ICP-MS U-Pb dating of the granitic gneiss yielded ages of 2157, 1427, and 631 Ma, while the Older Granite (OG) yielded the age of 620 Ma, suggesting that metamorphic event at 1.43 Ga, interposed between two magmatic episodes: 2.16 Ga (Eburnean orogeny) and 0.63-0.62 Ga (Pan-African orogeny). The OG exhibits characteristics of moderately evolved calc-alkaline granites that are peraluminous, and show ferrous and high-K characteristics. These granites exhibit weak negative Eu anomaly, alongside elevated contents of Ba, Sr, and K/Rb, coupled with low concentrations of U, Th, Nb, and Ta, Rb, and very low HREE and Y, resembling the typical features of high Ba-Sr granitoid. The low Mg# (<40) observed in the OG, along with the range of ratios of some trace elements, notably low Nb/La (average = 0.33), Nb/U (average = 10.60), typify a magma sourced from the crust. The zircon εHf(t) values ranging from negative to positive (Granitic gneiss = −16.25 to +6.09 and OG = −3.96 to +3.86) suggest the involvement of partial melting of older crust with mantle input in the genesis of the parent magma. Furthermore, the low Y/Nb (average = 1.02), and Yb/Ta (average = 1.34) ratios in the OG also indicate mantle input signatures. The physicochemical conditions of the magma, inferred from biotite chemistry and whole-rock analyses, suggest that the OG are ilmenite series granites formed under low $fO2$ conditions ($\log fO2$= −15.63 to −17.18) condition. The crystallization temperature and pressure of the OG are moderate (T = 706–770^{O}C and P = 100 to 295 MPa), with the depth of emplacement estimated at 5.2 to 8.6 km using the newly improved Qtz-geobarometer. Metamorphism, represented by the syn-collisional 631 Ma granitic gneiss, and magmatism represented by the post-collisional 620 Ma Older Granite, are contemporaneous with other granitoids in the ENT. The genesis of the granitic gneiss magma is attributed to slab-melt derived from sinking oceanic crust subduction, which convects and underplates the lower crust (reworked older crust). Subsequently, slab break-off during the waning stage of the Pan-African orogeny induced the upwelling of the asthenosphere, leading to partial melting of the sub-continental lithospheric mantle (SCLM) and the lower crust, thereby generating the parent magma of the OG. The ascent of this magma follows a vertical tectonic extensional fault to the shallow crust, ultimately culminating in the

formation of the Older Granite.

Microgranular enclaves in granitoids are products of mafic to hybrid magma globules mingled and undercooled into partly crystalline host granitoids: Distinct field and microstructural evidences from calc-alkaline granitoid complexes

Santosh KUMAR[1]*, Department of Geology, Kumaun University, Nainital 263001, India (skyadavan@yahoo.com)

Abstract

Many calc-alkaline granitoid complexes have magmatic enclaves that are fine-grained to porphyritic, mesocratic to melanocratic, and rounded to elliptical. These enclaves are called microgranular, microgranitoid, or mafic magmatic enclaves. However, there is still ongoing debate regarding their nature, origin and evolution, which has led to the proposal of two diverse processes for their origin: autolith/cumulate/cognate (cogenetic) facies of host granitoid or mafic to hybrid enclave magma globules that injected, mingled and undercooled into host granitoid magma. This paper documents a series of field and microstructural features which strongly favour the mingled and undercooled origin for mafic to hybrid microgranular enclaves. These enclaves serve as a potential tool to understand the processes of coeval mafic and felsic magma interaction in volcanic and plutonic environments. The changing rheology solely controls the shape and geometry of enclaves within a timeframe from the initial to the waning stages of the host granitoid magma chamber evolution. Synplutonic mafic to hybrid dykes may inject and disrupt at the waning stage of granitoid magma evolution, forming angular to brecciated enclaves. The enclaves commonly show irregular distribution but may be uniform over a relatively large area, and they may be concentrated in swarms governed by the flow of host granitoid magma, suggesting that both were deformed during semi-solid (crystal-charged) magmatic conditions. The occurrence of enclave inside microgranular enclave (double or composite enclave), features like magmatic flowage, mafic-felsic xenocrysts, acicular apatite, and sharp and pillow-like contacts indicate co-existence and mingling of magmas with contrasting composition and temperature. Other vital features supporting mafic-felsic magma mixed, mingled, and undercooled origin for the enclaves are a round shape of enclaves with crenulated and chilled margins with partly digested hornblende crystal towards thermal front of enclave magma globule; a few crystals (xenocrysts) in enclaves are disequilibrated, rounded through partial dissolution and may be coated by another mineral, giving rise to a rapakivi-like texture; and presence of quartz ocelli. Mantle-derived mafic magma may provide thermal input, mass and volatile transfer to the granitoid melts, generating a convectively active mafic-felsic magma system. The system may be solidified at any stage of mafic-felsic magma mingling and mixing, a chaotic process during which a portion of mafic to hybrid magma can survive mixing and form the enclaves. The field and microstructural evidence of enclaves oppose the cumulate/cognate/cogenetic relation with host granitoid and instead strongly favour the origin and evolution of microgranular enclaves as mafic to hybrid magma globules that mingled and undercooled against relatively cooler, partly crystalline host granitoid

magma in a plutonic condition, as opined firstly by Ron H Vernon, and later by Robert A Wiebe, and several others.

Geochemistry, zircon U-Pb geochronology, and Lu-Hf-O isotopes of Paleoproterozoic granite gneisses from Askot-Chiplakot klippe, Kumaun Lesser Himalaya, India: Insight into petrogenesis and evolution of north Indian continental lithosphere

Kapil Singh PANWAR[1]*, Kumaun University (kapilspanwar1@gmail.com)
Santosh Kumar[2], Kumaun University

Abstract

The Askot-Chiplakot klippe marks the northern extremity of the inner Lesser Himalaya within the Kumaun region, which includes the Paleoproterozoic magmatic and sedimentary lithological units belonging to the pre-Himalayan northern India continental margin. The felsic magmatism in this region is represented by Askot granite gneiss (AGGn) and Chiplakot granite gneiss (CGGn), some of which bear augen structures. The present paper aims to understand the nature, timing, and source of Paleoproterozoic magmatism based on field relations, whole rock geochemistry, zircon typology, U-Pb geochronology and Lu-Hf-O isotopes. The results are used to interpret the Columbia supercontinent assembly and growth-related magmatism and its geologic correlations for understanding the evolution of the northern Indian continent that participated in the geodynamic evolution of the Himalaya. The AGGn and CGGn bear bt-ms-pl-Kf-qz-zrn-ap±mag assemblage with subordinate muscovite in the CGGn. Modally, the AGGn represents syenogranite and monzogranite, whereas CGGn corresponds mostly to monzogranite and a few to quartz-rich granite. The AGGn is moderately peraluminous S-type (molar A/CNK=1.39-1.80), whereas the CGGn is moderately to strongly peraluminous (A/CNK=1.48-2.70). The AGGn and CGGn were formed from the melting of metasediments, where CGGn is influenced more by mafics in the source. The elemental variations demonstrate fractional differentiation of biotite and feldspars with a minor role of apatite and heterogenous sorting of K-feldspar in the evolution of AGGn and CGGn under a syn-collisional tectonic regime. The zircon typology suggests a hybrid (metaluminous and peraluminous) nature for the AGGn and CGGn melts. Zircons from AGGn samples yield crystallization ages of 1838±56 Ma, 1852.1±7.8 Ma, 1853.6±8.4 Ma, and 1854.8±5.8 with inherited zircon cores of 2407±12 Ma and 2453±26 Ma, while zircons from CGGn samples provide zircon crystallization ages of 1846±8 Ma, 1850±9 Ma, and 1884±12 Ma, with an inherited zircon core of 2605±12 Ma, suggesting the Columbia supercontinent assembly and growth-related episodic felsic magmatism by the reworking of Neoarchean-Paleoproterozoic crust. Two-stage Hf model ages of zircons range from 2.2 to 2.48 Ga, and the zircon εHf(1856 Ga) (-5.9 to 12.12) strongly suggest a role of ancient crust as well as juvenile magmatic input in varied proportion in the formation of AGGn and CGGn. The involvement of heterogeneous sources can also be depicted from zircon typology and variable initial 176Hf/177Hf ratios. The unimodal distribution of zircon ∂18O ‰ (+5.89 to +9.92) corresponds to the derivation of AGGn from crustal sources. In contrast, the observed bimodality of ∂18O (+1.17 to +10.02) indicates mantle and crustal components in the genesis of CGGn. The progressive enrichment in ∂18O ‰

from the zircon core to the rims of CGGn probably points towards incorporating 18O-enriched components in the CGGn melt during the growth of zircons. The presence of inherited zircons and radiogenic mantle involvement strongly suggests that the significant reworking of Neoarchean to Paleoproterozoic crustal components occurred in the northern Indian lithosphere during the Paleoproterozoic era. This process ultimately led to Paleoproterozoic felsic magmatism with some juvenile or mafic crust-derived magma input, which now exists in the Leser Himalayan domain.

Boundary issue of the Cretaceous granitoid realm in between the Karakoram terrane and the Ladakh magmatic arc along Shyok Suture Zone, Ladakh Trans-Himalaya, India

SITA BORA[1]*, Department of Geology, Government Degree College, Kanda (Bageshwar), India (sitabora@yahoo.com)
Santosh Kumar [2], Kumaun University
Keewook Yi[3], Korea Basic Science Institute,162 Yeongu-Danji-ro, OChang, CheongWon-gu, Cheongju, Chungbuk 28119, Republic of Korea

Abstract

Could the boundary of granite be determined in a suture zone which evolved after amalgamation of the continents? This issue first time came to notice when the Sensitive High Resolution Ion Microprobe (SHRIMP) U-Pb zircon investigations done in the Cretaceous granitoids of the Shyok Suture Zone (SSZ) of Ladakh Trans Himalaya that is considered a boundary between the Ladakh magmatic arc system in the southwest and Karakoram terrane in the northeast. The SSZ consists of volcano-sedimentary sequences along with ophiolitic melange and intruded by granitoids in diverse time and space. Earlier scientific geochronological studies suggested that the majority of the Ladakh and Karakoram magmatic history were existed during 109 Ma, 95 Ma, 70 Ma, and in the Miocene period along the southwestern, the Northeaster parts and within the SSZ. The complexity of the Cretaceous magmatism arises because the SSZ is later affected by the geologically mapped boundary that is the Karakoram fault and the central part of the KF is sheared and deformed during Miocene. It is observed that the Cretaceous magmatism was vast which had been documented not only parallel to the NW and SE trending SSZ and KF but also recorded across the SSZ and central part of the Karakoram shear zone. It was earlier considered that most of the Karakoram batholith was feed by the leucogranite of Miocene which is not the case rather the Karakoram batholith is of Cretaceous as similar to the Ladakh granitoid. Therefore, the main question still remains that weather the Cretaceous magmatism in Ladakh regime and Karakoram terrane could consider under same magma chamber process that emplaced at same time and/or it is to be separated in the map because it lies across the Suture zone and affected by KF which is so far till date consider a boundary between Karakoram and Ladakh magmatic arc system.

Geochemical signature of Tinkoto, Tiguida, Koulountou and Dioudioukounkou plutonic masses of the transitional zone between volcanic belt / Dialé basin (Kedougou-Kenieba Inlier South-Est Senegal/West Africa Craton)

MAME CODOU NDIAYE[1]*, ENSMG/UCAD/DAKAR/SENEGAL
(mamecodou1.ndiaye@ucad.edu.sn)

Abstract

The Kédougou-Kéniéba inlier (KKI) is a Birimian formation located in the western part of the West African Craton. Bassot (1963, 1966, 1987) subdivides KKI into Mako and Dialé-Daléma Supergroups. The geochemical study shows that large plutonic masses of the Mako-Dialé transitional zone are all calc-alkalin and peraluminous or metaluminous. These are Dioudioukounkou, Tiguida, Koulountou and Tinkoto granites. The granite of Koulountou show cobalt content of 12.3ppm, nickel 51.4ppm), vanadium 46.6ppm and chromium 106.6ppm. The levels of zirconium are 130.5ppm while the levels of radioactive elements are low: Th 10.3ppm and U 6.3ppm. The granite of Dioudioukounkou is richer in light rare earths with a LaN/SmN ratio equal to 4.63. It has SiO2 levels of 73.28%. The alkali content (Na2O+K2O) of the Dioudioukounkou granite is 6.82%. The Tiguida granite is marked by a low enrichment of light rare earths with a LaN/SmN ratio below the detection limit. The Tinkoto granite has a SiO2 content of 67.93%. The alkali content is 7.30%. The proportion of CaO of Tinkoto granite is higher (3.38%). The rare earth content (∑REE) of the Dioudioukounkou granite is 286.1 ppm; 28.7ppm for Tiguida; 75.6 for the Tinkoto granite and 111.3 for the Koulantou granite. Sun and McDonough's (1995) normalized rare earth spectra have a relatively medium to high slope. These plutonic rocks have low fractionation rates with LaN/YbN ratios of 17.45 for the Dioudioukounkou granite and below the detection limit for the other granites mentioned above. There is an enrichment in light rare earths with a LaNSmN ratio equal to 4.61 for the Dioudioukounkou granite, 3.76 for the Tinkoto granite, 1.94 for the Koulountou granite and below the detection limit for the Tiguida granite. The granites in the study area are globally enriched (12 to 103) times the primitive mantle while the peraluminous granodiorites are poorly enriched (16 times the primitive mantle).

Genesis of tonalite-granodiorite batholith during subduction to accretion period of the Altai orogen (NW China) and its implications for continental crustal growth

Jianjun ZHANG[1]*, Institute of Geology, Chinese Academy of Geological Sciences, Beijing, 100037, China (jianjunzhang@live.cn)

Abstract

The model and accretionary mechanism of continental crust in the Altai orogenic belt is still widely debated. The formation of calc-alkaline I-type granitoid (mostly granodiorite and tonalite) is often considered a crucial process in continental crustal growth. This paper focuses on the widely distributed tonalite-granodiorite plutons formed during the Silurian to Devonian subduction-accretionary stage in the Altai orogen, NW China. Utilizing emerging non-traditional isotopic methods such as O, Li isotopes, along with conventional isotopic approaches, we investigate five tonalite and granodiorite bodies with decoupled Nd-Hf isotopes features and contain Precambrian inherited zircon grains in the southeastern margin of the Altai orogenic belt, to carry out detailed mineralogy, petrology, and geochemical studies. Through the analysis of the internal structure, trace elements, and in situ O and Hf isotopes of the newly identified Precambrian inherited zircon from these granitic rocks, we will discuss their origin, source, and palaeogeographical significance. Furthermore, we will trace the contribution of subducted oceanic sediments in the source of these calc-alkaline I-type granites and the mafic enclave they hosted. Combined with experimental simulations, we further explore the genesis of these tonalite-granodiorite batholith, the mode of continental crust accretion in the Altai orogenic belt and whether it is related to the ‘andesite model’.

Silicic microgranular enclaves from the Port Mouton pluton of the Northern Appalachians: implications for the development of the peripheral plutons of the Meguma terrane

Greg Gregory SHELLNUTT[1]*, National Taiwan Normal University (jgshelln@ntnu.edu.tw)
Jaroslav Dostal[2], Saint Mary's University

Abstract

The Meguma terrane of the Northern Appalachians is primarily composed of Cambro-Ordovician metapelites and metapsammites that were intruded by Late Devonian (390-360 Ma) granitic plutons. The South Mountain Batholith is composed of a number of smaller plutons (378-373 Ma), but represents the largest (~7300 km2) of the Late Devonian spatially contiguous intrusions. Peripheral and to the south are a series of smaller plutons (e.g., Port Mouton, Barrington Passage, Shelburne) that are contemporaneous or slightly younger than the South Mountain Batholith (SMB) and represent petrogenetically distinct magma pulses. The Port Mouton pluton (373 +/- 1 Ma) is composed of tonalite and monzogranite with silicic microgranular enclaves and was intruded by lamprophyric dykes. The silicic enclaves are peraluminous, magnesian, and calc-alkalic to calcic which is similar to the host rocks of the Port Mouton pluton (PMP). The enclaves can be divided into two groups based on their Al2O3 content. Group 1 is Si-rich (SiO2 = 74.3-79.7 wt%), Al-poor (Al2O3 = 10.0-12.2 wt%), and has lower Na2O (2.18-2.34 wt%) whereas the Group 2 is similar to the host rocks (SiO2 = 65.6-74.3 wt%; Al2O3 = 14.7-17.9 wt%; Na2O = 2.76-3.82 wt%). Moreover, the Group 1 enclaves have higher TiO2 and Fe2O3t at lower SiO2 then the most evolved rocks of the PMP. The higher SiO2 and lower Al2O3 and Na2O contents reflects the lower mode of albitic feldspar and higher quartz mode. Rhyolite-MELTS modeling shows that fractional crystallization of the most primitive rocks (P = 3 kbar; fO2 = dFMQ +1; H2O = 3.0 wt%) of the PMP can generate the Group 2 enclaves. The Group 1 enclaves cannot be generated by fractional crystallization and may represent a late stage magma that incorporated additional Fe-Ti oxide minerals. Nevertheless, these granitic rocks are compositionally similar to volcanic-arc granites from the main portions of Cordilleran batholiths. However, trace element-based tectonomagmatic discrimination diagrams show the enclaves and host rocks of the PMP to be similar to “slab failure” plutons whereas the SMB rocks mostly classify as volcanic-arc. Therefore, it is possible that the peripheral plutons of the Meguma terrane represent a younger period of magmatism related to slab failure that migrated southward whereas the older SMB plutons represent an older period of volcanic-arc magmatism.

Geo-characterization of Late Cretaceous mafic microgranular enclaves and host granites: A case study in the Eonyang granite, South Korea

Hui Je Jo[1]*, Korea Institute of Geoscience and Mineral Resources (jhj8218@kigam.re.kr)
Ho-Sun Lee Lee[2], Pusan National University
Sung Won Kim[3], Korea Institute of Geoscience and Mineral Resources

Abstract

Cretaceous–Paleogene plutons, generated in response to slab rollback and trench retreat, are concentrated in the Gyeongsang Arc System (GAS) along the southeastern margin of the Korean Peninsula. Cretaceous plutons, exposed in the GAS, are classified into three distinct age groups and most Late Cretaceous plutons (Palgongsan, Eonyang-Yangsan, Yucheon, Taejongdae, Bonggilri, Goheung) with a high-K calc-alkaline affinity are characterized by their mafic magmatic/microgranular enclaves (MMEs). The 76 to 71 Ma MMEs, which exhibit various textures and chemical compositions, are found within the synchronous host plutons.

This study investigates the interaction between the mafic and felsic magmas during the Late Cretaceous, using new geochronological, geochemical, and Hf isotope data from whole rock and zircon of the MME and host Eonyang granite in the Unmunsa area, adjacent to the previously reported Eonyang-Yangsan and Yucheon granites. The zircon U-Pb ages and εHf(t) values of the host granite (70 ± 1 Ma, 6.6 ± 2.4) and MME (73 ± 1 Ma, 6.4 ± 5.5) are identical within errors to those of the Eonyang and Taejongdae plutons. This implies extensive interaction between the primitive magmas with less involvement of source materials and pre-existing crustal materials. The whole-rock geochemical compositions and trends depict complex magmatic processes (fractionation and mixing/mingling) between the felsic and mafic melts. In contrast to earlier studies, the zircons from the MME and those from the host granite show clear differences. The MME zircons show relatively more positive Ce anomalies, enrichment in middle to heavy REEs, and textural differences, suggesting the MME and host zircons crystallized in felsic melts under different T-fO2 conditions. The combined data from whole-rock and zircon element compositions of the MMEs and host rocks offer valuable insights into the petrogenesis of Cretaceous granitic plutons in the GAS, indicating the roles of fractional crystallization, assimilation, and magma mixing.

Abstract

Magma mixing and fractional crystallization are fundamental processes in the origin of granites. Apatite is one of excellent minerals to trace magma mixing and fractional crystallization processes using its chemical components. However, it is difficult to distinguish these two processes only using the compositions of apatite. Here we present the integrated geochemical and Sr isotopic composition of apatite from the mafic microgranular enclaves (MMEs) and their host biotite granite in the Early Cretaceous Qianshan pluton to identify some apatite geochemical indicators for differentiating magma mixing and fractional crystallization. The variable Sr isotopic compositions of apatites in the enclaves (0.7097 to 0.7216) and the host biotite granite (0.7132 to 0.7201) directly constrain the magma mixing process. Discontinuous variable Sr isotope and/or trace elements such as Sr and Y content, and Eu/Eu* in apatite within the same sample are effective methods for identifying magma mixing. Additionally, the variation trends of trace element ratios, such as Sr/Sm and Sr/Y can also reveal magma mixing. However, the effect of fractional crystallization on the apatite composition depends on the partition behavior of elements in different minerals. For example, Eu/Eu* and Sr/Y may be effective indicators for the progressive crystallization of feldspar, while La/Lu may be an effective indicator for amphibole. Based on these observations, a magma mixing-fractional crystallization model ("MFC" model) of apatite composition establishes the genesis of MMEs and the host biotite granite in the Qianshan pluton. The observed discontinuous decrease in apatite Sr content, Sr/Y and Eu/Eu* is attributed to the mixing between the mafic and felsic magmas. The increase of LREE/HREE in localized apatite grains (Sr/Y>1) can be ascribed to fractional crystallization dominated by amphibole, plagioclase and alkali-feldspar. Subsequent alterations in the apatite composition predominantly result from the mixing of this differentiated magma and the felsic magma. Therefore, the mixing of mantle-derived mafic magma and crust-derived felsic magma is the main factor in the formation of MMEs, and the early crystallization of amphibole and plagioclase, as well as subsequent crystallization of alkali-feldspar and biotite, also play crucial roles. The biotite granite was formed by a felsic magma with minor involvement of mafic magma, coupled with the crystallization of plagioclase, alkaline feldspar and biotite. This study confirms the sensitivity of

apatite Sr isotopes and trace elements content and ratios to magma mixing and fractional crystallization, thus providing valuable insights into the intricate magma evolution processes and petrogenesis of granitoids that may be attenuated in the whole-rock compositions.

Early Cretaceous high-δ56Fe rhyolites in central Tibetan plateau: Insights into genesis of A-type magmas

Lu-Lu HAO[1]*, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences (haolulu@gig.ac.cn)

Abstract

The role played by felsic igneous magmatism in crustal differentiation is of importance for the evolution and habitability of the Earth system. However, the petrogenesis of felsic igneous rocks, particularly A-type rocks, remains highly debated, hindering our understanding of crustal differentiation processes. One key issue worthy of investigation is whether A-type rocks are produced by partial melting of crustal rocks or via extreme crystal-melt fractionation, which corresponds to two different ways of forming and refining continental crust. Recently Fe isotopes have been used to trace the origin and magmatic differentiation of granites. A-type granites generally have heavier Fe isotope compositions than I-, and S-type rocks and were conventionally considered to result from protracted, closed magma chamber fractionation of moderately reduced mafic magmas. However, increasing studies have revealed several other mechanisms that could explain heavy Fe isotopic signatures of granites, e.g., exsolution of fluids with isotopically light Fe isotopes, magma compositional control. Therefore, the genetic model of extensive crystal fractionation for generating A-type granites remains questionable and requires further validation. Here we report Fe isotope ratios of Early Cretaceous A-type rhyolites in Gerze area of central Tibetan plateau to constrain their genesis. Gerze rhyolites show high near-chondritic Zr/Hf and Nb/Ta ratios, indicating insignificant fluid-melt/rock interaction during their formation. Fe isotope variation caused by partial melting generally is small, which cannot explain the very high δ56Fe values of Gerze rhyolites. Combined with bulk-rock Sr-Nd-Hf isotopes, crustal assimilation as the origin of heavy Fe isotope signature can be ruled out. Fe isotope fractionation can be affected by magma compositions, yet, Gerze rhyolites show low (Na + K)/ Al (~0.8) and (Na + K)/ (Ca + Mg) (4-11) values, which should not be expected to yield very high δ56Fe values (up to 0.7‰). Finally, we suggested the removal of isotopically light Fe-bearing minerals as the main mechanism to produce Fe isotope variation in Gerze rhyolites. Thus, this study supports fractional crystallization to yield A-type granitic magmas and provides key insights into the evolution of continental crust.

Early Cretaceous fayalite- and ferrosilite-bearing rhyolitic porphyries and associated biotite-bearing rhyolitic porphyries from the Baishuizhai area, South China: high-temperature crustal melting and magmatic evolution

Xiao LIU[1]*, Guilin University of Technology (liuxiao@glut.edu.cn)
Qiang Wang[2], Guangzhou Institute of Geochemistry
Xi-Jun Liu[3], Guilin University of Technology
Lin Ma[4], Guangzhou Institute of Geochemistry

Abstract

Fayalite- and ferrosilite-bearing felsic igneous rocks are a distinctive category of A-type granitic magmas, and the origins of these rocks have proved controversial. Here, we report a study of earliest Early Cretaceous (145–142 Ma) fayalite- and ferrosilite-bearing rhyolitic porphyries (FFBRPs) closely associated with biotite-bearing rhyolitic porphyries (BBRPs) from the Baishuizhai area, Guangzhou, Guangdong Province, South China. The Baishuizhai suite provides an excellent opportunity to establish the magmatic origins and evolutionary processes responsible for the FFBRPs. Rocks from the Baishuizhai suite have SiO2 contents of 73.2–77.7 wt.%, Na2O + K2O contents of 7.83–9.42 wt.%, and Fe2O3T contents of 1.52–2.97 wt.%, respectively. They have A-type granite mineral assemblages (euhedral fayalite and ferrosilite in addition to anhedral amphibole and biotite) and geochemical characteristics [e.g., high 10,000 × Ga/Al (3.7–4.7) and FeOT/MgO (13.0–34.8) ratios, and high Zr + Nb + Ce + Y contents (496–906 ppm)]. The rocks have slightly enriched in situ plagioclase Sr [(87Sr/86Sr)i = 0.7070–0.7076] and whole-rock Nd [εNd(t) = −2.3 to −2.0] compositions, depleted zircon Hf isotopic compositions [εHf(t) = −0.9 to +7.0], moderate to low zircon δ18O values (6.3‰–7.8‰), and intermediate in situ plagioclase Pb isotopic compositions [(206Pb/204Pb)i = 18.368–18.727, (207Pb/204Pb)i = 15.488–15.673, and (208Pb/204Pb)i = 38.049–38.801]. We infer that the primary magmas of this rock suite were formed by the partial melting of a hybridized source consisting predominantly of juvenile crustal rocks (60%–80%) with subordinate metasedimentary rocks (20%–40%). Fayalite and ferrosilite in the FFBRPs were most likely crystallized from dry, hot, and reduced magma in a deep (~20 km) chamber. The deep magma gradually evolved during ascent to water-enriched magma in a chamber at intermediate depth (3–4 km), followed by residence in a shallow (<3 km) chamber. According to the established temporal–spatial distribution of Early Cretaceous A-type granites in South China, we suggest that partial melting of the hybridized source was induced by the underplating of mantle-derived mafic magmas, which were produced by decompression melting of upwelling asthenospheric mantle in response to slab rollback of the Paleo-Pacific Plate.

Late Mesozoic high Ba-Sr granitoid in the Xiao Qinling area of Eastern Qinling Orogen, Central China: Petrogenesis and tectonic setting

Chengli ZHANG[1]*, Department of Geology, Northwest University, Xi'an, Shaanxi Province, China (clzhang@nwu.edu.cn)
Huan Yang[2], Department of Geology, Northwest University, Xi'an, Shaanxi Province, China

Abstract

Muhuguan pluton is outcropped at the southwest end of Xiao Qinling area in the Eastern Qinling orogenic belt. The LA-ICP-MS U–Pb zircon dating yield ages from 160 to 150 Ma, representing the earliest magmatism in the late Mesozoic and being of great significance to reveal the early stage of late Mesozoic tectonic setting of Qinling Orogenic Belt, central China. This pluton is composed mainly of monzogranites and some granites, and some coeval mafic microgranular enclaves (MMEs) and mantle-derived mafic dykes are occurred within them. The granitoids are characterized by high and variable SiO2 (62.01~73.55%) and Al2O3(13.6~17.5%, A/CNK=0.97~1.06), high K2O(2.89~5.28%; K2O/Na2O=0.71~1.49), LREE and LILE, insignificant Eu anomalies (δEu=0.80~1.13), depletion in HREE and Y, especially anomalous high Ba (762~3265×10-6) and Sr (200~959×10-6)as well as high Sr/Y(12.6~87.9) and K/Rb (218-530), indicating the high Ba-Sr granitoids. Furthermore, they have moderate Mg# (30.2~43.0), and low Cr, Ni contents and low and variable radiogenic Nd isotopes (εNd(t)=-13.7 to -4.9), suggesting production from the partial melting of the basic-basic-rocks and clastic rocks in the Qinling complex. The occurrences of coeval mafic enclaves and mantle-derived dikes within the host granitoids as well as highly variable Nb/Ta ratio of granitoids suggested that pluton were modified by mantle-derived magmatic activity during the formation process. In addition, K2O, Rb, Rb/Sr and Rb/Ba of rock mass increase with the increase of SiO2, while CaO, Sr, Ba and their K/Rb are negatively correlated with SiO2, indicating that there was fractional crystallization of some hornblande, clinopyroxene and plagioclase during process of the magmatic evolution. All characteristics mentioned above fully prove that the Muhuguan high Ba-Sr granitoids was most likely formed by the partial melting of the crustal material due to the heating from the upwelling of mantle material under the adjustment of the thickened crust resulted from the collision between the southern and northern continental blocks as well as the lithosphere extension and thinning during the transitional period form post-collision to intraplate in the late Jurassic, which has no directly connection with the magmatic activity caused by westward subduction of the Paleo-Pacific Ocean to the eastern mainland of China since late Jurassic of the late Mesozoic.

The extensional tectonic environment within the Urumieh-Dokhtar magmatic belt, NW Iran

REZA MONSEF[1]*, Department of Geology,Estahban branch, Islamic Azad University,Estahban,Iran (r.monsef@kce.ir)

Abstract

The Urumieh-Dokhtar magmatic belt as a part of the Alpine-Himalayan orogenic belt represents a linear igneous activity, extending from the northwest to the southeast of the Iranian plateau. The Urumieh-Dokhtar magmatic belt consists of Miocene magmatic rocks in the central part, which are mainly composed of volcanic and pyroclastic rocks of basaltic to dacitic compositions as well as lower amounts of intrusive bodies with calc-alkaline to high-K calc-alkaline to shoshonitic affinities. The U-Pb zircon geochronology from monzodiorite, micro-granodiorite, and dacitic rocks reveals the crystallization ages of 15 to 20 Ma (Burdigalian-Langhian). These rocks exhibit enrichment in large ion lithophile elements and light rare earth elements and depletion in Nb, Ta, and Ti, characteristics of the subduction-related environment. Samples are characterized by a high 87Sr/86Sr ratio (0.7056 to 0.7071), εNd value (0 to -3.5), and high 143Nd/144Nd ratio (0.51246 to 0.51267). The Pb isotopic evidence is particularly high with 208Pb/204Pb ratio (38.731 to 39.097), 206Pb/204Pb ratio (18.770 to 19.004), and 207Pb/204Pb ratio (15.645 to 15.706). AFC modeling shows magmas evolved through assimilation combined with fractional crystallization, and that the effects of assimilation range combine to crustal thinning phenomena. Geochronological data show that the Urumieh-Dokhtar magmatic belt magmatism was active and widespread during the Miocene when trans-tensional basin systems were working due to mantle diapirism. The convectively upwelling asthenosphere and partial melting of earlier metasomatized subcontinental lithospheric mantle may trigger such magmatism. These geochronological data in conjunction with geological and geochemical data suggest that the Miocene magmatic flare-up was the most active event in the Central part of the Urumieh-Dokhtar magmatic belt and was a high-flux magmatism in an extensional tectonic setting.

Granitoids of the north of the Urals: U-Pb geochronology (SIMS, LA-ICP-MS, ID TIMS) and isotope geochemical (OZrn, Sm-Ndwr, Lu-HfZrn) characteristics

Oksana Vladimirovna UDORATINA[1]*, Institute of Geology of Komi Science Centre of the Ural Branch of the Russian Academy of Sciences (taykey@yandex.ru)
Ksenia Viktorovna Kulikova[2], Institute of Geology of Komi Science Centre of the Ural Branch of the Russian Academy of Sciences
Alexander Sergeevich Shuisky[3], Institute of Geology of Komi Science Centre of the Ural Branch of the Russian Academy of Sciences
Anna Alekseevna Soboleva[4], Institute of Geology of Komi Science Centre of the Ural Branch of the Russian Academy of Sciences
Valentin Leonidovich Andreichev[5], Institute of Geology of Komi Science Centre of the Ural Branch of the Russian Academy of Sciences
Irina Igorevna Golubeva[6], Institute of Geology of Komi Science Centre of the Ural Branch of the Russian Academy of Sciences

Abstract

Granitoid magmatism in the north of the Ural orogen is represented by derivatives of two large geodynamic stages - pre-uralids (pre-uralids, proto-uralids, timanids) and uralids. Granitoids of the Central Ural megazone record the pre-Ural history of the evolution of the active margin and the collision of Baltica and Arctida. In the pre-uralids, there is a change from island-arc magmatism (735–720 Ma) with the melting of I- (M-) granitoids to accretionary (670 Ma) – I-granitoids, then to collisional (620–520 Ma) – simultaneous melting of A-, I-, S-granitoids, then riftogenic (520–480 Ma) – melting of I- and mainly A-type granites.

Granitoids of the East Ural megazone (Shchuchinsky and Voykar-Rayiz zones) are already associated with the Ural history - the formation and closure of the Ural paleoocean. Island-arc uralides of the primitive island arc (460–430 Ma, I-granitoids), replaced by granitoids of the mature island arc (412–368 Ma) and ending with collisional granitoids, early (360–316 Ma) and late (277–249 Ma) years).

Thus, the development of the pre-uralid orogen covers a fairly long period of time, starting from 620 to 520 million years. With this age, granitoids of all types are observed in the north of the Urals. After the turn of 520 Ma, only type I and A granites are observed, marking the rifting stage. It began a new tectonic cycle, the actual Ural cycle, which ended with the formation of the Ural folded region. The composition points of non-collision I- and A-type granites gravitate more towards the fields of intraplate formations and have a more mantle source. I-type granites, formed already in the Ural time, are characterized by typically island-arc characteristics.

Isotopic studies have shown that the values of oxygen and hafnium isotopes in zircons and neodymium in rocks show variability in the maturity of the granitoid substrate from the Northern to the Polar Urals. Markers of the most mature recycled material are recorded in pre-uralid granitoids of the Northern and Subpolar Urals: $\delta^{18}O$ from +7.10 to +8.51‰, εNd = -4.8 – -0.3, $\varepsilon Hf(t)$ = -3.35 – -1.95. Granitoids of the pre-Uralids of the Polar Urals are characterized by

components of mantle origin, as well as a more moderate contribution of crustal material to the original magma: δ18O from +4.7 to + 6.22‰, εNd = +0.6 – +5.6, εHf(t) = +2.15 – +15.1. In general, an older model age (TDM2) of the protolith is noted for pre-uralid granitoids of the Subpolar (1.76–1.03 Ga) and Northern (2.09–1.11 Ga) Urals compared to that for the Polar Urals (1.48–0.64 Ga). Isotopic characteristics of Uralide granitoids indicate a significant contribution of the mantle component during their formation: δ18O from +4.19 to + 5.69‰, εNd = +4.1 – +7.4, εHf(t) = +8 – +15.7. The model age (TDM2) of the protolith for the Uralide granitoids of the Polar Urals is 1.01–0.37 Ga. Thus, almost all the obtained data δ18OZrn, εHf(t)Zrn, εNd(t)wr show a significant contribution of the mantle component during the formation of granitoids of various types in the north of the Urals.

Formation and tectonic implication of the late Mesozoic Yunmengshan batholith, North China Craton: new constraints from zircon Hf-O isotopes and apatite geochemistry

Jin-Feng SUN[1]*, University of Chinese Academy of Sciences (sjf@ucas.ac.cn)
Miao-Miao Ling-Hu[2], University of Chinese Academy of Sciences
Ji-Heng Zhang[3], University of Chinese Academy of Sciences
Zi-Mu Li[4], University of Chinese Academy of Sciences
Jin-Hui Yang[5], Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

Yunmengshan batholith is a typical late Mesozoic intrusion in the western segment of the Yanshan belt, northern margin of the North China Craton, and well known as the “Yunmengshan metamorphic core complex”. It includes Yunmengshan granitoids and Shicheng diorite, which formation records important information for the westward subduction of the Pacific plate and the destruction of the North China Craton. In-situ zircon U-Pb and Hf-O isotopes, coupled with whole-rock and apatite geochemical compositions, are carried out for diorites from the Shicheng intrusion and monzogranites (medium-grained and fine-grained) from the Yunmengshan intrusion, aim to probe into their magma sources and petrogenesis. Our newly obtained zircon U-Pb ages show that the diorite was formed at about 156 Ma, while the medium-grained and fine-grained monzogranites were formed at 143-142 Ma and 139-136 Ma, respectively. Shicheng diorites have relatively low SiO2 and high MgO contents, with zircon εHf(t) values of-17.8 to -13.4 and δ18O values of 5.7 to 6.9‰, indicating their parental magma were derived from an isotopically enriched lithospheric mantle, with the involvement of ancient crustal materials during their formation. The medium-grained and fine-grained monzogranites have relatively high SiO2 contents (67.8-74.4 wt.%),with enriched zircon εHf(t) values of -21.3 to -14.7 and -25.6 and -12.2, and zircon δ18O values of 5.8‰ to 6.8‰ and 5.9‰ to 7.0‰, respectively. All their geochemical features indicate that they were generated by the partial melting of the basaltic lower continental crust at about 2.5 Ga. However, apatite from the medium-grained and fine-grained monzogranites show significantly distinct geochemical characteristics, precluding the fractional crystallization progress as their genetic link. Combined with whole-rock geochemical compositions, REE patterns for apatites from different rock types provide key evidence for their origin of distinct source materials. Thus, the Yunmengshan batholith record multi-stages magmatic activities (Late Jurassic and the Early Cretaceous), which derived from distinct magma source as enriched mantle and lower crust. Geochemical features of apatite can be an useful tool to trace magma sources and process.

Tectonic understanding of Syenites and Quartz Syenites from Peralimala and Angadimogar plutons, Kerala, India

SAI KRISHNA PRIYA VALLURI[1]*, OSMANIA UNIVERSITY (krishnapriyavalluri@gmail.com)
AMARENDHAR S[2], OSMANIA UNIVERSITY
SRINIVAS M[3], OSMANIA UNIVERSITY

Abstract

Syenite and Alkali granite intrusives of NeoProterozoic age sporadically puncture the Precambrian granulite facies terrain of charnokites and migmaties of SW India. The intrusive bodies understudy occurs at Peralimala (PM) and Angadimogar (AM) and are prominent ones amongst the 18 bodies that invaded the Peninsular shield of India, providing the evidences of prominent felsic magmatic events during Pan African period. An elongated body of PM [$11^0$53'N - $75^0$39'E] occurs in Kannur district of Kerala and believed to have emplaced along the Bavali lineament. On the other hand, the AM pluton [$12^0$38'N - $75^0$00'E] in Kasaragod district of Kerala is emplaced close to the continental margin and along a NW-SE trending fault lineament. Petrochemically both these bodies have distinctive characters which differentiates one from the other.

The PM is dominantly a syenite body composed predominantly of perthitic K-Feldspar (microcline > orthoclase) and pyroxene > amphiboles with +biotite, while AM pluton is a quartz-syenite body showing variation to quartz monzonite and alkali granite from core to periphery and is composed of predominant K-feldspar with orthoclase > microcline, plagioclase and quartz, Mafic minerals such as amphibole dominant over pyroxenes and biotite.The AM rocks are well fractionated peraluminous and high calc-alkaline series rocks. They are high in Na2O (~5.5%) and low in K2O (~4.3%) along with high Zr, Nb, Th & U, and low Rb, Sr, Cu, V and Ba. The ∑REE of these rocks range between 60 to 715 ppm and characterized by positive Eu anomaly. They also show an enriched LREE pattern. On the contrary, the PM rocks are peraluminous to metaluminous high potassium shonsonite series rocks. They show low Na2O (~3.3%) and high K2O (~9.7%) along with high Rb, Sr, Cu, V & Ba, and low Zr, Ga, Nb, Th and U. The ∑REE of these rocks range between 30 to 105 ppm and show a distinctive negative Eu anomaly. The AM and PM rocks when normalized with mantle compositions show similar pattern for their incompatible elements, but their compatible elements show irregular pattern. Their normalized pattern further shows negative Nb, Ti and P anomaly, while Sr of AM rocks show negative anomaly and PM rocks show a distinctive positive anomaly.

The diversity in the geochemical features between the two plutons is interpreted to be because of the heterogeneity of the source or may be related to fractional crystallization of a homogenous source. Their alkaline nature indicate that the magma was derived from the deep crust or upper mantle. These two plutons are generally considered to be anorogenic or post orogenic in nature representing the within plate-volcanic arc zones, and that which have formed away from active continental margin. In Peninsular India these alkaline plutons have a strong Pan-African imprint similar to the Pan-African post-kinematic plutons from the Afro-Arabian shield having high SiO2,

K2O (~12%) & Na2O, and low CaO, FeO & MgO.

A Method for Calculating Magma Oxygen Fugacity with Uraninite in Granites

Jian GUO[1]*, Beijing Research Institute of Uranium Geology (guojian9818@163.com)
Ziying LI[2], Beijing Research Institute of Uranium Geology
Jiangtao NIE[3], Beijing Research Institute of Uranium Geology
Yuyan ZHANG[4], Beijing Research Institute of Uranium Geology

Abstract

Oxygen fugacity is an important physicochemical parameter of magmas beside temperature, pressure, and elemental concentrations, and is a major research topic in natural and experimental petrology. In previous studies, apart from direct measurement with oxygen probe, it is more common to use valence-varying elements in rocks and minerals to indirectly estimate the magma oxygen fugacity. Uraninite is the main U-bearing accessory mineral in granites. Uranium in uraninite occurs mainly as U4+ or U6+, depending on the magma oxygen fugacity. Li (2015) utilized X-ray photoelectron spectroscopic (XPS) in-situ micro-analytical technique to determine the elemental valency of natural U-bearing minerals. In this study, we used XPS to directly measure the uraninite U6+ and U4+ contents in granites, estimated the magma oxygen fugacity, and discussed the reliability of this new technique.

The granite samples for the oxygen fugacity estimation were collected from the Wuliting intrusion (24°46′41.08″N, 114°23′20.87″E) in Jiangxi Province, China. Scanning electron microscope (SEM) observation was conducted to determine the crystallization states and paragenesis of uraninite grains. Uranium valence state analysis was conducted at the Key Laboratory of Catalytic Material Science in the South Central University for Nationalities, using a Thermo Scientific MultiLab 2000 XPF system.

For our uraninite samples, we chose five grains (with better uranium XPS signals) for 25eV U-valency narrow scanning, calibrated using C1s = 284.6eV. To obtain better imitating results, we picked the uranium oxide 4f7/2 channel U4+ and U6+ standard binding energy to 380.31 ± 0.47eV and 381.75 ± 0.47eV, respectively.. The U4+ peak binding energy is of 379.94 ~ 380.19eV, and its full width at half maximum (FWMH) values of 1.78~1.90eV. The U6+ peak binding energy and FWMH values are of 381.64 ~ 381.77eV and 1.60 ~ 1.84eV, respectively. The uraninite U6+/U4+ ratios are of 0.30 ~ 0.46.

Using Jiang (2005)’s estimation of average crystallization temperature of magmas, the Wuliting granites may have formed at 680℃. We caculated and suggested that the Wuliting granitic magma has oxygen fugacity of -18.26 to -17.89 (average -18.08).

As a common accessory mineral in granites, uraninite records the oxygen fugacity of early-stage magmatic evolution. The XPS in-situ microanalytical technique adopted in this study represents a rapid way to determine the U-valence states, and can effectively avoid the impacts of redox reactions (between uranium, decomposition medium and interfering elements) on the analytical accuracy in conventional wet-chemistry analytical techniques. Uraninite is an independent uranium mineral, and thus the analytical error of uranium is smaller than those of the trace

elements (e.g., Ce) in zircon. Analysis of uraninite can also avoid the issue of crystal-melt partitioning relationship of the valence-varying elements, and lower the theoretical derivation and analytical errors. Therefore, the calculation results are relatively reliable.

Petrogenesis of mafic enclaves hosted in the Zouzan pluton, Eastern Iran: Insight from the U-Pb zircon geochronology, whole-rock Nd-Sr isotopes, and elemental geochemistry of amphibole and apatite

Seyed Ali Mazhari[1], Research Center of Geographical Sciences and Social Studies, Hakim Sabzevari University, Sabzevar, Iran
Kwan Nang Pang[2], Institute of Earth Sciences, Academia Sinica, Taipei, Taiwan
Santosh KUMAR[3]*, Department of Geology, Kumaun University, Nainital 263001, India (skyadavan@yahoo.com)
Kazem Aliabadi[4], Research Center of Geographical Sciences and Social Studies, Hakim Sabzevari University, Sabzevar, Iran

Abstract

The calc-alkaline granitoids often contain mafic to hybrid magmatic enclaves. There has been a debate about whether these enclaves are a cumulate of host granitoids or a result of a mixed origin of mafic and felsic magmas. To better understand the origin and evolution of enclaves and their relationship with the host rocks, we investigated the mafic enclaves and associated lithological units of the Zouzan pluton. The observed enclave-host field relationships and microstructures strongly suggest that the mafic enclaves (MEs) originated as pockets or blobs of mafic magma that intruded, mingled, and mixed within the coeval crystallizing host granitoid magma. The newly obtained U-Pb zircon ages reveal that the granitoids, gabbro-diorites, and MEs, mainly constituting the Zouzan pluton in the northeastern part of the Lut Block in Eastern Iran, were formed during the Eocene period (40 Ma). The MEs exhibit intermediate Nd-Sr isotopic signatures ($^{87}Sr/^{86}Sr_i$= 0.704-0.705 and εNd_t= +2.21 and +2.82) as compared to the gabbro-diorites ($^{87}Sr/^{86}Sr_i$= 0.7030-0.7034 and εNd_t= +4.46 and +5.38) and granitoids ($^{87}Sr/^{86}Sr_i$= 0.7063-0.7078 and εNd_t= +0.48 and +1.22). Amphiboles in the Zouzan pluton rocks consist predominantly of magmatic origin belonging to calcic amphiboles. The granodiorite amphiboles exhibit higher Al_2O_3, K_2O, Na_2O, Ba, Hf, U, and Th contents, whereas diorite-gabbro amphiboles show enrichment in SiO_2, MgO, Sr, Sc, V, Y, Nb, and rare earth elements (REE). The ME amphiboles display a bimodal distribution of trace elements, encompassing characteristics of both mafic and felsic rocks amphiboles. Apatites in the Zouzan pluton rocks can be classified as magmatic fluorapatite. Granodiorite apatites exhibit higher F, Rb, Cr, Nb, Ta, Zr, Pb, U, and Th contents, whereas diorite-gabbro apatites are characterized by an elevated content of Cl, Sr, Sc, V, Co, and Y. The ME apatites display intermediate trace element compositions, bridging the apatite compositions found in the mafic and felsic magmatic rocks of the Zouzan pluton. The diverse geochemical behaviour observed in the ME apatite and amphiboles suggests a complex magmatic process involved in forming the Zouzan pluton. The most likely dominant process is the interactions between crystal-charged mafic and felsic melts, synchronously coinciding with the physical and chemical interactions between the mafic enclave and the host felsic magmas.

An amphibolitic source for “adakitic” I-type plutons in continental collision zones

Qiwei LI[1]*, China University of Geosciences (qwli@cug.edu.cn)
Junhong Zhao[2], Institute of Geochemistry, Chinese Academy of Sciences
Oliver Nebel[3], Monash University

Abstract

Rocks with “adakitic” affinities are widespread in continental collision zones, recording important information about crustal thickening. Residual garnet during partial melting of the lower crust is traditionally considered to be responsible for heavy rare earth element and Y depletion, which is a key characteristic feature of these rocks. However, magmatic garnet is rarely observed in such adakiticigneous rocks and associated protolithic eclogite is also rarely reported. Instead, amphibole is a proposed abundant phase in lower arc crust. Whilst both garnet-and amphibole-rich assemblages can act as potential sources for intracrustal intermediate-silicic melts, their distinctive fractionation of fSm/Ndand fLu/Hfshould, with time, lead to different Nd-Hf isotopic compositions in high Sr/Y rocks. Here we report whole-rock radiogenic Sr-Nd-Hf and stable Fe isotope compositions of well-characterized Oligocene to Miocene (33-14 Ma), post-collisional high-K adakiticintrusions from the Gangdese belt, South Tibet. The plutons have a low alumina saturation index and depleted Dy/Yb, pointing to negligible amounts of sediment contribution. They are characterized by variable initial 87Sr/86Sr ratios (0.7048 to 0.7078), mostly negative εNd (−4.9 to +0.3), positive εHf values (+1.5 to +8.3), and variable but heavy δ57Fe values ranging from +0.04 ±0.08‰ to +0.35 ±0.08‰. Modeling of Fe isotopes and fractionation factors of fSm/Ndand fLu/Hfindicate an amphibolite source. A Nd-Hf isotope correlation that is quasi-parallel to the mantle array can be best explained by the evolution of amphibolitic lower crust with a residence time of ca. 400 Myrs. Although these adakitic rocks have depleted, mantle-like Hf isotope compositions, they are part of an existing, older crustal foundation and thus represent a process of crustal reworking, instead of crustal growth. Therefore, proportions of mantle-derived materials that contributed to the Phanerozoic crustal growth based on Hf-in-zircon signatures alone may be overestimated. Combined mineral and whole-rock radiogenic and stable isotopes are required to address this issue in the future.

Petrological and geochemical characteristics of the mafic-ultramafic complexes in the Bhavani Shear Zone, South India: implications for crustal evolution.

ABEENA PV[1]*, CENTRAL UNIVERSITY OF KERALA (abhipv25@gmail.com)
PRATHEESH P[2], CENTRAL UNIVERSITY OF KERALA

Abstract

The South Indian shield encompasses two main geological features: the Archaean granite–greenstone terrains of the Dharwar craton in the northern region, and the high-grade South Indian Granulite Terrain (SIGT) in the southern region, intersected by a network of major faults or shear zones. Within the SIGT, there is extensive evidence of magmatic activity, ranging from acidic to ultramafic intrusives. Notable examples include the layered anorthosite complexes of Sitampundi and Bhavani, as well as multiple occurrences of Precambrian mafic dyke intrusions, anorogenic carbonatite-syenite, alkaline mafic-ultramafic, and anorthosite units dating to the late Precambrian period (800-600 Ma). Field observations and structural studies conducted within the Bhavani shear zone (BSZ) indicate a history of multistage deformation, accompanied by multiple magma emplacements. The mafic and ultramafic rocks within the BSZ exhibit distinct field characteristics, reflecting variations in emplacement processes, as well as differences in post-emplacement deformation and alteration. Certain mafic dykes within the BSZ have been dated to approximately 1980±25 Ma based on 40Ar/39Ar, K/Ar, and Rb/Sr dating methods. The geochemical features of these complexes reveal the presence of cumulus/phenocryst olivine phases along with slightly enriched Large Ion Lithophile Elements (LILE) and depleted High Field Strength Elements (HFSE), characterized by prominent negative anomalies in Nb and Ti, which exhibit a typical arc signature. The pattern normalized to Mid-Ocean Ridge Basalt (MORB) of the amphibolite indicates depletion in HFSEs (such as Zr, Sm, Ti, and Y) and enrichment in LIL-elements (like Rb, Ba, Sr), with negative Nb anomalies suggesting the involvement of a subduction component in the depleted mantle source, indicating formation within a supra-subduction zone tectonic environment. Ultramafic rock samples from the Bhavani Shear Zone (BSZ) display a La/Nb ratio ranging from 1.78 to 8.77 with an average of 3.65, Ba/Nb ratios ranging from 7.68 to 278.67 (average of 71.57), and Zr/Ba ratios varying from 0.01 to 2.23 with an average of 0.28. Conversely, mafic rocks exhibit La/Nb ratios between 0.72 and 9.32, Ba/Nb ratios ranging from 4.84 to 75.87, and Zr/Ba ratios ranging from 0.03 to 0.60, with average values of 2.68, 27.56, and 0.24, respectively. These elemental ratios bear closer resemblance to Ocean Island Basalt (OIB) types, likely derived from a supra-subduction source. Furthermore, the tectonic discrimination, trace element ratios, and mantle source characteristics of these mafic-ultramafic complexes suggest a supra-subduction zone OIB mantle with a significant amount of upper crustal contamination. Certain mafic dykes exhibit characteristics of both OIB and Island Arc Tholeiite (IAT), indicating the possibility of multiple emplacement characteristics or mixing of pre-existing mantle sources during the late Archaean or Palaeo-Proterozoic period. This study, in conjunction with the correlation of other complexes, sheds light on the Paleoproterozoic process

of crustal amalgamation and suturing between the South Indian crust and the Dharwar craton.

Geochemical characteristics of exsolved deep crustal aqueous fluid in a granitic system: Insights from the quartz reefs in the Bundelkhand craton, India

DIVYANSHI SHUKLA[1]*, Lucknow University (sdivva020@gmail.com)
Sarajit Sensarma[2], Lucknow University

Abstract

Understanding the deep crustal supercritical aqueous fluids and its dissolved accessory phases as an effective transport agent for trace elements and REE have been receiving much attention. The abundantly present ~2.0Ga quartz reefs (SiO2 >93wt%; quartzolite on IUGS classification plot), associated with Bundelkhand granitoid offer a suitable plutonic setting to study the evolution of exsolved Si-rich supercritical aqueous fluid in a silicic to intermediate magmatic system having a protracted history of approximately >300Myr. Here, we report for the first time on the chemical compositions of the primary mineral phases (quartz, zircon, magmatic epidote, Fe-Ti oxides, and mafic clots) present in quartzolite, and estimate the p-t history using multiple mineral calibrations compatible to silicic magmatic system in order to better constrain the emplacement depths and evolution for the exsolved silicate-dissolved fluid.

Chemical composition of quartz from both quartzolite and the granite-quartz reef contact have high Ti-content: Ti >100ppm, comparable to magmatic quartz of adjacent granitoid (Ti>100ppm), later subjected to low temperature dissolution-reprecipitation process with high Al2O3 (~2 wt.%), low Ti. Zircons have sub-rounded grain margins, yet still preserving the original euhedral prismatic character with Ca >1000ppm, Al >10000ppm and Fet >10000ppm, coupled with low Hf/Zr ratio (0.0072-0.2194) displaying characteristic of a hydrothermally altered magmatic zircon. Magnetite in the samples is rich in Ti (~22000ppm), Al (~10452ppm) and Mn (~132ppm). Vanadium-bearing rutile (V: ~7400ppm) have high Mg (~892ppm) though Mg is usually extremely incompatible to rutile; Al content (~5669ppm) also significant. Mg-rich rutile is usually characteristic of high-grade rocks of mantle origin. Magmatic epidotes in the rocks have comparable pistacite values (Ps: 0.27-0.33) and have trace amounts of MnO and MgO (≤ 0.304 wt.%). Mafic clots (look like chlorites) contain exceptionally high CaO up to ~25 wt.%, hitherto unknown in these rocks. Centimeters to meters thick contemporaneous mantle-derived carbonatitic dykes in the area may have contributed to high enrichment of Ca in mafic clots.

Combining results of Ti-in-quartz, rutile saturation temperature, Ti-in-Zircon, and diagnostic microstructures in the samples, temperature range of crystallisation from 1342ºC- 452ºC is obtained, i.e., a temperature interval of 900ºC, though xenocrystic zircon may have yielded >1000ºC, in compliance with zircon in adjacent granitoid. The estimated minimum temperature is notably below the granitic solidus (~700ºC), suggestive of a magmatic-hydrothermal origin.

Our results imply that crystallization progressed from hypersolidus condition to near hydrothermal precipitation. Euhedral magmatic epidotes supplemented by microstructural evidence suggest crystallisation depth at about 25-28 km for quartzolites (~8 kb), in coherence with results for adjacent granitoid (9-2 kb). Temperatures and pressure estimate thus point towards emplacement

of exsolved solute-rich aqueous fluid (quartz reefs) at deeper part of the crust unlike earlier suggestions of their shallow-level emplacement. Present study also provides some important results on elemental mobilization in a high P-T extremely silica-rich supercritical fluid in a plutonic setting, not much known in literature.

Inés Rodríguez[7], Universidad Católica de Temuco

Abstract

Boron (B) is an ideal geochemical tracer for hydration of the overlying mantle wedge at subduction zones. Magmatic B-isotope compositions are useful in detecting and quantifying exchange processes between the slab and mantle due to B-affinity for silicate melts and aqueous fluids with no significant isotopic fractionation during crystallization.

This study presents new and published whole-rock B-isotope data from eruptive units of volcanoes of the Pleistocene-Holocene San Pedro-Linzor Volcanic Chain in the Central Andes (west to east/youngest to oldest): La Poruña (21°53′S; 68°30′W), San Pedro (21°53’S, 68°23’W), Paniri (22°03’S, 68°13’W), and Toconce (22°11’S, 68°04’W). Our obtained δ11B values are relatively low (La Poruña: -1.39 to +0.94; San Pedro: -2.09‰ to +1.26‰; Paniri: -6.11‰ to +0.23‰; Toconce: -11.16‰ to -5.06‰) compared to mantle-derived magmas affected by fluids released by subducting altered oceanic crust (0 ‰ to 18‰). This is consistent with suggestions that such low δ11B values require a role for a 11B-depleted component, like MORB-mantle (δ11B = ca. -7.1‰) or Central Andean basement (δ11B = ca. -8.9‰). Since 87Sr/86Sr ratios from these volcanoes reflect significant degrees of crustal contamination, their low δ11B values likely also reflect contamination from low-δ11B continental crust.

Based on δ11B-87Sr/86Sr covariations (lower δ11B and higher 87Sr/86Sr values = more contamination vs higher δ11B and lower 87Sr/86Sr values = less contamination), our regional study reveals progressive lessening of crustal assimilation over time on three spatial scales: I. within individual eruptive units from early-erupted distal samples to later-erupted proximal samples (initial to final effusion); II. between stratigraphically older units to younger units within each volcano; and, III. from the older volcano located within the interior of the Altiplano Puna Magma Body (APMB), a large long-lived, mid-crustal melt zone, to younger volcanoes located progressively towards its edge, i.e., Toconce to Paniri and to San Pedro to La Poruña.

The ~2.5 Ga peraluminous monzo-granite (north-central India) with superchondritic Zr/Hf and OIB-like Nb/Ta: constraints for role of mantle fluid in crustal evolution and crust-mantle interactions

Abhishek Kumar Madhesiya[1], Department of Geology, University of Lucknow, India
Sarajit Sensarma[2]*, Department of Geology, University of Lucknow, India
(sensarma2009@gmail.com)

Abstract

Magmatic-hydrothermal crystallization in the evolution of silicic magmatic system is of considerable importance. Co-magmatic metaluminous coarse monzogranite to quartz monzodiorite transition into peraluminous fine-grained phyric monzogranite to quartz monzodiorite in the 2.6-2.3 Ga Bundelkhand Granitoid (India) having a common plutonic history, with significantly higher proportions, perhaps >80%, of 'recrystallized-look' polygonal-amoeboid subgrain developed along early formed large quartz and feldspars boundaries (textural change), are concomitant to increasing thin mafic veins network (fluid activity) in the latter. Combining two-feldspar thermometry, TitaniQ, and accessory phase thermometry of the Bundelkhand granitoid covering nearly >26000 km2 in northcentral India, this work seeks to decode dissolution-precipitation in the late stage of crystallization with development of fine-grained peraluminous monzo-granites. Field observations refute to the development of any secondary foliation though quartz and feldspars 'recrystallized-look' polygonal-amoeboid subgrains; the latter formed during magmatic-hydrothermal crystallization (subsolidus). Microstructures (e.g., undeformed lamellar twined albite, zoned plagioclase with oligoclase rim, antirapakivi feldspar) of hypersolidus origin are preserved in the rock, even though magmatic-hydrothermal transitional crystallization may have inhibited it. In bulk compositions and trace elements including REEs concentrations both magmatic crystallization and dissolution-precipitation processes are deterministic; however, they differ showing increasing persistency in HFSE (e.g., Zr/Hf, Nb/Ta) and HREE behaviour during interaction with mantle-derived fluids. The superchondritic Zr/Hf (>40) and OIB-like Nb/Ta (14-16) suggest deeper eclogite/peridotite-sourced fluid-rock interactions, plausibly also linked to coeval carbonatite magmatism in the craton. Al-rich mafic vein network (mantle/crust-mantle-derived fluid) induced peraluminosity to the bulk rock.

The dissolution-precipitation process caused 'recrystallized-like' domains temperatures (≤ 600°C) well below known granitoid solidus (< 700°C), in tune with the temperature of Mn-rich ilmenite exsolved phase in Ti-rich magnetite pairs at about 500°-400°C. The phase equilibria support that the system is fluid-induced and bulk compositions shifted from water saturated cotectic line towards Qz-Or line on the Qz-Ab-Or system. The trace element showed consistent pattern; negative Ba- and Sr- anomalies do not suggest significant feldspar fractionation of the crystallizing granitoid, rather of deeper fluid-induced origin. Also, the presence of Nb-Ta-Ti negative anomalies in the N-MORB normalized plot is consistent with deep mafic source melt/fluid involved in granitoid crystallization. The F-bearing primary Fe-rich biotite and

accessory minerals (apatite, titanite, rutile) support that this deep fluid was reasonably F-rich as well. The data testify that the observed dissolution-precipitation was indeed as high-temperature process with active role of F-rich silicate-dissolved mantle-derived fluids. Usually hot fluids, which can be strongly halogen rich, precede asthenospheric mantle upwelling, which can be derived by their immiscible separation of mantle supercritical fluid into aqueous-silicic and mafic melts in addition with CO2-F-rich fluid/hydrous carbonatitic liquid; the mafic melts emplaced as intrusive dolerite and carbonatite dykes. Our previously published as well as the new data thus point to deep fluid of mantle / crust-mantle origin played a prominent role in the formation of peraluminous granitoid in Bundelkhand, unlike the commonly held model metapelites source, at the Archean-Proterozoic transition. The present contribution provides an evidence of hydrous mantle-derived fluids linked to wet-metasomatised subcontinental mantle in crustal evolution and chemical differentiation.

Abstract

Most world-class magmatic sulfide deposits formed in the uppermost crust. Extending the search space for such deposits to exhumed mid-to-lower crustal rocks is an important goal of economic geology research. To guide the exploration for deep-seated deposits, it is important to constrain the processes that control metal transfer between the subcontinental lithospheric mantle (SCLM) and the overlying crust. One field area that allows to study the processes that control lower crustal sulfide ore-forming processes in outcrops is the Ivrea Verbano Zone (NW Italy), an exposed cross section of the SCLM and the overlying lower continental crust. The IVZ was intruded by a series of alkaline ultramafic pipes that host Ni-Cu-PGE-Te-Au sulfide mineralization locally intergrown with carbonates and hydrous silicates (i.e., phlogopite, amphibole). Previous studies of the best-preserved pipe at Valmaggia speculated that mantle sulfides might have attached to bubbles and were transported into the lower crustal Valmaggia pipe. To test this hypothesis, we integrated petrographical observations with mineral compositional data obtained by electron microprobe and laser ablation ICP-MS analysis from the Valmaggia pipe. Sulfides in the pipe display a wide range of textures from semi-massive to disseminated and blebby. Sulfide-associated carbonates either occur at the margins of large sulfide blebs or as inclusions in sulfides. Hydrous silicates commonly rim, or are intergrown with, sulfides. Blebby sulfides show heterogeneous unmixing in their rim portions adjacent to carbonates and/or hydrous silicates, characterized of increased concentrations of both lithophile and siderophile/chalcophile trace elements. Carbonate inclusions in sulfide blebs are generally Mn-rich calcite, whereas carbonates at the margins of large sulfide blebs are dolomite. Carbonates not in contact with sulfides are primarily Fe-rich magnesite. The three different modes of carbonate occurrence indicate that the carbonate composition is sulfide-dependent. The fractionation of carbonates (calcite-dolomite-magnesite) in spatial relation to the sulfides, as well as the trace element heterogeneity in sulfides, is interpreted to represent a co-precipitation relationship in which Ca/Ca-Mg carbonate and sulfide melts are entrained in an ascending metasomatic fluid/melt until becoming trapped in an olivine cumulate mush and co-precipitating in-situ. Such a model is distinct from the previously suggested bubble-pair transport model. Future work will be aimed at further unraveling the mechanisms that control carbon, sulfur and metal flux from the mantle into the crust and, consequently, the genesis of deep-seated ore deposits.

Formation of amphibole rich selvege in high P mafic granulite and its relation with the regional hydration of CGGC

Somdipta CHATTERJEE[1]*, Jadavpur University (somdipta.chatterjee@gmail.com)
Sanjoy Sanyal[2], Jadavpur University
Pulak Sengupta[3], Jadavpur University

Abstract

Chotanagpur Granite Gneiss Complex (CGGC) predominantly consists of a vast area of felsic orthogneiss lithounits, formed by episodic felsic magmatism throughout the Proterozoic times. The study area situated in the eastern margin is also dominated by various felsic orthogneiss litho units. The felsic litho package also contains a minor amount of mafic units of distinctly different origins. One is enclave suite mafic rocks with profuse garnet, and leucosomal segregation, representing high P granulite facies condition of peak metamorphism. The other is mafic dyke intrusion within the felsic units, with rare garnet, thin grain size, and lack of leucosomes corresponding to a medium-pressure amphibolite facies metamorphism (6.5-7 kbar; 650-700 °C). Detailed study of lithology, petrography and mineral chemistry of the mafic granulite suggests that peak metamorphism has been accompanied by amphibole dehydration melting that resulted in leucosomal segregation of various types, in combination with profuse peritectic garnet at 12-13 kbar and 850-900 °C. The leucosomal segregations are rimmed by an amphibole-rich selvedge of variable thickness. Growth of such amphibole-rich selvedges at the interface between leucosome and melanosome is commonly interpreted as a product of hydration caused by quenching of the leucosomes. Though in-situ crystallisation of melt resulted in a relatively anhydrous assemblage and limited melt loss suggests that the melt-released fluid probably played a role in the amphibole selvedge formation, several features suggest that these selvedges are the results of an independent infiltration-driven metamorphic event. Features include, (a) pervasive growth of amphibole in both leucosome and melanosome, and both are affected by extensive hydration, (b) absence of internal deformation of amphibole and replacement of recrystallised grains in the leucosome by amphibole, (c) hydration induced over a large volume of rock cannot be explained by a relatively small proportion of melt (<15%) suggest fluid infiltration from an external source, which is facilitated along structurally weak zone (e.g. interface between leucosome and melanosome). Amphibolte facies metamorphism of the mafic dyke is identical to the P-T condition of amphibole selvedge formation of the mafic granulite. In CGGC, similar hydration is observed in other parts of the CGGC and the host felsic orthogneisses and signifies a major metamorphic event that represents a continental collisional tectonic setup during the long Tonian period. Such a regional extent of fluid infiltration suggests a relatively large quantity of fluid in the lower crustal conditions. Such a large quantity of regional fluid infiltration probably indicates a mantle source of the fluid.

Whole rock geochemistry and isotopic constraints on the mafic-ultramafic rocks of the Madawara Igneous Complex, Bundelkhand Craton (central India)

Abhishek Kumar PANDEY[1]*, Indian Institute of Science Education and Research (IISER), Bhopal (bhu.manuabhi3@gmail.com)
Arundhuti Ghatak[2], Indian Institute of Science Education and Research (IISER), Bhopal

Abstract

The Madawara Igneous Complex (MIC) in the southern part of the Bundelkhand Craton is composed of a plutonic sequence of ultramafic-mafic rocks, surrounded by metamorphosed volcano-sedimentary supracrustals (e.g., pillow basalts, banded iron formations) and tonalite-trondhjemite-granodiorite gneisses (TTG). The sill-like ultramafic-mafic rocks are represented by dunite (now serpentinized), pyroxenite, gabbro, and pegmatitic gabbro. Whole-rock Sm-Nd analysis of the plutonic sequence gives a TDM age of serpentinized dunite and pyroxenite of 3.70 Ga–3.34 Ga (avg. 3.50 Ga), while the gabbro and pegmatitic gabbro ranged from 3.41 Ga–2.90 Ga (avg. 3.19 Ga). Large uncertainties in crystallization ages may be due to perturbation of the Sm-Nd system caused by 2.7 Ga amphibolite-facies metamorphism, as well as the latter magmatic intrusions that are reported from the Central Bundelkhand Craton. The whole-rock Pb-Pb isotopic system is also perturbed, which is possibly influenced by intrusive magmatic activity such as the emplacement of mafic dykes at 1.98 Ga, 1.8 Ga, and 1.0 Ga in the craton.

Comparison of major and trace elements of the studied rocks with global data of komatiite and komatiitic basalts from Archean greenstone belts suggests similarity of the serpentinized dunite, pyroxenite, and gabbro-pegmatitic gabbro with komatiite, komatiitic basalt, and tholeiitic basalt, respectively. Well-constrained positive correlations of major and trace elements with MgO (wt%) and the nearly parallel trend of the studied rocks with global fractionation trends of komatiites to komatiitic basalts indicate the ultramafic rocks formed through fractional crystallization processes and may thus be genetically related, while the mafic rocks seem to be formed as a different group of rocks with a younger emplacement age than the ultramafic rocks. Archean greenstone-belt rocks experience multiple episodes of metamorphic and low-temperature hydrothermal alteration events. However, plots of Ti vs. other trace elements suggest that element mobility was restricted for most elements, except for LILEs (such as Ba and Pb) that show a larger scatter. Trace-element modelling, as well as ratios such as Th/Yb, Th/La, Zr/Y, and Nb/Y, all helped to filter out the effects of crustal contamination. Positive εNd(TDM) (2.26 to 3.97) indicates an initially depleted magma source. Chondrite-normalized REE plots exhibit super-chondritic LREE [ultramafic: (La/Sm)N = 2.1-2.9; mafic: (La/Sm)N = 2.02 to 2.35] patterns, with flat to slightly depleted HREEs [ultramafic: (Gd/Yb)N = 1.02 to 1.39; mafic: (Gd/Yb)N = 1.8 to 2.1]. Two distinct magma sources of the examined rocks are established by various bivariate plots and the REE pattern, which indicate that the ultramafic rocks originated from a spinel lherzolite source, and the mafic rocks originated from a deeper spinel-garnet mixed source. The LREE-enriched patterns, along with the negative anomalies shown by the HFSEs (Nb, Ti, and Ta) and enrichment of trace

elements like Th, Pb, and U, suggest derivation of the magmas from subduction zone settings, where the mantle was contaminated by slab-derived fluids.

PETROGENESIS OF MIGMATITES AND LEUCOGRANITE FROM MAIN CENTRAL THRUST ZONE IN AND AROUND MUNSIARI, KUMAUN HIGHER HIMALAYA

CHITRA JOSHI[1]*, Kumaun University, Nainital (chitrajoshi.333.jk@gmail.com)

Abstract

PETROGENESIS OF MIGMATITES AND LEUCOGRANITE FROM MAIN CENTRAL THRUST ZONE IN AND AROUND MUNSIARI, KUMAUN HIGHER HIMALAYA

Author: Chitra Joshi
Organization: Kumaun University, Nainital
E-Mail: chitrajoshi.333.jk@gmail.com

The Himalayan belt extends laterally about 2500 km from west to east with 250-300 km width have undergone deep burial, deformation, remobilization, metamorphism and Tertiary
Leucogranite intrusions due to the active collisional tectonics between Indian and Eurasian plate. The relationships among the migmatization, evolution of Higher Himalayan Crystallines (HHC) and generation of leucogranite in the HHC in the tectonic and time framework have been one of the major fields of petrological interests in Himalayan geodynamics. The leucogranite magmas are interpreted to have been derived by melting of pelitic/metasedimentary rocks commonly found in the upper portions of thickened crust. Geochronology of migmatites is complicated by the complex behavior of accessory mineral chronometers in melt-bearing rocks. An interesting feature of the Himalayan leucogranites is extreme heterogeneity in Sr isotope ratios, even in the scale of outcrop, such that reliable Rb-Sr isotopic ages are difficult to obtain.
Miocene granites and migmatites are some of the most studied features of the Himalayan Tibetan Orogen. They are central to understanding its evolution and the basis for many evolutionary models. Their relative timing in relation to major structures, the origin of the heat source for melting and the tectonic impact of melting, are fundamental to understanding the Orogen. Establishing the protolith of migmatites is important for understanding the tectonic history of high-temperature metamorphic terranes. However, the most important use of wholerock geochemistry in migmatites is to understand the various open- and closed-system processes that operate in the anatectic crust. Whole-rock compositions of the residue compared with the unmelted protolith can be used to calculate the amount and composition of extracted melt as well as to evaluate the mobility of elements in anatectic systems.

Madabooshi Srinivas[5], Department of Geology, UCS, Osmania University, Hyderabad, India-500007

Abstract

A new occurrence of carbonatite at Kudakkal in the Pakkanadu-Mulakkadu Alkaline Carbonatite Complex, Tamilnadu. The carbonatite occurs within the alternate bands of pyroxenite. The carbonatite exhibits pale pink to white (colourless) colour and is composed of calcite (80% modal volume), pyroxene, amphibole, olivine, mica (phlogopite), and opaques. The presence of mafic-rich (olivine, pyroxene, amphibole, mica) cumulate segregations and euhedral phenocrysts indicate that magma stored at deeper chamber and underwent partial crystallization before emplacement. The carbonatite has a high CaO various from 34 to 37 wt%, SiO2 various from 14 to16 wt%, and has high LREE to HREE with high sum of the REE content (1472 to1731 ppm), which classifies them as calcio-carbonatite or sovites. The enrichment of Sr over Rb is a hallmark feature of calico-carbonatite and the stable isotope (δ18OV-SMOW and δ13CV-PDB) values range from -5 to -8 and 7 to 8 respectively. The distinctive δ13C signatures confirm the primary nature and mantle origin for these carbonatites. There is a lack of systematic correspondence between δ13C and δ18O values. The O and C isotopic values correspond with mantle values mainly calico-carbonatites. Geochemical signatures and field relations of the Kudakkal carbonatites are associated with pyroxenite and syenites which indicates that a carbonated alkali magma from which carbonatite are derived by liquid immiscibility and confirms their origin from a mantle source.

Melt inclusions study on Chamundi granite from southern India: Entrapment conditions and compositions

MOHD AQIB[1]*, Department of Studies in Earth Science, University of Mysore, India (aligaqib@gmail.com)
K.G. Ashamanjari[2], DOS in Earth Science, University of Mysore, Mysore, India
Sakthi Saravanan Chinnasamy[3], Department of Earth Sciences, Indian Institute of Technology Bombay, Powai, Mumbai, India
Mohd Qaim Raza[4], Department of Earth Sciences, Indian Institute of Technology Bombay, Powai, Mumbai, India

Abstract

Chamundi granite (CG) is an anorogenic plutonic rock with a highly varying grain size. It shows very coarse-grained porphyritic granite to very fine-grained aplite. These variations in grain sizes represent the genesis and depth of granite formation. This granite intrudes into the associated Peninsular gneisses at a prominent landmark place called Mysore. This intrusion exhibits a sharp contact with gneisses, and that gives evidence of contact metamorphism. The CG contains composite plutons or plutonic complexes, ranging in composition from undifferentiated quartz granites to K-feldspar granites to extremely evolved granites containing biotite-mica.

The CG exhibits several types of structures like platy or planar, flow lines, joints, as well as small intrusions are well exhibited in this granite with a number of quartz veins. The youngest rock in the Dharwar supergroup area relates to the anorogenic Chamundi granite intrusion at 790 Ma (Crawford, 1969), which also reflects a zircon, U-Pb age of 800 Ma of the Closepet granite which indicates that this granite has perhaps several age components. The granites of this region contain abundant melt and fluid inclusions, and these are potential candidates for contrasting melt and fluid composition and granite emplacement conditions.

In the present study, melt inclusions (MI) were identified in the granites based on colour i.e. brown to black and granular texture. The diameter of MI ranges from 10 to 20 μm and, at times goes up to 100 μm.

Outermost portion of some MIs of the crystal contain devitrified glass. Microthermometric studies were carried out in the MIs of the CG, they are generally crystalline and appear glassy which shows textural differences and must be homogenized before analysis. After heating experiments, we observe three MI types (A, B, and C) in quartz based on homogenization temperatures and composition. Type-A, -B and -C with their homogenization temperatures are <800°C, 800 to 1000°C and 1000 to 1200°C respectively. Wide temperature variations must be reflecting wide compositional differences in MIs from Chamundi granite, India.

[Keynote] The Panjal Traps: a synthesis

Greg Gregory SHELLNUTT[1]*, National Taiwan Normal University (jgshelln@ntnu.edu.tw)

Abstract

The Panjal Traps are composed of basalt with subordinate silicic volcanic rocks. Zircon U-Pb dating of the silicic (289 ± Ma; 287.2 ± 2.5 Ma; 287.3 ± 2.8 Ma) and mafic (288.2 ± 0.3 Ma) rocks confirm their Early Permian eruption age. The initial basalt eruptions from the eastern Kashmir Valley and Lidder Valley have chondritic Sr-Nd isotopes (87Sr/86Sri = 0.7043 to 0.7073; εNd(t) = -1.4 to +1.3) whereas the later flows have a wide range of Sr-Nd (87Sr/86Sri ≥ 0.7083; εNd(t) = -6.8 to -1.5) isotopic values. The basalt from the northern Pir Panjal Range are compositionally similar to ocean-floor basalt (87Sr/86Sri = 0.7081 to 0.7172; εNd(t) = +2.4 to +4.3) whereas the basalt from the southern Pir Panjal Range are similar to rocks from eastern Kashmir Valley (87Sr/86Sri = 0.7086 to 0.7110; εNd(t) = -6.1 to -4.4). Os- and O-isotopic data confirm that the northern Pir Panjal Range rocks are distinct (δ18OVSMOW = 6.8-7.9‰; 187Os/188Osi = 0.1230-0.1256) from others regions of the Panjal Traps (δ18OVSMOW = 9.0-12.9‰; 187Os/188Osi = 0.1343-0.2832) and indicate that they may be derived from different mantle sources. The silicic volcanic rocks were derived by partial melting of the Himalayan crust (87Sr/86Sri = 0.7073 to 0.7119; εNd(t) = -7.2 to -8.9) as they contain Early Paleozoic to Archean inherited zircons. The primary melt composition of the basalt from the northern Pir Panjal Range is picritic and have mantle potential temperatures (TP) of 1400-1450oC. The early lavas erupted just after the retreat of the Late Paleozoic Gondwanan ice sheet within a continental rift setting that eventually transitioned into a nascent ocean basin and formed of Neotethys Ocean.

Molybdenum isotopes in intraplate basalts record slab-mantle interactions in Earth's deep mantle

WEI FANG[1]*, University of Science and Technology of China (wfang15@ustc.edu.cn)
Li-Qun Dai[2], University of Science and Technology of China
Zi-Fu Zhao[3], University of Science and Technology of China

Abstract

Existing Mo isotope data shows that intraplate basalts have highly variable Mo isotopes. However, the heterogeneity of Mo isotopes in intraplate basalts was interpreted to be inherited from recycling of different slab components, and the related slab-mantle interaction processes remains unclear. We synthesize Mo isotope and other geochemical data for global intraplate basalts, which provide insights into Mo recycling in Earth's deep mantle. Global intraplate basalts display highly variable δ98Mo values of -0.84‰ to 0.10‰, suggesting mantle Mo isotopic heterogeneity. Most of the basalts have low δ98Mo values and high Ce/Mo ratios that are similar to those of the oceanic eclogites, indicating that recycled dehydrated oceanic crustal components were involved in their mantle sources. However, some intraplate basalts have heavy Mo isotopes. This reveals that shallow slab components were dragged by the downgoing slab and have carried heavy Mo isotopes into the deep mantle. Significantly, high δ98Mo values of these basalts are associated with low Ce/Mo ratios, high fluid-mobile element contents, and depleted radiogenic Sr-Nd isotopes. Given that recycled basaltic oceanic crust and sediment are generally efficiently dehydrated during subduction and sequester light Mo isotopes, subducted serpentinised lithospheric mantle is a plausible candidate to transfer fluids with heavy Mo isotopes into the deep mantle. Thus, Mo isotope systematics of intraplate basalts record complex geochemical fluxes from subducting slab to the deep mantle, in which subducted serpentinites play an important role in the Mo isotope recycling. Our study highlights the effectiveness of Mo isotopes as indicators for slab-mantle interactions in Earth's deep mantle.

Geochemical characterization of Jonnagiri greenstone belt of eastern Dharwar craton, India: Insight into the crustal evolution of Jonnagiri greenstone terrane.

Saumyodeep DAS[1]*, Indian Institute of Technology Bombay (smdpds@gmail.com)
Sakthi Saravanan Chinnasamy[2], Indian Institute of Technology Bombay

Abstract

The Jonnagiri greenstone belt (JGB), located in the eastern Dharwar craton of southern India, stands out as a distinctive and economically important greenstone belt. The greenstone sequence of Jonnagiri comprises of metabasalts, meta-felsic volcanics, and schistose meta-tuffs collectively encircled by granitoid intrusives. One of these intrusives are unique as it hosts orogenic-type gold deposit, particularly within the Dona sector of the JGB. Our current research is dedicated to investigate the greenstone sequences of the JGB, focusing on their geochemical evolution and deciphering their tectonic settings. The geochemical study involves the distribution patterns of major and trace elements to understand the petrogenetic processes and tectonic evolution of the area. Petrographic analysis reveals the presence of amphibolites (metabasalts) and meta-felsic volcanic rocks (ranging from meta-rhyolite to meta-rhyodacite), along with schistose rocks such as quartz-sericite-schist and talc-chlorite-schist. Various geochemical discriminant diagram suggests that the rocks are subalakliine in nature and showed varying trends in the Harker diagrams depicting a variable calcic, sodic and potassic content and magnesian deficient characteristics. The reason of the variability can be attributed to metamorphism and the limited extend of hydrothermal alteration. The trace element distribution, behaviour supports a minimal influence from hydrothermal alterations, exhibited by a weak elemental mobility. The metabasalts and meta felsic-volcanics showed depletion of HREEs over LREEs with evident negative Nb-Ta, Zr, Ti and Yb anomaly suggesting their high incompatible nature during the mantle melting process and factional crystallization. The tuffaceous schistose rocks exhibited fractionation of MREE over LREE/HREE due to fractionation from amphibole phase and depletion of Nb-Ti is prominent. All these characteristics indicates a subduction driven activity. Previously proposed tectonic models show an arc-back-arc settings for the Jonnagiri metabasites, indicating a back-arc type of tectonic setting adjacent to the main arc. Elemental distribution patterns and ratios, particularly Zr/Nb and Nb/Th, confirms that the mantle source for the JSB is likely from wedge melting, with varying tectonic regimes ranging from arc to back-arc or forearc settings. Observations from Th/Nb and Nb/La confirm crustal-lithospheric contamination and proxies from Th-Nb indicates involvement of mantle-crustal interaction. Geochemical signatures reveal typical characteristics of island arc basalts (IAB), with enrichment of LREE, LILE, and Pb, and depletion of HREE and HFSE due to fluid mobile scavenging during subduction. In conclusion, the JSB likely underwent subduction-related processes, including crust-mantle interactions, crustal recycling, and plume contamination, contributing to their diverse tectonic signatures.

Subduction of an oceanic plateau and its effect on magmatism through the analysis of melt inclusions: The case of the Hikurangi plateau subduction in the Kermadec arc

Bruce Charlier[5], School of Geography, Environment and Earth Sciences, Victoria University of Wellington, PO Box 600, Wellington, 6140, New Zealand

Abstract

The geochemical characteristics of primary arc magmas are the product of the particular conditions and interactions of the subducted slab and the source mantle wedge. Incompatible trace and volatile elements are transferred from the slab to the source mantle through the release of a liquid phase (fluids, melts and/or supercritical liquids). The composition and nature of the slab liquid is in turn controlled by the physical and geochemical characteristics of the slab layers. Studies of along-arc geochemical variations have shown some correlations with progressive changes in the subduction architecture (e.g., subduction rate, sediment cover).

In some cases, abrupt changes in subduction conditions occur along a single subduction setting that can considerably affect magma genesis. One of these cases is the subduction of oceanic plateaus. The Kermadec arc represents this unique case, where the subduction of the thick (15-23 km) Hikurangi plateau in the southern section of the arc (south of c. 35°S) contrasts with the subduction of the thin oceanic crust of the Pacific plate.

In this study we analyze major and trace element compositions of olivine-hosted melt inclusions found in dredge samples collected along the Kermadec arc. The objective is to identify the effect that the subduction of the thick Hikurangi plateau has on magma genesis, by comparing the geochemical signatures of volcanic products generated by the subduction of a normal oceanic crust and a thickened oceanic plateau.

Abstract

Currently, experimental and methodological studies are being conducted at the A. P. Karpinsky Geological Institute to identify areas of hydrothermal-metasomatic rocks in order to predict potentially promising areas for the search for solid minerals. The work is based on the application of spectral analysis of hyperspectral aerial photography data in the spectral ranges: visible, near and middle infrared (380-2500 nm), with 625 channels.

The research includes a technological chain that includes a number of sequential works: - conducting an area aerial survey with an aviation hyperspectrometer; - preliminary processing of aerial survey materials; - creation of a hyperspectral remote basis (GDO) based on aerial survey materials for the work area; - field spectrometry of rocks using the PSR+ spectroradiometer (spectral range 350 nm – 2500 nm, 1024 channels); - creation of a library of rock spectra - spectral analysis of GDO using a library of spectra to identify hydrothermal-metasomatic rocks; - creation of a scheme for the spatial distribution of hydrothermal-metasomatic rocks as indicators of minerals; - analysis of the scheme using geological, geochemical, mineralogical and geophysical data to identify (localize) potentially promising areas for solid minerals.

The most effective methods for extracting information contained in hyperspectral images are specially developed algorithms and methods that involve comparing the spectrum of an image pixel with the reference spectrum of a mineral. It seems that a multi-stage information processing scheme with cascading use of various algorithms should give the best results. Algorithms were developed aimed at solving the following tasks: - isolation of indicator minerals and their display in the form of figurative dots and halos; - identification of spectrometric halos by a complex of minerals as search signs for the identification of minerals; - detection of hydrothermal-metasomatic rocks by spectra obtained as a result of spectrometry of rock samples selected within ore fields and/or deposits; - identification of a specific association of indicator minerals for a certain type of minerals; - identification of hydrothermal-metasomatic rocks by mineral associations.

The following are selected as indicator minerals of near-ore metasomatites: - propylitization: feldspar (albite) + carbonate + chlorite + epidote + sericite; - beresitization: quartz + sericite + pyrite; - hardening: quartz; - sulfidization: pyrite; - kaolinization: kaolinite.

Halos of near-ore rock changes (propylitization, berezitization, acidification and sulfidization) have been identified for the Kuznetsovsky site. The probabilistic scheme of spectrometric halos of near-ore metasomatites reflects their model distribution in accordance with geological data - spatially convergent hydrothermal transformations of ore-bearing rocks (propylitization and berezitization) form halos in the crushing zones of intrusive rocks of the Kogtakh complex in the vicinity of the Vostochnoye and Kuznetsovskoye deposits.
At the May site, the probabilistic scheme of spectrometric halos of near-ore metasomatites presents a model of their distribution, which correlates with geological materials. The halos of propylitization and berezitization, which are natural, are developed by effusions of medium-basic composition and subvolcanic rocks of the Azyrtalsky complex and cover the most extensive areas in the vicinity of the Mayskoye and Tibekskoye deposits. They are associated with halos

[Keynote] Oceanic propagators and the formation of oceanic crust in divergent margins

Webster Ueipass Mohriak[1]*, State University of Rio de Janeiro - UERJ (webmohr@gmail.com)

Abstract

Oceanic crust can form mid-ocean spreading ridges in various tectonic settings, including divergent, transform, and convergent margins. The development of continental margins in the South Atlantic is a diachronous process associated with oceanic propagators. The Santos Basin, the largest salt basin in the South Atlantic, is a unique region that provides insight into the role of oceanic propagators in the development of conjugate divergent margins in southeast Brazil, southern Angola, and Namibia. The incipient oceanic ridges formed an oceanic propagator in the southernmost South Atlantic that advanced from the Pelotas Basin and penetrated the continental crust of the southern Santos Basin. The marine incursions in the Aptian Gulf resulted in the precipitation of evaporite sequences associated with a Late Aptian transitional phase. The oceanic propagator advanced northward and started to split the salt basin during the Late Aptian or Early Albian, but it was aborted and shifted eastward, forming the Mid-Atlantic Ridge. As a result, most of the salt basin was left on the Brazilian margin, and only a narrow region in the distal margin of southern Angola records thick salt masses in the Namibe Basin.

Some deeps in the axial trough of the central Red Sea exhibit incipient spreading ridges associated with neo-formed oceanic crust. Mabahiss Deep in the northern Red Sea is a possible analog for salt basin splitting by oceanic ridges formed in the past 5 million years. In the southern Santos Basin, geophysical methods suggest a possible oceanic ridge associated with the Florianópolis Fracture Zone. Plate reconstruction of the South Atlantic salt basins in the Albian reveals that the aborted spreading center developed neo-formed oceanic crust, separating two salt provinces in the Santos Basin. The interpretation of regional seismic reflection lines in the southern Santos Basin supports the model of an incipient spreading center that advanced northward in the Late Aptian and was aborted in the Early Albian. This caused a clear V-shaped depression in the crust that separates the asymmetric salt masses in the Santos Basin and the conjugate margin in Angola.

Abstract

Chrome-spinel occur as accessory grains or layers in ultramafic, mafic and related rocks of different geological environments and have distinct chemical composition, linked primarily to their parental magmas. Chromite in mafic-ultramafic and related rocks reveals the magma chemistry and source rock characteristics as well as mechanism of operative mantle processes viz., tectonic provenances. The mafic-ultramafic rocks of Pauni and Taka area occurred as small linear to lensoidal bodies within granite gneisse and chlorite schist. The ultramafic rocks are represented by talc-tremolite-chlorite schist, serpentinite, chromitite, peridotite and talc-treolite-serpentine schist. The serpentinite and associated talc-tremolite-chlorite ± serpentine schist occurs as enclaves and small lensoidal bodies within granite gneiss around Taka area, western Bastar craton, Central India. Serpentinite and talc-tremolite schist consists of chromite in the form of fine dissemination, cumulates and at places as bands. Chrome spinel is black to dark brown, euhedral to subhedral and equant crystals. At places occurs as anhedral and highly fractured crystals. The fractures are filled by secondary quartz-carbonate, talc and serpentine matrix. Petrographically, ultramafic rocks are made up of talc, tremolite, chlorite with minor serpentine and chrome spinel in the different forms. Serpentinite is medium grained and show mesh and hour glass textures. Mesh rims are of fibrous serpentine (lizardite) and magnetite. Cr-spinel are oxidized to ferritchromite to magnetite, but the chrome spinel retains their primary composition. In EPMA study, Chrome-spinel from both the areas contain high Cr # from 0.70 to 0.94 wt %, Mg# from 0.32 to 0.61 wt %, TiO2 from 0.04 to 0.23 wt % (low to high) and Fe3+ from 0.01 to 0.05 wt %. The tectonic discrimination diagram such as Al2O3 vs TiO2 and Al2O3 vs Fe2+/Fe3+ suggests suprasubducion zone (SSZ) peridotite field. High Cr# and low TiO2 indicate arc tectonic settings and probably were formed in the mantle beneath fore arc tectonic setting. Parental magma compositions of this high Cr- spinel specify the reaction between boninitic melts and depleted peridotites that generated by partial melting in deep mantle. High Cr#, high Mg# and low SiO2 indicate primary composition for Cr-spinel and low TiO2 values are typical of ophiolitic chromitite. The above chemical characteristics of the chromitite indicate that they are of typical Cr-rich podiform chromitites. Cr-spinel from studied areas are primary in composition, formed in

the 550ºC to 500ºC temperature and in green schist facies metamorphism. During the late-Archaean time, the subduction of oceanic crust beneath continental margin produces mafic melt in arc type tectonic setting.

Abstract

Various petrogenetic models regarding the origin of Jeju magmatism have been proposed, such as diapiric ascent from the depleted asthenospheric mantle (Tatsumi et al., 2005), contribution of a subducted oceanic crust indicated by the δ18O values of the basaltic lava samples (Kim J.I., 2023) and so on. Volatile components such as H2O or CO2 are known to play a crucial role in the mantle melting process. However, there is no comprehensive study on primitive volatile contents in the Jeju basalts, yet. Melt inclusion (hereafter MI), trapped within phenocrysts, can contain primitive melt composition, particularly volatiles, if MIs were trapped before degassing. In this study, we focus on MIs in olivine phenocrysts from Jeju scoria samples collected from Seondol (~95ka, JS07) scoria cone, located in the eastern region of Jeju Island. Samples were subjected to analyses of whole-rock major element compositions, major element compositions of host olivine and MIs, and volatile element concentrations (H2O, CO2, F, S, Cl) of MIs. The main purpose of this study is to find out the volatile contents of the primary melts and understand the petrogenesis of the Jeju basalt.

Volcanic rocks of Jeju Island have been classified into three types, having distinct parental magmas (Tatsumi et al., 2005): High-Alumina Alkali (HAA), Low-Alumina Alkali (LAA), Sub-Alkali (SA). The whole-rock compositions of JS07 scoria is intermediate between LAA and SA. On the other hand, the compositions of MIs are broadly scattered ranging from LAA to SA despite a single scoria unit. The effect of crystal fractionation on the major element compositions of the MIs was investigated using the chi-square test, and it was found that there are at least seven parental magmas to reproduce the broad chemical composition of the MIs.

At the root of the differentiation trend in LAA, parental magmas (LPM-1, 2) exhibit a minimum of 1.0 wt% H2O and 1,000 ppm CO2. However, other LPMs, such as 3, have undergone significant degassing of volatile components, while 4, despite its low H2O content, exceeds 2,100 ppm in CO2. In the case of SA, all parental magmas (SPM-1~3) contain at least 0.8 wt% H2O and 1,000 ppm in CO2.

To evaluate the influence of the subducted oceanic plate, we compared the volatile contents and ratios (H2O/F and Cl/F) of the primitive melts obtained from this study with those of MORB and basalts from Japan (Kuritani et al., 2021). The results indicate that Jeju MIs exhibits higher in halogen concentrations, as well as H2O/F and Cl/F ratios compared to MORBs. The ratios are rather similar to those of the Gotō Islands, which are 200km away to the east of Jeju Island. This result suggest that source mantle of Jeju magma has been influenced by the subducted oceanic

plate.

Abstract

Mantle sources may be subject to distinct modifications due to the variable possibilities of magma generation and changes in the mineral chemistry recorded in melt and fluid inclusions. Melting infiltration in the sublithospheric-lithospheric mantle and further enrichment in light rare-earth elements and volatiles (e.g., F, Br, Cl, H2O, CO2) is an important mechanism associated with mantle metasomatism, which process has been invoked to explain REEs enrichment, carbonatitic and/or silicatic paragenesis besides highly alkaline signature in volcanic rocks mainly in ocean island basalts. Mineralogy is a crucial study to interpret magmatic evolution and to understand thermodynamic process during fractional crystallization. Some features marked in mineral history reveal several magmatic processes that allow us to elaborate hypotheses to elucidate an evolutionary model. Feldspars and pyroxenes present an extensive window of crystallization and compositional variation depending on physical parameters such as oxygen fugacity, pressure, temperature, and chemical composition (P-T-X-M). These possible parametric changes are to be associated with time that allow the minerals to register, in their crystalline structures, physical-chemical modifications. The Brazilian southeast margin presents a ca. 1,200 km long alkaline volcanic complex composed of over 30 seamounts, banks, guyots and islands aligned in the W-E direction at the Espirito Santo State parallel (20º S). Seamounts, banks and guyots present volcanic rocks characterized by OIB-like rocks presenting LREE enrichment as well as isotopically heterogeneous mantle source related to a mixing of depleted (DMM) and enriched mantle sources (HIMU, EMI and EMII) with minor constitution of FOZO and C mantle components. We propose an evolutionary model for the youngest Brazilian volcanism and distinguish both islands, Trindade and Martin Vaz, as two different contemporary plumbing systems based on new lithogeochemistry, isotopic and mineral chemistry data and compiled data from the literature.

The geochemical nature of serpentinites from the Mashhad mafic-ultramafic complex as an evidence for Palaeotethys oceanic crust subduction in NE Iran

KOUROSH MOHAMMADIHA[1]*, Geological Survey and Mineral Exploration of Iran
(K.Mohammadiha@gmail.com)
Mohssen Moazzen[2], University of Tabriz
Uwe Altenberger[3], Potsdam University
Robab Hajialioghli[4], University of Tabriz

Abstract

Abstract
The Mashhad ultramafic complex with a Permo-Triassic stratigraphic age is exposed at the NE of Binaloud Mountain and adjacent to the Mashhad city (SW to NW of Mashhad). This area is located in within the Kopet Dagh zone and at NE of the Binaloud Mountain range. This area is mainly composed of mafic and ultramafic rocks, metamorphosed carbonate and pelitic rocks and granitoids in a NW- SE trend. Serpentinized peridotites, especially amphibole peridotites are the main types of ultramafic rocks in this area. Minerals in these rocks include olivine, orthopyroxene, clinopyroxene, brown amphibole and opaque minerals as the original minerals and serpentinite group minerals (lizardite and antigorite), tremolite-actinolite, chlorite, talc and carbonate minerals are the secondary minerals. MgO content of ultramafic rocks, Mg, Al and Cr contents in spinel, Ti and Na contents in clinopyroxene and Ti content in primary amphiboles (pargasite and hornblende pargasite) all show mantle origin for the Mashhad area ultramafic rocks. High pressure-low temperature metamorphic rocks, which are indicative of subduction are not present in this area, but according to the major, minor and rare earth elements chemistry of the Mashhad serpentinites, these rocks show subducted serpentinites features, with a peridotite protolith derived from lherzolite or olivine-poor harzburgite. The protolith of these rocks metasomatized and refertilized by melt formed in a subduction zone before serpentinization. Serpentinized peridotites of Mashhad are of subducted serpentinites type, which are more enriched in in trace elements in comparison with abyssal serpentinites. The origin of these serpentinites are lherzolite or olivine-poor harzburgite. Considering Mg# and Cr# of spinel and high oxygen fugacity for clinopyroxene formation conditions in Mashhad ultramafic rock in comparison with oxygen fugacity in mid ocean ridge, Mashhad peridotites can be related to supra-subduction zone. Serpentinized peridotites occur in alternation with metapelitic rocks. These rocks are remnants of Paleotethys oceanic crust which are emplaced during late Triassic as an accretionary prism in the subduction zone and is thrust on the Iranian crust.

Ophiolites in the westernmost South Tien Shan: geochemical characterization and tectonic settings.

Bakhtier NURTAEV[1]*, Institute of geology and geophysics (nurtaev@ingeo.uz)
Svetlana Zenkova[2], Institute of geology and geophysics
Oksana Tsay[3], Institute of geology and geophysics
Dilshoda Kurbanova[4], Institute of geology and geophysics

Abstract

The ophiolitic rocks, discovered in the westernmost region of South Tien Shan play a crucial role in understanding the Paleozoic tectonic evolution of the Turkestan ocean. These rocks can provide valuable insights into the suturing and terrane-accretion processes. The current study includes mineral chemistry, whole-rock geochemistry, and field observations of igneous and sedimentary rocks from ophiolitic mélange outcrops of the South Tien Shan. The study aims to determine the nature and timing of the formation and emplacement of the ophiolite belts.

The Southern Tien Shan region is home to the main ophiolite massifs that are distributed across two separate belts. These belts are the northern belt that stretches from Sultan-Uvais to South Fergana and the southern belt that runs from Kuldjuktau to Karatyube and South Gissar. Ophiolites have varying geochemical characteristics and a crustal architecture that is laterally discontinuous and vertically heterogeneous. These differences are due to variations in igneous and tectonic processes that were involved in the formation of ancient oceanic crust in different geodynamic settings.

The Turkestan suture which separates the Kazakh-Kyrgyz continent from the Kyzylkum-Alai microcontinent is marked by the presence of ophiolites in several areas adjacent or parallel to the suture trace, for example, in the Bukantau, Tamdytau, North Nuratau, South Ferghana, and Atbashi-Inylchek areas, some of which are also associated with metamorphic rocks.

The Gissar suture zone is a geological formation that comprises a mixture of lower Carboniferous basalts and serpentinized ultramafic fragments, as well as carbonate and clastic sedimentary rocks. The Gissar suture zone is positioned to the south of the Gissar batholith and marks the boundary of the Gissar back-arc ocean basin, which was a short-lived basin that opened along the northern passive margin of the Karakum-Tarim terrane during the early Carboniferous and closed during the Late Carboniferous. The origin of the Gissar Suture is uncertain with several possible interpretations, including an oceanic or a rifted/marginal basin, or backarc rifting with subsequent partial breakup. It is crucial to identify the precise nature of the ophiolites in the westernmost parts of the Tien Shan to link them to independent oceanic basins.

The Southern Tien Shan has ophiolite associations that vary in age, with the older formations located towards the west, and the younger formations towards the east. We will explore different models that explain the formation of these ophiolite types and the processes that led to their evolution.

The Talas-Ferghana and Ural-Tien Shan Faults have played a crucial role in the region’s

development, as they may have acted as a partial barrier that controlled the distribution of syn-collisional convergence and magmatism in the South Tian Shan. The Late Paleozoic orogeny of the western Central Asian Orogenic Belt was influenced by strike-slip tectonics, which is connected to oblique plate interactions.

Abstract

Plate tectonic-driven material circulations between plate and deep Earth is the first order force to control the Earth geodynamic system. The presence of Pacific-type and Indian-type mid-ocean ridge (MORB) isotopic source domains in the upper mantle is a clear manifestation of global-scale mantle compositional heterogeneities. The heterogeneity reveals systematic differences in the Pb isotope composition between the Indian Ocean-South Atlantic mantle in the Southern Hemisphere and the Pacific-North Atlantic mantle in the Northern Hemisphere at the spatial scale. This large-scale difference in mantle isotopes in the Southern Hemisphere is known as the DUPAL anomaly. The DUPAL anomaly of the Indian-type mantle domain is a long-lived feature that can be traced back to the Palaeozoic Tethyan mantle domain.Tethys DUPAL mantle domains are the largest and long-lived mantle domain, but the origin are unclear. We present the compared Nb-Pb isotope evolution of these two mantle domains and found that the Tethyan mantle and circum-Pacific (PAO, Paleo- and modern Pacific) mantle. The results showed the Tethyan and circum-Pacific mantle domains underwent marked different Th/Pb and U/Pb fractionation events. The Tethyan mantle displays lower εNd(t) and higher 206Pb/204Pb(t), 207Pb/204Pb(t), 208Pb/204Pb(t) and (208Pb*/206Pb*)(t) for ratios than that of the circum-Pacific realm mantle, a typical characteristic of DUPAL anomaly mantle. Such a large-scale and long-lived DUPAL anomlay in Tethyan mantle domains most likely reflects the contribution of plate tectonics-driven crustal recycling in producing large-scale mantle domains. The Tethys and Panthalassic-Pacific ocean realms underwent different tectonic evolution history. The Panthalassic-Pacific ocean realm had remarkable permanency existing as a big ocean at lease throughout the Phanerozoic, that implies that continental materials were limit to recycle into underlying mantle, thus the underlying mantle was relative free of the continental material contamination and then result in the low Th/U Panthalassic-Pacific ocean realm mantle domain. In contrast, the break-up of the Gondwana supercontinent makes the Tethys realms to experience repeated opening and closures, which transferred large volume of continental materials into the underlying mantle and then produce the high Th/U Tethyan mantle domain. This study shows that plate tectonic-driven material circulation should play a role in producing large-scale and long-lived mantle heterogeneity and thus plate tectonic evolution may genetically link mantle chemical geodynamics. This is crucial for understanding how Earth system works.

Abstract

Macrodiamond (>1mm) is known to occur mainly in alkaline ultramafic rocks (i.e., kimberlites) in the continental lithosphere. However, new research has discovered that microdiamonds (<1mm) can be produced in various tectonic settings and rock types globally. This contribution compares microdiamonds from different geological environments, including microdiamonds found in ancient oceanic lithosphere in Phanerozoic ophiolites and Precambrian greenstone belts, in kimberlites and basic intrusions in the continental lithosphere, and in volcanic rocks occurring in ocean – continent transition zones. Although the geological histories of these microdiamond grains are different, most of them have significant common characteristics: (1) the grain size of diamonds is commonly several hundred micrometers, they are generally yellow green and colorless, they have cubic octahedral crystal form, and they are mainly Ib and Iab types; (2) microdiamonds have light C isotope characteristics δ 13C between -20 and -30 ‰), interpreted as organic in origin, different from kimberlite macrodiamonds with mantle origin characteristicsδ 13C is between -10 and 0 ‰; (3) inclusions in microdiamonds commonly exhibit chemical characteristics of crustal sources, such as Mn and fluids containing Si and H2O; (4) mineral assemblages of strongly reduced environments accompanied by microdiamond particles, containing alloy minerals such as SiC and elemental minerals such as natural iron; (5)high pressure phase mineral inclusions have been found in some microdiamonds, as well as high-pressure phase (>10 GPa) mineral assemblages found in accompanying host-rocks. These characteristic features indicate that the formation environment of microdiamonds is comparable, likely in an ultrahigh pressure and super-reduced geological environment, and their material source may originate from deeply subducted crust. Thus, we infer that microdiamonds were most likely derived from deep recycling of subducted crustal materials, and that mantle plumes may have played a significant role in the transport of microdiamonds into lithospheric mantle depths. Firstly, deep subduction delivers oceanic crust to the lowermost mantle or even into the mantle transition zone. Following the decomposition of oceanic crust in this environment, biogenic carbon forms carbon rich fluids. Then, due to the disturbance of mantle plumes rising from the core – mantle boundary and changes in the temperature –pressure conditions, diamonds begin to crystallize in carbon rich fluids and are rapidly carried by mantle plumes to the continental and oceanic mantle lithosphere at shallow depths. Accompanied by plate extension and deep rifting,

microdiamond-bearing melts and fluids ascend to the shallow mantle; alternatively, they may be quickly transported along with kimberlitic and alkaline-basic magmas to the Earth’s surface. Microdiamonds occurring in various geological environments clearly provide a new concept and tool for studying the Earth’s deep, two-way recycling system, mantle circulation patterns, and deep mantle dynamics. We think that through a systematic comparative study of microdiamonds in oceanic mantle rocks, greenstone belts, and continental basic rocks and kimberlites, we can establish a global scale, deep Earth material recycling model.

Tectono-magmatic and metamorphic development of Shyok Ophiolite Belt from Ladakh Trans-Himalaya, India: Insights from microstructures, phase petrology, and P-T trajectory

Ravi Ranjan Kumar[1]*, North- Eastern Hill University, Shillong, Meghalaya (raviranjan.bhu.5679@gmail.com)
Shailendra Pundir[2], Wadia Institute of Himalayan Geology, Dehradun, India
Santosh Kumar[3], Department of Geology, Centre of Advanced Study, Kumaun University, Nainital, India

Abstract

The subduction of the Neo-Tethyan Oceanic lithosphere below the Eurasian Plate formed the magmatic arc system, and subsequently, the oceanic lithosphere obducted at places with the closure of Neo-Tethyan Ocean along the Indus Suture Zone (ISZ) and Shyok Suture Zone (SSZ) in the Ladakh Trans-Himalaya. The remnants of the oceanic lithosphere, the Shyok Ophiolite Belt (SOB), are exposed in the SSZ in the northern margin of the Ladakh Batholith and south of the Karakoram Block. The phase petrology of SOB gabbro and meta-gabbro is carried out to infer the nature and origin of gabbro, and P-T trajectory and tectono-metamorphic regime of metagabbro, and their implication on the geodynamic evolution of the India-Eurasia convergence zone. The SOB gabbro comprises the clinopyroxene, calcic amphibole, plagioclase, biotite, and Fe-Ti oxides, whereas the metagabbro contains additional phases of albite and quartz. The phase chemistry of SOB gabbro reveals largely subalkaline to calc-alkaline orogenic, boninite, island arc Alaskan-type tholeiitic gabbroic intrusion, which follows the ophiolite evolutionary trend at 1000-1150°C, moderate to high-P, and elevated oxygen fugacity. The SOB metagabbro records a prograde metamorphic overprint on primary igneous phases. The calculated T–M(H2O), T–M(O2), and P–T pseudosection reveal the peak metamorphic conditions at ~8.85 kbar and ~780 °C, developed during burial subduction. The nearly-isobaric cooling retrograde stage characterizes the melt-out and magnetite-in and its stable P–T condition at 3 kbar and 650°C, indicating a rapid exhumation to a shallow crustal depth. The metamorphic reaction pathways integrated with P–T pseudosection modelling define a near-clockwise P–T loop. The apparent high thermal gradient of 22-24°C/km corresponding to a maximum burial depth of ~32 km and the P–T trajectory suggest a warm and mature stage of an intra-oceanic subduction zone setting for developing the SOB metagabbro. The petrological results on SOB rocks and their correlations with ISZ and other ophiolitic massifs suggest development of an intra-oceanic subduction/collision-related system within the Neo-Tethyan during Indian-Eurasian plate convergence.

Investigating Ca-Mg ionic exchange in Macquarie Island unobducted abyssal serpentinites

Cesare Nico ALBASIO LODI-CUSANI[1]*, Curtin University
(cesare.albasiol@postgrad.curtin.edu.au)
Katy Evans[2], Curtin University

Abstract

Macquarie Island (MI), located in the ocean south of New Zealand, offers access to unobducted oceanic lithosphere rocks, including abyssal peridotite samples. These samples avoid the typical limitations of drilled or dredged samples. The MI island rocks are depleted abyssal peridotites (spinel Cr# around 50) with geochemical and textural similarities to ODP 209 1274A rocks from the Mid-Atlantic Ridge (MAR).

However, the specific petrology and degree of serpentinization of the ultramafic rocks on MI have yet to be thoroughly explored, in comparison to other prominent ultramafic bodies. To understand the characteristics of serpentine and other minerals, a comprehensive analysis was conducted using optical microscopy, SEM (Scanning Electron Microscope) imaging, Electron Dispersive Spectrometry (EDS) and EPMA (Electron probe microanalyzer) on thin sections.

The serpentinization grade of the rocks was determined using the visual scale developed by Birner et al., with 0.25 steps implemented (0 is unaltered, 5 is completely serpentinized). MI samples serpentinization score range from 3.5 to 4.75.

The MI abyssal peridotites offer the opportunity to study Ca–Mg ionic exchange associated with serpentinisation. In this process, bulk rock Ca is lost to the fluid, and Mg is taken up by the rock. This process has been observed in controlled experiments on serpentinization. However, this effect has not been studied thoroughly in real settings, despite its significant implications for planetary ecosystems, via the seawater Mg/Ca ratio.

A comparison between the MI rocks and serpentinized abyssal peridotites from ODP Leg 209 1274A was used to constrain the impact of Mg–Ca exchange on the MgO/SiO2 ratio. The positive contribution of Mg uptake parallel to the lost Ca in ODP 209 1274A whole-rock MgO/SiO2 ratio is around 0.03-0.05.

At the mineral scale the effect in MI serpentinites is observable in bastite: with a Mg# change parallel to CaO decrease. The effect of 1:1 Ca-Mg exchange on a hypothetical fully serpentinized reconstructed MI protolith from mineral analyses has an impact around 0.02-0.03 on MgO/SiO2. This is consistent in order of magnitude with the observation in ODP 209 1274, suggesting Ca-Mg exchange is approximately 1:1.

In-situ Mg isotope analyses of clinopyroxene and alteration minerals are required to better constrain Mg–Ca ionic exchange on the grain scale.

Identification of ca. 520 Ma MOR-type ophiolite suite in the inner Cathaysia Block, South China: Evidence from shearing-type oceanic plagiogranite

Longming LI[1]*, Hefei University of Technology (longming_li@hfut.edu.cn)
Shoufa Lin[2], University of Waterloo
Guangfu Xing[3], Nanjing Center, China Geological Survey
Fan Xiao[4], Nanjing Center, China Geological Survey
Wenjiao Xiao[5], Xinjiang Institute of Ecology and Geography

Abstract

An ophiolite suite, predominantly composed of residual mantle peridotites, mid-ocean ridge basalts (MORB)-like ultramafic rocks and oceanic plagiogranites, has been identified in the Zhenghe-Dapu fault zone, Cathaysia Block, South China. The peridotites experienced strong serpentinization and are characterized by low 187Os/188Os ratios of 0.11621 to 0.12008 and very low 187Re/188Os values of 0.031-0.129, similar to those from highly refractory mantle residues. Thus, this indicated that the lithospheric mantle was transported through tectonic processes to the Earth's surface. The meta-ultramafic rocks, mainly amphibolites, can be classified into two groups. Group I is characterized by high Ni, Cr and low K2O content. Their spoon-like REE patterns, along with lower concentrations of highly incompatible elements, indicate that its protolith was of cumulate origin. Group II displays depleted REE patterns and low Nb/Yb, Th/Yb and Ti/V ratios, which are geochemically similar to N-MORB. Both groups exhibit positive εNd (t) values (1.2-4.1) and relatively high (87Sr/86Sr)i ratios (0.7046-0.7096), suggesting their origin from partial melting of depleted mantle sources in a mid-ocean ridge setting that experienced greater extent of fluid-rock alteration. The meta-plagiogranites intercalated with the mylonitic amphibolites are characterized by low K2O (0.09-0.21 wt.%) and ∑REE contents along with low K2O/Na2O and Rb/Sr ratios, which are consistent with those of typical oceanic plagiogranite. They exhibit strongly positive zircon εHf (t) values (+9.5 to +15.1) and positive whole rock εNd (t) values (+2.8 to +3.6). Their extremely low MgO (0.6-1.65 wt.%), Cr (0.22-6.26 ppm), and Ni (0.77-4.74 ppm) compositions and low Mg# (22.4-31.9) preclude their origination from mantle-derived primary magma but oceanic crust. Low zirconδ18O values (4.02 to 5.4‰) and decoupled Sr-Nd isotope feature imply the involvement of high-temperature seawater alteration in their source region. The enriched light rare earth elements (LREE) patterns with strongly positive Eu anomalies, similar to the East Karmoy type plagiogranite in Western Norway, imply that the plagiogranites were derived from anatexis of amphibolite in an active shear zone near the mid-ocean ridge. The magmatic and metamorphic zircons from the meta-plagiogranites yield nearly identical secondary ion mass spectrometry (SIMS) U-Pb age ranging from 523 to 521 Ma and 522 to 518 Ma, respectively. The simultaneous magmatism and metamorphism also prefer such an active high-temperature shear zone, where the plagiogranites were formed slightly later than the oceanic crust. The age of ca. 520 Ma represents the formation age of the oceanic crust rather than its emplacement age. The identification of the ca. 520 Ma ophiolite suite along the Zhenghe-Dapu

fault zone indicates that the Cathaysia Block should consist of at least two different terranes rather than a single tectonic unit in the Cambrian, and the final amalgamation of the eastern and western Cathaysia Block may have occurred far later than ca. 520 Ma, most likely during the late Early Paleozoic.

Neo-Tethyan ophiolites of Iran: formation of nascent oceanic lithosphere above double subduction

Iman MONSEF[1]*, Department of Earth Sciences, Institute for Advanced Studies in Basic Sciences (IASBS), Zanjan 45137-66731, Iran (iman_monsef@yahoo.com)

Abstract

Zagros and Makran ophiolites represent remnants of Neo-Tethyan oceanic lithosphere exposed along the Zagros suture zone and Makran accretionary prism in southern Iran. Zagros and Makran ophiolites are classified into two distinct belts with different spatial and temporal characteristics. The older Jurassic-Early Cretaceous ophiolitic belt includes the Sikhoran, Soghan, and Abdasht ophiolites in Zagros, and the Kahnuj, Fanuj, and Iranshahr ophiolites in Makran. The Kurdistan, Kermanshah, Neyriz, and Hajiabad ophiolites in Zagros, and the Sorkhband and Rudan ophiolites in Makran constitute the younger Late Cretaceous ophiolitic belt. Initially, the Neo-Tethyan oceanic lithosphere was formed in a mid-ocean ridge extending between the Arabian and Eurasian plates. Geological, geochronological and geochemical lines of evidence reveal that the Zagros and Makran ophiolitic belts formed in distinct nascent fore-arc basins related to Neo-Tethyan intra-oceanic double subduction. Early Neo-Tethyan intra-oceanic subduction at the southern margin of Eurasia produced an older Zagros and Makran fore-arc basin. This first stage of subduction led to the upwelling of asthenosphere and resulting melting to generate fore-arc basalt (FAB)-like melts. Penetration of slab-derived components into the mantle wedge due to continued subduction caused a depleted metasomatized mantle and generated island-arc tholeiitic (IAT)-like melts. During the Late Cretaceous time, a new south-verging Neo-Tethyan intra-oceanic subduction formed a younger fore-arc basin at the north margin of Arabia. The initiation of subduction has caused a slightly metasomatized depleted residual mantle resulted in FAB-like melts production. The continuation of true subduction generates a metasomatized depleted residual mantle and IAT-like melt extraction. Finally, the onset of rapid slab rollback led to asthenospheric upwelling, which caused a metasomatized ultra-depleted residual mantle producing boninitic (BON)-like melts.

Abstract

Melting of the sediments in the mantle region could provide invaluable information on the crust-mantle interaction, however, such rocks are rare on account of specific conditions of preservation. A small number of felsic intrusions in the mantle section of the Neoproterozoic Fuchuan Ophiolite in the South China Block display geochemical features typical of melts derived from subducted sediments, thus providing a record of melting of oceanic sediments at depth, offering an opportunity to evaluate mass transfer from the descending plate. These felsic bodies, dated to ca. 837-848 Ma (zircon U-Pb ages), were emplaced during the slab subduction rather than obduction onto the continental margin. The Zircon trace element chemistry and Hf-O isotopes ($\delta^{18}O$ up to 11.3 ‰), and whole-rock geochemistry (e.g. K_2O=4.25-9.10 wt.%) and Nd-isotope (εNdt=-2.2 to -0.4) characteristics of these felsic intrusions indicate subduction zone melting of sediments. The P-T estimates for these sediment-derived melts suggest a temperature range of 650-790℃ and the plagioclase stability regime pressure conditions. Considering the thermal structure of the subduction channel, these felsic intrusions clearly mark the subduction initiation. Further, the presence of sediment-derived melts in the Fuchuan ophiolite supports a spontaneous subduction that may serve as a proxy for the modern-style plate tectonics in the mid-Neoproterozoic.

Abstract

The main tectonic elements of Western Chukotka from north to south are the Western Chukotka terrane (WCh), South Anyui suture (SAS), and Yarakvaam terrane (YR). The SAS separates the structures of the Chukotka fold belt (including WCh) from the Alazeya-Oloy fold zone that is participating in the Kolyma Structural Loop to the south. The suture formed as a result of closure of an oceanic basin and collision of the North American and Siberian continents (Seslavinsky, 1979; and others). The collision took place at the end of the Early Cretaceous and terminated in Aptian time (Sokolov et al., 2009). The age of undeformed post-collision granites ranges 31 from 115.7±1.7 Ma to 112±1.3 Ma (Katkov et al., 2007). While there is general agreement on the timing of the closure of the basin, there are different viewpoints as to its origin. The SAS was customarily regarded as a structure that originated after the closure of the rift-related Late Mesozoic oceanic basin that separated Asia from the Hyperborean (Arctic) plate. As the Aluchin and the Gromadny-Vurguveem massifs are regarded as a part of the Alazeya-Oloy fold zone (Ganelin, 2017), the new study contains new data on the composition, geodynamic setting, and age of the ophiolites and discusses their possible interpretations.

The studied northwestern part of the ophiolite Gromadny-Vurguveem massif, where previously unstudied plutonic rocks (gabbroids, plagiogranites and ultrabasites) are exposed, makes it possible to correlate age and material characteristics with previously studied rocks from the central part of the massif.

Studies of the age of volcanics of the volcanogenic sequence near the village of Stadukhino allow us to answer the question of whether this sequence is part of the ophiolite association together with the gabbros of the Gromadnensko-Vurguveem massif, as previously assumed (Radzivil, 1975). The features of the evolution of volcanism and the geodynamic conditions of the formation of volcanics have been established.

In The Aluchinsky ophiolite complex the Middle-Late Palozoic volcanic-terrigenous deposits, exposed on the right bank of the river Bolshoi Anyui in the cliffs, were studied, opposite the mouth of the river Aluchin. These are the most representative outcrops of the Late Paleozoic volcanic complex known in the area. The obtained factual material allows us to make modern dating, as well as answer the question of whether these formations are the third (upper crustal) member of the Aluchinsky ophiolite association.

The northern and southern parts of the northern plate of ultramafic rocks of the Aluchin massif were studied, which was previously studied in the central part, where only lower crustal

cumulative peridotites were identified. The obtained material allowed us to establish the presence of mantle peridotites in this plate, which are an important (diagnostic) member of the ophiolite association.
The conducted studies confirm the synchronicity and comagmatic nature of the plutonic rocks of the Gromadnensko-Vurguveem and Aluchinsky massifs, and also made it possible for the first time to identify the upper crustal complex of this ophiolite association, which is represented by previously unstudied Late Paleozoic volcanics.

Abstract

Platinum group element (PGE) geochemistry of mantle-derived magmas can provide important information on partial melting conditions, which include fertility of mantle sources, degree of partial melting, and oxygen fugacity. Mid-ocean ridge basalt (MORB) magmas are known to be sulfide-saturated and PGE contents are depleted in evolved MORB magmas. However, the timing of sulfide saturation and the presence of PGE-bearing minerals in primitive MORB magmas remain in debate. MORB glasses and cogenetic picrites from Macquarie Island, SW Pacific offer a unique opportunity to address this issue. In this study, we investigated sulfide petrography and PGE geochemistry of 24 MORB glasses and 13 picrites from Macquarie Island to constrain sulfide saturation history and PGE host phases in the early stage of MORB magma differentiation.

Results show that progressive decrease in PGE contents in MORB glasses with decreasing MgO, which indicates compatible behavior of PGE during magma differentiation. Most glasses and picrites show positive correlations between PGE concentrations, suggesting that liquid sulfide is a major PGE host during magma differentiation. The presence of magmatic sulfide inclusions in olivine phenocrysts with Fo# of 88 – 90 mol% in picrites shows sulfide saturation in primitive magmas. Multiple in-situ LA-ICP-MS analyses were conducted on individual sulfide blebs in the groundmass and olivine of a picrite sample (38277) to investigate their PGE compositions. The primitive mantle-normalized PGE pattern of the average sulfide composition closely mirrors that of the whole-rock PGE composition of the host picrite (except for Pt), showing sulfide is the predominant PGE host in the picrite. It should be noted that some picrites exhibit significant differences in the whole-rock PGE contents between replicate analyses due to the nugget effects of PGE-bearing phases. The compositions of the nuggets inferred from the difference in replicate analyses are best explained by Ru-Ir-Os(-Pt) alloys, Pt alloys, or Ru-Ir sulfarsenide as well as sulfide liquid. Whether the PGE minerals are liquidus phases in primitive MORB magmas requires further investigation.

Abstract

The origin and evolution of the Precambrian Lhasa Terrane in the central Tibetan Plateau remain enigmatic. In this contribution, we focus on the early Neoproterozoic amphibolites and quartzites from the Nyainqentanglha Group in the northern Lhasa Terrane. We present U–Pb age and Hf isotopic data for detrital zircons from early Neoproterozoic quartzites in the Lhasa Terrane, Tibet. An integrated petrological, geochronological, geochemical, and Sr–Nd–Hf isotopic study was also undertaken on amphibolites associated with the quartzites. The depositional age of the quartzites is constrained to be between ca. 931 Ma (youngest detrital igneous zircon core) and 869 Ma (oldest metamorphic zircon rim). The detrital zircons have a main age population from 1200 to 1000 Ma, and lack zircons with ages of 1000–900 Ma. Zircons from the amphibolites yield concordant ages of ca. 913–902 Ma, which are comparable to the depositional age of the quartzites. The amphibolites have N-MORB-like compositions and are characterized by high positive zircon εHf(t) (+7.2 to +14.0) and whole-rock εNd(t) (+5.5 to +6.0) values. Their compositions have been modified by crustal contamination. The formation of these quartzites and amphibolites was related to the transitional process from continental rift to embryonic oceanic crust, marking the opening of part of the Mozambique Ocean adjacent to the African side of the northern East African Orogen.

Abstract

The Luobusa ophiolite in the southeastern Tibet holds the largest chromitite resource in China. These rocks present an ideal opportunity to study the origin and evolution of ophiolite-related chromitite ores. The Luobusa Ophiolite Scientific Drilling (LSD) program resulted in two boreholes (LSD-1 to a depth of 1478 m with a core recovery of 94% and LSD-2 to a depth of 1854 m with a core recovery of 97%). The profile of both pilot-boreholes includes three main lithological units, i.e., mantle tectonites (harzburgite and lherzolite with lenses of residual dunite), mantle-crust transition (mainly cumulative dunite), and crustal cumulates (i.e., gabbros). The crustal cumulates occur at the bottom of the borehole, whereas the mantle tectonites form the upper part of the section. This stratigraphic reversal reflects the complex tectonic evolution of the Luobusa ophiolite.

A large dataset of whole-rock geochemical compositions integrated with microanalytical data of olivine, pyroxene, and Cr-spinel suggests formation of the Luobusa ophiolites by variable degrees of mantle partial melting (540 %) and evolution from a MOR to a SSZ setting. The mantle-normalized PGE patterns of mantle tectonites and transitional zone dunites are distinctive, with different IPGE and PPGE anomalies coupled with variable Pd/Ir ratios, suggestive of complex origins. Similarly, the heterogeneous 187Os/188Os ratios of the Luobusa peridotites, with γOs values overlapping those of depleted mantle, primitive mantle, and enriched mantle sources, imply a polygenetic or multi-stage model of formation. Most of the mantle tectonites have 187Os/188Os

ratios lower than the present-day primitive mantle value, and overlap with the chondritic values. Cumulative dunite, on the contrary, has 187Os/188Os ratios close to the primitive mantle value. Negative γOs values calculated for some samples may indicate disturbance of the Re-Os isotope system by cryptic metasomatism and/or serpentinization. The Re-Os isotopic characteristics of Luobusa ophiolites and the olivine and orthopyroxene separates are suggestive of a residual phase origin. The higher 187Re/188Os and 187Os/188Os ratios in the crustal cumulate rocks can be interpreted as a manifestation of extraction and enrichment of melt phases in a slow spreading ridge setting, where interplay of melt extraction and melt-peridotite interaction is typical.

Abstract

The variations of mantle sources and plume-ridge interaction beneath mid-ocean ridges are crucial to controlling the oceanic lithosphere's rock assemblage and accretion processes. Here, we present a combined analysis of petrological, chronology, and geochemical characteristic data for the North Renco ophiolite, central Tibetan Plateau. The North Renco ophiolite comprises tectonic remnants of oceanic crustal rocks and is stratified into two units (V1 and V2 units). The V1 units mainly consist of large-scale sheeted dikes, cumulated gabbros, and shallowly metamorphosed oceanic island fragments. Zircon U-Pb dating suggests the sheeted dikes were formed at ~170 Ma, while the oceanic islands were spawned during 167-165 Ma. Geochemical analysis indicates that the sheeted dikes exhibit typical E-MORB characteristics, lacking any imprints of subduction. This is complemented by a relatively depleted Nd-Hf isotopic composition, which hints at their derivation from an asthenospheric mantle subject to metasomatism by deeply enriched mantle components. The oceanic island remnants are distinguished by their classic interstratification of basalt with limestone (marble), with geochemical indications aligning with typical oceanic island basalts (OIB), implicating their origins in an intra-oceanic mantle plume/hotspot domain.

The V2 units are primarily composed of gabbro and pillow basalt structural blocks. Geochemical characteristics reveal that these are of the typical N-MORB sequence, consistent with the southern Renco ophiolite we previously reported. This suite of rocks originates from a depleted asthenospheric mantle, the product of the spinel lherzolite mantle's decompression partial melting (~1350°C, and 10-20% partial melting). The zircon U-Pb dating approximates the formation of this phase to ~150 Ma, well consistent with the southern Renco ophiolite, which indicates the oceanic crust accretion process under a rapid spreading ridge during the Late Jurassic.

Integrating the results of these studies, we suggest that the North Renco ophiolite encapsulates a dual-phase record of oceanic lithospheric accretion. The inaugural phase, entwined with plume-ridge interaction, reflects the influential role of the Meso-Tethys intra-oceanic mantle plume/hotspot in guiding crustal accretion. The succeeding phase underscores a rapid expansion of oceanic crust at distances far away from the plume/hotspot amidst the context of spreading mid-oceanic ridges, culminating in the development of the Penrose-type ophiolite as epitomized by the southern Renco ophiolite. The superposition of two magmatic episodes may be associated with the reduction in the size of the oceanic basin and the adjustment of the spreading ridge position attendant upon the northward drift of the Lhasa terrane.

Mantle heterogeneity caused by melt addition to mid-ocean ridge peridotite: Evidence from the Mid-Ocean Ridge Taitao ophiolite, southern Chile

Weiwei WU[1]*, Nanjing University (cugcags@163.com)
Jingsui YANG[2], Nanjing University

Yun WANG[4], Nanjing University
Dongyang LIAN[5], Nanjing University

Abstract

The heterogeneity of oceanic mantle likely resulted from variations in the degree of melting and in the initial compositions, and interaction with melts. However, the metasomatic enrichments in the sub-ridge mantle lithosphere at fast-spreading ridge are generally assumed to be limited. Peridotites in the Mid-Ocean Ridge Taitao ophiolite give us an excellent opportunity to understand the spatial extent of the mantle heterogeneity and to examine the patterns of mantle melting, melt addition process at a fast-spreading ridge. Based on the mantle textures, petrological, mineralogical and geochemical characteristics, we can distinguish two mantle components: (1) Type 1 residual lithospheric mantle, pertaining to partial melting occurred at or near the Chile Ridge; (2) Type 2 reacted lithospheric mantle, ascribed to Type 1 residual lithospheric mantle affected by multi-stage melt-rock interactions that occurred at different lithospheric depths during progressive exhumation on the Neogene (~6 Ma) Taitao seafloor. The compositions of Type 1 residual harzburgites display minor variations and encompass the entire abyssal peridotites trend (i.e., Cr# of spinels range from 29.6 to 37.0). Type 2 reacted peridotite shows textural features, exhibits elevated Cr# values of spinel (34.5 to 58.0) and strong incompatible element zonation and negative Eu anomalies in clinopyroxene, indicating a short-term percolation of a evolved mid-ocean ridge basalt (MORB). We attribute such mantle metasomatic enrichments to the lateral infiltration of variably evolved melts from a local magmatic center, which may be now exposed as the gabbroic rocks. The collective results of this study provide important information to understand the formation of lithosphere and of substantial mantle heterogeneity at the mid-ocean ridges.

Exhumation of mantle peridotite in an embryonic oceanic basin at slow to ultraslow spreading ridge within the Dahomeyide belt in Ghana, West Africa

Daniel KWAYISI[1]*, University of Johannesburg (danielk@uj.ac.za)
Jeremie Lehmann[2], University of Johannesburg
Marlina Elburg[3], University of Johannesburg

Abstract

The occurrence of exhumed mantle peridotite, gabbro, tectono-sedimentary breccias, volcanic rocks, and marine and continental sedimentary units in the Buem structural unit (BUSU) of the Pan-African Dahomeyide belt in Ghana share similarities with typical ophiolite sequence. The BSU ophiolite complex, however, is incomplete (with the absence of sheeted dyke complex) compared to the classical Penrose ophiolite sequence, such as the Oman and Troodos ophiolite and its lithological components are in both primary and tectonic contacts. Nonetheless, the BSU is characterised by features that are consistent with ocean-continent transition ophiolites similar to those of Iberia-Newfoundland and Alpine-Apennine. In the BSU, the serpentinised peridotite dominates in terms of volume, and it is either overlain by oceanic sediments or mafic volcanic or plutonic rocks, which are subordinate. The geochemical and isotopic characteristics of the mafic volcanic and plutonic rocks associated with the BSU serpentinised peridotites are mostly similar to those of magmas formed by melting of the depleted mantle. These MORB-type rocks have been interpreted as an embryonic oceanic crust formed during the transition from rifting to seafloor spreading during the opening of the Pharusian Ocean. Slow and ultraslow spreading ridges are amagmatic with episodic magmatic activities resulting in the thin oceanic crust (<7 km); thus, the high effect of serpentinisation is due to sufficient exposure of peridotites to the ocean floor. Thus, the significant effect of serpentinisation of the BSU serpentinised peridotite may indicate exhumation in a slow to ultraslow-spreading ridge. Geochemical and geochronological data for the clastic sedimentary rocks of the BSU associated with the mafic-ultramafic rocks suggest passive margin sequences deposited during the opening of the Pharusian Ocean. Comparing the results from this study to data from the Novo Oriente Group indicates an evolution of the West Gondwana Orogen from initial mantle exhumation followed by syn-rift magmatism (Novo Oriente Group) and early stages of seafloor spreading (BSU mafic-ultramafic rocks) as has been proposed for the Alpine ophiolites. Therefore, ophiolites in the West Gondwana Orogen are of two main domains: proximal OCT of the Novo Oriente Group and distal embryonic oceanic crust of the BSU, formed during the break-up of the supercontinent Rodinia.

Tectonomagmatic evolution of mantle complexes of the North Balkhash and Dzhalair-Naiman ophiolite zones (central and south Kazakhstan, western part of the Central Asian Orogenic Belt)

Aleksandra MILYUKOVA[1]*, Geological Institute, Russian Academy of Sciences, Pyzhevsky Lane, 7, Moscow, Russia (aleksandramilyukova@gmail.com)
Anfisa Skoblenko[2], Geological Institute, Russian Academy of Sciences, Pyzhevsky Lane, 7, Moscow, Russia
Kirill Degtyarev[3], Geological Institute, Russian Academy of Sciences, Pyzhevsky Lane, 7, Moscow, Russia

Abstract

Western segment of the Central Asian Orogenic Belt (CAOB) comprises Palaeozoic fold-and-thrust complexes of Kazakhstan, Tien Shan and Northwestern China that include island-arc and accretionary prism formations associated with dismembered fragments of ophiolites. The most complete and well-preserved mantle ophiolite suites in the west CAOB are known from the North Balkhash (NBOZ) and Dzhalair-Naiman (DNOZ) ophiolite zones of Kazakhstan.

Serpentinite mélange of the NBOZ in Central Kazakhstan contains varisized blocks of igneous and metamorphic (high-pressure) rocks, as well as slivers of volcanic-sedimentary strata. The largest igneous blocks are composed of spatially disintegrated fragments of the residual (dunite-harzburgite) and layered (dunite-wehrlite-pyroxenite-gabbro-plagiogranite) complexes, subordinate lherzolites are also found. Variably serpentinized harzburgites and dunites of the NBOZ are characterized by low Al2O3 (0.33–0.86 wt%), CaO (0.51–0.86 wt%) and Na2O (0.07–0.25 wt%) concentrations. The rocks contain high-Mg olivine (Fo91–92) and orthopyroxene (En92–93) contents, together with moderately-high spinel Cr-numbers of 63–68. The ultramafites are depleted in incompatible elements (ΣREE, Nb, Sc) and enriched in compatible elements, such as Cr (up to 2817 ppm) and Ni (up to 2327 ppm). Whole-rock compositions and primary mineral chemistry of these rocks suggest that they represent refractory mantle residues after 19–23% of partial melting to produce boninitic melts in a forearc tectonic setting. Re–Os isotope systematics (187Os/188Os = 0.1202-0.12599, 187Re/188Os = 0.230-0.316) indicates the formation of the ultramafites in two stages at ca. 1.5 Ga and ca. 668–589 Ma, as determined by the estimated TRD model ages.

The DNOZ includes deformed fragments of ophiolite suites associated with volcanic-sedimentary rocks. Plutonic parts of the ophiolite sequence comprise well-preserved dunite-harzburgite with hornblendites and dunite-wehrlite-pyroxenite-gabbro complexes. The rocks are rodingitized and serpentinized to varying degrees. The ultramafites of residual complex possess SiO2 contents < 47.7 wt.% with Mg# = 90–91, and notable Cr (<6162 ppm) with Ni (<2400 ppm) concentrations, suggesting their mantle origin and high degrees of partial melting of their mantle source of ~18–20%. Selected samples of harzburgites are notably enriched in basaltic components (Al2O3 <

3.53 wt.% and CaO < 2.55 wt.%), possibly resulting from an interaction of the rocks with Ca-Al-rich melts during serpentinization and rodingitization. Compared to DMM, the ultramafites and pyroxenites of the DNOZ demonstrate an enrichment in LILEs, U, while showing a depletion in HFSE concentrations, including Nb, Hf, REE, implying their affinity to suprasubduction zone setting and metasomatic overprinting.

This work was funded by the Russian Science Foundation (project No. 22-17-00069).

Haitao Ma[4], Nanjing University
Yun Wang[5], Nanjing University

Abstract

To advance our understanding of the deformation characteristics, rheological behaviors, and melt-rock reaction of the Indus-Yarlung suture zone (IYS) ophiolitic mantle, we analyzed mineral fabrics for ophiolitic mantle rock at multiple locations along the Indus-Yarlung suture zone, ranging from east to west. Prominent plastic deformation microstructures are observed in olivine and orthopyroxene, accompanied by significant crystallographic preferred orientations (CPOs), which suggest dislocation creep deformation. Electron backscatter diffraction measurements revealed that the D-type (characterized by a strong alignment of [100] close to the lineation and by a distribution of [010] and [001] in a girdle normal to the [100] maximum) and B-type (characterized by a point concentration of [001] axes subparallel to the lineation and of [010] axes nearly normal to the foliation plane) olivine CPOs occur in dunite samples from Luobusha (eastern part of IYZ), might formed under high stress environment. Olivine shows transitional CPO symmetry from [010]-fiber to orthogonal type (AG-type and A-type) in Sangsang (central part of IYZ), indicating a representative of the original oceanic lithosphere fabric with a low instantaneous melt/rock ratios during the impregnation process. Olivine CPO within the Xiugugabu ophilitic massif (central part of IYZ) is characterized by (100)[001] fabric (C-type), which is considered to cause by high water contents in a suprasubduction-zone setting during exhumation. Olivine in the Purang peridotite display an orthorhombic symmetry fabric, which is characterized by a point concentration of [100] axes subparallel to the lineation and of [010] axes nearly normal to the foliation plane, which is referred as A-type (Western part of IYZ) representing the remnants of the original fabric in oceanic mantle rocks formed in the spreading center of the New Tethyan ocean. Our new microstructural and fabric data, provide constrains for the tectonic evolution of the Indus-Yarlung suture zone.

Abstract

Serpentinites play a crucial role in recycling of elements and volatiles in subduction zones. We studied the geochemistry of Changawuzi serpentinites from Chinese southwestern Tianshan, which underwent ultrahigh-pressure (UHP) metamorphism. The bulk-rock major and trace element compositions indicate that the Changawuzi serpentinites originated from a depleted mantle source, representing a section of the oceanic lithosphere with local occurrences of pyroxenites. The variations in major and trace elements suggest different protolith compositions and different melt-peridotite evolution before serpentinization. During the process of oceanic serpentinization, the protoliths of Changawuzi serpentinite absorbed FMEs such as B, As, and Sb from seawater, acquiring a bulk Sr isotope composition similar to that of Silurian seawater. However, the bulk Pb and Nd isotope compositions remained consistent with the depleted mantle, indicating no significant influence from sediment-derived fluids during early serpentinization or at forearc conditions. During subduction, there is a redistribution of major and trace elements among metamorphic minerals. In the early stage, most elements decrease during the transformation from lizardite to antigorite. Regarding FMEs, over 50% of B is released into the subduction zone during the lizardite-to-antigorite transformation, while Sb and As show no significant change. At peak metamorphism, minerals such as olivine, TiChn, and TiChu contain trace elements released during the antigorite partial dehydration and clinopyroxene recrystallization. Metamorphic Ti-bearing olivine and TiChu/TiChn are potential carriers of HFSE and FMEs, especially B and Li, into the deeper mantle beyond the dehydration zone of serpentinites, which may impact arc magma characteristics and global geochemical recycling. The trace element and Sr–Nd–Pb isotopic compositions of the Changawuzi serpentinite suggest that it likely resided in a slab interior setting with limited interaction with subduction zone sediment-derived fluids.

Petrogenesis of chromitites in the Bulqiza ophiolite massif, Albania and its records of Ti metasomatism

Tian QIU[1]*, Institute of Geology, Chinese Academy of Geological Sciences (tianqiu@pku.edu.cn)
Jingsui YANG[2], School of Earth Sciences and Engineering, Nanjing University
Weiwei WU[3], School of Earth Sciences and Engineering, Nanjing University
Fahui XIONG[4], Institute of Geology, Chinese Academy of Geological Sciences

Abstract

Podiform chromitites are one of the main sources of the key metal chromium, however the genesis of the chromitites located in crust-mantle transition zone of ophiolite has yet to be resolved. The Bulqiza ultramafic massif, which is part of the eastern Mirdita ophiolite of northern Albania, is world renowned for its high-Cr chromitite deposits hosted in the mantle section and high-Al chromitite deposits in the mantle-crust transition zone. The Cerruja high-Al podiform chromitites (Cr# of spinels varying from 0.56 to 0.58) and dunite wall-rocks (Cr# of spinels varying from 0.52 to 0.55) are widespreadly intruded by pyroxenite dikes in the crust-mantle transition zone of the Bulqiza ultramafic massif, Albania. Highly brecciated spinel and Ti-bearing mineral assemblages such as rutile, ilmenite and titanite were found in pyroxenite dike and in the interaction zone between pyroxenite dikes and high-Al chromitites. Spinels in the pyroxenite dikes and also the interaction zone between pyroxenite dikes and chromitites are characterized by obviously higher Cr# (0.72-0.83 and 0.57-0.67, respectively) than chromitites ores. Contents of TiVMnScCoZn and Ga of spinels in the interaction zone are higher with the closer distance to the pyroxenite dikes. According to the texture characteristics of spinel and the change of mineral chemical composition, we propose that the chromitites in the crust-mantle transition zone of Bulqiza massif is the result of a multi-stage process: first, high-Al chromitites are produced by the reacts between peridotites and the transition melts which has the geochemical properties both of MORB and boninitic melts during the evolution of initial subduction of the Mirdita-Pindos ocean basin (~165 Ma) ; and then, residual melts which are Ti- and Fe-rich are produced by intercumulus crystal fractionation of the MORB melt in a crystal-melt mush, penetrating into and metasomatizing extensively the surrounding chromitites during upon colling, and also crystallizing Ti-rich minerals such as rutile, ilmenite and titanite.

Abstract

The Proto-South China Sea (PSCS) is a vanished Cretaceous to Eocene oceanic basin speculated to have existed in the location of the modern South China Sea. Details about its nature, evolution, and eventual consumption remain contentious. Ophiolites present in the southeastern margins of the South China Sea are postulated to be the only remaining vestiges of the PSCS. One of the ophiolites inferred to be associated with it is the Southern Palawan ophiolite (SPO) in the western Philippines. It is composed of dismembered outcrops of mantle peridotites, gabbros, and volcanic rocks exposed from Quezon to Balabac Island.

Field investigation of the volcanic section exposed in Quezon, Brooke's Point, Bataraza, and Balabac reveals both effusive and explosive modes of submarine volcanism. Effusive volcanism is represented by basaltic lava flows showing sheet, lobate, and pillow morphologies. On the other hand, explosive volcanism is suggested by the presence of pyroclastic breccias that unconformably overlie pillow lavas. Sub-rounded, lapilli-sized glassy clasts are embedded within pyroclastic breccias. Basalts from lava flows are generally composed of plagioclase, orthopyroxene (OPX), and clinopyroxene (CPX) grains set in a glass groundmass. The clasts in pyroclastic breccias are andesitic and composed of OPX, CPX, and plagioclase set in a groundmass of glass and feathery quenched pyroxenes. Whole-rock geochemistry suggests the existence of three main lithological groups in the SPO's volcanic section: tholeiitic, boninitic, and alkalic. Tholeiitic rocks, identified as medium-Fe basalts and basaltic andesites, are distributed in Quezon, Bataraza, and Balabac. Samples have nearly flat REE patterns comparable to normal MORB (N-MORB) except for Bataraza samples which are 1.2-2 times more depleted than N-MORB. Boninitic volcanics are observed in Quezon and co-exist with tholeiitic lavas. Boninitic samples, classified as fractionated boninite of low silica subtype, are silicic and have low TiO2 contents (0.21-0.31 wt%) albeit MgO values (4.55-7.09 wt%) are below the prescribed criteria for true boninites. Trace element signatures of both tholeiitic and boninitic lithologies (e.g., negative Nb-Ta anomaly, high Ba/Th values) indicate the incorporation of subduction-related fluids

released at shallow depths. Alkalic samples, identified as alkali basalts, are spatially constrained in Brooke's Point. The samples are notably enriched in light REE relative to middle and heavy REEs as evidenced by (La/Sm)N and (La/Yb)N values ranging from 2.86-3 and 7.37-8.04, respectively. Three samples exhibit elevated Nb (54.2-57.4 ppm), Y (42.4-46.2 ppm), Yb (3.99-4.49 ppm), and Zr (265-279 ppm) concentrations comparable to high-Nb basalts (HNB). The alkalic samples have signatures akin to enriched MORB (E-MORB) and ocean island basalt (OIB).

Although the disrupted nature of the SPO's volcanic section hindered direct stratigraphic sampling, the diverse geochemical signature of the volcanic rocks shows some similarity with forearc regions (e.g., Izu-Bonin-Mariana) and suprasubduction zone ophiolites (e.g., Zambales, Oman) intimately linked with subduction initiation (SI) processes. The presence and co-existence of geochemically varied rocks in the SPO suggest SI origins that can be linked with the initiation of subduction and eventual consumption of the PSCS. Further volcanostratigraphic and geochemical work will be done to constrain the evolution of the SPO's volcanic section.

Abstract

Ophiolites and ophiolitic complexes occur in western Philippines and neighboring areas such as Borneo. These fragments are believed to form part of the proto-South China Sea (proto-SCS), a fully consumed Mesozoic plate that once existed between the South China-Eurasian margin and Borneo. In the Philippines, Cretaceous and Eocene ophiolitic lithologies occur in the central and southern portions of the Palawan island. The Cretaceous Southern Palawan Ophiolite (SPO) comprises mostly of exposures of peridotites and pillow basalts. The peridotites are often cut by troctolite and olivine gabbro dikes. Isotopric olivine gabbros and biotite-bearing gabbros are also observed as float. The Eocene Central Palawan Ophiolite (CPO) is composed of mantle peridotites, isotropic and layered gabbros, and massive and pillow lavas. While a sheeted dike complex was not observed, mafic dikes with distinct bake-and-chill margins cut the CPO, from the metamorphic sole to the crustal section.

The CPO crustal rocks and mafic dikes show back-arc basin basalt affinities. Geochemical signatures of the SPO lithologies are more diverse ranging from ocean island basalt-like signatures with a mafic dike showing island arc basalt-like compositions. Radiometric dating of a plagiogranite sample from Puerto Princesa in Central Palawan yielded an Eocene age (40.01 ± 0.54 Ma), while olivine gabbro and syenite samples from Southern Palawan are determined to have a minimum age of Early Cretaceous (100.73 ± 1.07 and 102.97 ± 1.07 Ma, respectively). The geochemical and geochronological characteristics of the SPO and CPO share similarities with the Darvel Bay and Telupid Ophiolites in Borneo, which are interpreted to originate from the proto-SCS. The juxtaposition and present day configuration of the Cretaceous and Eocene ophiolites in Palawan may have been due to inception of multiple subduction and rifting events involving the proto-SCS in the past.

Yuan-Hsi Lee[7], NCCU

Abstract

Several ophiolites and ophiolite complexes occur as basement of the Philippine archipelago. In northern Philippines, Early Miocene to Recent volcanic centers of the Luzon Arc form on top of these ophiolites. Multiple intrusive units occur in the northern Luzon segment of the arc due to the subduction of the South China Sea Basin along the Manila Trench. In particular, gabbros, diabases, and plagiogranites occur in northern Zambales and Pangasinan. These rocks possibly preserve records of the formation of the Zambales Ophiolite Complex and the inception of the Luzon Arc. This work aims to conduct petrographic, geochemical, and geochronological analyses of these intrusive rocks in northern Zambales and Pangasinan to provide new constraints on the tectonomagmatic evolution of northern Luzon.

Isotropic gabbros and associated rocks occur in the localities of northern Zambales (e.g. Sta. Cruz) and Pangasinan (e.g. Sual, Bugallon, Mabini, and Infanta). Massive isotropic gabbros are exposed in Sual, Infanta, and Sta. Cruz. Gabbros in Sual and Bugallon are cut by diabase dikes and their apophyses. A chilled margin between the contact of the diabase and gabbro was observed in Bugallon. A dunite exposure in Sta. Cruz is cut by gabbroic and plagiogranite dike swarms with prominent baked and chilled margins. Tonalites associated with isotropic gabbros are also noted in Infanta, Mabini, and Sual, Pangasinan. Isotropic gabbros in Sta. Cruz, Infanta, and Bugallon are gabbronorites that exhibit orthocumulate and sub-ophitic textures. The crystallization order is olivine → pyroxene → plagioclase → hornblende. Gabbros from Sual show orthocumulate and ophitic textures. Plagioclase formed first before clinopyroxene in the Sual gabbros. The diabases are composed of pyroxenes, plagioclases, and Fe-Ti oxides with intergranular and sub-ophitic textures. The tonalites are composed of interlocking crystals of quartz, plagioclase, amphiboles, and Fe-Ti oxides which at times show myrmekitic texture.

Whole-rock geochemical analysis of the gabbronorites, gabbros, diabases, and tonalites revealed island arc tholeiite signature. An increasing trend of TiO2 and FeO* and a decreasing trend of MgO, Cr2O3, and Ni were observed with increasing FeO*/MgO. While the tonalites have very high FeO*/MgO ratio and Na2O with very low concentrations of TiO2, Cr2O3, and Ni. Trace element concentrations of the samples revealed a slight depletion of LREEs relative to HREEs and

negative Nb, Hf, Zr, and Ti and positive Pb and Sr anomalies. U-Pb age dates of the zircon grains from an olivine-bearing gabbronorite from Bugallon and a gabbro from Sual have ages of 45.64 ± 0.97 Ma and 45.28 ± 0.30 Ma, respectively. Our results show that the intrusive rocks from northern Zambales and Pangasinan generally have island arc tholeiite affinity and were formed during the Middle Eocene.

Abstract

Field and geochemical evidence indicate that most supra-subduction zone (SSZ) ophiolites originated by sea-floor spreading following subduction initiation. Most of our understanding of intra-oceanic subduction initiation derives from the Eocene forearc of the Western Pacific, where the locus of subduction initiation has been described as an intra-oceanic transform. Here we present a more recent example from the Miocene Timor ophiolites related to the Banda arc-basin system, where mineral and whole-rock geochemical data from boninites and peridotites demonstrate that subduction initiation took place beneath a continental margin. Specifically, the Timor peridotites include lherzolites with LREE-depleted rare earth patterns, chrome spinels with low Cr# giving oxygen fugacities close to the QFM buffer and incompatible trace element data (analyses by EMP and ICP-MS), all indicative of an origin as slightly depleted attenuated continental margin peridotite. These lherzolites are interspersed with more harzburgitic peridotites with LREE-depleted to U-shaped rare earth patterns, spinels with higher Cr# giving elevated oxygen fugacities, and elevated trace element reaction proxies. On diagnostic chrome spinel projections such as Cr# versus oxygen fugacity and Ti/FeIII versus Ga/FeIII, the data form reaction trends between continental margin lherzolites and Timor boninites that differ in detail from the abyssal peridotite- boninite trends found in Western Pacific subduction initiation systems. This emphasizes that the precise location of subduction initiation can significantly influence the petrology and geochemistry of SSZ ophiolites.

The Ginebra Ophiolithic Complex: Origin and evolution of an Ophiolite in Colombia from geochemistry and U-Pb geochronology.

Jonathan Adolfo HERNANDEZ PRIETO[1]*, National University of Colombia (joahernandezpr@unal.edu.co)
Juan Carlos Molano Mendoza[2], National University of Colombia
Ana María Martínez Ardila[3], Loma Linda University

Abstract

The Ginebra Ophiolithic Complex consist of mafic to ultramafic rocks located in the department of Valle del Cauca in Colombia, on the western flank of the Central Cordillera. The study of this ophiolitic body is of great importance in the reconstruction of the geological and tectonic evolution of the Andes Mountains in the country.

The aim of this study is to reconstructs the evolution of the Ginebra Ophiolithic Complex based on the analysis and geochemical characterization of the complex, U-Pb dating of zircons from 7 samples taken throughout the study area and the compilation of geochemical data reported in other studies.

The rocks of the Ginebra Ophiolithic Complex are geochemically characterized as part of the subalkaline series and classified as gabbros, gabbroic diorites and diorites, and with a toleiitic trend. Using geotectonic discrimination diagrams and the methodology proposed by Pearce in 2014 for ophiolites, it was found that this secuence of rocks has an origin associated with MOR-type geotectonic environments, although with negative Nb anomalies, indicating additional processes in the evolution of the complex. Finally, it was determined from radiometric U-Pb dating in six zircons found in the collected samples, that this ophiolitic body has a crystallization age of 93.78 ± 1.38 M.y., age corresponding to the Turonian, within the Upper Cretaceous.

According to the data obtained for the Ginebra Ophiolithic Complex in the geochemical and geotectonic environment characterization comparing the geochemical data obtained for the complex with the geotectonic discrimination diagrams proposed by Pearce (2014), the geochronological analysis developed and the age comparison with adjacent units, is concluded that this ophiolite has a genesis independent of the Western Cretaceous Oceanic Lithospheric Province (PLOCO), which would be more related to a Mesoceanic ridge environment and its emplacement in the continent could have occurred at the beginning of the Paleogene, taking into account the temporal relationships with the intrusive bodies reported in this complex reported by Brito et al. (2010).

[Keynote] East Asian Blocks: From Breakup of Rodinia to Assembly of Pangea

Guochun ZHAO[1]*, The University of Hong Kong (gzhao@hku.hk)

Abstract

Pangea is the youngest supercontinent in Earth's history and its main body formed by assembly of Gondwana and Laurasia about 300-250 Ma ago. As supported by voluminous evidence from reliable geological, paleomagnetic and paleontological data, configurations of major continental blocks in Pangea have been widely accepted. However, controversy has long surrounded the reconstructions of East Asian blocks in Pangea. To determine whether or not the East Asian blocks were assembled to join Pangea before its breakup, we carried out geological and paleomagnetic investigations on East Asian blocks and associated orogenic belts, supported by a NSFC Major Program entitle "Reconstructions of East Asian blocks in Pangea". Our results indicate that the breakup of Rodinia around 750 Ma ago led to the opening of the Proto-Tethys and Paleo-Asian oceans in East Asia, with the former separating the South China, North China, Alex Qaidam and Tarim blocks from other East Asian blocks at the margins of Australia and India, whereas the Paleo-Asian Ocean existed between the East Asian blocks and Siberia-Eastern Europe. The Proto-Tethys Ocean closed in the early Paleozoic (500-420 Ma), leading to the collision of South China, North China, Alex, Qaidam and Tarim with other East Asian blocks at the northern margin of Gondwana. The subduction of the Paleo-Asian Ocean formed the Central Asian Orogenic Belt, the largest accretionary orogen in Earth's history, and its closure was diachronous, with its western, central and eastern segments closing at 310-280 Ma, 280-265 Ma and 260-245 Ma, respectively, leading the Tarim, Alex and North China blocks to join Eastern Europe-Siberia as part of Pangea. During the early Devonian (420-380 ma), the East Paleo-Tethys Ocean opened with two branches, of which the north branch is called the Mianlue Ocean that separated the Tarim-Qaidam-Central Qilian-Alex and North China blocks in the north from North Qiangtang-Indochina-South China in the south, and the south branch is the stricto sensu East Paleo-Tethys Ocean that separated North Qiangtang-Indochina-South China from the Sibumasu and South Qiangtang-Lhasa blocks at the northern margin of Gondwana. In the Triassic, the East Paleo-Tethys Ocean (stricto sensu) closed along the Longmu Co – Shuanghu – Changning – Menglian – Inthanon belt, leading to the collision of North Qiangtang-Indochina-South China with Sibumasu and South Qiangtang-Lhasa, forming a single southern continent, which then collided with the Tarim-Qaidam-Central Qilian-Alex and North China blocks to form a coherent East Asian continent that had become part of Pangea by 220 Ma, when the Mianlue Ocean closed, leading to the formation of the E-W-trending Central China Orogenic System.

This research was supported by NSFC Major Program "Reconstructions of East Asian blocks in Pangea" (41190070), Hong Kong RGC GRF (17308023) and HKU Faculty Start-up Funds (000250348).

The review on the Permo-Triassic continental collision process in the Northeast Asia during the final amalgamation stage of Pangea supercontinent and the geological correlations between Korea, China, and Japan.

Chang Whan OH[1]*, Jeonbuk National University (ocwhan@jbnu.ac.kr)
Byung Choon Lee[2], Chonnam National University
Sang Bong Yi[3], Jeonbuk National University
Seung Hwan Lee[4], Korea Institute of Geoscience and Mineral Resources
Bo Young Lee[5], Korea Institute of Geoscience and Mineral Resources

Abstract

Asia is the youngest continent formed during the last stage of the amalgamation of the Pangea during Permo-Triassic period. The amalgamation of Northeast Asia began to receive much attention after discovering HP and UHP eclogites in Dabie and Sulu areas in China during the late 80s. Several tectonic models were proposed for the amalgamation of Northeast Asia, including the Korean Peninsula, China, and Japan. However, the tectonic evolution of Northeast Asia during Permo-Triassic time is still under argument. One of the leading causes of such controversy was the lack of geological information on the Korean Peninsula. Fortunately, over the past 30 years, several critical geological discoveries necessary for interpreting the Permian-Triassic tectonic evolution have been reported on the Korean Peninsula. The followings were reported as direct evidence of the continental collision. 1) The Permo-Triassic eclogite in the Hongseong area, 2) the extensive occurrences of Triassic post-collisional igneous rocks in the northern Gyeonggi Massif (GM), Imjingang Belt, and southern boundary of the Nangrim Massif which locate north of the Hongseong-Odaesan Belt, and 3) the Permo-Triassic intermediate-P/T metamorphism in the Imjingang and Okcheon Belts and the GM associated with the strongest Permo-Triassic metamorphism along the E-W trending Hongseong-Yanpyeong-Odaesan Belt locating in the middle part of the GM. Other indirect evidence for the collision were reported as follows. The Imjingang Belt was confirmed to form as the backarc basin at Devonian, and Devonian sedimentary rocks were also found in the other parts of the GM. The Honam Shear Zone was confirmed to be initiated from the early Jurassic, indicating that it can not be matched to the Tanlu Fault. These date indicate that the Qinling-Dabie-Sulu Collision Belt between the North China Craton (NCC) and South China Craton (SCC) extends not into the Imjingang Belt but into the Hongseong-Odaesan Belt within the Korean Peninsula. This tectonic interpretation is also supported by the followings. The northern and southern parts of the Gyeonggi Massif (NGM and SGM), separated by the Hongseong-Odaesan Belt, experienced different tectonic evolution during the Paleoproterozoic and Neoproterozoic. Furthermore, the Neoproterozoic igneous rocks in the NGM and SGM correlated well with those in the NCC and SCC. There is a systematic change of metamorphic age and P-T conditions along the Qinling-Dabie-Sulu-Hongseong-Odaesan Collision Belt. The Hongseong-Odeasan Belt extends into the inner part of southwest Japan and then into the Dumangang Belt in the northeast Korean Peninsula, formed by the collision between the NCC and the Khangka-Jiamusi Block. During the collision between the North Korea-China Craton

(NKC) and the South Korea-China Craton (SKC), the transition from the passive to active margin occurred with the initiation of subduction along the southern margin of the SKC from late Permian. These interpretations and data are most consistent with the tectonic model suggested by Oh and Kusky (Oh, C.W., and Kusky, T.M., 2007, The Late Permian to Triassic Hongseong–Odesan collision belt in South Korea, and its tectonic correlation with China and Japan. International Geolology Review, v. 49, pp. 639–657).

Tectonic and metallogenic evolution of the North China (Sino-Korean) Craton and the connection to the East Asian Continent

Mingguo ZHAI[1]*, Institute of geology and geophysics, Chinese Academy of Science (mgzhai@mail.iggcas.ac.cn)
Ligang ZHOU[2], Institute of geology and geophysics, Chinese Academy of Science
Yanbin ZHANG[3], Institute of geology and geophysics, Chinese Academy of Science

Abstract

Ancient rocks with ages of >4.0-3.8 Ga have been determined in the North China (Sino-Korean) Craton. The diversity of magmatic and sedimentary rocks older than 3.3-3.0 Ga indicates that there were several independent ancient continental nuclei in the North China Craton (NCC). The NCC experienced large-scale growth of continental crust in 2.7-2.5 Ga and then extensively reconstructed during 2.55-2.42 Ga, ultimately forming a stable ancient continent block. The main mineral deposits are BIFs in the Archean, with a small amount of Cu-Zn sulfide massive deposits at the end of Neoarchean.

During 2.35 to 2.20 Ga, the magmatic rock assemblages in the NCC indicate the occurrence of a rift event derived by uplifted mantle during the Paleoproterozoic “quiescence”. Subsequently, subduction-collision orogeny occurred at 2.0-1.8 Ga, characterized by the appearance of a wide HTHP-HTUHT metamorphic belt, indicating the involvement of the NCC into the process of the Colombian Supercontinent. During 1.80-0.7 Ga in the Meso-Neoproterozoic, multiple extension-rifting-drifting events occurred in the NCC, with geological records of red beds, black shales, biogenic carbonates and tillite. The main minerals in this period are sulfide Pb-Cu deposits, Fe-Mg (magnesite) - B-P sedimentary deposits, and graphite deposits.

In the Paleozoic era, the NCC entered the stage of platform evolution, with the absence of strata from middle Ordovician to middle Carboniferous and with the development of coal-bearing deposits during upper Carboniferous to Jurassic. In the late Paleozoic era, strong orogeny occurred both in southern and northern margins of the NCC, leading to the convergence of the NCC with the Siberian Block, South China Block, and Tarim ancient Block, forming the basic outline of the East Asian continent. Orogenic Cu-Mo deposits were developed in the southern and northern margins of the NCC.

During the Mesozoic, the NCC was compressed by the ancient Pacific Plate and surrounding blocks, resulting in large-scale lithospheric thinning with a peak period of 130-120 Ma. In addition to the strong crustal activation, it was also marked by the large-scale gold mineralization within the continent.

As a consequence, the structural and mineralization evolution of the NCC substantially reveal the basic laws of the Earth's continental crust and material evolution.

Early to Late Mesozoic Tectonic Evolution and Associated REE Mineralization in Southern Mongolia: A Comparative Study of the Mushgai-Khudag and Lugiin Gol REE Deposits

Otgon-Erdene DAVAASUREN[1]*, Critical Minerals Research Center, Korea Institute of Geoscience and Mineral Resources (geotec13@kigam.re.kr)
Bum Han Lee[2], Critical Minerals Research Center, Korea Institute of Geoscience and Mineral Resources
Sang-Mo Koh[3], Critical Minerals Research Center, Korea Institute of Geoscience and Mineral Resources
Namhoon Kim[4], Research Institute for Earth Resources, Kangwon National University
Chul-Ho Heo[5], Critical Minerals Research Center, Korea Institute of Geoscience and Mineral Resources

Abstract

The alkaline province in Southern Mongolia represents one of the most economically significant belts of rare-earth elements (REE) mineralization in Mongolia, featuring notable deposits such as Mushgai-Khudag and Lugiin Gol. The REE mineralization in these deposits is spatially and temporally associated with the carbonatite type. This study compares the REE mineralization characteristics of the Mushgai-Khudag and Lugiin Gol deposits. The Mushgai-Khudag carbonatite-alkaline complex is composed of sheet-like magnetite-apatite ore bodies along the contact of Jurassic syenite porphyry and the host Paleozoic sedimentary rocks. In contrast, Lugiin Gol is characterized by nepheline syenite host rocks and carbonatite dikes intruding Permian sedimentary formations. The REE ore bodies in the Mushgai-Khudag deposit are hosted by carbonatites and syenite. Major REE minerals in the Mushgai-Khudag deposit are monazite and parisite, while Lugiin Gol carbonatites comprise bastnäsite, monazite, and parisite. Considering chondrite normalized REE patterns, they exhibit similar characteristics, showing enrichment of light REE relative to heavy REE with small negative Eu anomalies. Rb-Sr results indicate that the syenite in the Lugiin Gol deposit was emplaced in the early Triassic, representing the oldest known age. On the other hand, SHRIMP dating of the carbonatite and syenite in Mushgai-Khudag suggests they were formed during the early Cretaceous, making this the youngest known alkaline carbonatite complex in southern Mongolia. Geochemical data suggest that the Mushgai-Khudag deposit originates from a lithospheric mantle source and formed in a within-plate tectonic setting associated with an extensional rift zone, consistent with the characteristics of the Lugiin Gol deposit. The emplacement ages of the studied rocks in the Mushgai-Khudag and Lugiin Gol deposits exhibit similarities to those associated with late Mesozoic alkaline–carbonatite magmatism within the Central Asian Orogenic Belt (CAOB). Specifically, these ages align with the early to late Mesozoic southern Mongolian alkaline province, which spans from 244 to 139 Ma. These rocks are also linked to alkaline magmatism involving carbonatites, implying a temporal relationship with late Mesozoic global plume activity.

Sota MUROI[5], Hiroshima University
Kosuke KIMURA[6], Osaka Metropolitan University

Abstract

The "Proto-Japan" has been formed along the continental margin of Northeast Asia since the earliest Paleozoic. Recent studies have revealed that part of the "Proto-Japan" was located between the southeastern and northeastern parts of the Korean Peninsula during the Triassic to Jurassic (Kawaguchi et al., 2023a, b). However, the tectonic correlation before the Triassic is highly uncertain because of the scarce occurrence of the Paleozoic rock units in the Japanese Islands. The Maizuru Belt (MB), Southwest Japan hosts the Paleozoic plutonic rocks and can be used as a key marker to track the origin of the Paleozoic Proto-Japan. The MB is known as an island arc-back arc basin system comprising of the ophiolite with ~295–275 Ma island arc magmatism (Southern Zone) and back-arc basin formation with Permian sedimentary rocks deposited on it (Central Zone) followed by the closure of the back-arc basin, resulted in the collision of Southern and Central Zones with some unknown areas of the Northeast Asian continent (Northern Zone) (Suda et al., 2004; Mavoungou et al., 2022). In the previous studies, the Northern Zone of the MB (N-MB) is suggested to have derived from the Khanka Massif based on the commonalities of the igneous activities including Siluro–Devonian and Permo–Triassic periods (e.g., Fujii et al., 2008). In this study, we report new zircon U–Pb ages and Lu–Hf isotopes from the Paleozoic granitoids in the N-MB to reveal the crustal evolution along with further detailed tectonic correlation. Weighted mean zircon U–Pb ages of the granitoids in the N-MB can be grouped into three periods: Ordovician (463.8 ± 9.7 Ma, 453.3 ± 4.0 Ma, and 447.2 ± 3.4 Ma), Late Carboniferous (310.6 ± 5.4 Ma and 300.6 ± 2.9 Ma), and Early Permian (288.7 ± 2.4 Ma, 283.6 ± 2.6 Ma, and 280.5 ± 3.0 Ma). εHf(t) values of zircon from the Ordovician and Late Carboniferous groups are slightly positive (+0.95 to +3.05 and +0.22 to + 1.71, respectively), whereas those of the Early Permian group are mostly highly positive (+4.40 to +12.22). Granitoids of the Ordovician and Late Carboniferous groups contain ~950 Ma to ~650 Ma inherited zircon constituting up to ~35% of the analytical spots, suggesting significant input of ~950–650 Ma crustal material during the magmatism. Collating all the analytical results, granitic crusts of the N-MB were formed by the melting of Precambrian crust dominantly of Neoproterozoic ages during the Ordovician and Late Carboniferous forming ~465–445 Ma and ~310–300 Ma granitoids, whereas the input of the juvenile source such as the lithospheric mantle increased during the Early Permian, that had formed the ~290–280 Ma granitoids. Timing of magmatism and evolutional

trend of the Lu–Hf isotopes of zircon of the N-MB are consistent with those of the Khanka-Jiamusi Massif (e.g., Zhang et al., 2018) indicating the common evolutional history between them during the Paleozoic.

Late Tonian (ca. 780–750 Ma) bimodal magmatism in the Ogcheon Metamorphic Belt, Korea, at the eastern margin of North China Craton

Wonseok Cheong[1], Chungbuk National University
Moonsup Cho[2]*, Seoul National University (moonsup@snu.ac.kr)

Abstract

Neoproterozoic rift-related rocks of the North China Craton (NCC), including the Korean Peninsula, provide crucial information for global supercontinent reconstruction during the Rodinia breakup and Gondwana assembly. Here, we report not only zircon and baddeleyite U-Pb ages but also zircon Hf isotopic and bulk rock compositions of amphibolites in the Ogcheon Metamorphic Belt (OMB), Korea. Zircon occurs as either primary phase or secondary one replacing igneous baddeleyite. Primary zircons analyzed from three amphibolites yielded the weighted mean 206Pb/238U ages of 755 ± 5 Ma (n = 19), 772 ± 3 Ma (n = 9), and 779 ± 13 Ma (n = 12), respectively; this result is corroborated by the baddeleyite age of ~760–745 Ma. Secondary zircons define discordia lines with lower intercepts corresponding to the Jurassic or Cretaceous age of granites emplaced adjacent to the amphibolite. In conjunction with the occurrence of coeval (ca. 762–745 Ma) metatrachytes, our result suggests that late Tonian bimodal magmatism has lasted for ~30 m.yr. in the OMB. Moreover, positive εHf(t) values (4.9–21.4) of zircon in amphibolites indicate a depleted mantle source of mafic magma, whereas trace element compositions attest to an intraplate setting for the crystallization. A compilation of Nb–Th and Zr–Zr/Y data suggests that the intraplate setting is also pertinent to ca. 950–750 Ma mafic rocks from the Gyeonggi Marginal Belt, Korea, as well as the NCC. Such a tectonomagmatic correlation is corroborated by detrital zircon age spectra of metasedimentary rocks in the OMB equivalent to those of early Tonian rocks in the NCC. In marked contrast to tectonic scenarios conjecturing a linkage between the OMB and the Nanhua rift, South China Craton, we conclude that the Ogcheon Belt provides rare geologic-geochronologic evidence for late Tonian breakup of the Rodinia supercontinent at the eastern NCC margin.

Petrogenesis of the circum-cratonic Triassic syenite province from the North China

Xu LIU[1]*, Institute of Geology and Geophysics, Chinese Academy of Sciences (liuxu@mail.iggcas.ac.cn)
Peng Peng[2], Institute of Geology and Geophysics, Chinese Academy of Sciences
Ross Nelson Mitchell[3], Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

Syenite and its relevant varieties are typically derived from the most metasomatized portions of the subcontinental lithospheric mantle (SCLM). Subduction-related metasomatism is identified as a key process in the replenishment of the SCLM. In return, volatile-rich syenite may provide an important link between such a deep carbon reservoir and its potential release into the atmosphere. There are multiple atmospheric CO2 pulses during the Late Triassic when the Late Triassic belt around North China craton—the only circum-cratonic syenite province in the world—was intruded. This time and this unique circum-cratonic syenite belt thus offer an opportunity to investigate the petrogenesis of extensive alkaline magmatism and its potential environmental effects. New and previous data consisting of whole-rock Sr–Nd and zircon in situ Hf–O isotopes of the syenite province indicate two distinct types of metasomatism characterized by an alteration of juvenile or ancient materials. The spatiotemporally distinct sources can be discriminated by melts from oceanic slabs subducting beneath much of the North China craton followed by deep subduction of the South China craton only to the south. The sodic intrusions, originated from metasomatization of oceanic slab, exhibit potential Nb-Zr-REE mineralization, which appear to be strongly related to hydrothermal metasomatism by halogen-CO2-rich fluid. The loss of residual fluids may thereby get released as volatiles into the atmosphere. According to our first-order calculation presented here, such craton-scale alkaline magmatism can cause significant CO2-release. Thus, multiple subduction systems surrounding North China in the Late Triassic collectively gave rise to SCLM heterogeneity, post-collisional extension inducing craton-scale alkaline magmatism, and ultimately the release of SCLM-derived carbon into the atmosphere, causing or at least contributing to the global environmental changes of the age.

Origin and evolution of the Maizuru Belt, Southwest Japan: Implications for the crustal rearrangement tectonics along the Northeast Asian continental margin

Yasutaka HAYASAKA[1], Hiroshima University
Masahiro FUJII[2], OYO Corporation
Kosuke KIMURA[3], Osaka Metropolitan University
Kenta KAWAGUCHI[4]*, Hiroshima University (kentakawaguchi2@gmail.com)

Abstract

The Maizuru Belt (MB), Southwest Japan is a Permian island arc-back arc basin system including the exotic blocks ranging from the Archean to Paleozoic. The MB comprising of the ophiolite with ~295–275 Ma island arc magmatism (Southern Zone) and back-arc basin formation with Permian sedimentary rocks deposited on it (Central Zone) followed by the closure of the back-arc basin, resulted in the collision of Southern and Central Zones with the Northeast Asian continent (Northern Zone) (Suda et al., 2014; Mavoungou et al., 2022). The occurrence of ~2.7–2.5 Ga and ~1.90–1.83 Ga magmatic-metamorphic rocks on the western most part of the Northern Zone of the MB (N-MB) indicates their origin as the North China Craton (NCC) (Kimura et al., 2019, 2021). Whereas the coexistence of Early Paleozoic and Permian granitoids on the eastern side of the N-MB shows their commonality with the Khanka-Jiamusi Massifs (KJM) (Fujii et al., 2008; Tsutsumi et al., 2014). These contrasting tectonic correlations can be testified by the detrital zircon U–Pb age dating of the Central Zone of the MB (C-MB). Detrital zircon U–Pb ages of the Middle to Late Permian formations throughout the C-MB mostly show prominent single peak at ~270–260 Ma with minor populations at ~500–400 Ma with very minor Precambrian zircons (Type 1). Whereas those of the Triassic formations in the C-MB show two different types depend on the location; the western half shows the two major peaks at ~250 Ma and ~1.95–1.85 Ga with subordinate ~2.5–1.9 Ga zircons (Type 2), whereas the eastern half has two prominent peaks at ~280–250 Ma and ~500–440 Ma with minor populations of Neoproterozoic (Type 3). The spatial-temporal distribution of three types indicates the change of the provenances from the Permian to Triassic as follows. 1) During the Middle to Late Permian, whole MB was located along the eastern margin of the KJM where the Permian magmatism were active with subordinate ~500–400 Ma igneous-metamorphic activities with minor Precambrian crusts to have formed the type 1 sedimentary rocks. 2) During the Triassic, the hinterlands of the Triassic formations of the eastern side of the C-MB were the KJM, same as the Permian period (deposition of type 3), whereas those of the western side have been changed to the NCC based on the commonalities of the major thermal episodes of the NCC and the detrital zircon age patterns of the Type 2. These drastic changes in their provenance suggest that the MB was formed along the KJM during the Permian and moved toward the south during the Triassic to have juxtaposed the western half of the MB to the NCC. The ~2.7–2.5 and ~1.90–1.83 Ga igneous-metamorphic rocks in the western most part of the N-MB are the exotic blocks derived from the NCC during the Triassic dextral strike-slip

movement. Considering the present configuration, the MB has been moved ~500 km towered the south as a dextral strike-slip movement along the eastern margin of the Northeast Asia.

Paleozoic tectonic evolution of the Guryong Group from detrital zircon records: Implications for the tectonic affinity of the eastern Gyeonggi Massif, Korean Peninsula

Ji Wan JEONG[1]*, Kyushu University (jiwan314@naver.com)
Nobuhiko Nakano[2], Kyushu University
Tatsuro Adachi[3], Kyushu University
Kenta Kawaguchi[4], Kyushu University

Abstract

The Permo–Triassic Qinling-Dabie-Sulu collision belt between the North China Craton (NCC) and South China Craton (SCC) in China is suggested to be continued to the Hongseong area of the western Gyeonggi Massif (GM) in the Korean Peninsula based on the report of the eclogite facies metamorphism (Oh et al., 2005). Moreover, Oh et al. (2006) reported that the collision belt extends to the Odesan area, located at the eastern GM based on the presence of UHT metamorphism. However, the Hongseong-Odesan collision model is still under argument and more study is needed to confirm this model. The Odesan area is mainly composed of the Paleoproterozoic paragneisses, with minor Mesoproterozoic to Paleozoic units, Paleozoic Guryong Group (GG), and the Triassic plutons (Yi et al., 2016). The Paleoproterozoic paragneisses underwent Paleoproterozoic and Permo–Triassic collision-related metamorphism leading to the difficulty to evaluate the Permo–Triassic metamorphism. However, metasedimentary rock in the GG is reported to have been deposited during the Late Paleozoic (Cho et al., 2014), indicating that the GG has the potential to evaluate the timing and nature of the Permo–Triassic metamorphism along with the tectonic affinity of the GG. In this study, LA-ICP-MS zircon U-Pb age dating was performed for the metasedimentary rocks in the GG. Major peak ages and their population (%) of the detrital zircon grains from two garnet-bearing metasedimentary rocks in the southwestern GG are ~760 Ma (population; 8%), ~370 Ma (14%), 350 Ma (17%), and ~330 Ma (19%) with the youngest detrital zircon age of ~311 Ma. The detrital zircon age peaks of combining Crd-Bt-Ms gneiss and quartzite layer are ~1840 Ma (5%), ~950 Ma (9%), ~410 Ma (10%), ~390 Ma (9%), ~370 Ma (15%), and ~350 Ma (17%) with the youngest detrital zircon age of ~325 Ma, and those of three Crd-Bt-Ms gneisses are ~1830 Ma (4%), ~1160 Ma (3%), ~940 Ma (2%), ~410 Ma (8%), ~390 Ma (11%), ~370 Ma (11%), ~350 Ma (24%), and ~330 Ma (10%) with the youngest detrital zircon age of ~293 Ma. In contrast, the calc-silicate rock in eastern GG shows a different detrital zircon age pattern range between 2501 Ma and 648 Ma, with the age peaks of ~1850 Ma (16%), ~1540 Ma (12%), ~1150 Ma (12%), ~750 Ma (16%), and other two Bt gneisses show age range between 3570 Ma and 2062 Ma, with age peak of ~3290 Ma (6%), ~2640 Ma (9%), ~2590 Ma (11%), and ~2450 Ma (30%) without any Paleozoic concordant detrital zircons. Our results suggest that parts of the GG were deposited during the Paleoproterozoic similar to the paragneiss in the GM. However, the Carboniferous–Permian deposition ages have been newly identified from paragneisses in the GG.

The Carboniferous magmatism has not been reported yet, however, the Carboniferous magmatism played an important role in supplying the detrital zircon grains to the sedimentary basin during the Carboniferous–Permian. This magmatism may represent the subduction-related arc igneous activities formed along the southern margin of the NCC before the collision between NCC and SCC.

Early Paleoproterozoic magmatism in the southern Trans-North China Orogen

Xiaoping LONG[1]*, Northwest University (longxp@nwu.edu.cn)
Jingyu WANG[2], Northwest University

Abstract

Magmatic rocks in the North China Craton (NCC) are crucial to unraveling the tectonic background during the tectono-magmatic lull (TML, 2.45–2.20 Ga) and to constraining the initiation of plate tectonics. In this study, previously published zircon U–Pb–Hf–O data and whole-rock geochemistry are collected from the early Paleoproterozoic felsic intrusive rocks in the southern Trans-North China Orogen (TNCO) and new data presented. The formation ages and petrogenesis of the early Paleoproterozoic felsic intrusive rocks in the southern TNCO are summarized to constrain the tectonic setting during the TML. Zircon U-Pb geochronology of the tonalite–trondhjemite–granodiorite (TTG) gneisses yielded intrusive ages of ~2.3 Ga and ~2.2 Ga. Geochemically, the gneisses can be classified as ~2.3 Ga high-Al and ~2.2 Ga low-Al types, and were likely derived from the partial melting of pre-existing lower crust at medium and low pressure, respectively. The heavy rare earth depletion and have high Sr/Y and La/Yb values of the ~2.3 Ga TTG gneisses indicates that they were derived from the partial melting of thickening lower crust in the garnet-hornblende phase, which is consistent with a gradual thickening of the crust. The potassic granitoids are geochemically divided into I-type and A-type granites and have early Paleoproterozoic ages at ~2.3 Ga and ~2.27 Ga. Zircon U-Pb geochronology of the dioritic gneisses yielded intrusive ages of ~2.3 Ga. These potassic granitoids and dioritic gneisses were generated by the partial melting of ancient basement rocks, with variable degrees of juvenile contributions. Considering the large variety of zircon εHf(t) values, and Sr/Y and (La/Yb)N ratios obtained for the early Paleoproterozoic felsic intrusive rocks, the crustal thickening that occurred via tectonic compression prior to ~2.3 Ga is most likely due to convergence. The high δ18O and low δ18O values in the southern TNCO may have been the result of slab subduction, which can effectively transfer surface material directly or indirectly to the lower crust, and the TTGs that formed as a result of the subsequent partial melting inherited the high δ18O characteristics to varying degrees. Glacial meltwater is an important source of low δ18O fluids and a large number of rift events developed during the 2.5–2.4 Ga interval. The resulting fractured environment provided sufficient space for the infiltration of surface water, and rocks with low δ18O characteristics are likely produced by the remelting of crustal rocks that have been thermally altered by surface water or atmospheric hydrothermal processes. Combined with evidence such as the Paleoproterozoic Alaska-type intrusive rocks, diabases, sanukitoids and sedimentary rocks, the TNCO is proposed to have been in a subduction compression setting at ~2.3 Ga. Meanwhile, the alkaline and related elements (such as Rb, Th, Ba and Nb), K2O/Na2O ratios, and zircon δ18O values of the magmatic rocks increased significantly during the TML, which indicate that plate subduction started prior to ~2.3 Ga. The difference in the intensity of the magmatism during the TML may be related to continental freeboards in different regions.

Ages, Geochemical Characteristics and Tectonic Environment of Mesozoic Diorites in the Central Sulu Orogenic Belt

Shikuo LU[1]*, China University of Petroleum (809924204@qq.com)
Tingyue LI[2], China National Petroleum Corporation Zhejiang Oilfield Branch

Abstract

Aside from a large volumes of granites, the Mesozoic diorites, named as Liulinzhuang superunit, are also widely distributed within the Sulu orogenic belt. However, there are some controversies and disagreements on their intrusive age and genetic mechanism. This research focuses on the Mesozoic diorites distributed in the Langya area in the central part of the Sulu orogenic belt. Firstly, the intrusive age of the diorites is determined based on the zircon U-Pb dating. Then, the petrographic and geochemical characteristics of the diorites are analyzed by microscopic observation and major and trace element testing techniques, respectively. Additionally, their magma sources and genetic mechanism are discussed. The results show that the intrusion of the diorites developed during the early Cretaceous at about 119.9-124.7Ma, different from the previous understanding that they were formed in the late Triassic, suggesting that this period of intrusive rock masses were not direct products of the Triassic tectonic movement of the Sulu orogenic belt. The major element data reveals that the diorites of the Liulinzhuang superunit in Langya area are high-magnesium, alkali-calcic, metaluminous syenodiorites. The Harker diagrams and petrographic characteristics indicate that H2O was involved in the magma crystallization process. The absence of obvious Eu negative anomaly in the REE distribution patterns shows that the magmatic differentiation process was not significant during the magma evolution. The high Mg# (average value ≥58), high Cr and Ni contents and the rare earth and trace element distribution patterns of the diorites illustrate that the magma source of this suite of rock masses was an enriched lithospheric mantle. It is inferred that the enriched mantle was mainly caused by the dehydration (or melting) of the South China plate during its subduction to the North China plate in the Indosinian period and the resulting metasomatism of the overlying lithospheric mantle wedge. Summarilly, this suite of intrusive rock masses formed in a post-orogenic environment in the Cretaceous period. The magma source is deduced to be a metasomatized enriched lithospheric mantle formed during the Late Triassic continental subduction process. However, the source melting occurred in the Early Cretaceous period, which may be related to the collapse of the orogenic belt or lithospheric mantle delamination of the Sulu orogenic belt caused by the change of the tectonic movement direction or rate of the Paleo-Pacific plate.

Cretaceous two stage extensional tectonics in Northeast Asia and its geodynamics

Wei LIN[1]*, State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences (linwei@mail.iggcas.ac.cn)
Wei Wei[2], State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

The Cretaceous tectonics of the North China Craton (NCC) and its adjacent regions were characterized by a general lithospheric extension and remarked by extensional dome structures. This makes one of the largest crustal scale extensional tectonic realm in the world. Based on our field and laboratory work, five extensional domains have been delineated, namely the Transbaikalia-Mongol-Okhotsk, the western part of NCC, the eastern part of NCC and Korea, Qinling-Dabie and its neighboring, and the interior of South China Block, respectively. These domains are featured by a NW-SE extensional direction with intensively extensional exhumation of middle to lower crust rocks to the surface along detachment faults. Two-stage extension tectonics have been suggested, which took place at ca. 130~120 Ma and ca. 118~85 Ma. The early stage constrains a narrow activity period, and the foundering of the lower part of the lithosphere could be a possible mechanism for this continent-scale extensional tectonics. This geodynamic model could help us to enhance the knowledge of the time, scale, and mechanism of the NCC destruction from the view of structural analysis. The timing of late-stage extensional tectonics is suggested by a younger trending from the northeast (Liaodong peninsula) to the southwest (Yuechengling massif in SW Hunan province). The slab roll-back of westward subducted ‘Palaeo-Pacific’ or Izanagi plate may lead to this regional extension event.

Triassic tectonic response of overriding North China block to the South China block continental deep subduction

Lingtong MENG[1]*, State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences (tone18@mail.iggcas.ac.cn)
Wei Lin[2], State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences
Zhiheng Ren[3], Xinjiang Institute of Ecology and Geography, Chinese Academy of Sciences

Abstract

During the Triassic, the South China block deeply subducted beneath the North China block, forming the Dabie-Sulu orogenic belt; the discovery of coesite and diamond indicates that low-density continental crust can subduct to mantle depths exceeding 200 km. Several studies focused on the formation and exhumation of high- to ultra-high-pressure metamorphic rocks. However, the Dabie-Sulu orogenic belt mainly records the tectonic event that is responsible for the exhumation of ultra-high pressure (UHP) rocks, in which the syn-convergence deformations were reworked by exhumation-related tectonics. Tracing the deformation events developed in the overriding plate, which are less affected by exhumation tectonics, may be an alternative and effective approach to investigating the syn-convergence processes. Furthermore, correlating the behavior of subducted and overriding plates is key to understanding the collisional orogenic belt evolution.

This work focuses on the deformations of the overriding North China block, carries out the structural analysis, and combines previous results, to understand the tectonic evolution of collision between the South China block and the North China block. Our study shows that the North China block (overriding plate) experienced Triassic NE-SW contractional tectonics, as the tectonic response to the South China subduction. The first contractional structure is characterized by Early-Middle Triassic top-to-the-NE ductile shearing and NE-directed folding and thrusting. From south to north, the ductile deformation evolves to the brittle-ductile one, and it seems that the deformation timing becomes younger. The second contractional structure is manifested by Late Triassic top-to-the-SW ductile shearing and SW-directed back-thrusting. Combined with the tectonics events developed in the Sulu orogenic belt, our new structural results allow us to build a three-stage evolution model for the continental collision between the South China block and the North China block. Our model also highlights that the flat-slab subduction of the South China block may account for the large-scale contractional tectonics developed in the overriding North China block.

lithofacies paleogeography of the Upper Cambrian-Lower Ordovician in Jiyang Sub-basin of North China Plate: An evolution driven by Huaiyuan movement, climate and see-level

Hao GUO[1]*, China University of Petroleum (East China) (794782283@qq.com)
Yanzhong Wang[2], China University of Petroleum (East China)
Yingchang Cao[3], China University of Petroleum (East China)
Chenglong Liu[4], China University of Petroleum (East China)

Abstract

Jiyang Sub-basin is a Meso-Cenozoic rifted basin superimposed on the middle of North China Craton and has an area of about 2.55×104 km2. The Huaiyuan movement is the movement of the Shangdan Ocean subduction to the North China Craton during the sedimentary period of the Zhangxia Formation in the Cambrian. The Huaiyuan movement made the Jiyang sub-basin form a pattern of high in the south and low in the north. The lithofacies paleogeography of the Late Cambian-Early Ordovician in Jiyang Sub-basin and its response to tectonic activity are studied by means of analysis of previous results, well logging data, seismic data, core data, thin section observation, geochemical test, considering the paleoenvironment, sedimentary facies markers, sedimentary facies types, sedimentary facies division of single well and cross-well profile. During the Late Cambrian-Early Ordovician, the Jiyang Sub-basin was located in the southern Hemisphere as a whole, with a latitude between 20° S-10° N and a warm and humid climate. Three types of sedimentary environment of open platform, restricted platform and evaporative platform were developed. During the depositional period of Changshan Formation of Upper Cambrian, the water body in Jiyang Sub-basin was deep and the depositional environment was mainly limited platform. During the early sedimentary period of the upper Cambrian Fengshan Formation, the Jiyang Sub-basin began to be affected by the Huaiyuan movement, and the southern area was uplifted and large-scale regression occurred. In the southwest of the Jiyang Sub-basin, the rock types were mainly crystalline dolostone and granular dolostone, and the evaporative platform developed. In the north, the crystalline limestone content gradually increased, and in the northeast of the Jiyang Sub-basin, the limited platform developed. In the middle and late sedimentary period of Fengshan Formation, Huaiyuan movement stopped temporarily and large-scale transgression occurred in Jiyang Sub-basin, the strata of middle and late sedimentary period of Fengshan Formation was mainly composed of crystalline limestone and granular limestone, with limited platform in the south of Jiyang Sub-basin and open platform in the north of Jiyang Sub-basin. During the depositional period of the Lower Ordovician Yeli Formation, the Huaiyuan movement was re-opened, and the southern area was uplifted to form an ancient land mass. The basement of Jiyang Sub-basin was high in the south and low in the north. The Yeli Formation as a whole was dominated by crystalline dolostone and granular dolostone, and the sedimentary environment were evaporative platform, with only a few limited platform and granular beach in the northern area. During the sedimentary period of the Lower Ordovician

Liangjiashan Formation, the Huaiyuan movement basically ended. Under the influence of small scale transgression, the development range of evaporative platform shrank to the south. The influence of Huai-Yuan movement on Jiyang Sub-basin lasted until the depositional period of Liangjiashan Formation, it can be inferred that the collision of Shangdan Ocean and North China Craton basically ended in the depositional period of the Liangjiashan Formation.

Abstract

The oldest known continental crustal materials that one could find—the Hadean to Eoarchean rocks—would provide the most direct constraints on the nature of the first crust on Earth and the magmatic process that formed it, which is of great significance for understanding the physical and chemical properties of our planet's early stage. At present, major Hadean to Eoarchean crustal blocks have only been identified in less than ten areas worldwide such as the Acasta Gneiss Complex and the Nuvvuagittuq Greenstone Belt. Limited by the scale of the rarely preserved early Archean rocks, major controversies exist on the tectonic models explaining the origin of the continental crust in the early Earth. Therefore, discovery and identification of new Eoarchean or even Hadean crustal exposures would provide new research opportunity, and will be the key for improving our understanding of the formation and evolution of early continental crust and its geodynamic driver in the early Earth.

Here, we report the new identification Eoarchean tonalitic gneisses in the Muzidian Gneiss Complex (MGC) of the northern Yangtze Craton. Zircon SHRIMP U-Pb dating of them yields ages of 3855±7 Ma and 3851±6 Ma. These granitic rocks may represent continental nuclei remnant in the Yangtze Craton, South China, and have been the oldest preserved rocks so far in Eurasia. Zircon Hf isotopic compositions indicate that the MGC gneisses were formed from remelting of pre-existing Hadean crust, suggesting early mantle differentiation and crust extraction before 4.1 Ga. These newly recognized rocks in the MGC mark an important, Hadean-crustal-derived, ancient gneiss complex, which is isotopically comparable to the Acasta Gneiss Complex in the currently established global Eoarchean geological record. Our findings provide new insights into the nature and origin of the first continental crust on the Earth and highlight the MGC as a unique natural laboratory for further exploration.

Abstract

The Tanlu fault is the largest fault in Northeast Asian and one of the largest in the world. The mechanism of its strike-slip movement has been controversial since its discovery in the 1950s. The very uncertainty lies in its timing of initiation and displacement nature of offset. It is recently proposed that the Tanlu fault was resulted from a ~16° clockwise intracratonic rotation along the fault, which has caused an offset of ~450 km within the North China craton and about half the distances in the Central Orogenic belt (Peng et al., 2022 Terra Nova 34: 381–394). This model is mainly proposed based on geology (distribution and geometry of basement, rifts/basins, large igneous provinces, plutonic suites, kimberlite/diamond fields, etc.), and is tested by paleomagnetic data. The earliest displacement was most likely happened during the collision of the North and South China cratons at the Middle Triassic – Early Jurassic. It has several implications in depicting the geological evolution of Northeast Asia, 1) shape and tectonic framework of the North China craton prior to its largest offset, as well as its configuration in historical supercontinents; 2) correlation of terranes, structural units, and mineral resources between regions west and east to the fault in Northeast Asia; 3) the effects of the fault in the forming of tectonic framework of Northeast Asia; and 4) potential roles of the fault in the Mesozoic mineralization.

Oceanic isolation of the Paleo-Tethys from the Panthalassa in the leadup to the Permian mass extinction: Consistent evidence from metamorphism in East Eurasia

lei Zhao[1]*, Institute of Geology and Geophysics, Chinese Academy of Sciences (zhaolei@mail.iggcas.ac.cn)
hu Tang[2], Institute of Geology and Geophysics, Chinese Academy of Sciences
Ross N. Mitchell[3], Institute of Geology and Geophysics, Chinese Academy of Sciences
Qiuli Li[4], Institute of Geology and Geophysics, Chinese Academy of Sciences
Mingguo Zhai[5], Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

The end-Permian mass extinction is the most devastating event in the history of the Phanerozoic biosphere and many of its paleontological records come from the Paleo-Tethys tectonic realm. Unlike the euxinic Paleo-Tethys Ocean, the much larger Panthalassa (aka paleo-Pacific) Ocean remained largely ventilated and provided potential refugia for marine taxa during the mass extinction. Distinctions exhibited by these two once-connected oceans imply that interactions between them must have been restricted and these two water bodies may have become isolated from each other shortly before the end-Permian extinction. However, detailed geological processes for the final disconnection of these two oceans, mainly due to the collision of North China and South China, is yet to be convincingly delineated. Previous geochronological studies on eclogite facies rocks in the Dabie–Sulu orogenic belt, which are the metamorphic products of the collision between North and South China, have yielded mainly Triassic metamorphic ages postdating the Permian. Nonetheless, a Permo–Triassic intracontinental orogen that developed in South China as a far-field effect of Dabie–Sulu-related stress may more closely associate this major tectonic event with the end-Permian extinction. New age dating, as well as a synthesis of recent studies on high-grade metamorphic rocks within the South China intracontinental orogen show that the onset of collisional orogenesis dates back to the Middle Permian (270–260 Ma), which is also consistent with the new geochronological results acquired on low-grade metamorphic rocks along the northern margin of the Dabie orogenic belt. We thereby provide a new tectonic model for the major continents of East Asia and their latest Paleozoic kinematics in the configuration of Pangea. Specifically, the initial collision between North and South China inferred here to have occurred during the Middle Permian should have isolated the Paleo-Tethys Ocean from the Panthalassa Ocean, facilitating the oceanographic transition of the critical Paleo-Tethys from a life-giving nutrient-rich ocean into a euxinic death trap and thereby serving as prelude to the end-Permian extinction.

Petrogenesis and structural analysis of pillow-like metabasalt rocks in Shangying in North China Craton defines Neoarchean fore-arc ophiolitic mélange in accretional wedge

Zhiyuan CHEN[1]*, China University of Geosciences (Wuhan) (jamiechen@cug.edu.cn)
Timothy Michael Kusky[2], China University of Geosciences (Wuhan)
Lu Wang[3], China University of Geosciences (Wuhan)

Abstract

Ophiolitic mélange is one of the important hallmarks of identifying the boundaries of ancient convergent plates or accretionary terranes, recording the important geological information of the process of plate convergence. The North China Craton (NCC) is the largest craton in Northeast Asia and has experienced a protracted evolution since the Eoarchean. However, there are still many controversies about the evolution process and tectonic background of the Eastern Hebei complex. Here, we describe aspects of the Archean Shangying ophiolitic mélange in the Eastern Hebei complex, based on detailed field mapping and structural analysis of the mélange belt. We report zircon U-Pb geochronological, geochemical, and petrological analyses on the mafic blocks within the mélange. The study can provide insights into the tectonic evolution of the Eastern Hebei complex and the North China Craton at the end of the Neoarchean era and reveal aspects of the style of plate tectonics in the Neoarchean.

The Eastern Hebei Complex is located in the northern part of the North China Craton, straddling the Central Orogenic Belt and the Eastern Block of the NCC. Through decades of field geological mapping and structural analysis on the Shangying area, Eastern Hebei Complex, our group has identified a lithological association consisting of pillowed metabasalt, metapelite, and felsic volcanoclastic rocks, which outcrop as classic “block-in-matrix” mélange. Within the ophiolitic mélange belt, a series of west-northwest trending low-angle thrust faults have been identified, which sliced the mafic blocks and showed similarity to the characteristics of modern accretionary wedges. Major and trace elements of the metabasalt, metapelite, and felsic volcanic-clastic rocks show that the disrupted ophiolite sequence originated from a supra-subduction zone (SSZ) system. Zircon dating from the metabasalt blocks shows that the basalt formed at 2.54 Ga. In addition, one of the thrust faults is intruded by a granitic pegmatite. The crosscutting relationship and the age of the pegmatite (2506±20 Ma) suggest that this episode of thrust movement occurred before 2.5 Ga, which indicates that horizontal plate movement may have existed in the Shangying area before 2.5 Ga.

All these field observations, geochronology, and geochemical studies above reveal that these ultramafic-mafic blocks in the Shangying area jointly experienced the Neoarchean subduction process. The Shangying tectonic belt formed as a fore-arc accretionary wedge in a tectonic setting of a convergent margin, defining the boundary of a Neoproterozoic subduction zone. This

mélange was formed at the end of the Neoarchean, indicating that plate tectonics may have been locally initiated in the Eastern Hebei area of the North China Craton.

The tectonic evolution from the Archean to Triassic in the north central Gyeonggi Massif (Hongcheon-Chuncheon area) in the Korean Peninsula, and its application to the tectonic evolution of the North China Craton

min su Kang[1]*, Chonnam National University (kms_9432@naver.com)
chang whan Oh[2], Junbuk National University
byung choon Lee[3], Chonnam National University
bo young Lee[4], Korea Insitute of Geoscience and Mineral Resources

Abstract

The Gyeonggi massif which located in the central port of the Korean Peninsula, mainly consists of the Precambrian rocks. These Precambrian rocks can provide a critical information to understand the tectonic evolution at that time. In this study, we have carried out detailed studies of the Precambrian rocks on the north central part of the Gyeonggi Massif, Hongcheon-Chuncheon areas. The Hongcheon-Chuncheon areas are composed of the Neoarchean (ca. 2.61–2.49 Ga) and milled-Paleoproterozoic (ca. 2.09 Ga) metagranitoids, the Euiam Gneiss Complex (ca. 1.89–1.87 Ga), and metasedimentary units (the Yongduri Gneiss Complex and Euiam Group). The Neoarchean metagranitoids intruded at ca. 2.61–2.49 Ga and experienced polymetamorphic events at ca. 1.92–1.87 Ga and 229 Ma. Geochemical data indicate that they were formed in the arc tectonic setting by partial melting of low-K mafic rock in the lower crust. The Paleoproterozoic metagranitoids are categorized into three types based on geochronology and geochemistry: ca. 2.09 Ga metagranitoid formed in an arc tectonic setting, ca. 1.90 Ga metagranitoid formed in a syn-collision tectonic setting, and ca. 1.89–1.87 Ga metagranitoids formed in a post-collision tectonic setting. Based on the metamorphism, the Paleoproterozoic sedimentary rocks can be subdivided into two stages; the 1st stage metasedimentary rocks (paragneisses) deposited in the Yongduri Gneiss Complex and the 2nd stage metasedimentary rocks deposited in the Euiam Group. The 1st stage metasedimentary rocks (paragneisses) were deposited after 2.05–1.95 Ga in an arc tectonic setting; they experienced intermediate-P/T metamorphism (780–860 ℃/8.7–11.0 kbar) at ca. 1.91 Ga and then low-P/T metamorphism (710−750 ℃/6.0−6.5 kbar) at ca. 1.86 Ga. The 2nd metasedimentary rocks were deposited after ca. 1.88−1.83 Ga and metamorphosed at ca. 234−230 Ma. Together with previous studies, these data imply that the Hongcheon-Chuncheon areas have Neoarchean remnants and underwent similar Paleoproterozoic tectonothermal events identified from the Jiao-Liao-Ji Belt formed by the collision between the Longgang Block of the North China Craton and the Nangrim Massif of the Korean Peninsula, suggesting that the northern Gyeonggi Massif can be correlated to the North China Craton.

Cenozoic intracontinental tectonics of Mongolia: A synthesized review

Ulambadrakh KHUKHUUDEI[1]*, National University of Mongolia (ulamaa.kh@gmail.com)
Tim Kusky[2], China University of Geosciences (Wuhan)
Brian Windley[3], University of Leicester
Orolzodmaa Otgonbayar[4], National University of Mongolia

Nie Jungsheng[7], Lanzhou University

Abstract

Mongolia, a major world-class site of Cenozoic intracontinental tectonics, provides a key proxy for the long-term dynamics of Eurasia, but there has been considerable debate about the principal driving forces responsible for the intracontinental deformation. Here, we show that the Cenozoic tectonic development of Mongolia and surrounding regions was largely a consequence of the interaction of four factors: the India-Asia collision, extension of the Baikal Rift, mantle upwelling beneath the Khangay Dome, and Pacific subduction.

The recent tectonic development of the Mongolian and Gobi Altay, the Gobi Tianshan Mountains, and western South Mongolia were controlled by the interplay of sinistral and dextral strike-slip faults that have formed since ~5-8 Ma by intraplate transpression. The Khangay Mountains formed on a deep, slightly warmer upwelling that was derived from >80 km depth in the upper mantle. Khangay consists of many Cenozoic basalts, the origin and evolution of which are linked to thinning of the lithosphere via upwelling of a mantle plume. The Khentey Mountains were slightly rejuvenated to form an arched uplift on the final forces junction of the transpression of the India-Asia collision and Pacific subduction during Cenozoic. The Cenozoic tectonics of East Mongolia preserves a weak inheritance from Mesozoic events related to Paleo-Pacific subduction. The Sayan-Khuvsgul mountainous region formed by NS-compression against stable Siberia at ca. 1 Ma. The bulwark of the Tibetan plateau displaced atmospheric Hadley Cells northward and has acted as an orographic climate barrier against the Indian monsoon that led to aridification, lack of drainage, and to local internal erosion during the Cenozoic in Mongolia.

Yao XIAO[6], Guangdong Provincial Key Laboratory of Geodynamics and Geohazards, School of Earth Sciences and Engineering, Sun Yat-sen University

Abstract

The Khondalite Belt is a newly identified Paleoproterozoic Himalayan-type continent-continent collisional orogen, located in the western part of the North China Craton. It well records the high- and ultrahigh-temperature and high-pressure metamorphic events, as well as the multi-stage anatectic events, that relate to the collision between the Yinshan Block and Ordos Block during Paleoproterozoic. In this study, the anatectic evolution of the metapelites from the Khondalite Belt is forward modelling, in which the melting reaction, melting amount and initial melt composition that involved in the anatectic process are simulated. By comparing the composition of the adjacent leucosome and the multi-stage S-type granites in the Khondalite Belt, the genetic mechanism of S-type granite is discussed, and the genetic relationship among the three is established. The results show that during the prograde metamorphic stage, the metapelites in the Khondalite Belt experienced water-saturated melting (WM), muscovite-dehydration melting (MM) and biotite-dehydration melting (BM), successively. Subsequently, in the near-isothermal decompression process, the main reaction is K-feldspar-garnet melting (KGM), while briefly occurred. The melt composition varies depending on different melting reaction that occurs. The early melt formed by WM and MM is similar to the composition of weakly peraluminous monzonitic granite, while the melt produced by BM is equivalent to the composition of moyite. Moreover, the melt produced by KGM is similar to the peraluminous-potassic granitic composition. Comparing the composition of the initial melt, the measured leucosome and the multi-stage S-type granites from the Paleoproterozoic Khondalite Belt, both the composition of initial melt and the measured leucosome can roughly fall within the range of the S-type granites of the 1.93-1.90 Ga and ~1.95 Ga from the Khondalite Belt. The result indicates that they do have a certain genetic relationship, which further supports that the S-type granites from the Khondalite Belt are produced by partial melting of metapelites. Additionally, by comparing the Rb/Sr ratio of the initial melt and the measured leucosome, and the relationship with the content of Ba and Sr, respectively, it is found that the composition of the melt produced at 50% and 60% melting (corresponding to 850℃/8.1

kbar and 850℃/6.5 kbar, respectively) during the decompression stage is similar to that of the measured leucosome. Coincidently, the high content of biotite in the metapelite, as well as the pervasive existence of the peritectic cordierite in the leucosome, together indicates that the melting process is dominated by BM and KGM. These melts are vital sources of the S-type granites of the 1.93-1.90 Ga and ~1.95 Ga in the Khondalite Belt. Combined with previous data, it is shown that the Khondalite Belt experienced a long period (100 Ma) of metamorphic-anatectic evolution, that related to the collision between the Yinshan Block and Ordos Block.

Petrogenesis of Paleoproterozoic granitic gneiss in the Geumsan area, Korea, and its tectonic implications for Northeast Asia

Kenichiro IWAMIZU[1]*, University of Toyama (ken-iwamizu@outlook.jp)
Ji-Hoon KANG[2], Andong National University

Abstract

We studied a Paleoproterozoic granitic gneiss body in the Geumsan area (36°03'27.2"N, 127°28'58.3"E) near the boundary between the Gyeonggi and Yeongnam massifs in Korea to clarify its petrogenesis and tectonic implications in Northeast Asia.

CL images of zircons from the granitic gneiss revealed three domains: an inherited detrital core, an anatectic mantle, and a metamorphic overgrowth rim.

Most (> 90%) zircons contained an inherited detrital core of ca. 3480–2100 Ma with relatively high Th/U ratios (0.016–4.137) and positive Ce anomalies (5.274–184.947), mainly suggesting a magmatic origin. Trace element compositions of ca. 2.5 Ga cores are plotted in the post-collisional field of the Hf vs. U/Yb diagram [1], indicating a North China Craton provenance [2].

U-Pb isotopic data from the anatectic mantle formed a discordia line on the concordia diagram with the upper and lower intercept ages of ca. 1.9 Ga and 283 Ma, respectively, indicating the ages of granite emplacement and metamorphism. The mantle data had low Th/U ratios (< 0.1) and Ce anomalies (< 2.9), suggesting a paragenesis with monazite. The emplacement age and low zircon Th/U ratios are compatible with the leucogranites in the Yeongnam Massif [references in 3].

The metamorphic overgrowth rim had U–Pb ages of ca. 227 Ma and 176 Ma, low Th/U ratios (< 0.1), and Ce anomalies (< 2.2), indicating a paragenesis with monazite.

Monazites from the granitic gneiss yielded Triassic–Jurassic Th–U–total Pb ages with the highest peak at ca. 173 Ma. One monazite grain exceptionally had a wide range of ages from ca. 1845 to 158 Ma, possibly suggesting that the monazite crystallized at ca. 1.9 Ga and reset their ages during later metamorphism. Widespread Triassic–Jurassic magmatism in Korea may have been the heat source for the metamorphism.

Whole-rock geochemistry of seven samples from the granitic gneiss indicates that partial melting of peraluminous psammite and mica-rich pelite produced their source anatectic magma. The zircon saturation temperature [4] of the magma was 713–629 °C. These geochemical and geothermal features and the abundance (> 90%) of inherited zircons in the granitic gneiss indicate the pressure condition of 0.6–0.45 GPa [5]. The ca. 1.9 Ga P-T conditions are compatible with the Yeongnam Massif but incompatible with the Gyeonggi Massif [3].

The whole-rock chemical compositions of the granitic gneiss in this study and the coeval leucogranites in the Yeongnam Massif [3] indicate the syn-collisional setting in the Rb-Hf-Ta diagram [6], whereas those of the coeval granites in the Gyeonggi Massif [3] indicate the volcanic arc setting.

From the above discussion, we suggest that the ca. 1.9 Ga granitic gneiss in the Geumsan area belongs to the Yeongnam Massif and originated from the North China Craton.

Geochronological and geochemical evidence of the Ordovician magmatism in the Lake Zone, Western Mongolia

Batkhishig Bayaraa[1]*, Mongolian University of Science and Technology (bkhishig@must.edu.mn)
Chimedtseren Anaad[2], Geoscience Center, MUST
Munkhtsengel Baatar[3], Mongolian University of Science and Technology

Abstract

The Namir Formation and Togtokhiinshil Complex rocks are representatives of the Ordovician magmatism developed in the Lake Zone, Western Mongolia.

In 1991, L.V.Chistoedov first discovered the volcanogenic-sedimentary rocks, whose actual thickness is not known, and any fossils and fauna were not identified, and it is distributed mainly along the Tsagaanshuvuut fault that separates the Hovd and Nuur zones. Later on, Minjin et al. classified it into the Namir Formation (Minjin, 2006) and now it is mapped as (O1-2nm) on the 1:200000 scale geological map of Mongolia.

The rocks of the Namir Formation are overlying the Togtokhiinshil complex and are cut by granitoids of the Ordovician Turgengol Complex, and an angular unconformity overlies the lower-middle Silurian Chargat Formation (Samozvantsev et al., 1982).

The Namir Formation, mainly andesite and dacite in composition, consists of brown-green lava breccia, red-brown colored mindal-textured lava, tuff conglomerate, course-grained tuff sandstone, gravellite, conglomerate, siltstone, and brownish-pink colored andesite-dacite lava, lava breccia and their tuffs.

Geochemically, the rocks of the Namir Formation are andesite and rhyolite by the classification of TAS, with SiO_2=57.07-71.46%; Na_2O+K_2O=4.89-8.77% calc-alkaline series, metaluminous, SiO_2<70, #Fe>0.6 which indicates the type of magnesian rock.

The primitive mantle normalized trace element spider diagram shows enrichment of LILE relative to LREE, and well developed Nb-depletion and Pb-enriched, whereas HFSE depleted. The total REE content is 64.97-101.47 ppm, and the LREE/HREE differentiation is slightly low; the ratios are $(La/Yb)_N$=1.95-5.66, $(La/Sm)_N$=1.16-2.26, and $(Gd/Yb)_N$=1.04-1.79. The chondrite-normalized REE diagram shows subparallel REE patterns with a weak negative Eu anomaly.

In this research, two andesite samples from the Namir Formation were selected for the absolute age dating by the LA-ICPMS zircon U-Pb method. The results show that 453±4.1 and 453.4±3.2 Ma which we interpreted as the time of emplacement of the andesitic magma.

All these data and the petrological characteristics of the Namir Formation rocks suggest that active continental margin arc magmatism developed in the Lake Zone. This research result confirms the Late Ordovician age of the Namir Formation and is important for explaining the geodynamic settings of the Lake Zone, western Mongolia.

Reporting the geochronology of the igneous rocks of the southern Jeonju area, located in the southwestern part of the Okcheon metamorphic belt, Korea

Hawon YUN[1]*, Department of Environment and Energy, Jeonbuk National University (yunhawon@jbnu.ac.kr)
Jinhyeok CHOI[2], Department of Earth and Environmental Sciences, Jeonbuk National University
Chang Whan OH[3], Department of Earth and Environmental Sciences, Jeonbuk National University

Abstract

The Jeonju area, located in the southwestern Okcheon metamorphic belt (OMB), South Korea, was reported to be composed of Cretaceous igneous and meta-sedimentary in the Jeonju Geological Map published in 1924. However, no evidence, such as age-dating analyses, supported the geological information in the Jeonju Geological Map. Previous studies reported the Precambrian, Triassic, and Jurassic intrusive igneous rocks from the Gimje, Sunchang, and Jeongeup areas near the Jeonju area. Furthermore, the meta-sedimentary rocks of the OMB have been reported to be depositional from the Neoproterozoic to the Paleozoic. These results suggest that the igneous and meta-sedimentary rocks in the Jeonju area were likely formed before the Cretaceous. In this study, the age-dating analyses on the igneous rocks of the southern part of the Jeonju area were carried out using SHRIMP and LA-ICP-MS at the Korea Basic Science Institute. This study confirms that the southern part of the Jeonju area is composed of Archean or Paleoproterozoic gneiss, Paleoproterozoic and Neoproterozoic foliated igneous rocks, Triassic foliated granite, Jurassic foliated granite, and granite porphyry. The gneiss, which may have intruded at ca. 2.5 Ga, underwent two metamorphisms during the Paleoproterozoic (1882±14Ma) and Triassic times. The Paleoproterozoic and Neoproterozoic igneous rocks intruded at 1889±10 Ma and 740±8 Ma, then underwent metamorphism. The intrusive ages at 211±3 Ma and 173-171 Ma from the Triassic foliated igneous rock and Jurassic granites, representing the Honam shear zone, implicate that the Honam shear zone occurred between ca. 211-173 Ma. These results indicate that the southern Jeonju area has experienced Archean, Paleoproterozoic, Triassic, and Jurassic igneous and metamorphic events and are well correlated with previous studies on the areas near the Jeonju area.

Six subduction-accretionary mafic zones identified in the Altai orogenic belt, Xinjiang, China

Liu YONG[1]*, Chinese Academy of Geological Sciences (CAGS) (liuyongfirst@163.com)

Abstract

China, Russia and Mongolia have been carrying out an international Greater Altai mapping and synthesis project since 2022 to carry out an international comparative study of the Greater Altai orogenic belt. To this end, the project is unifying the study of the Altai orogenic belt from the point of view of plate tectonics and oceanic plate geology. Oceanic plate geology is a sub-discipline of plate tectonics, which is a method of studying the oceans from mid-oceanic ridge tension to trench subduction closure. It is developed on the basis of oceanic plate stratigraphy, and the study includes oceanic plate stratigraphy, rocks (ophiolite, magma rock, sedimentary rock, metamorphic rock), tectonic deformation, and regional tectonic evolution. At present, the project team has preliminarily established the research framework of oceanic plate geology, and has sequentially defined the Chinese Altai orogenic belt from north to south as Algdai-Kurti-Burgan-Mayin Ebo (Erqis) (S-C), Kujibai-Hongguleng (∈-C), Zaheba-Alman (∈-C), Tangbal-Mayil-Baluk (O-S), and Tangbale-Mayil-Baluk (∈-S). Barruk (O-S), Dalbut (D-C) and Karamari (D-C) six subduction accretionary mafic belts. They consist of a series of ophiolites, ophiolite-green mélange, intra-oceanic arcs, and oceanic islands and seamounts of retrograde stacking tectonics, which record the complex subduction-collision orogenic process of the Tethys Ocean. Among them, the North Junggar intra-oceanic arc consists of edakite, niobium-rich basalt, boenite, boninite, bitter olivine, and pyroxene-rich olivine basalt, etc. It represents the Early Devonian to Early Paleolithic period. They represent the products of the northward subduction of the Erqis Minor Ocean Basin from the Early Devonian to the Early Carboniferous.

Acknowledgments
I sincerely want to express my deepest gratitude to all the participants, contributors, guides, and supporters of the comprehensive geological survey of the geological background of copper nickel gold mineralization in the northern edge of Junggar, Xinjiang (DD20242127). This project is not only a geological academic challenge, but also a process of team collaboration, intellectual collision, and passionate burning. Let's work together to create a more brilliant future!

Petrology and Geochemical Studies of late Cenozoic basic-intermediate volcanic rocks Southwest of Ghezel- Ozan (NW Iran)

Hamoon MEMARIAN[1]*, Research Institute for Earth Sciences (RIES)
(Hamoonmemarian@yahoo.com)
Elnaz Aghaali[2], Research Institute for Earth Sciences, Geological Survey of Iran
Nima Banar[3], Research Institute for Earth Sciences, Geological Survey of Iran

Abstract

The studied area, located in Hashtjin 1:100,000 geological sheets, in Azerbaijan province (Northwestern Iran). The study area restricted in 48 ˚30′ to 48 ˚00′ E longitude and 37 ˚30′ to 37 ˚00′ N latitude. Based on our field investigation, the studied area comprise of intermediate to acidic volcanic rocks. Trackyandesite to trachyte and tuffs alternatively extend through the quadrilateral. Based on lava the field studies and previous geological map indicate that the volcanic succession formed in Oligocene period. Petrography studies revealed the evidences of magma mixing and mingling including basic enclaves inside acidic groundmass sieve texture and in plagioclase phenocrysts and quartz xenocrysts with pyroxene reaction margins. The samples selected for analysis are healthy and intact samples, and this analysis was carried out on some samples in the Geology and Mineral Exploration Organization of the country.

Interpretation of the geochemical diagrams indicates calc-alkaline and high potassium calc-alkaline magmatic trends. In the tectonomagmatic diagrams normalized by primitive mantle values, they display enrichment of LILE and LREE in relative to HREE and depletion in HFSE that comparison with subduction- related magmatism. The geochemical evidence indicate that the source of the lherzolite. These evidences show that volcanism in the study area has occurred in a tensile envelope associated with collision or post collision.

Carbonatization and silicification of ophiolitic ultramafic rocks and formation of gold-bearing listvenites in the Arabian-Nubian Shield

Mokhles Kamal AZER[1]*, National Research Centre (mokhles72@yahoo.com)
Amany Seddik [2], New Valley University
Bassam Abuamarah[3], King Saud University
Simon Wilde[4], Curtin University
Mahmoud H. Darwish [5], New Valley University

Abstract

Listvenite bodies of various compositions are present in the Al-Barramiya District in the northwestern corner of the Arabian-Nubian Shield (ANS), associated with serpentinites and talc-carbonate rocks. Here, a late Neoproterozoic mantle section in the Gabal Al-Barramiya area contains variably serpentinized peridotites that are highly altered along shear zones and thrust planes to form gold-bearing listvenites. The latter occur as lenses and dyke-like bodies that vary in color from yellowish brown to reddish brown to greyish. They can be categorized into carbonate listvenite, silica-carbonate listvenite and silica listvenite (birbirite). Carbonate listvenite is composed mainly of carbonate minerals (70-85%), quartz (15-20%), sulphides, Cr-spinel and rare gold. Silica-carbonate listvenite consists mainly of quartz (45-60%) and carbonates (40-50%) in varying proportions, with minor amounts of serpentine, chlorite, Cr-muscovite (fuchsite), sulphides, goethite, Cr-spinel and gold. Silica listvenite consists mainly of quartz (˃80 %) with lesser amounts of carbonates and minor Cr-spinel, sulphides and gold. Carbonate listvenite is characterized by the presence of schistosity and deformation fabrics similar to the host serpentinites, but such fabrics are absent in the silica-carbonate and silica listvenites, suggesting that this postdates carbonate listvenite and serpentinization. The presence of listvenites along shear zones and the presence of relics of serpentine and Cr-spinel reflects their formation through metasomatism of ultramafic rocks by hydrothermal fluids circulating along the thrust faults. All three varieties of listvenites show relative enrichment in Ni (623-1876 ppm) and Cr (517-1828 ppm). In addition, silica-carbonate listvenite is characterized by the presence of fuchsite and is enriched in Zn, Pb, Cu, Ag, and Au; this enrichment is correlated with SiO2 and Au content. The enrichment in these elements can be related to fluid-rock interaction and their addition through hydrothermal solutions. This is supported by the presence of granitic intrusions in the study area which led to enrichment of specific elements. Rare earth element (REE) contents differ between the studied listvenites. Silica -carbonate listvenite has the lowest total REE (∑=0.98-2.56 ppm), whereas the silica listvenite contains the highest total of REE (∑ = 15.70-21.42 ppm). Based on the above, carbonate listvenite is the earliest to form by the infiltration of CO2–bearing fluids released during serpentinization of the original fore-arc peridotite slab, followed by formation of silica-carbonate listvenite due to the activities of SiO2–saturation and CO2-bearing fluids released during ophiolite obduction. Fuchsite in silica-carbonate listvenite formed as a result of metasomatic reactions of Si- and K-rich fluids with Cr-spinel due to hydrothermal alteration of

serpentinized peridotite. Silica listvenite formed at the final stage by the silicification of the early formed silica-carbonate listvenite. Listvenitization of the mantle section of the Al-Barramiya ophiolite led to concentration of Au, Pb, Zn, Cu and Ag. The silica-carbonate listvenite contains higher concentration of gold (899-2199 ppb) than the carbonate listvenite (119-191 ppb) and silica listvenite (156-233 ppb).

Signature of Himalayan Orogenesis in Quaternary Sediments, Lalmonirhat District, Bangladesh: Evidence from Petrography and Mineral Chemistry

ISMAIL HOSSAIN[1]*, University of Rajshahi (ismail_gm@ru.ac.bd)
KARIMA SULTANA[2], University of Rajshahi
PRADIP KUMAR BISWAS[3], Institute of Mining, Mineralogy and Metallurgy (IMMM)

Abstract

The present study describes the petrography and chemical characterization of minerals in the Quaternary sediments at Patgram upazila, Lalmonirhat district, NW Bangladesh. The borehole sediments have been investigated vigilantly to classify the sediment types and to ascertain their possible provenance and genesis. The petrographic data reveal that sediments hold mostly monocrystalline quartz, K-feldspar, lithic grains, mica, rutile, zircon and some opaque minerals. The sediments show predominantly sub-angular to sub-rounded, coarse to medium-grained, consisting of quartz (avg. 63 %), feldspar (avg. 11 %), micas (avg. 10 %) and lithic fragments (avg. 9 %). Overall, these data demonstrate sub-arkose and sub-litharenite equivalent rock types which also exemplify that these sediments were derived from plutonic granitic protolith source (or felsic source) within the tectonogenetic suites of recycled orogens, transitional continental blocks of the craton interiors.

Mineralogical analyses of biotite, Fe-Ti oxide, magnetite, rutile and zircon by SEM-EDX method provide consistent mineral characteristics to the Lesser Himalayan sequences in Sikkim and Darjeeling areas. For example, most of the biotites are compositionally annitic, while a few eastonitic in nature and their FeO*/MgO ratios fluctuate from 1.07 to 1.38 with an average of 1.27, which typically resembles biotites crystallized in a calc-alkaline (subduction-related) suite. Higher concentrations of Ti (0.21–0.37) in biotite mainly indicate primary magmatic sources resemble chemically consistent with those rocks belonging to low-grade metamorphic terrains rocks. From the studied biotite, the calibrated oxygen fugacity is about 10-12.4 and 10-12.9 within the temperature ranges from 850°C to 900°C, respectively. These data suggest that the studied biotites were formed comparatively at higher temperatures. The BSE images of the Ti-rich magnetite display textures of granular (30%), sandwich (50%), and trellis-type (20%) ilmenite lamellae where magnetite indicates the genesis of a dissected arc, whereas ilmenite indicates the formation of a recycled orogen or continental block. This studied ilmenite lamellae had lower TiO2 levels (43.6–49.4 wt.%) than pure ilmenite (52.6 wt.%). Ilmenite contains up to 4% Fe2O3 and relatively low MgO and MnO where the Fe2O3 level is similar to that of Brahmaputra River bar sediments. Temperature and less than 5% MnO indicate the gabbroic type magmatic protolith. On the other hand, the temperatures estimated from the study of the magnetite-ilmenite assemblage vary between 540 and 575°C, and the fO2 fluctuates between 10-21.4 and 10-22.1 and these findings are compatible with magnetite-ilmenite in Brahmaputra River bar sediments, with temperatures ranging from 548 to 558°C and fO2 values ranging from 10-21.4 to 10-21.7 and inconsistent with Cox's Bazar beach sands, which showed temperatures ranging from 625 to

850°C and fO2 values ranging from 10-12 to 10-21. The calibrated temperature and oxygen fugacity of the studied minerals, Brahmaputra bar sediments and Cox's Bazar beach sands equilibrated in a T-fO2 field extremely close to the FMQ buffer curve, indicating a crustal source. So, overall isogradic and tectonogenic signatures suggest that most of the sediments in the study area are very similar to the Lesser Himalayan Sequences in Sikkim Himalaya of the Sikkim-Darjeeling section.

Carbonatite, ultramafic breccia, syenite, and alkaline basalts from the igneous and sedimentary association of the Bolivian rift

Ramiro Matos[1]*, Universidad Mayor de San Andrés (rmatoss@yahoo.com)

Abstract

The Upper Permian-Lower Cretaceous period of Eastern Cordillera in the Central Andes of Bolivia is characterized by continental environment basins characterized by shallow and sporadic marine ingressions that deposited chemical sediments with limestone and chert. This rock group forms a volcano-sedimentary association resulting from lithospheric thinning that led to the formation of a rift that was subsequently aborted. The igneous association is made up of subvolcanic, shallow plutonic bodies, lava flows, stocks, dikes, and sills of mafic-ultramafic of alkaline composition. During the Cenozoic, due to a tectonic inversion process, these basins suffered shortening that led to the formation of a steep relief of regional anticlines and synclines associated with reverse and strike-slip faults. Mapping work, satellite images, igneous and sedimentary petrography, mineral chemistry, isotopic data, and whole rock led to the discovery of a carbonatite the first identified in the Bolivian Andes, intruded into Ordovician metasedimentary rocks. The carbonatite is 1200 meters long and 500 meters wide, it consists of a ferrocarbonatite and a magnesium carbonatite or beforsite with low levels of bastnaesite, accompanied by pyrochlore and monazite as accessory minerals. The most significant feature is the anomalous content of Zn, Pb, and Mo. The carbonatite is associated with syenite rocks containing sodalite, ankerite, barite dyke, ultramafic breccia bodies, and alkaline basalt dykes and sills. The ultramafic breccia contains mantle xenoliths of olivine, pyroxene, and garnet of the melanite variety and subordinate amounts of nepheline, sodalite, apatite, serpentine, phlogopite, pyrite, sphalerite, hematite, and chalcopyrite. K-Ar dating on ultramafic breccia phlogopite and lamprophyre yielded 101 to 99 Ma. Alkaline breccia bodies are exposed, constituting subcircular protuberances that protrude into the landscape. The fragments of the breccia are of supporting matrix of variable size, shape, composition, and color. In composition, they are clasts of nepheline syenite, alkaline gabbro or theralite, pyroxenite, ijolite, and hornfels. The objective focuses on the igneous and sedimentary association of the rift and the structural style shown on the maps. The region is of special interest due to the complexity of alkaline rocks, and the folds, faults, and the close relationship between stratigraphy and structure.

Pb isotope disequilibrium in metasediment-derived granitic melts

Lingsen ZENG[1]*, Institute of Geology, Chinese Academy of Geological Sciences
(lzeng1970@163.com)
Li-E Gao[2], Institute of Geology, Chinese Academy of Geological Sciences

Abstract

Radiogenic isotope compositions of magmatic rocks have been widely used to infer the nature of their sources. However, updated studies have demonstrated that crustal derived granites can carry a large magnitude of isotope (Sr, Nd, and Hf) disequilibrium which could be used to infer the melting reactions as well as the nature of sources. The Himalayan Cenozoic granites are typical products from melting of crustal sources. Experimental results and theoretical calculations suggest that the Himalayan leucogranites are characterized by Sr, Nd, Hf isotope disequilibrium. Exception for the reported trace element compositions and ratios and the initial Sr isotopic ratios, radiogenic Hf and Pb isotopic ratios are heterogeneity. Leucogranites from Malashan-Gyirong area consist of two groups of granites formed fluid-absent melting of muscovite (Group-A) and fluid-fluxed melting of muscovite (Group-B), respectively. Except for substantial differences in key trace element compositions and their ratios, and Sr isotope compositions, follow-up studies show that as compared to Group-A granites, Group-B granites have much higher Th, Th/U, and 208Pb/204Pb ratios. However, their 206Pb/204Pb and 207Pb/204Pb ratios are similar. Such characteristics could be explained by enhanced solubility of monazite (high Th/U and 208Pb/204Pb phase) relative to zircon during fluid-fluxed melting of metasedimentary rocks. Our findings suggest that zircon and monazite play an critical role in shaping Pb isotope systematics in crustal-derived melts.

Chronology and geochemistry of Triassic sanukitoids in Funing area, South China: Implications for petrogenesis and geodynamic processes

Zhenglin LI[1]*, Guilin University of technology (lizhenglin@glut.edu.cn)
Xijun Liu[2], Collaborative Innovation Center for Exploration of Nonferrous Metal Deposits and Efficient Utilization of Resource, Guilin University of Technology, Guilin 541004, China

Abstract

The Nanpanjiang Basin, located at the southern margin of the South China block, is interpreted as either a back-arc foreland basin resulting from the subduction of the Paleo-Pacific plate or a peripheral foreland basin associated with the closure of the Paleo-Tethys ocean and continental collision during the Indosinian orogeny. Abundant igneous rocks, such as arc-like intrusion and volcanic rocks, indicate subduction processes in the basin. However, the genesis of the magmatism remains controversial, with different tectonic models proposed:(1)Subduction of the Paleo-Pacific plate; (2)Intraplate tectonic activity related to Emeishan mantle plumb; (3)Subduction of the Paleo-Tethys plate beneath the South China block;(4)Joint subduction by both the Paleo-Tethys and Paleo-Pacific plates.

High-Mg andesites have generally been produced at convergent plate margins, especially where young or hot plate subduction occurs, and have become an important indicator of the evolution of the lithospheric mantle at convergent plate margins, detailed isotopic and chronological studies will be valuable in determining the mantle source and the tectonic evolution of Nanpanjiang Basin and South China. In this study, we present new geochronological, geochemical, and Sr-Nd-Pb isotopic data of Early Triassic sanukitoids from the Funing area. Our findings aim to explain the origin of these magmatic rocks and reveal the characteristics of the lithospheric mantle in the region.

Our new zircon U-Pb dating results show that these sanukitoids have a weighted mean 206Pb/238U age of approximately 250 Ma. They are calc-alkaline rocks characterized by moderate SiO2 contents (51.62-54.44 wt%) and high MgO contents (4.52-10.22 wt%) and Mg# values (59-75). These sanukitoids are enriched in large ion lithophile elements (LILEs) and depleted in Nb and Ta, resembling typical arc magma. The sanukitoids also have relatively medium to high initial 87Sr/86Sr ratios (0.7016 to 0.7129), negative whole-rock εNd(t) values (–6.2 to −9.8), and zircon εHf(t) values (−0.4 to −8.6), as well as extremely high initial Pb isotopic ratios [(206Pb/204Pb)i = 18.486–18.760, (207Pb/204Pb)i = 15.760–15.777 , and (208Pb/204Pb)i = 38.904–39.319]. Our new data, combined with previous studies on Permian to Triassic magmatism in the Nanpanjiang basin, suggest that the Triassic sanukitoids in the Funing area primarily originated from an enriched lithospheric mantle that underwent metasomatism during the subduction process, involving slab fluids and sediment melts. The extremely high initial Pb isotopic ratios of the sanukitoids cannot be explained by the subduction of Paleo-Tethys and Paleo-Pacific plates, which have low initial Pb isotopic ratios. Instead, they may be attributed to the emeishan mantle plume and lithospheric mantle beneath South China.

We proposed that the formation of Early Triassic sanukitoids in the Nanpanjiang Basin was influenced by the extensional setting during oceanic subduction, which was caused by the roll-back of the Paleo-Tethys oceanic lithosphere around 250 Ma. This provides potential insights into the interaction between Paleo-Tethys, the Emeishan mantle plume, and the lithospheric mantle beneath South China.

The significance of isotopic decoupling in the mafic-ultramafic layered sequence of the Bushveld Complex, South Africa

Peace ZOWA[1]*, University of the Witwatersrand (2399607@students.wits.ac.za)
Ben Hayes[2], University of the Witwatersrand
Grant Michael Bybee[3], University of the Witwatersrand

Abstract

The mode of emplacement, magma source(s) and the metallogenesis of the Rustenburg Layered Suite (RLS) of the Bushveld Complex remains controversial despite decades of research. There is an agreement, however, that the RLS was formed through (1) the mixing of multiple pulses of magma in a chemically evolving magma chamber and (2) there was significant pre-emplacement crustal and/or lithospheric mantle contamination of the parent magmas. This is evident in bulk rock variations in Sr-Nd isotopes. On the other hand, Lu-Hf isotopes of accessory zircon show a limited range in εHf (at 2.06 Ga) of -8.6 ± 1.2 throughout the entire RLS. The homogenous zircon Hf isotopic values indicate that there is decoupling between the major rock-forming silicates and the accessory minerals. The bulk rock Sr-Nd isotopic data only, therefore provide a partial story about the solidification history of the RLS. Competing models have been suggested for the origin of the homogeneous εHf isotopic signature, including melting/contamination of asthenosphere-derived Bushveld magmas by the sub-continental lithospheric mantle and high-level crustal contamination of the RLS by fluids derived from the Transvaal Supergroup during crystallisation. In this study, we analysed Sr-Nd isotopes in apatite, which is also an accessory mineral in the RLS, that crystallised in close association with zircon. Our new Sr-Nd isotopes measured using LA-MC-ICP-MS show that apatite records homogeneous isotopic compositions (average initial 87Sr/86Sr of 0.7088 and εNd of ~-7 ± 1.4 at 2.06 Ga). Additionally, we show that apatite in the Phalaborwa Complex (coeval to the Bushveld Complex) has similar Sr-Nd isotopic values to the RLS (average initial 87Sr/86Sr of 0.7107 and εNd of ~-8 ± 0.8 at 2.06 Ga). Samples from the Main Zone and Upper Zone of the RLS and the Phalaborwa Complex predominantly contain F-rich apatite, while in contrast, the pyroxenites in the PGE-Cr mineralised Critical Zone contain Cl-rich apatite. Norites in the Tennis Ball Marker are distinct as they contain both F-rich and Cl-rich apatite, which may reflect an influx of chemically distinct hydrothermal fluids and/or melts in a chemically evolving magma chamber. Our new Sr-Nd isotopic data in apatite corroborate the existence of isotopic decoupling in the cumulates of the RLS. We speculate on the origin of this isotopic decoupling with hypotheses including (i) melt percolation in the crystal mush that led to isotopic homogenisation of the trapped melt from which zircon and apatite crystallised and (ii) the emplacement of isotopically distinct cargoes of silicate crystals in an isotopically homogeneous carrier liquid during the emplacement of magmas into the RLS chamber. We provide new isotopic insights into the magmatic processes involved in forming the RLS, advancing the current understanding of the existing models.

Determination of low-content Ti in zircon by LA-ICP-MS/MS

junlong NIU[1]*, +8615321376370 (junlongniu@hotmail.com)
shitou WU[2], +8613521286485
yueheng YANG[3], +8613651212376

Abstract

Ti-in-Zircon thermometer provides temperature constrains for various geological settings. However, accurate determination of Ti content in zircon is the prerequisite for the effective use of this thermometer. Zircon commonly contains trace-level Ti (< 10ug g-1), and Ti determination by traditional LA-ICP-MS is a challenge due to the critical interferences of isobaric and double charged ions. In this study, triple quadrupole mass spectrometry (LA-ICP-MS/MS) was investigated to eliminate the interferences of 48Ca+, 96Zr2+ on 48Ti+. The results indicated that using NH3 as the reaction gas could effectively remove the 48Ca+ and 96Zr2+ interferences on 48Ti+ with analysis reaction product 48Ti(14N1H3)4(14N1H)+(mass shift +83). We also found that a small amount of N2 could improve the signal intensity by ~2 fold. Moreover, the LA-ICP-MS/MS will undergo initial mass screening at Q1 (First quadrupole), followed by collision reactions at Qcell (Collision reaction pool), resulting in mass shift. Therefore, the background value of this technique is very low (<10cps).The precision and accuracy of this new technique are verified by analysis of various zircon reference materials. This study has demonstrated that LA-ICP-MS/MS has the capability of precise determination of low-content Ti (<10 ug g-1) in zircon at high spatial resolution (< 30um), which has significant effect on Ti-in-zircon thermometer.

(Withdrawn) Controlling Factors of Granite Chemical Diversity and Implications for Early Crustal Evolution: Migmatites from the Southwestern Daqingshan Complex, North China Craton

Xingzhou JIANG[1]*, Guilin University of Technology (304588685@qq.com)
Shengyao Yu[2], Ocean University of China
Xijun Liu[3], Guilin University of Technology

Abstract

Crustal evolution and the genesis of granite are closely linked to anatexis in the lower or middle crust, followed by the ascent of granitic magmas to the upper crust. The Daqingshan complex in the North China Craton is characterized by the extensive development of Precambrian migmatites and granites resulting from crustal anatexis. Understanding the controls on the geochemical diversity of these granitic magmas during their formation and extraction would enhance our understanding of crustal evolution from the late Neoarchean to early Proterozoic. In this study, we investigated the diverse types of migmatite and felsic–granitic rock related to partial melting in the Daqingshan complex using systematic petrographic, whole-rock geochemical and Sr–Nd isotope, and zircon U–Pb–Hf isotope analyses. Our new results, combined with data from the literature, allow reconstruction of the complete process of magma formation, extraction, and evolution for migmatites in the study area. The following new insights are obtained. (1) The Daqingshan migmatites record two main periods of metamorphism (at ~2.45 and ~2.37 Ga) and one period of anatexis (at ~2.37 Ga). (2) The migmatites originated from the Daqingshan supracrustal rocks via Bt-dehydration melting. (3) During magma extraction, decomposition of the magma was controlled predominantly by the entrainment of residuum; incongruent melting of plagioclase and its early-stage crystallization and compaction led to the fractionation of plagioclase and K-feldspar within the in situ to semi in situ magmatic accumulation site. (4) Factors such as protolith composition, rock and mineral melting mechanisms, residuum entrainment, fractional crystallization, compaction, and the assimilation of surrounding rocks played crucial roles from initial melting to magmatic evolution, and collectively contributed to the chemical diversity of migmatites and granitoids in the southwestern margin of the Daqingshan complex. (5) From the late Neoarchean to early Paleoproterozoic, substantial fractionation of plagioclase and K-feldspar during Bt-dehydration melting of metasedimentary rocks may have resulted in the extensive migration of K-rich melt from the anatectic source.

Early-mid Cenozoic extensional arc volcanism of the North Patagonian and the Southern Central Andes (33-43°S)

Lucia FERNANDEZ PAZ[1]*, Instituto de Estudios Andinos "Don Pablo Groeber" (UBA-CONICET) (luciafernandezpaz.gl@gmail.com)
Sofia IANNELLI[2], Instituto de Estudios Andinos "Don Pablo Groeber" (UBA-CONICET)
Vanesa LITVAK[3], Instituto de Estudios Andinos "Don Pablo Groeber" (UBA-CONICET)

Abstract

The volcanic arc of the Southern Central and Northern Patagonian Andes (33-43°S; Chile and Argentina) in the early to middle Cenozoic exhibits distinctive features that shed light on the dynamics of subduction-related volcanic activity in extensional tectonic settings. The late Eocene to early Miocene interval is particularly significant in the Andes, as it records a widespread extensional regime leading to the opening of forearc, intra-arc, and backarc basins, accompanied by prolific volcanism. This period precedes the final major uplift phase of the Andes. It is hypothesized that this extensional event occurred in two phases, associated with changes in the geometry of the subducting slab: i) oblique convergence at low rates during the late Eocene to early Oligocene, and ii) orthogonal convergence at high rates during the late Oligocene to early Miocene. This study presents new field, petrographic, geochemical, and isotopic data from volcanic sequences in the Northern Patagonian Andes, along with an extensive compilation of geochemical data from the Southern Central Andes, aiming to analyze petrogenetic processes at different stages of arc evolution.

During the late Eocene to early Oligocene, subduction-related volcanism manifests in two parallel belts located 100 and 300 km from the trench. In this period, both belts exhibit intermediate composition and a relatively homogeneous geochemical signature, transitioning between tholeiitic and calc-alkaline series. Multi-element patterns show enrichment in mobile elements (Rb, Sr, Ba, Th, U, Pb) compared to high field-strength elements and rare earth elements. Moreover, Sr and Nd isotopes indicate a derivation from depleted mantle sources with limited crustal contributions. Trace element ratios used as tectonic discriminants (Ba/Ta, La/Ta, Th/Yb, among others) suggest development in a subduction environment with contributions from fluids derived from the subducting slab. In contrast, the record of volcanic activity during the late Oligocene to early Miocene, at the peak of the extensional regime, displays significant geochemical differences along the Andes. In the Southern Central Andes, volcanism displays more basic compositions and less influence from the subducting slab. Conversely, in the Northern Patagonian Andes, subaerial and subaqueous lava flows intercalate with marine deposits, indicating a regime of rapid subsidence. These rocks exhibit geochemical signatures both transitional to arc, E-MORB, and even OIB. These geochemical singularities suggest a genesis primarily dominated by decompression melting of a heterogeneous mantle wedge.

In summary, this study emphasizes how tectonic conditions play a fundamental role in the magmatic response of subduction-associated volcanism in the Southern Central Andes and

Northern Patagonian Andes. The geological and geochemical evidence presented reveals that the stress conditions of the margin significantly influence the composition, distribution, and evolution of magmatic manifestations in these volcanic arcs, highlighting the complexity and sensitivity of these systems to tectonic conditions.

Petrological characteristics of the volcanic rocks of the Pugo Formation and Zigzag Formation: Insights on the arc evolution of the Central Cordillera, Philippines

ARA JOY APONGAN ABATAYO[1]*, National Institute of Geological Sciences, University of the Philippines Diliman (aaabatayo@up.edu.ph)
Betchaida Payot[2], National Institute of Geological Science, University of the Philippines Diliman
Gabriel Theophilus Valera[3], National Institute of Geological Science, University of the Philippines Diliman

Abstract

Island arcs are tectonically active belts of intense seismic activity and magmatism. The Philippine island arc system is ideal for studies focusing on the evolution and formation of island arcs. The Central Cordillera in northern Luzon partly defines the principal magmatic arc of the current subduction zone system. It corresponds to the uplifted and tectonized magmatic arc associated with the subduction of South China Sea along the Manila Trench. The Central Cordillera is floored by the Late Cretaceous to Eocene Pugo Formation. The Pugo Formation is composed of basaltic to andesitic volcanic rocks with minor interbeds of sandstone, argillites, cherts and pyroclastic rocks. Low-grade metamorphism is evident in some places. Overlying the Pugo Formation is the Oligocene Zigzag Formation. The Zigzag Formation is a sequence of conglomerates, shales, andesitic lavas and tuffs. Despite the similarities in the stratigraphic units, the ages of the formations vary which suggests that each formation records the petrological characteristics of a distinct magmatic episode. This work aims to determine the petrographic and geochemical analyses of the volcanic rocks of the Pugo and Zigzag Formations and how they correlate to the evolution of the Central Cordillera.

Exposures of pillow basalts belonging to the Pugo Formation occur in Sabangan, Mountain Province while those of the Zigzag Formation were encountered in Suyo, Ilocos Sur. Petrographic analyses of representative volcanic rocks of the Pugo and Zigzag Formations reveal that these rocks mostly consist of plagioclase and clinopyroxene phenocrysts with volcanic glass, plagioclase laths, and clinopyroxene micrograins groundmass. The Pugo Formation volcanic rocks exhibit sub-trachytic texture while Zigzag Formation volcanic rocks show felty texture. In general, the Zigzag Formations samples have larger mineral grains than the Pugo Formation. Epidote-calcite-chlorite replacement minerals are also more evident in the Pugo Formation samples.

Geochemical analyses of representative volcanic rocks reveal that the Pugo Formation volcanic rocks are mostly basalts while samples from Zigzag Formation are mostly basaltic andesite. The Pugo Formation volcanic rocks are tholeiitic while those of the Zigzag Formation are calc-alkaline signature. The Pugo Formation volcanic rocks exhibit positive trend of FeO* and negative trends of MgO, Cr with increasing FeO*/MgO. Meanwhile, the Zigzag Formation volcanic rocks show negative trends of FeO*, MgO with increasing FeO*/MgO. In general, the Zigzag Formation

basaltic andesites exhibit higher FeO*/MgO and lower concentrations of MgO, TiO2, Cr, and Ni relative to the Pugo Formation basalts. Trace element concentrations reveal that both formations have enriched LILE, LREE and depleted HFSE. Pronounced negative Nb-Ta-Ti anomalies which are typical of arc volcanic rocks are also observed. The Zigzag Formation volcanic rocks have enriched Sr, Ba and Pb relative to the LREEs while the Pugo Formation volcanic rocks have depleted Sr and Ba. The results suggest that the Pugo and Zigzag Formation volcanic rocks possibly record the evolution of an island arc from inception to maturity.

A tale of two metamorphic belts in eastern Taiwan: petrological characteristics

Chin-Ho TSAI[1]*, National Dong Hwa University (tsaich@mail.ndhu.edu.tw)

Abstract

The eastern Central Range of Taiwan is traditionally divided into two elongated metamorphic terranes, the Tailuko belt in the west and the Yuli belt in the east. Differences between the two belts are mainly in rock type, age, and peak pressure-temperature (P-T) condition. These two belts are separated by a shear zone. Both belts are dominated by pelitic-psammitic schists but these rocks' P-T conditions are difficult to constrain unless garnet is present. Metacarbonate and metagranitoid are absent from the Yuli belt, but abundant in the Tailuko belt. By contrast, metaserpentinite is a characteristic rock type of the Yuli belt, but rare in the Tailuko belt. Metabasite occurs in both belts. The Tailuko belt is subjected to polymetamorphism, with metamorphic records in Jurassic, Cretaceous, and late Cenozoic. The Yuli belt is essentially late Cenozoic. Amphibole compositions of representative rock types from the Tailuko belt are all calcic, whereas those from the Yuli belt are in the range of calcic, sodic-calcic, and sodic. Calculated amphibole formulas show significant differences between the two belts. Amphibole unit formulas from the Tailuko belt are intermediate to low in [B]Na (< 0.448), whereas those from the Yuli belt are high in [B]Na (up to 1.498; excluding sodic amphibole). On [B]Na vs. [IV]Al plot, the Tailuko belt's amphibole data show flat and low-angle slopes but the Yuli belt's data mostly show steep slopes with complex scattering. The amphibole compositions indicate that metamorphism of the Tailuko belt includes intermediate and low P/T types, and metamorphism of the Yuli belt is high P/T type.

Keyword

Petrological and geochemical characteristicsof a suite of calc-alkaline granite from Mercara Shear Zone, West Dharwar Craton, India: Implications for tectono-magmatic process from a paleo continental arc setting & evidence of deep crustal melting.

Rigzin NORBOO[1]*, Geological Survey of India, India (rigzin.norboo@gsi.gov.in)
Prantick Santra[2], Geological Survey of India
Anindya Bhattacharya[3], Geological Survey of India

Abstract

Mercara Shear Zone (MSZ) is an intensely deformed, curvilinear shear zone presents in between Western Dharwar Craton (WDC) at the north, north-east and the Coorg Block (CB) at the south and south-western direction. The MSZ exposes numerous bands and enclaves of granulite grade meta-supracrustals and mafic granulites hosted in charnockite or felsic orthogneiss (retrogressed charnockite) and is intruded by granite along the mid axis of the shear zone that bears no signature of metamorphism. Several contradictory views regarding the evolution of the rocks from the MSZ exists and the unmetamorphosed suite of granite has not been studied in detail to understand the evolutionary history of the terrain. To address this issue, we investigated the field disposition, petrography and bulk rock geochemistry of the suite of unmetamorphosed granites from the MSZ. The rock is leucocratic, coarse grained contain biotite and epidote as mafic minerals. Microscopic study shows presence of quartz, K-feldspar and plagioclase as major minerals. Normalised volume percentage of quartz, K-feldspar and plagioclase are as 19-40% (avg~29%), 22-41%(avg~30%) and 28-49% (avg~41%) respectively. Petrological study shows presence of magmatic epidote along with sphene, apatite, monazite, zircon, magnetite as common accessory phases. Absence of hornblende is noted from the intrusive. Geochemical data of the studied sample indicates an I-type affinity and a similar to the trend of Cordilleran granitoids and the I-type granitoids of Lachlan Fold Belts. Trace and rare earth element pattern suggest evolution in a continental magmatic arc setting. The rocks are calc-alkaline, REE pattern is fractionated (La/Yb) CN ≈ 12.62–56.29; average 30.42), enriched in Ba, Sr, Pb, Th and depleted in high field strength elements(HFSE) like Nb, Ta, Ti with almost no significant negative Eu anomaly (Eu/Eu* ≈0.91–1.09). These characteristics indicate dominance of crustal involvement over mantle in the generation of melt. Studied rock sample shows an ‘adakite-like’ geochemical features (high Sr/Y, La/Yb) but are not product of a typical slab melting. Our study indicates that the granites were derived by partial melting of a thick crustal source in an oxidised condition (fO2 between NNO and HM buffer) at 941–987oC and 10–12.5 kbar pressure (corresponding to 30–40 km depth).

Petrogenesis of the Early to Middle Miocene Mafic Volcanism of the Huantraico Sequence, Argentina

Carina Liliana GRECO[1]*, Universidad de Buenos Aires (cari_greco@hotmail.com)
Sofía Iannelli[2], Universidad de Buenos Aires - CONICET
Vanesa Dafne Litvak[3], Universidad de Buenos Aires - CONICET
Silvia Leonor Lagorio[4], SEGEMAR

Abstract

The Huantraico sequence (Early – Middle Miocene) is located in the present-day Andean back-arc between 37°10'S - 37°40'S and 69°44'W - 69°30'W in Argentina. It is composed of basaltic to andesitic lava flows interbedded with thick pyroclastic rocks, such as crystal and lithic tuffs. Geochemical and petrological studies characterize the volcanic rocks of the Huantraico sequence to evaluate the ancient subduction zone configuration in the Andean margin. In the lower stratigraphic sections, up to 30 m thick tuffs predominate, alternating with aphanitic basalts. These pyroclastic rocks are associated with a ferriferous mineralization that consists of pure magnetite with apatite gangue, occurring as centimetre-mantles, veins, and veinlets. Towards the upper stratigraphic levels, lava flows predominate with minor breccias and pyroclastic rocks intercalations. In thin section, the basaltic flows exhibit a porphyritic texture with phenocrysts of plagioclase, olivine, and clinopyroxene phenocrysts embedded in an intergranular to pilotaxitic groundmass in the more andesitic varieties. The pyroclastic rocks are composed of plagioclase and quartz fragments, and porphyritic volcanic rocks lithoclasts immersed in a pyroclastic matrix with devitrification textures. The main pyroclasts are pumice fragments and shards with triaxone shapes. Geochemically, the rocks are transitional to alkaline basalts, trachybasalts, trachyandesitic basalts, and trachyandesites (45.7 - 63.6% SiO2). The La/Ta (~12 - 26), Ba/Ta (~191 - 398), and Ba/La (~9-33) ratios indicate a slight influence of slab fluids in the mantle source. The HFSE ratios, such as Th/Hf, Ta/Hf, and Nb/Y (0.53 - 1.5, 0.27-0.38, 0.6 - 1.5, respectively), suggest an enriched intraplate-like source. Multielement diagrams show minor positive anomalies of Sr and LILE and negative anomalies of Ti. The geochemical signature of this volcanism is associated with a transitional composition between intraplate and arc-like rocks in a back-arc environment within an extensional setting. A new U-Pb age from a crystalline tuff yielded an age of 20.9 ± 0.4 Ma for the lower sections of the sequence. The current hypothesis regarding the evolution of the Huantraico magmatic sequence is associated with changes in slab geometry and upper plate configuration through time. In the Middle Miocene (~ 18 Ma), a shallow subduction regimen named "Payenia shallow subduction zone" was installed between ~ 34° 30´S and ~ 38° S in the Southern Central Andes (Argentina) and consequently arc-like magmatism migrated towards the east. Then, by the Latest Miocene – Early Pliocene, the Nazca plate destabilized and re-steepened, allowing an asthenospheric upwelling and the development of intraplate-like volcanism in the back-arc area. As the Huantraico sequence is the first magmatic eruption that exhibits a weak but increasing arc signature towards the younger levels, it would represent the earliest evidence of the

development of the Middle to Late Miocene Payenia shallow subduction zone, thus constituting an essential record for understanding the Miocene magmatic evolution of the Southern Central Andes. The new U-Pb age provides precise constraints of the Huantraico sequence pyroclastic activity linked to the magmatic arc expansion.

An improved Faraday cup configuration for Sr isotopic analysis using LA-MC-ICP-MS and its applying on rich-REE apatite

Xirun Tong[1]*, Wuhan Center, China Geological SurveyGeosciences Innovation Center of Central South China (tongxirun@mail.cgs.gov.cn)
Qiu Xiaofei[2], Wuhan Center, China Geological SurveyGeosciences Innovation Center of Central South China
Lu Shansong[3], Wuhan Center, China Geological SurveyGeosciences Innovation Center of Central South China

Abstract

Correction of the interference of REE2+ in Sr isotopic analysis using LA-MC-ICP-MS remains challenging. In this study, we addressed this issue by employing the Peak Stripping Method (PSM) combined with an Improved Faraday Cup Configuration (IFCC) of MC-ICP-MS, which allows for synchronous detection of REE2+. Our evaluation of IFCC revealed that no decoupling of REE2+ signals was observed, indicating that IFCC is well-suited for use with PSM to correct the interference of REE2+. The measured ratios of Er2+ and Yb2+ signals (r: 166, 168, 170Er2+/167Er2+ and 170, 172, 174, 176Yb2+/173Yb2+) are approximately equal to the natural isotopic abundance ratios of Er and Yb (R: 166, 168, 170Er/167Er and 170, 172, 174, 176Yb/173Yb). This property allows PSM to accurately correct the interference of REE2+ with R and the measured signals of 167Er2+ and 173Yb2+. We also determined the Sr isotopic compositions of the Er and Yb-spiked 0.1μg/g NBS987 Sr solutions using SN-MC-ICP-MS with IFCC, and the results indicate that PSM can correct the interference of REE2+ in solutions with Sr/Er > 3, while the Enhanced Peak Stripping Method (EPSM) can correct the interference in solutions with Sr/Er > 1, where a measured r is used as the interference correction factor. The Sr isotopic compositions of two rich-REE apatite reference materials (Durango with Sr/Er = 7.4, and UWA-1 with Sr/Er = 2.8) were determined using LA-MC-ICP-MS with IFCC, and the determined 87Sr/86Sr of the two apatites are 0.70627 ± 0.00014 (2SD, n = 19) and 0.70476 ± 0.00019 (2SD, n = 20), respectively. Both well agree with previously published data (determined by TIMS or MC-ICP-MS) within uncertainties.

Abstract

Earth and other terrestrial planets are characterised by complex evolutionary stages reflected in the formation of a large variety of igneous rocks. During the last fifty years, IUGS has led the efforts of groups of petrologists in proposing widely accepted and easy-to-use tools to classify igneous rocks providing updated approaches based on mineralogy, petrography and geochemistry. Igneous rock classification was unwieldy by the 1980s, riddled with type locality nomenclature that obstructed recognition of significant geological processes and often referring to similar rock types with different local names.

Concerted efforts by an IUGS Subcommission on the Systematics of Igneous Rocks led to unified classification that has been fully adopted by the geoscientific community [1, 2]. These efforts reduced igneous rock nomenclature from over 1000 names to less than 350 endorsed terms of global significance. Despite these improvements, problems remain with classification schemes, and new issues emerge after more than two decades from the last edition of the IUGS book. For example, widely used concepts (e.g., the distinction between tholeiitic and calc-alkaline rock series or the tools to distinguish sodic to potassic and ultrapotassic variants) are not fully treated if not completely avoided in the 2002 IUGS edition [2]. In addition, the definition of "subalkaline" rocks (actually "subalkali" rocks) is reported as "rocks that are not alkaline in character", but not indication of the essential features of alkaline rocks is reported. To continue, the classification and nomenclature of potassic and ultrapotassic rocks (e.g., kalsilite-bearing rocks, kimberlites, lamproites, lamprophyres), as well as other relatively common (e.g., MgO-rich volcanic rocks) and rare lithologies (e.g., carbonatites) needs profound revisions.

In 2021, a new IUGS task group was created aiming to solve the problems with igneous rock

classification systems and to work towards solutions in aid of petrogenetic studies. Extraterrestrial magmatic rocks will be included for the first time into classification schemes to capture progress made in planetary studies. Geochemical data platforms, such as GEOROC and PetDB, use the vocabularies recommended by disciplines that generate the data, but often new challenges are created along the way. In this contribution we provide an update on the latest efforts to further improve igneous rock classification, to stimulate cross-disciplinary discussions about how to make magmatic petrology and geochemistry fit for the future.

Revisiting the crustal growth of the eastern Central Asian Orogenic Belt: Insights from the Erguna Massif and Duobaoshan area

Chenyang SUN[1]*, Northwest University (chenyang.sun@nwu.edu.cn)

Abstract

The Central Asian Orogenic Belt (CAOB), as the largest accretionary orogenic belt on Earth, provides a natural laboratory in which to understand the crustal evolution history. Crustal growth within the eastern CAOB was previously thought to be occurred mainly during the Phanerozoic, as inferred from the highly positive εNd(t) values and low initial 87Sr/86Sr values of granitoids in the belt. Increasing evidence suggests that this phase of crustal growth may has been overestimated. Taking the Erguna Massif and the Duobaoshan arc as examples, we summarize the data from our team in recent years and combine them with other studies to establish the regional crustal evolution history.

A crustal growth curve for the Erguna Massif was established based on the calculation formula proposed by Belousova et al. (2010). The growth curve indicates that the proto-crust of the Erguna Massif formed in the Mesoproterozoic, and shows an episodic feature with three growth periods at 2.9-2.7, 2.1-1.9, and 1.7-0.5 Ga. Moreover, these three growth stages are closely related to the evolution of three supercontinents, indicating lateral crustal growth induced by their convergence. The calculated crustal reworking ratio and established reworking curve indicate that significant inhibition of crustal growth rates occurred during four crustal reworking periods. Crustal reworking is regarded as an important factor contributing to the crustal heterogeneity of the Erguna Massif.

Detrital zircons from river sediments provide large-scale geological records. We reanalyzed the detrital zircon data obtained from modern rivers in NE China and further established the crustal growth curve of the eastern CAOB. The curve exhibits a typical three-phase crustal growth similar to that of the Erguna Massif, demonstrating that the crust of the eastern CAOB reached a volume comparable to that of the present crust by the late Precambrian.

However, it should be emphasized that the crustal growth during the Phanerozoic in the eastern CAOB did not entirely cease. Based on our detailed study of the Duobaoshan arc, formed during the accretionary process of the Xing'an and Songnen massifs, the crust in the Duobaoshan area exhibits characteristics of early Paleozoic neogenesis, resulting from the closure of the Paleo-Asian Ocean branch, the Nenjiang Ocean. Subsequent granitoids in this area all have Paleozoic model ages, indicating the reworking of early Paleozoic crust.

In summary, the microcontinents in the eastern CAOB contain Precambrian basements. Previous studies have to some extent overlooked the Precambrian crustal evolution. However, it cannot be denied that areas represented by Duobaoshan continental arc still exhibit unique Phanerozoic crustal growth.

This study was financially supported by the National Natural Science Foundation of China (Grant

No. 42202050; 41772047).

Chromite formation during 0.3 GPa crystallisation of magmas produced by peritectic orthopyroxene entrainment during incongruent melting of garnet + clinopyroxene + olivine assemblages in the upper mantle: An experimental investigation

Tahnee OTTO[1]*, Stellenbosch University (tahneeotto@sun.ac.za)
Gary STEVENS[2], Stellenbosch University

Abstract

The Rustenburg Layered Suite (Bushveld Complex, South Africa) is uniquely enriched in chromium (Cr), hosting several laterally continuous chromitite layers. The two main requirements for the formation of the chromitites: 1) Unusually Cr-enriched magma, and 2) a period of chromite only crystallisation at emplacement conditions. Several models exist that attempt to explain both caveats, involving mechanisms such as magma mixing, changes in pressure or oxygen fugacity (fO2), water addition, etc. Using a phase-equilibrium modelling approach, Otto et al. (2024) recently proposed that the chromitite and silicate layering of the suite formed due to processes occurring in the mantle source, where the entrainment of Cr-bearing peritectic orthopyroxene to the magma during the partial melting of peridotite results in a MgO- and Cr2O3-rich magma composition, 'A4', that produces chromite saturated crystal-melt slurries during magma emplacement.

Using a 19 mm non-end-loaded piston-cylinder apparatus, we experimentally investigated the crystallisation behaviour of model magma A4, assessing the potential of Cr to crystallise independently of other silicates by exploring the assemblages that form close to the liquidus at 0.3 GPa. The solubility of Cr in melt is strongly dependent on fO2, with more reducing systems favouring higher solubility. By using graphite-lined Pt capsules, the experiments were locked into the graphite-buffered range of fO2 values. The high MgO content of A4 made synthesising a crystal-free glass at 1 atm impossible. Thus, the starting material was prepared as an anhydrous glass, synthesised at 1400 ºC and 1 atm in a CO2-CO atmosphere, mixed with 20 wt.% dry MgO to produce the desired composition. In addition, 3 wt.% H2O was added to the starting material, as the presence of water has been shown to depress the crystallisation of silicate minerals (Veksler & Hou, 2020).

The results show that magmas with compositions consistent with formation by peritectic orthopyroxene entrainment, in the presence of water and when buffered to fO2 values below QFM, encounter the 0.3 GPa liquidus at between 1250 ºC and 1300 ºC. Olivine or chromite may define the liquidus, as the 1250 ºC run product contained both olivine and chromite in addition to quenched melt. The Cr2O3 contents in the melts are in good agreement with the work by Poustovetov & Roeder (2000), highlighting the control fO2 exerts on the solubility of Cr in the melt. With only chromite and olivine present with melt in all experiments below the liquidus, the

effect of water has been to supress the crystallisation of pyroxene to a greater degree than olivine.

The experiments demonstrate that mantle-derived magmas of low fO2 will intrude at crustal pressures with a potentially high content of dissolved Cr. The interaction of this high-Cr magma with small amounts of Transvaal Supergroup derived metamorphic fluids may result in a more oxidised, volatile-bearing magma, which may trigger chromite saturation whilst depressing the silicate solidus. Thus, chromitite layers may form as cumulates, even in hot magma able to thermally corrode the cumulate pile, with chromite formation principally driven by an increase in oxygen fugacity.

Geochemistry and petrogenesis of Janga Iron-Copper skarn deposit, Kerman province

Maliheh NAZARI[1]*, PNU (nazarimaliheh100@yahoo.com)
Shohre Hassanpour[2], PNU

Abstract

The Kerman magmatic belt is located in the southern part of the Urmia-Dokhtar magmatic arc (UDMA) and consists of various intrusive and volcanic-sedimentary rocks. This belt was formed due to the closure of the Neo-Tethys and the subduction of the oceanic crust beneath central Iran in an arc-continent collision environment. Magmatism in this region is believed to have started during the Oligocene period. Skarn mineralization occurred in the area adjacent to the Cretaceous limestone, with a range of minerals including garnet, clinopyroxene, epidote, and other minerals such as chlorite, tourmaline, actinolite, quartz, and calcite. Additionally, there were ore minerals such as pyrite, chalcopyrite, pyrrhotite, and minor amounts of sphalerite and magnetite. The abundance of magnesium-bearing minerals like diopside and calcium-bearing minerals such as garnet and epidote in the host rock suggests a calcitic-dolomitic type. Two principal types of garnet were identified in the skarn zones: (I) weakly-altered euhedral coarse-grained isotropic garnet exhibits minor variation in the overall composition (And25.95–39.41 Grs54.95–62.25 Alm + Sps + Py5.39–13.04); (II) strongly-altered anhedral to subhedral isotropic to anisotropic garnet shows a wide variation in the overall range of composition (And25.91–55.25 Grs41.37–61.15 Alm + Sps + Py1.48–12.85) in which FeOt increases, whereas Al2O3 decreases rimward. The formation of skarn and mineralization in this region is believed to have occurred in three stages. During the first stage, anhydrous minerals such as garnet and grossular diopside were formed at high temperatures. The second stage was marked by the formation of andradite. In the third stage, anhydrous minerals were replaced by hydrous minerals at lower temperatures, resulting in the formation of minerals like epidote, chlorite, and tourmaline.

Eoarchean crustal evolution of the North China Craton revealed by U-Pb ages, trace elements and Hf-O isotopes of detrital zircons from the Caozhuang quartzite

Hao WANG[1]*, Institute of Geology and Geophysics, Chinese Academy of Sciences (wanghao@mail.iggcas.ac.cn)
Jin-Hui Yang[2], Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

Earth has undergone irreversible geodynamic evolution from magmatic ocean, though some unknown tectonic modes (possibly stagnant or sluggish lid), to modern-style plate tectonics due to secular cooling of Earth's interior. The exact timing and mechanisms controlling the transitions between different tectonic modes from one to another continue to attract controversy, and this bears on the fundamental question of when the modern-style plate tectonics started. The modern-style plate tectonics is characterized by a global network of plate boundaries, and thus any indicators for the operation of plate tectonics on early Earth should be globally synchronous. However, the rock records for the early Earth are very sparse, which limits our exploration for the global simultaneity of geodynamic transitions. Zircon has strong resistance to physical and chemical changes and can be survived from multiple sedimentary and metamorphic cycles, so continued records from Hadean to present can be retrieved from zircon. Studies on detrital zircons from several ancient cratons (e.g., the Yilgarn and Singhbhum cratons) revealed obvious shift of detrital zircon trace elemental and Hf-O isotopic evolutions during Eoarchean, which was suggested to witness the onset of modern-style plate tectonics during Eoarchean. Here, we explore the possible Eoarchean geodynamic transitions from the perspective of the Caozhuang quartzite of the North China Craton. The Caozhuang quartzite had the youngest concordant age cluster for detrital zircons at 3.55 Ga and underwent high-grade metamorphism at 3.5 Ga, which makes the Caozhuang quartzite among the oldest clastic sedimentary rocks around the world. The detrital zircons were euhedral or subhedral in shape, indicating they were of local provenance. The detrital zircon U-Pb age spectra of the Caozhuang quartzite show continued records from 3.89 Ga to 3.55 Ga with two main peaks at 3.80 and 3.68 Ga, which resemble those of the Anshan gneissic complex. In addition, the concordant detrital zircons in the Caozhuang quartzite show variable $\delta^{18}O$ (mainly from 3.37 to 8.12) and $\varepsilon Hf(t)$ (mainly from -4 to +4) values, which are also comparable with those of the Anshan gneissic complex. Accordingly, the Anshan gneissic complex was the most probable source rocks for the Eoarchean to early Paleoarchean zircons in the Caozhuang quartzite. Most importantly, the Caozhuang detrital zircons show continuous and smooth evolution trends without obvious shift for $\varepsilon Hf(t)$, $\delta^{18}O$, Ti-in-zircon temperatures, oxygen fugacity, Eu/Eu*, Th/Nb, and the inferred SiO_2 contents of their host rocks. This indicates the lack of global simultaneity of geodynamic transitions during Eoarchean, and thus the proposal that modern-style plate tectonics started during Eoarchean is not supported by the study presented here. The binned averages of $\varepsilon Hf(t)$ values for every 20 m.y. interval decrease monotonically from

+1 at 3870 Ma to -2 at 3570 Ma, and binned average δ18O values are elevated in relative to the normal mantle zircon and fall in a narrow range of 6 to 7. These isotopic characteristics indicated that the Eoarchean felsic continental crust of the North China Craton formed by partial melting of mafic rocks that underwent low-temperature water-rock interaction after separation from chondritic mantle source.

BAIGALMAA Norov[6], National University of Mongolia

Abstract

The Bargilt iron deposit is located in the Bor-Undur ore district in the South Kherlen-Buyant metallogenic belt of the Central-Eastern Mongolia metallogenic province The host rocks of the deposit are schist, biotite gneiss, biotite-amphibolite gneiss, limestone and quartzite. Some of their ages has been on the assumption as the Neoproterozoic unclassified metamorphic complex and acidic volcanic rocks of the Lower-Middle Permian Burentsogt formation, Quaternary sediments the Paleozoic unnamed intrusive complex, the Middle Permian Burentsogt intrusive complex and the Late Triassic-Early Jurassic Bor-Undur intrusive complex. However, there has been few reports on the constraints of the absolute age of them including U-Pb geochronology. Here we report the description of whole rocks petrography and zircon U-Pb age results of the deposit. Based on petrographical observation, the major host rocks distributed in the open pit of the Bargilt deposit were classified into quartzdiorite gneiss, fine-medium grained hornblende-biotite plagiogranite gneiss, subalkaline granite gneiss, irregular grained leucocratic granosyenite, fine to medium-grained biotite bearing granite and rhyolite. Zircon grains from seven samples were separated from the Bargilt iron deposit and the U–Pb isotopic analyses were conducted using a SHRIMP IIe at KBSI, South Korea. In this deposit, there are different ages rocks distributed such as Neoproterozoic, Cambrian, Devonian, Permian (Guadalupian and Lopingian). These various age range of the rocks in the Bargilt deposit indicate the occurrence of the complex and multiple intrusion events in the study area.

Petrography and Geochemistry of Metamorphic Rocks in Logbadjeck Quarries (Littoral Region, Cameroon): Environmental Impact

Nkeng Enstein FORCHENALLAH [1]*, Ministry of Mines Industry and Technological Development (nkengenstein8@gmail.com)
Tiabou Feudjio Anicet[2], University of Buea

Abstract

*This work presents principally the textural and mineralogical characteristics of metamorphic rocks mined as aggregates for construction materials and the environmental impact of blasting in Logbadjeck quarries located between latitudes N*3°54'-3°60' *and longitudes E*10°01'-10°10' *in the Nyong Series, which form part of the Congo Craton in Cameroon. Thin sections of selected samples were described under a petrographic microscope. These samples were further analyzed by XRF and ICP-MS methods for major and trace elements respectively. Preliminary results show that, the main rock types in the study area are biotite gneiss which exhibit a granoblastic microstructure made up of quartz* (40-45%), *plagioclase* (<21%), *biotite* (20-25%), *amphibole* (1-2%), *and opaque minerals* (5%) *as accessory minerals and amphibolite showing a granoblastic microstructure consisting of amphibole* (60-70%), *quartz* (~5%), *plagioclase* (~5%), *biotite* (15%), *zircon* (~2%) *and opaque minerals* (~3%). *The paragenesis of these rocks indicate that they were metamorphosed under greenschist and amphibolite facies respectively. The mineral assemblages and geochemistry suggest that biotite gneiss* (*SiO*2: 64-72%) *is tholeiitic, peraluminous with S-type composition and plots in the igneous protolith. Amphibolite* (*SiO*2: 39-48%) *is tholeiitic, metaluminous with I-type composition and also plots in the igneous protolith. Both rock types display negative correlation of major oxides and trace elements against SiO*2 *with some exceptions. Their REE pattern show negative Eu anomaly which is an indication of LREE enrichment over HREE and a plagioclase fractionation during partial melting. Multi-element normalized diagrams possess Ba, Nb, Sr, and P anomalies which are characteristics of crustal source. In the study area, the rocks examined are blasted to aggregates of different sizes* (0-5 *mm*, 4-6 *mm*, 5-15 *mm*, 6-10 *mm*, 10-14 *mm*, *and* 15-25 *mm*) *and rubble. These aggregates are sold to individuals and professionals for construction purposes including the fabrication of building blocks and road constructions* (0-5 *mm*), *the construction of roads and bridges* (4-6 *mm*, 6-10 *mm*, *and* 10-14 *mm*), *the construction of houses, roads, reinforcement of concretes, driveways, decoration and recreation* (5-15 *mm*) *and the construction of road pavements and floor tiles* (15-

25 *mm*). *The rubble is used for the construction of walls and building demolition in mortars. In this area, the environmental impact of blasting include induced ground vibrations, air blast, flyrock, blasting fumes, dust and water pollution.*

Syn-collisional crust-mantle interaction in Himalayan passive continental margin: a response to lithospheric flexure

Lin MA[1]*, Guangzhou Institute of Geochemistry Chinese Academy of Sciences (malin@gig.ac.cn)
Qiang Wang[2], Guangzhou Institute of Geochemistry Chinese Academy of Sciences
Andrew Kerr[3], Cardiff University
Zheng-Xiang Li[4], Curtin University
Wei Dan[5], Guangzhou Institute of Geochemistry Chinese Academy of Sciences

Abstract

More than 95% of global magmatism occurs in mid-ocean ridges and subduction zones. In addition, except for oceanic plateaus and large igneous provinces, other intra-plate magmatism, especially in passive continental margins, is very rare and provides a crucial window for probing the composition of mantle and deep processes.

The Himalaya belt is the most active collisional orogen in the world and has a profound impact on the Asian geomorphology and climate during Cenozoic. Generally, collisional orogenic zones are considered to be unfavorable to formation of magmatic rock. However, in Himalaya orogen, the syn-collisional magmatism occurred on both sides of the suture zone with different features. The southern margin of the Asian plate above subduction-collision zone is characterized by thickened juvenile crust and a relatively high crustal thermal state. In contrast, the northern edge of the Indian plate is marked by a thickened ancient crust with a moderate geothermal gradient during the early stage of collision. The 48–35 Ma Tethyan Himalaya magmatism, consisting of high Sr/Y granitoids within gneiss domes and coeval gabbro and mafic dike, is slightly younger than the magmatic peak in the Lhasa block (southern margin of the Asian plate) (51 ± 3 Ma). However, the generation mechanism and dynamics of syn-collisional magmatism is poorly understood due to the lack of critical evidence.

Here, based on our study of newly found Eocene Himalaya OIB-like mafic dykes and existing evidence of magmatism, metamorphism and tectonic, a new model is proposed to understand the mechanisms of magma generation and orogenic evolution within the lower-plate (a previous passive margin) side of a convergent orogen.

During early continental collision, break-off of the Neo-Tethyan oceanic slab and/or lithospheric delamination of the southern Lhasa terrane caused melting to produce the ca. 51 Ma magmatism in the southern Lhasa block along the suture zone. After the 51 Ma magmatic event, lithospheric flexure formed along the northern Indian continent parallel to the suture, causing brittle cracking (i.e., bending-induced faults) and the 48–45 Ma melting in the northern Himalaya. The melts derived by decompression melting of the lithosphere-asthenosphere boundary intruded to shallow levels of the lithosphere along extensional fractures below a neutral plane of downwarped lithosphere. Emplacement of these mafic magmas likely provided the heat source for the formation of coeval (51–40 Ma) orogen-parallel crustal anatexis, and thus the orogen-parallel gneiss domes. This study may provide new insight into generation of syn-collisional granitoids.

Late Ediacaran Magmatic Activity in the Southern Dom Feliciano Belt (Northeastern Uruguay): Insights from U-Pb Zircon Dating and Hf Isotopic Composition of Dikes

Elena Peel[1]*, Faculty of Science - UDELAR (elena@fcien.edu.uy)
Belén Viera[2], PEDECIBA - Geociencias (UDELAR)
Rossana Muzio[3], Faculty of Science - UDELAR
Lucía Olivera[4], Faculty of Science - UDELAR
Santiago Fort[5], Faculty of Science - UDELAR

Abstract

This study presents an integrated geochronologic and isotopic analysis of two sets of dikes intruding the Pelotas Batholith in northeastern Uruguay. The aim is to contribute to unraveling the petrogenetic processes and tectonic evolution of the Dom Feliciano Belt during the late Ediacaran, related to the waning stages of the Brasiliano-Pan-African orogenic cycle. One set of dikes comprises acidic rocks, primarily porphyritic rhyolites, characterized chemically as slightly peraluminous with a high-K calc-alkaline affinity. The other set includes basic dikes corresponding to microgabbros, known as the Corral de Piedra dike swarm, which exhibit a tholeiitic affinity and metaluminous nature. Until now, no ages were available for either type of dike.

The methodology employed in the study involved the separation of zircon crystals, followed by their analysis using LA-ICP-MS to provide U-Pb ages and Hf isotopic compositions. Zircons from two samples, representative of each dike swarm, were analyzed at the Arizona LaserChron Center (USA). The U-Pb data were obtained using a Nu Plasma HR ICP-MS coupled to a New Wave 193 nm ArF laser ablation system equipped with a New Wave SuperCell. Hf isotope analyses were performed using a Nu HR ICP-MS connected to a Photon Machines Analyte G2 excimer laser. Standards were used for fractionation correction and to ensure the accuracy of the results. Cathodoluminescence images were utilized to ensure that the ablation pits did not overlap multiple age domains or inclusions.

The results reveal very similar crystallization ages of 573.3 ± 4.2 Ma for the rhyolitic dikes and 571.7 ± 5.4 Ma for the microgabbro dikes, placing them in the late Ediacaran period. Furthermore, the initial εHf values obtained range from -12.6 to -1.18 for the acidic dikes and from -11.1 to +0.42 for the basic dikes, indicating significant crustal involvement in the magma genesis of both dike swarms. Hf T_DM ages spanning from 1.96 to 1.34 Ga for the acidic dikes and from 1.98 to 1.45 Ga for the basic dikes suggest the participation of older crustal components in the magma source.

Based on these results, the acidic dikes can be assigned to the Sierra de los Ríos Formation, a unit that occurs in the area and comprises rhyolitic and ignimbritic flows with similar ages. Additionally, in southern Brazil, acidic and basic dikes, as well as volcanic and subvolcanic rocks, are described in association with the post-collisional stage of the Dom Feliciano Belt. Notably, similar ages have been determined for the acidic volcanic rocks in that region, suggesting a

synchronous magmatic framework during the Late Ediacaran that spans northern Uruguay and southern Brazil.
In conclusion, the results indicate coeval basic and acidic magmatic activity, implying a complex evolution in the region during the late Ediacaran. This highlights the intricate nature of post-collisional magmatism and provides evidence supporting the involvement of both crustal reworking and potential mantle contributions, thus reflecting the dynamic geological processes during the late stages of the Brasiliano-Pan-African orogeny.

A Preliminary Study of the Geostandards of the Granites and Obsidians using Neutron Activation Analysis and Electron Probe Micro Analysis

JIN MI-EUN[1]*, HANARO Utilization Division, Korea Atomic Energy Research Institute (jin4860228@gmail.com)
Sun Gwang-Min[2], HANARO Utilization Division, Korea Atomic Energy Research Institute
Dasari Kishore Babu[3], Department of Geology, Gyeongsang National University
Jwa Yong-Joo[4], Department of Geology, Gyeongsang National University

Abstract

Geostandards, pivotal in geoanalytical research, enable the acquisition of precise geochemical data and the refinement of analytical techniques. Despite the increasing demand, the development of Korean geostandards ceased in the 1990s. This study endeavors to lay the foundation for new Korean geostandards by selecting representative granites and Baekdusan obsidians. Neutron Activation Analysis (NAA) and Electron Probe Micro Analysis (EPMA) were utilized to determine major/minor/trace element concentrations. Selections for reference material candidates needed to meet specific criteria: representing typical Korean rock types, showcasing homogeneous chemical compositions, free from structural irregularities like fissures or folds, and available in significant fresh rock volumes. Hence, two Jurassic granites and one Cretaceous granite, emblematic of Korean granite rocks, were chosen. While synthetic glass reference materials are prevalent in microanalysis, they may introduce a matrix effect due to differing compositions from geological samples. To address this, we chose to establish a glass geostandard sample. Consequently, we prepared glassy rocks (obsidian), specifically selecting Baekdusan obsidian devoid of inclusions such as microlites. We evaluated the precision and accuracy of our analytical techniques using reference materials from the USGS and GSJ. Subsequently, we determined the chemical composition concentrations within granite rocks. The potential for development as a Korean Geostandard will be assessed by comparing our analysis results with those from other analytical institutions and establishing reference values. We anticipate these reference materials will serve various purposes across research institutes, universities, laboratories, and analytical institutions supporting geoanalytical studies.

Jusun Woo[5], School of Earth and Environmental Sciences, Seoul National University

Abstract

The formation and evolution of supercontinents has been one of the main research topics in geological community over the past few decades, and detrital zircon is useful for the study particularly in area of limited access or rare outcrops. In order to constrain the crustal evolution of the paleo-Pacific margins of East Gondwana, the U¬–Pb-O-Hf isotopic compositions of detrital zircon from metasedimentary rocks in the Wilson and Bowers Terrane, northern Victoria Land, Antarctica, were measured. The former terrane is a continental arc complex primarily composed of metasedimentary rocks and arc-related plutons whereas the latter one comprises weakly metamorphosed marine sediments intercalated with oceanic arc/back-arc volcanic rocks of Cambrian age, and molasse-type shallow marine to deltaic siliciclastic rocks of Late Cambrian to Early Ordovician age. All samples analyzed in the study yield large U–Pb age population of zircon at 1200–1000 Ma and 600–470 Ma without significant isotopic variations in Hf and O. Two major groups of detrital zircon at ~600 Ma and ~1200 Ma show the average δ18O values of 7.5‰ and 6.5‰, respectively. In addition, at all the analytic spots the δ18O values increase with decreasing ages after 2.6 Ga. The εHf(t) regression line, defined by the low δ18O (~4.5–6.5 ‰) zircon, shows that primary magma were extracted from the depleted mantle mainly at either ~1.4 Ga or ~3.4 Ga. Taken together, the formation and evolution of the paleo-Pacific margin of East Gondwana was driven by at least two main pulses of basaltic magma from the depleted mantle, and the differentiation of the primary magma was accompanied by the crustal reworking in the continental lithosphere.

Sr–Nd–Hf isotope and trace-element constraints on the origin of the HIMU reservoir of mafic-ultra mafic intrusions, Pechenga Greenstone Belt: A Potential mantle plume source in the asthenosphere

Sakine MORADI[1]*, State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550081, China (sakinemoradi2017@gmail.com)
Lie-Meng Chen[2], State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang 550081, China

Abstract

Extensive Precambrian Ni–Cu sulfide-bearing mafic–ultramafic complexes within the Pechenga Greenstone Belt (PGB), northwestern Russia, provide an excellent opportunity to assess the mantle characteristics in the back-arc related magmatism. Despite numerous studies conducted on the genesis of sulfide ore deposits in the Pilgujarvi Formation, the source, enrichment processes, and geodynamic evolution of the host intrusion complexes remain widely debated. Therefore, we present new geochemical and Sr–Nd–Hf isotopic data for Ni-Cu-bearing mafic–ultramafic intrusions located in east and west of the Pilgujarvi formation, combining them with previously published data from coeval intrusive rocks in the Kola Peninsula, to constrain the formation of these complexes and associated world-class Cu–Ni oxide deposits. These intrusions are containing three different magmatic rock contain gabbro, pyroxenite, and wehrlite.

Gabbroic samples exhibit higher trace element and REE contents, overlapping with the OIB-like patterns. In contrast, peridotite, and pyroxenite samples are characterized by depletion in the LILEs (e.g., K, Ba, and Sr) but moderately enriched in the HFSEs (e.g., Nb, Ta, P, and Ti) similar to gabbroic rocks. All samples with display low initial 87Sr/86Sr ratios (0.7006–0.7042), un-radiogenic to radiogenic εNd (− 4.7 to 3.4) and εHf (− 10 to 8.7) values, demonstrate the mantle sources beneath the Pechenga are heterogeneous compositionally. The isotope compositions of these rocks plot along a mixing line between HIMU and DMM mantle end-members in isotopic diagrams, with a minor contribution from an EM component and minor decoupling observed between Nd and Hf isotopic compositions. These characteristics resembling the “HIMU”-like component that was derived from mixing between a peridotite and the depleted component (depleted MORB) that is known by pyroxenite from recycled young oceanic crust. Trace-major and isotope modelling also indicating that a pyroxenite mantle type for all type of rocks. Thus, the chemical and isotopic-compositions of the Pechenga mafic-ultramafic rocks are the best explained by decompression partial melting of an ancient and hybrid asthenospheric source. This source likely contains residual garnet within upwelling plume that had previously undergone modification through interactions with subducted Pacific oceanic lithospheric slabs and overlying marine sediments. This scenario can answer the observed slightly enriched Sr–Nd–Hf isotopic compositions, as well as the decoupling between Nd and Hf isotopic compositions in these samples. Our findings are providing a new perspective on the evolution of magmatism in the Pechenga region that have important global implications for understanding the nature, age, and

evolution of the HIMU mantle source in the extensional setting within back-arc basins.

Protolith and metamorphic ages of eclogites from the Eastern Alps

Ruihong Chang[1]*, University of HongKong (changrh@hku.hk)

Abstract

The Austroalpine mega-unit contains the type locality of eclogites (Haüy, 1822) but their protolith age is largely unknown except that of the Permian Bärofen eclogite, for which three Sm-Nd ages between 275 ± 18 and 275 ± 18 Ma have been reported (Thöni & Jagoutz, 1993, Geochim. Cosmochim. Acta 56, 347–368; Miller & Thöni, 1997, Chem. Geol. 137, 283–310). Therefore, we studied the non-gabbroic eclogites from the Saualpe-Koralpe and Sieggraben Complexes, which are considered to represent a previously coherent subducted and then exhumed fragment of a continental rift, which led to the formation of the late Middle Triassic Meliata oceanic basin. A combined zircon U–Pb and Hf isotopic study, whole rock geochemistry of two complexes revealed a protolith age of 242.3 ± 2.6 Ma (Middle Triassic) in the Sieggraben Complex, and 283 ± 5 Ma, 255 ± 3 Ma (Early and Late Permian), 251 ± 3 Ma, and 241 ± 3 Ma (Early to Middle Triassic) in the Saualpe-Koralpe Complex. Magmatic zircons from the Sieggraben eclogites have 176Hf/177Hf ratios of 0.283067–0.283174, εHf(t) values of +15.7 to +19.4, and that from Saualpe-Koralpe eclogite have 176Hf/177Hf ratios of εHf(t) 0.282935–0.283090, εHf(t) values of +10 to +17.4 showing their juvenile mantle source rather than significant crustal assimilation. In both complexes, N-MORB geochemical characteristics are established. Associated ultramafic rocks of Sieggraben eclogites as part of oceanic or Permian subcontinental mantle lithosphere suggest a depleted mantle source and a deep subduction environment. Two zircon grains of Sieggraben eclogites with low Th/U ratios yield ages of 113 ± 2 Ma and 86 ± 4 Ma and represent the approximate age of eclogite metamorphism during Cretaceous. A trondhjemite dike cutting through the eclogite gives a crystallization age of 82.19 ± 0.4 Ma and is formed by partial melting of likely eclogite during decompression. The host metasedimentary rocks of Sieggraben and Saualpe-Koralpe Complexes are interpreted as old continental crust close to the margin of the Meliata basin and were affected by Permian migmatitic metamorphism. Metamorphic zircons of one eclogite from the Saualpe-Koralpe Complex give an age of 87–93 Ma (peak at 91 ± 1.2 Ma). The results of this study combined with previous results are used to present a new model for the tectonic evolution of the distal Austroalpine unit associated with the Meliata Ocean in a Wilson cycle: The Austroalpine Sieggraben and Saualpe-Koralpe Complexes represent a location on the distal continental margin during Permian to Middle Triassic rifting. The mafic rocks are associated with numerous Permian and potential Triassic acidic pegmatites, whereas structurally separated thick Triassic sedimentary cover successions lack any magmatism, likely excluding the present-day eclogite-bearing units as Triassic basement of the sedimentary cover successions.

The now eclogite-bearing piece of continental crust was adjacent to the Meliata oceanic lithosphere subducted during Early Cretaceous times to mantle depth. The subducted continental crust was then exhumed incorporating even ultramafic mantle rocks. During exhumation and decompression of mafic rocks, partial melting took place forming the trondhjemite dike in Late

Cretaceous times.

Proterozoic Zircons in Neogene Semporna Peninsula volcanic rocks and its indication of ancient continental crust in Northeastern Borneo

Elvaene JAMES[1]*, Universiti Malaysia Kelantan (elvaene@umk.edu.my)
Azman Abdul Ghani[2], Universiti Malaya
Chung Sun Ling[3], National Taiwan University

Abstract

Volcanic activity was active during Miocene after the subduction in Semporna Peninsula, Northeastern Borneo, Malaysia. However, the volcanic activity started to terminate following the arc-continental collision after the Proto-South China Sea. The timing of magmatism in Miocene implying the major events of Miocene subduction in Southeast Sabah. The Semporna Peninsula is dominantly composed of mafic to felsic volcanic rocks of subalkaline/tholeiitic series ranging from basalt, basaltic andesite,
andesite, dacite and rhyolite. This study reports a study of zircon U-Pb geochronology for Miocene intermediate and felsic volcanic rocks from Semporna Peninsula, Northeastern Borneo. Based on the concordia plot, the age indicates Proterozoic xenocrystic zircons ranging from 0.6 to 2.0 Ga are incorporated within the Miocene Semporna Peninsula volcanic rocks. Not to mention the Th/U ratios suggest the zircon grains for Miocene volcanic rocks showing magmatic origin with combination of mafic and felsic melts. The result from zircon U-Pb for Miocene volcanic rocks suggests that some part of fragment from Western Australia might drifted to Northeastern Borneo. Based on the Lu-Hf isotope data, it can be further suggest that the Semporna Peninsula basements are heterogeneous sources and dominantly in Proterozoic. The zircon U-Pb data provide new insight on the Precambrian evolution history in Semporna Peninsula area.

Age and Petrogenesis of appinite suites and high Ba-Sr granites in Chuncheon at the central Gyeonggi Massif, Korea

In-Hye MOON[1]*, Kangwon National University (mih@kangwon.ac.kr)
Young-Rok PARK[2], Kangwon National University
Kideok D. KWON[3], Kangwon National University

Abstract

There are coeval appinite suites and granites in the Chugokri area in Chuncheon at the central Gyeonggi massif. Appinite suites consist of hornblendite, hornblende gabbro, quartz hornblende gabbro, pegmatitic gabbro, diorite, which all contain hornblende as dominant mafic mineral. Granites are composed of major porphyritic biotite granite and minor equigranular biotite granite, and are classified into high Ba-Sr granite. At the boundary between granites and appinite suites, evidence of magma mingling and mixing are observed. We measured LA-MC-ICP-MS zircon U-Pb dating of the hornblende gabbro, pegmatitic gabbro, and porphyritic biotite granite, and the results are 184.3±0.36 Ma, 184.3±0.37 Ma, and 185.3±0.64 Ma, respectively. This indicates that appinite suites-granite complex formed penecontemporaneously at Early Jurassic Pliensbachian. Geochemical data and modelling result indicate that appinite suites originated from a single magma derived by partial melting of metasomatized mantle peridotite through assimilation and fractional crystallization (AFC) process, and granites adjacent to appinite suites formed from distinct felsic magmas derived through partial melting of continental crustal rocks by crustal anatexis process, which triggered by heat addition from mafic magma producing appinite suites. Geochemical features such as spider diagram, rare earth element pattern, geotectonic discrimination diagram, and predominance of hydrous mafic mineral of amphibole in appinite suites suggest that appinite suites and granitoid in the study area were generated at subduction zone. The igneous activity occurred in association with the Early to Middle Jurassic igneous activity (about 200-164 Ma) of the Korean peninsula.

Role of basement tectonics and structural features in the seepage potential at the Cham –e Shir dam site, SW Iran

Arash Barjasteh[1]*, Khuzestan Water & Power Authority (KWPA) (barjasteh@hotmail.com)

Abstract

Cham-e Shir RCC dam was constructed over Zohreh River in the southwest of Iran. This article aims at explaining the role of basement tectonics and structural elements on possible seepage through the dam site and quality decrease of the river based on the data obtained from the previous reports, field surveys, satellite images and aerial photos. The dam site is located in a NW-SE trending highly fractured synclinal growth structure composed of marlstones and limy marlstones of Miocene Age with evidence of karstification. The region is in the Zagros Active Fold Belt of Iran with several faults cutting the area including Cham-e Shir normal fault perpendicular to dam axis and N-S trending dextral basement fault i.e., Kharg-Mish Fault. The longitudinal profile of the river shows a knickpoint with 100 m length at the dam axis. The dam reservoir area is mostly underlain by Oligo-Miocene Evaporates. The study showed that the minimum length of seepage path at the site is about 180m regarding to the fracture spacing and opening that is about 40m and 0.5m, respectively on average. The TDS of the river changes from 5000 to 650 mgrs /lit upstream and at the dam axis due to high permeability and opening of the fracture system which indicates high leakage through the rocks. Due to dam site fracturing especially in the right abutment, 36 percent of Lugeon tests show very high permeability. The estimated 320000 m^3/day possible seepage through the site can be reduced to 21000 m^3/day by establishing a grout curtain.

Research on Key Technologies of 3D Geological Model Rendering in Cloud Environment

Yue SONG[1]*, Natural Resources Comprehensive Survey Command Center, China Geological Survey (sally_syue@qq.com)
Zhenji Gao[2], Natural Resources Comprehensive Survey Command Center, China Geological Survey

Abstract

3D model is a 3D digital representation of objective things, which has been widely applied in fields like urban construction, disaster prevention and mitigation, medical research, biological science, industrial manufacturing, agricultural production, etc. As a special 3D model, 3D geological model possesses the characteristics of 3D model and plays a fundamental role in geological survey, mineral exploitation, underground engineering and smart city construction.

With the development of intelligent sensing technology and 3D geological modeling technology, the scale of 3D geological model data increases exponentially. Meanwhile, with the pace of large-scale underground engineering and smart city continuing to increase, 3D geological model with fine large scenes is being eagerly required. The rapid growth of data and the refinement of large application scenes bring new challenges to the real-time dynamic visualization of 3D geological models.

This paper studies the above issues and puts forward the corresponding solutions. The validity of the technology has been proved by the simulation test of cluster cloud environment consisting of 5 computers. The technique has been applied in the construction of 3D geological information and visualization system in transparent Xiong'an.

(1)The distributed storage mode of 3D geological model is established to improve the efficiency of data access.

(2) The efficient rendering optimization strategy of single node 3D geological model is designed to improve the rendering efficiency of 3D geological model.

(3) A texture mapping method of 3D geological model based on machine learning is proposed to improve the texture mapping effect of 3D geological model.

(4) A cloud-based 3D geological model visualization platform based on Spark big data technology was built to provide support for large-scale 3D geological model visualization.

From the experimental data, the node invocation optimization strategy with "GPU+CPU" can ensure that the frame rate of the four rendering nodes and the end-user scene in the cloud environment is stable at about 35 frames per second, and can achieve satisfactory cluster load balancing effect.

Good Practices and Current Challenges of 3D Geological Modelling at the Czech Geological Survey

Ondřej ŠVAGERA[1]*, Czech Geological Survey (ondrej.svagera@geology.cz)
Jan Franěk[2], Czech Geological Survey
Jan Jelínek[3], Czech Geological Survey
Jakub Kryl[4], Czech Geological Survey
Jan Jelének[5], Czech Geological Survey
Otmar Petyniak[6], Czech Geological Survey
Zita Bukovská[7], Czech Geological Survey

Abstract

Although the Czech Republic is situated in Central Europe and, from a geological standpoint, occupies a stable position, its geological history has been dynamic over geological time. This has resulted in a complex and interconnected geological and structural landscape encompassing everything from unmetamorphosed Paleozoic sediments to remnants of the Variscan orogeny in the form of crystalline complexes, overlaid by well-preserved Cretaceous sedimentary basins, later punctuated by Cenozoic volcanism.

Detailed geological and geophysical mapping conducted over the past century, combined with modern geological databases, forms the foundation of the 3D geological models currently being produced at the Czech Geological Survey (CGS). These models have primarily been created on-demand, serving as frameworks for infrastructure projects such as railroads or highways, deep geological repositories, or the reevaluation of natural resources. According to collaboration with various stakeholders from both the public and private sectors, there is an increasing demand for 3D geological models.

Given the geological heterogeneity mentioned earlier, our 3D models are now being created as watertight meshes representing prevalent geological bodies and structures. Key data sources for these models include detailed digital elevation models, geophysical profiles or grids, large-scale geological maps, and newly acquired or revalidated borehole data. The scale of the models produced varies from a few hundred cubic meters, such as visualizing joint systems for experimental niches in underground laboratories, to tens of cubic kilometers, encompassing projected deep geological repositories for radioactive waste.

With growing interest in subsurface utilization across various branches of the geosciences, engineering, urban planning, and computational science, collaboration is essential. In recent years, a functional chain of data transfer from geological models to hydraulic, discrete fracture network (DFN), or geomechanical models has been established. However, seamless portability remains a significant challenge. Given the multitude of modeling software available, each discipline requires an individualized approach to data transfer. Another critical milestone to address is presenting data validity to a broader audience through uncertainty assessment and visualization, acknowledging the inherent uncertainties in 3D geological models. The CGS is continually working on both of these aforementioned challenges.

Construction of jurisdictional, federal, and multinational 3D geology to facilitate digital twins needed to address societal needs

Leonard Harvey Thorleifson[1]*, University of Minnesota (thorleif@umn.edu)

Abstract

The UN Sustainable Development Goals outline aspirations regarding health, safety, and prosperity, along with respect for our human and natural heritage. Among the requirements needed for fulfillment of these human aspirations are energy, infrastructure, minerals, security, and water, while research underpins everything that we know. In turn, geoscience is essential for fulfillment of all of these requirements, as conceptual research, spatial mapping, temporal monitoring, and dynamic modeling to guide decisions. Observational data and multi-resolution 3D geological mapping now enable digital twins - sustained dynamic models that include a framework, monitoring, and management outputs. This digital twin approach is well known in the atmospheric sciences of meteorology and climatology, and there is growing implementation in fields such as soils and the marine. This approach is well implemented at local scales, and is now needed at subnational, national, and multinational scales, for example to help ensure groundwater sustainability. The requirement includes a global solid earth digital twin, needed for study of earth material and history, resources such as geothermal and groundwater, and hazards such as earthquakes. The purpose of global resolution is to support global analyses, and to establish protocols that will guide continental, national, regional, and local levels of resolution. Also, the global solid earth digital twin will stimulate coordination in transitioning the geological mapping paradigm from a focus on publications, to concurrent seamless evergreen databases. The observations and inferences needed to enable this apparatus are built and maintained for countries by national geological surveys, as well as by subnational surveys in federal nations. We rely on the Commission for the Geological Map of the World (CGMW) to provide leadership in publication of geological maps for the world, for continents, and for multinational regions. Users demand standardization that also allows efficiency, so needed geoscience information standards are maintained by the Commission for Geoscience Information (CGI). OneGeology (1G) is an international initiative of the world's geological surveys and partners that is focused on accessibility of global geoscience data via standardized web services. CGMW, CGI, and 1G therefore are in a position to play coordinated roles in solid earth digital twin modeling by making available the framework geology that will be required by all.

The Loop Project - an open-source platform for 3D geological modelling: towards better management of underground resources

Laurent AILLERES[1]*, Monash University (laurent.ailleres@monash.edu)
Lachlan Grose[2], Monash University
Roy Thomson[3], Monash University
Noelle Cheng[4], Monash University
Mark Jessell[5], University of Western Australia
Rabii Chaarani[6], Monash University
Angela Rodrigues[7], Monash University

Abstract

Loop is a OneGeology initiative, initiated by Geoscience Australia and funded by Australian Territory, State and Federal Geological Surveys, the Australian Research Council and the MinEx CRC. The project is led by Monash University and involves research groups from the University of Western Australia, the RING consortium at the Universite de Lorraine, Nancy, France and RWTH Aachen in Germany. In-kind research is also provided by Natural Resources Canada (Geological Survey of Canada), Geoscience Australia and the British Geological Survey. Other partners include AuScope and the USGS.

A socially-licensed greener future depends on improving our ability to predict subsurface geology and better manage our underground resources: water, critical metals. The mine of the future must have a reduced footprint and economic, socially-accepted mineral resource discoveries and extraction activities will depend on how well we are able to map the subsurface geology, including the ability to generate models of physical and geochemical properties in mineralized systems while estimating and mapping associated uncertainties. This requires the ability to probabilistically forecast geology, allowing for rapid model updates.
We present the current state of the Loop project, an open-source interoperable, integrative, probabilistic 3D geological modelling platform. The platform consists mainly of two libraries in an attempt to automate the model building process from geological observations reported as maps and along drill holes. The map2loop library automatically augments geological information from maps and generates parameters for the modelling library. In LoopStructural, we have defined a parameterisation of 3D geological models in a forward modelling sense. LoopStructural is based on the concept of the structural frame: a coordinate system defined for each object (faults, intrusions) or geological events (folding). These coordinate systems consist of 3 perpendicular scalar fields that are interpolated and fitted to data in 3D and then combined according to the geological history. The structural frames are conformable to layering throughout the models. We present the concept for LoopResources, our proposed property modelling library. Using this deformed cartesian coordinate system, we propose to adapt geostatistical and interpolation methods to curvilinear coordinate systems using classical XYZ-UVW transformations. This will ensure that lithological anisotropies are enforced during resource estimation and property

modelling to provide better digital twins of the subsurface and characterize geological uncertainty throughout the entire workflow. We present a webapp which allows users to automatically analyze map information and generate summarized outcomes of map2loop for user confirmation, e.g., a stratigraphic or lithological column, the fault topological relationships with themselves and the stratigraphy, the geometrical characteristics of the lithologies. The outcome of map2loop are valuable in a sense that they allow the user to better understand the geological map and check the 3D modelling input before proceeding with structural interpolations to generate the 3D models.

LoopResources: Using structural frames for geostatistical simulations of geological resources.

Lachlan GROSE[1]*, Monash University (lachlan.grose@monash.edu)
Laurent Ailleres[2], Monash University
Angela Alfonso Rodrigues[3], Monash University
Rabii Chaarani[4], Monash University

Abstract

The transition from fossil fuels to renewable electric technologies will require a significant increase in discoveries of natural resources such as critical metals, base metals, and water. To facilitate the increased demand we need to improve our ability to find new resources and improve our abilities to extract existing resources reducing environmental impacts. To do this we need to be able to predict and estimate the distribution of these properties in the subsurface from limited observations (surface, drillhole, geophysics). We need to build tools that are capable of propagating uncertainties throughout the mining value chain allowing for informed decision-making to be made throughout the process. One of the challenges facing this workflow is our ability to automatically integrate geological uncertainties into the tools and techniques used to build resource models. In a standard workflow, the geological integration within a resource model is defined by assigning domains with different geostatistical models. This approach can be subjective and difficult to automate, meaning that any uncertainties are only associated with the geostatistical model and not the geology.

We use the open-source 3D modelling library, LoopStructural, to build a geological model of the geological features of interest. For each geological feature in the model (fault, conformable series, foliation) a curvilinear coordinate system aligned to the feature of interest is built. The structural frame coordinates are aligned with the major structural feature (fault surface, fold axial surface, or foliation), the structural direction (fold axis, fault lineation, or other lineations), and an intermediate direction. The structural frame can be used to calculate a distance within a geological feature conformable to geological anisotropies. Using the structural frame distance standard geostatistical tools can be applied, for example, calculating an experimental variogram to analyze the distribution of a property within the structural frame coordinates. We apply this approach to a synthetic proof of concept model of a refolded fold and compare the results to geostatistical simulations in cartesian space.

Abstract

The Geological Service for Europe (GSEU) project is a 5-year EU funded project bringing together 35 geological surveys and 13 additional partners to deliver a cooperative and comprehensive information and communication campaign about the subsurface. The key focusses are critical raw materials, geothermal energy resource and storage and groundwater management. It started in September 2022 and is anchored on the European Geological Data Infrastructure (EGDI) platform, where all subsurface data collected before or during the project is shared with a broad audience. Notably, the platform serves as a dynamic central repository of various 3D geological models.

Within GSEU Task 6.3, we aim to pool tools and best practices related to the conception and visualization of these 3D geological models. Our work involves identifying these tools, assessing their use, documenting them, and providing expert insights to aid in the creation of shareable models. We also discuss common limitations, individual strengths, and collectively desired developments for the future. The initiation of this output involved compiling an inventory of practices from different geological surveys, sharing in-house tools, and conducting a series of open-tool webinars, all aimed at fostering transparent and constructive discussions on 3D geological modeling tools and practices. The overarching goals of this task include formulating a conclusive deliverable that compiles best practices and documentation on presently available open-source tools within the scientific community. Furthermore, it extends to the establishment of

a sustainable network of experts in 3D geological modeling across European geological surveys.

3D Geological Modeling at BRGM (French Geological Survey)

François PROGNON[1]*, BRGM (f.prognon@brgm.fr)
Simon Lopez[2], BRGM
Philippe Calcagno[3], BRGM
Nicolas Clausolles[4], BRGM
Laure Pizzella[5], BRGM

Abstract

3D modeling has become a major asset for the understanding and quantitative characterization of subsurface geology. With the advent of new acquisition techniques, a large amount of heterogeneous measurements, over a wide range of scales, now complement the traditional field mapping activities with comparatively scarce observations. Delivering relevant subsurface models and maintaining reference databases to store them and disseminate geological knowledge need joint interpretations to deliver so-called shared earth models. This talk aims at giving an overview of the current practices and tools used at BRGM and the practical challenges to achieve such integration in 3D geological modeling.

Along with the use of many commercial software, BRGM has been developing several geological data management and modeling tools as well as collaborations at different levels (eurogeosurveys...) to overcome these challenges. The theoretical framework of the tools strongly relies on geostatistical techniques and efficient interpolation algorithms adapted to geological field data. Intuitive and meaningful rules to describe geological architecture must complement them to assemble interpolated surfaces into complex geological structures. The extension of such formalism to describe all observed architectures is still a field of research as well as interpolation techniques that can exploit all available observations. As regards technology, our current goal is the progressive structuration of an open geological modeling platform with the use of smaller modular interconnected tools and services along with a web frontend to share both produced models and modeling methods. Finally, the analysis of practices stresses the value of geological modeling as a unifying link and the need to change traditional linear workflows to include trans-disciplinary interactions.

[Keynote] Geomodelling by geological survey organisations: game changers, perspectives and challenges

Michiel Jan VAN DER MEULEN[1]*, TNO, Geological Survey of the Netherlands
(michiel.vandermeulen@tno.nl)
Florian WELLMANN[2], RWTH Aachen University
Denise MALJERS[3], TNO, Geological Survey of the Netherlands

Abstract

Since the turn of the 21st century, geomodelling, i.e. mapping the subsurface three-dimensionally, has been taken up by several geological survey organisations worldwide as an addition to, and in few cases replacement of, national geological mapping. Spearheaded by a group of early adopters, geomodelling is coming of age as a systematic effort, the results of which are finding their way to end users ever more seamlessly.

In terms of practical use and impact, geomodelling has seen its biggest successes in the geotechnical, hydrogeological and geo-energy application domains. In geological terms, the greatest successes are in mildly to undeformed sedimentary basins (as opposed to strongly tectonised, metamorphic or magmatic terrains). Applications and associated geological settings are reflected in common modelling concepts and tools, which have mostly been developed by and for the hydrocarbon, water and engineering sectors.

The related energy and materials transitions will change the game of geomodelling by geological survey organisations fundamentally. When it comes to geothermal energy and geological storage, the frontrunners will be able to satisfy much of the information needs with existing geomodelling approaches, often by revisiting the same basins. However, decarbonisation also raises the demand for minerals, supplies of which have come to be considered critical. The exploration for such minerals requires our community to step up in different, more complex, geological settings. Additionally, a better appraisal of uncertainties and related exploration risks requires an investigation of suitable geomodelling tools on all scales. This means that geomodelling needs a boost, i.e. higher investment levels in research, skills and tools, as well as in their deployment in new approaches and workflows.

Heterogeneous internal architecture and engineering properties in an exhumed crustal scale strike-slip fault zone

Namgwon KIM[1]*, University of Strathclyde (namgwon.kim@strath.ac.uk)
Zoe K Shipton[2], University of Strathclyde
Yannick Kremer[3], University of Strathclyde
Christopher D Jack[4], COWI

Abstract

In subsurface engineering projects, understanding ground conditions and their uncertainties is essential to reduce the risk of cost and time overruns. At the initial stages of a project, accurate forecasting of the rock mass properties in 3D geological models is challenging due to the limited data available. Fault zones, especially, are characterized by complex internal architecture, exhibiting structural and lithological heterogeneities governed by various factors. Fault zone architecture can control rock mass strength and, therefore, must be considered in geological engineering projects. Here, we demonstrate a workflow to continuously refine 3D fault zone models using additional information acquired during progressive stages of infrastructure project development.

The case study area is a crustal scale strike-slip fault with several hundreds of kilometres of displacement, exhumed from the elastic-frictional regime. It is characterized by a complex internal architecture resulting from host-rock heterogeneities, multiple episodes of reactivation, igneous intrusion, and exhumation.

We built a prototype 3D fault zone model from pre-existing geological maps and well-established scaling relationships of fracture attributes. We then refined the fault zone model to incorporate geologic and engineering elements measured during a major subsurface infrastructure project. The ground investigation data from the infrastructure project enables detailed mapping of the structural geological and rock mass properties, particularly within a focussed transect perpendicular to the fault. The structural geological and rock mass property mapping shows that the fault zone comprises numerous foliated cataclasites, intrusions, lenses of protolith, and fractured wall rock with variable structural, hydrological, and engineering properties. Within the fault core, minor faults filed with clay gouge tend to be less predominant than calcite and quartz veins toward the damage zone. Several structural domains can be defined: characterized by sets of structural discontinuities based on geometry, spacing, persistence, and infilling materials. These domains are mainly bounded by narrow zones rich in faults and fractures filled with clay gouge and/or calcite and quartz. Rock mass Q-values are highly variable but are largely controlled by the structural domains. Local large increases in Q-value are observed in areas of weak foliation, wall rock lenses, and near dyke-rich zones. Structural domains showing fluctuating Q-values are typically accompanied by groundwater seepage along the structural discontinuities.

The continuously refined 3D fault zone model reveals complex spatial patterns in structural geological and rock mass heterogeneities. The complex heterogeneities across the fault zone

highlight the need to integrate structural geological analysis into engineering workflows. We argue that this will yield more robust forecasting of hydro-mechanical engineering properties within and around fault zones and contribute to reducing geotechnical risks.

Germany 3D - Overview of 3D modelling activities of the German geological survey BGR

Stephan Steuer[1]*, Federal Institute for Geosciences and Natural Resources (stephan.steuer@bgr.de)

Abstract

The Federal Institute for Geosciences and Natural Resources (BGR) is the central geoscientific authority providing advice to the German Federal Government in all geo-relevant questions. It is subordinate to the Federal Ministry for Economic Affairs and Climate Action (BMWK) and therefore obligated to provide neutral and independent advice and information related to all aspects on geoscientific and natural resources. In particular, the following fields of scientific research are included: energy resources, mineral resources, groundwater, soil, deep subsurface use, geological disposal of radioactive waste, and geohazard assessment. In all of these fields, static and dynamic 3D-modlling is conducted at different scales.

We will provide examples of various 3D-models ranging from basin-wide to very small. The largest model presented is a 3D-model of the North German Basin that was created in close collaboration with the State Geological Services of the German federal states. Comprising of 13 horizons, 273 complex salt structures, 5,300 faults and covering an area of around 170,000 km^2, this model is one of the largest 3D-models worldwide. Smaller presented models are reservoir models, groundwater and geophysical 3D-models and a very detailed model of a repository site for nuclear waste. The smallest model is the model of a single fracture, created in a geothermal well.

BGR is not only conducting various kinds of 3D-modellling, we are also working on new ways of communicating the outcomes of the modelling to the public (e.g. VR/AR, Gamification,…) and to provide information about uncertainties of a model.

Context is Everything: Leveraging a Common Reference Geological Model to Enhance Modeling Efficacy and Accuracy – A Case Study from Poland.

Zbigniew MALOLEPSZY[1]*, Polish Geological Institute (zbigniew.malolepszy@pgi.gov.pl)
Ewa Szynkaruk[2], Polish Geological Institute

Abstract

The Polish Geological Survey has recently completed the construction of a country-wide Framework geological model of Poland. This model provides a comprehensive, albeit generalized, overview of Poland's geology, capturing its intrinsic complexity and offering numerous possibilities for further structural modeling and parameterization. Equally important, it provides a contextual framework for the development of more detailed, regional models, which form the cornerstone of our understanding of the subsurface and our ability to utilize it effectively. As articulated by one of our most experienced geologists: "I prefer to work on basin-scale models as this is where the data points are truly related and these relations can be unpicked and interpreted most clearly."

Prior to completing the Framework geological model of Poland, we developed two basin-scale structural and parametric models from scratch, based on all available and meticulously integrated data. Now, as we embark on the construction of a third model, the difference that having a general model provides is already apparent: sharing it with our team of interpreters specializing in regional geology ignites an overwhelming urge to check, repair, detail, and test different interpretations. The motivational impact of having a pre-existing model cannot be overstated. Importantly, providing this model can be done without the use of complex software not everyone can operate. The model is served on the web using the Geo3D viewer, significantly enlarging the area of impact and accessibility of the model's context. Link: https://geo3d.pgi.gov.pl/model_Poland/index.html

The broader-scale model allows us to contextualize our new interpretations from the very beginning, potentially leading to more rigorous and coherent outcomes across different, more detailed works. It can also be manipulated beforehand (e.g., balanced) to guide new interpretations and, when combined with pre-collated data, serves as a springboard to significantly streamline our work processes. Furthermore, it establishes a benchmark that distinctly delineates the extent of our learning. Moreover, it serves as a general reference in cases of contradictions or problems beyond our current scope, providing a reliable fallback option.

This approach, while demonstrated in the context of Poland's geology, holds promise for geological surveys in other countries. By adopting similar methodologies and tools, local geological surveys worldwide can enhance their modeling efficacy and accuracy, ultimately leading to a more comprehensive understanding of their respective geological landscapes. The

common reference model coupled with Geo3D viewer has the potential to significantly improve geological modeling practices on a global scale, facilitating collaboration, knowledge sharing, and informed decision-making in the field of geosciences.

Key Technologies for Geologic Modeling of Complex Fault Block Oil Reservoir

Xing DENG[1]*, China University of Petroleum (East China (892583840@qq.com)
Chengyan LIN[2], China University of Petroleum (East China

Abstract

Fault block oil reservoir features an important reservoir type in the Shengli Oilfield, accounting for 32.4% of its mining-employed reserves. The distribution of reserves in complex fault block oil reservoir varies widely with small scale, posing challenges in achieving high-efficient development. A fine characterization of the fault system and reservoir in complex fault block oil reservoir, alongside the establishment of a geological model that aligns with both geological and developmental understandings, is vital for enhancing oil recovery in the complex fault block oil reservoir. During the geological modeling process of complex fault block oil reservoir, there are internal synsedimentary faults that control the reservoir's sedimentary architecture. Different developmental types of synsedimentary faults and their combined forms determine the distribution range and scale of the reservoir. The generation, migration, and accumulation of oil and gas are closely related to sedimentary filling and tectonics. Additionally, during the pressure-driven displacement process in complex fault block oil reservoir, excessive pressure can lead to fault juxtaposition. Therefore, it is necessary to conduct modeling research on fault sealing and fracture distribution. This paper takes complex fault block oil reservoirs such as the Pan 40-80 and Zhan 27 as examples, and establishes three different sedimentary distribution models of sand bodies under the control of the synsedimentary faults at different activity intensities. It provides technical guidance for the fine characterization of reservoir geological modeling in complex fault block oil reservoir. Additionally, it combines the fault zone coring data and fracture pressure tests to model and calculate the structural characteristics inside the fault zones and the displacement pressure difference of fracture filling, which helps to guide the vertical and lateral sealing evaluation of the fault zones. The application of the above two key technologies for geologic modeling of complex fault block oil reservoir provides a clear direction for improving oil recovery through complex fault block geological drilling and pressure-driven displacement schemes.

Syn-kinematic granite emplacement in a transpressional corridor and its influence on the formation of dome-and-basin fold interference patterns

Gideon Rosenbaum[1]*, The University of Queensland (g.rosenbaum@uq.edu.au)
Alana Barrett[2], The University of Queensland
Raiza Toledo Rodrigues[3], The University of Queensland
Charlotte M Allen[4], Queensland University of Techonology
Roberto F Weinberg[5], Monash University

Abstract

Folding of layered sequences is influenced by the presence of igneous intrusions, which form competent bodies that control fold distribution and geometry. We show an example from the Broken River Province (northeastern Australia), where macroscopic folding affected sedimentary rocks and felsic intrusions, forming a dome-and-basin pattern. Field relations indicate syn-kinematic emplacement of the granitic intrusions, which occur as folded sill-like microgranitic bodies, mildly deformed stocks at structural domes, and undeformed granite that cuts across the folded sedimentary sequence. U-Pb zircon ages from the various intrusions yielded an age range of 335–320 Ma, thus constraining the timing of folding. The deformed zone is restricted to a ~30 km wide corridor bounded by two crustal-scale shear zones. Kinematic indicators show that folding was generated by dextral transpression, giving rise to the dominant orientation of folds. Domes and basins are generally concentrated in the proximity of the granitic intrusions, indicating that their development was likely controlled by the syn-kinematic emplacement of these plutons. The added volume of granite to the exposed section could have altered the local strain regime, switching the horizontal stretching direction during transpression to a shortening direction. We therefore suggest that forced intrusion of syn-kinematic plutons into a confined transpressional zone (dominated by flattening strain) can create local constrictional strain where shortening occurs in two broadly orthogonal horizontal directions. The results demonstrate a link between Carboniferous granitic dome-and-basin patterns and syn-transpressional magmatism. It is plausible that similar processes involving constrictional strain were responsible for the development of granitic dome-and-basin patterns in Archean terranes.

Stages of Shear Zone Evolution in an Isotropic Medium: An Account of Fluid Induced Rheological Transformation in ~2.6 Ga Bundelkhand Granitoids of India

SAYAN MAITY[1]*, Banaras Hindu University (maity21s.geo@bhu.ac.in)
Sayandeep Banerjee[2], Banaras Hindu University

Abstract

Shear zones are sheet-like planar to curviplanar zones where the localization of deformation is notably higher relative to the surrounding low-strain or undeformed region. A plethora of existing studies have discussed the nucleation and widening of shear zones in response to progressive deformation. It is believed that nucleation of shear zones in an isotropic medium often needs a pre-existing mechanical or compositional heterogeneity e.g., pre-existing brittle fractures, along with the influence of many other intrinsic and extrinsic factors. However, the evolution of ductile shear zones (DSZs) from a nascent stage to a well-developed broad one in an isotropic medium like that of granitoids is still debated due to the lack of preservation of the intermediate stages. It is reported by many workers that the fluids in and around granites play a key role both in nucleation and widening of the DSZs. However, very few studies have been done so far taking the mineralogical, textural, and chemical changes from core to boundary and low-strain hosts into consideration. Also, the exact mechanism(s) of fluid-rock interaction and the role of fluid prompting and driving the progressive change from undeformed host to intensely deformed core of DSZs still remain ambiguous. The Archean (~2.6 Ga) granitoids of Bundelkhand Craton (BuC) preserve excellent exposures of DSZs with varying thickness and grade of deformation in meso-scale. In the field as well as under a microscope, the transition from apparently undeformed host granites to intensely deformed ultramylonites with/without the development of proto- and meso-mylonites are recorded. The change in mineralogy, texture, and petrofabric studied across the DSZs clearly indicates a gradual increase in grain size reduction, ductile behavior of minerals showing preferred orientation in the trend of the shear zone, and increase in porosity as well as secondary epidote-rich material towards the core, where strain localization is maximum. The contact between brittle with plastic deformation, along with the preserved brittle-ductile in between indicate that the widening of DSZ has started from the core first and then gradually engulfed the wall rock i.e. the host granitoids. So, from field, microstructural, and mineralogical investigations we suggest that the DSZs evolved along the pre-existing fractures in the presence of an epidote-rich aqueous fluid by the process of hydrolytic and reaction-driven weakening. We also show evidence of intermediate brittle-ductile transition structures as well as different stages of evolution of DSZs that are present at several locations across the craton. Finally, through this study, we propose a model for the evolution of the DSZs in Archean Bundelkhand granitoids based on field, textural, and mineralogical data.

Structural investigation in the Madurai Block of Southern Granulite Terrane, India: Insights from Shear Zones

JOHN DSOUZA[1]*, Department of Geology, St.Xavier's College, Mumbai, India 400001 and Department of Geology, Savitribai Phule Pune University, Pune, India 411007 (john.dsouza@xaviers.edu)
DURGA PRASANNA MOHANTY[2], Department of Geology, Savitribai Phule Pune University, Pune 411007

Abstract

Southern Granulite Terrane (SGT) of granulite facies rocks lying south of the granite-greenstone terrane of the Dharwar Craton is separated by the Fermor Line. SGT is also recognized for comprising various crustal blocks amalgamated along subduction and collision zones. Situated south of the granite-greenstone terrane of the Dharwar Craton, the Southern Granulite Terrane primarily comprises granulite facies rocks. The SGT is also recognized for consisting of several crustal blocks combined along subduction and collision zones. The Palghat-Cauvery Shear Zone and the Achankovil Shear Zone split the Southern Granulite Terrane into three sub-divisions: the Madurai Block, the Trivandrum Block, and the Nilgiri-Namakkal Blocks. The evolution of the SGT across the Archean-Proterozoic boundary involves a complex history of magmatic, sedimentation, and metamorphic events. The terrane has experienced multiple tectonothermal events, including subduction-related granitoid magmatism. The shared Ediacaran-Cambrian metamorphism between the SGT, the basement rocks of Madagascar, and the Precambrian rocks of Sri Lanka suggests that these regions may have been part of a coherent landmass before the late Archean. Karur-Kambam-Painavu-Trichur shear zone (KKPTSZ) of SGT has been identified in the Madurai block as a V-shaped Neoproterozoic ductile shear zone with deformation of an early and a later phase ranging from 700-550 Ma. Several workers have identified another major shear zone as Suruli Shear Zone (SSZ) Madurai block, also reported as an S-W extension of the Theni-Madurai Shear Zone (TMSZ). The Kambam Ultra High-Temperature Belt (KUHTB) is one of the SGT's ultra-high temperature belts identified in the Madurai Block, which coincides with the alignment of the SSZ. The present investigation of structural data gathered from the SSZ demonstrates a clear foliation orientation of NE-SW along the Kambam-Theni transect, which begins to deviate towards NNE-SSW in the Theni area with its south-easterly dip direction. Interference folding with differing intensity is observed in the parts of the SSZ. The structural features, the mafic granulites, sillimanite-garnet-biotite gneisses, calc-granulite gneisses, and quartzites, are preserved throughout the Madurai block. Enclaves or raft-like structures are also common within the mafic granulites. The southern part of the SSZ calc-granulites shows intensive folding along with the σ-type clasts and asymmetric shear-related minor folds within sillimanite gneisses. These calc-granulites also show distinct development of the simple non-cylindrical hook-shaped folds throughout the southern extension. This structural investigation intends to look at the association between SSZ and KKPTSZ in the context of the tectonic evolution of SGT.

Shear Zones of Southern Granulite Terrane, India: Networks and complications

Durga Prasanna Prasanna MOHANTY[1]*, Savitribai Phule Pune University (durgaiitb@gmail.com)

Abstract

Southern Granulite Terrane (SGT), India, is the host to rocks of Neoarchean to Neoproterozoic age with granulite to ultra-high temperature grade metamorphic rocks with granitic, mafic and ultramafic intrusions. SGT is separated into various blocks by crustal-scale shear zone networks. East-West trending Cauvery Shear Zone System (CSZS), which is a wide zone of 400 km in length and 60-70 km in width. Thee SZS includes various shear zone networks like Kasargod-Mercara Shear Zone (KMSZ), Moyer Shear Zone (MoSZ), Bhavani Shear Zone (BSZ), Salem Attur Shear Zone (SASZ), Palghat Cauvery Shear Zone (PCSZ) etc. The CSZS, as a major tectonic unit, divides the SGT Northern Granulite Block (NGB) to its north and Madurai Granulite Block (MGB/MB) to its south. The CSZ has its western extension to the Madagascar as Betsimisaraka Shear/Suture Zone and Shear Zone to the east exposed in the Antarctica continent. The Madurai Granulite Block (MGB) is again separated from the southern tip od the India i.e. Trivandrum Bock, by means of Achan-Kovil Shear Zone, whose western and eastern extension is mapped in Madagascar (Ranotsara Shear Zone) and Sri Lanka respectively. Each of these shear zones have their unique structural deformation patterns which are well exposed in the out-crop scale. CSZS has also been reported to be the host to several dismembered ophiolites of Neo-Archean and Neo-Proterozoic age. This adds complications to the interpretations of the entire SGT with respect to setting up its regional stratigraphy, deformational history in connection to the multi-phase metamorphism reported by various researchers. Presence of Ultra High Temperature metamorphic rocks in the MGB has become a very interesting topic for the workers in that particular domain. MGB again has been subdivided into Northern Madurai Block and Southern Madurai Block by some workers where as some have different opinions as the divisions are Eastern Madurai Block and Western Madurai Block.

Kinematic vorticity and deformation thermometry analyses of the exhumed mylonites from the Xiaohe ductile shear zone in the sourthern Xiaoqinling gold province, North China

Hui-Min MA[1]*, China University of Geosciences (Wuhan) (mahm0821@163.com)
Shao-Yong Jiang[2], China University of Geosciences (Wuhan)
De-Liang Liu[3], China University of Geosciences (Wuhan)
Ying Ma[4], China University of Geosciences (Wuhan)
Wen-Tian Li[5], China University of Geosciences (Wuhan)

Abstract

Quantitative determination of kinematic vorticity analyses and temperature conditions of the mylonites provide significant information regarding the kinematic characteristics and deformation mechanisms. The Xiaohe shear zone located in the southern section of the Xiaoqinling gold province on the southern margin of North China, extends ~80 km from east to west, and is characterized by well-developed SE-dipping mylonites in the east and S-dipping mylonites in the west. The shear zone exhibits a top-to-the-SE or top-to-the-S sense of extensional ductile shearing deformation, as indicated by several kinematic indicators, such as S-C fabric, extensional folds, and σ- and δ-type porphyroclasts. The vorticity of flow (Wm) along the sear zone is estimated using the Wallis plot, Rigid Grain Net (RGN) plot and oblique-grain-shape/quartz c-axis fabric. The corresponding Wm values range from 0.49 to 0.58, 0.47 to 0.58, and 0.59 to 0.83, respectively, suggesting that pure shear dominated the deformation. Integration of strain and vorticity analyses revealed a shortening of 8-11% perpendicular to the Xiaohe shear zone and an extension of 8-13% (assuming plane strain deformation) measured parallel to the flow plane-transport direction. The quartz lattice-preferred orientation (LPO) patterns also indicate extensional shearing deformation, and the opening angles of the quartz c-axis fabric show deformation temperatures ranging between 500 °C and 600 °C. A Ti-in-quartz (TitaniQ) geothermometer was also applied to assess the deformation temperature during mylonitization in the Xiaohe shear zone. In the mylonite samples from the Xiaohe shear zone, cathodoluminescence (CL) images of the quartz ribbons show no clear zonation, and back-scattered electron (BSE) images of the samples show the presence of rutile, suggesting a TiO2 activity value of 1.0. Based on the known pressure of 5.7 kbar, the deformation temperatures calculated via TitaniQ geothermometry (four methods) range from 507 °C to 603 °C, 450 °C to 561 °C, 565 °C to 704 °C, and 476 °C to 611 °C, with concentrated values ranging between 475 °C and 650 °C. Therefore, the Xiaohe shear zone records extensional ductile shear deformation, which possibly resulted from back-arc extension induced by rollback of the subducted Paleo-Pacific Plate during the Early Cretaceous when gold mineralization occurred in this region.

Deep crustal expressions of exhumed continental-scale fault zone systems: Shear zone nucleation and initiation on rheological boundaries

Shuyun CAO[1]*, China University of Geosciences, Wuhan 430074, China (shuyun.cao@cug.edu.cn)
Franz Neubauer[2], Dept. of Geography and Geology, Paris-Lodron-University of Salzburg, Hellbrunnerstr. 34, A-5020 Salzburg, Austria
Wenyuan Li[3], School of Earth Sciences, China University of Geosciences, Wuhan 430074, China

Abstract

The formation and evolution of major continental-scale exhumed strike-slip faults represent one of the most important dynamic processes affecting the evolution of the Earth's lithosphere. Detailed studies and models of the potential initiation and driving mechanism, their properties and architecture of orogen-scale exhumed strike-slip faults are rare. Here, we present an integrated study of tectono-metamorphism, anatexis and deformation in the strike-slip shear zones. We propose the nucleation and initiation of shear zone is at depth, where temperature-controlled rheological weakening mechanisms play the essential role localizing future strike-slip faults. We highlight that in pluton and metamorphic core complex (MCC)-controlled tectonic settings, as end-members, the initiation of strike-slip faults occurs by rheological weakening along hot-to-cold contacts deep within the crust and mantle lithosphere, respectively. These endmember processes are potential mechanisms for the initiation of orogen-scale exhumed strike-slip faults at depth result in a specific thermal and structural architecture (Cao and Neubauer, 2016). A major aspect of many exhumed strike-slip faults is their lateral thermal gradient induced by the lateral juxtaposition of hot and cold levels of the crust controlling relevant properties of such fault zones, and thus the overall fault architecture (e.g., fault core, damage zone, shear lenses, fault rocks) and its thermal structure. Finally, we integrate all available data with crustal evolution and develop a comprehensive model for the progression of tectonic evolution in fault zone systems.

Polyphase deformation derived from meso- and microstructural observations along the brittle-viscous shear zone in the Hamyang, Korea

Sang Yeol Bae[1]*, Pukyong National University (teriousbae8@gmail.com)
Jin Hyun So[2], Pukyong National University
Young-Seog Kim[3], Pukyong National University

Abstract

Shear zones can generally be classified depending on their dominant deformation mechanisms. The deformation mechanism strongly depends on the temperature and pressure, relying on the depth. In this study, we conducted a meso- and microstructural analysis based on geometry, kinematics and deformation mechanism of NE-SW trending brittle-viscous shear zones which are located in Gyeonsangnam-do, Hamyang-gun. The geology in the vicinity of the study area consists of Triassic foliated porphyritic granites which are may related to post-collisional igneous activities triggered by slab roll-back and/or crustal delamination in subduction zone. Primary foliations, Interbedding of alternating biotite-and feldspar-rich layers, are influenced by segregation. On the other hand, mylonite zone is characterized by steeply plunging stretching lineations and asymmetric geometry, indicative of a top-to-the-southeast sense of shear. The dominant deformation mechanisms of both quartz and feldspar in the viscous shear zone are interpreted as dynamic recrystallization (bulging and subgrain rotation), indicative of the medium-grade mylonites. The subsequently developed brittle-viscous shear zones, characterized by deformation localized in narrow ultramylonite zone with horizontally plunging stretching lineations, indicate dextral sense of shear. The latest stage of deformations at the study area are sinistral shearing which is locally reactivated as flanking structures or deformed mafic dikes. These changes in deformation mechanism can contribute to deciphering the tectonic evolution of Korean Peninsula.

Importance of Mechanical Anisotropy on Strain Partitioning across a Transpressional Shear Zone (Okdong Fault) in Korea

Jinhyeon SO[1]*, Pukyong National University (so1005kr@pukyong.ac.kr)
Yeoeun SEO[2], Pukyong National University
Jinhyun LEE[3], Pukyong National University
Sangyeol BAE[4], Pukyong National University
Young-Seog KIM[5], Pukyong National University

Abstract

Strain partitioning is one of the important mechanisms, explaining the deformation patterns across transpressional shear zones. The imposed strain across the shear zone is partitioned into pure shear (contractional deformation) and simple shear (shear deformation) domains by strain partitioning. The deformation patterns in each domain may vary depending on the mechanical properties of the rocks, where mechanical anisotropy such as foliation and bedding is a significant controlling factor. The studied Okdong Fault located in Danyang, the central part of the Korean Peninsula, shows how mechanical anisotropy accommodates deformation within the shear zone. Based on the the C' shear bands from analyzed and mapped deformation structures we calculated the kinematic vorticity number (Wm). The result of this research suggests that contractional deformation predominantly occurs in the zones far from the Okdong Fault, while shear deformation dominates in zones close to the fault. The Wm derived from C' shear bands exhibits a decreasing trend with the distance from the Okdong Fault. This indicates that local strain partitioning is due to rotation of mechanical anisotropy associated with folding or thrusting. Furthermore, these variations in deformation style across the Okdong Fault indicate regional scale strain partitioning. This study give insight into the importance of mechanical anisotropy for understanding the deformation patterns associated with shear zones in other similar tectonic settings.

This research was supported by a grant(2022-MOIS62-001(RS-2022-ND640011)) of National Disaster Risk Analysis and Management Technology in Earthquake funded by Ministry of Interior and Safety(MOIS, Korea).

Abstract

Foliations and lineations with different directions and the superpositions among them have long been used to distinguish deformational phases. However, this standard procedure, involving the identification and description of geometric and kinematic relationships among tectonic structures and structure hierarchization, presented amazing short-lived polyphase deformations and frequently changing stress fields even within a hundred million years. Over the past few decades, advances in strain analysis have shed new light on understanding the heterogeneity and localization of the deformation in noncoaxial viscous flow. This study presents coaxial and non-coaxial deformation structural data on the Wuliangshan transpression zone in the Biluoxueshan-Chongshan shear zone. The Wuliangshan transpression zone comprises three units: the northern unit of southward thrust faults, the middle unit of sinistral strike-slip shear zone, and the southern unit of extension joints. Structural analysis was presented on three cross sections, two across the shear zone and one across the thrust fault. Three deformation sequences (S1, S2, and S3) are distinguished. The S1 is characterized by the penetrative foliation (S1) defined by oriented muscovite. The S2 altered the S1 and is marked by small- and medium-scale compressional structures approximately E-W-oriented. A nearly N-S-striking anticlinorium with a steep axial plane was developed during the S2 accompanied by brittle faults. The S3 defined by the N-S-trending strike-slip shearing and west-verging thrusting, altered the existing S1 and axial plane. Of the S3, the maximum principal stress ($\sigma 1$) oriented approximately NE50°-SW230° in the middle unit of the shear zone, NW330°-SE150°-oriented in the northern unit of the thrust zone, and NNW-SSE-oriented in the southern unit of extension zone. The ductile deformation is weaker in both the northern and southern units relative to the middle unit. Finite strain measurement and principal stress analysis performed on the S3 confined the coherence between the thrust faults and the strike-slip fault. To test this understanding, we also constructed a 3D finite element model with elastoplastic rheology. This analog modeling developed structures and stress fields in good agreement with the Wuliangshan coherent fault system (WCFS). This suggests that the structural styles around fault tips in nature are more complicated than predicted. The correlation of WCFS

with regional strike-slip faults reveals that the Biluoxueshan-Chongshan shear zone could not extend southward into the Lanping-Simao Basin, and the Ailaoshan shear zone was still active during the Miocene. Combined with research in strain partition, we provide a possible explanation that the flatting deformation and simple shearing in perpendicular directions may be the results of strain partition instead of multiple episodes of deformation. This is consistent with the long-lived oblique convergence by the India-Asia collision.

The role of long-lived shear zones in reconstructing the tectonic and deformational history of ancient active margin systems – the case of the Clarke River Shear Zone (NE Australia)

Raiza Toledo Rodrigues[1]*, University of Queensland (raizatoledo.r@gmail.com)
Gideon Rosenbaum[2], University of Queensland
Rashed Abdullah[3], Department for Energy and Mining, Geological Survey of South Australia, Adelaide

Abstract

Shear zones can provide crucial information on orogenic systems, including the timing of deformation and the strain distribution. The Clarke River Shear Zone, located in northeastern Australia, is an example of a long-lived structure that was active during the development of the active margin of eastern Gondwana (northern Tasmanides). Situated in northeastern Queensland, the Clarke River Shear Zone marks the boundary between two distinct components of the Tasmanides, the Thomson and Mossman orogens. To reconstruct the evolution of the Clarke River Shear Zone, we conducted field investigations, aeromagnetic data interpretation, microstructural analysis, and zircon U-Pb dating. Our results reveal that the shear zone was reactivated at least three times during the Palaeozoic. Evidence of the early phase of activity along the shear zone is characterized by gently plunging stretching lineation and sinistral kinematic indicators, including asymmetric porphyroclasts, and steeply plunging asymmetric folds, suggesting sinistral strike-slip ductile shearing. Subsequent pure-shear deformation is inferred from the presence of S-tectonites, symmetric porphyroclasts, and kinematic indicators showing both sinistral and dextral shear senses. These structures formed concurrently with the syn-tectonic emplacement of the Craigie Tonalite, for which we obtained a new zircon U-Pb crystallization age of 410.3 ± 1 Ma. Later reactivation, evidenced by cataclasite zones and chlorite-epidote alteration, occurred under brittle conditions. Considering our findings and regional information on the tectono-magmatic evolution of the northeastern Tasmanides, we propose that the shear zone acted as a sinistral transform fault during its early stages of development, in the Silurian. During the Devonian, this structure segmented the orogenic system, conditioning its architecture and magmatic activity. Increased trench retreat rates south of the Clarke River Shear Zone potentially caused counterclockwise rotations of crustal blocks, leading to oroclinal bending and pure shear deformation along the shear zone. Finally, during the Carboniferous, brittle deformation, possibly associated with dextral transpression, marked the final phase of activity along the Clarke River Shear Zone.

Delineation of a new Crustal-Scale Shear Zone in the Northern Bundelkhand Craton: The ~E-W trending Datia Shear Zone

AISHWARYA MOHAN[1]*, BANARAS HINDU UNIVERSITY (amohan.geo@bhu.ac.in)
SAYANDEEP BANERJEE[2], BANARAS HINDU UNIVERSITY

Abstract

The Bundelkhand Craton is an Archean craton which is located in North-Central part of the peninsular India and is infringed on Western, Southern and Eastern part by Vindhyan Supergroup of rocks and its extent is delimited on the Northern and North-Eastern side by the Ganga alluvium. The aerial extend of the BuC is around 29,000 km2 and over 90% of this area is occupied by K-rich granitoids which showcase a wide variety of chemical compositions comprising of syeno- to monzo-granites, granodiorites, and diorites which date back to the Neoarchean time; collectively referred to as Bundelkhand Granitoids. The Bundelkhand Craton houses fantastic primary and secondary structural features and elements comprising of magmatic foliations and lineations, prominent shear fractures, intra terrane shear zones, crustal scale shear zones, small scale faults, etc. Till now, there are three established Crustal-scale shear zones viz. Raksha Shear Zone (RSZ), Bundelkhand Tectonic Zone (BTZ) and Madawara Shear Zone (MSZ) trending in ~E-W direction and these are the zones of mylonitised and ultramylonitised granitoids.

In the present study, we have conducted extensive field studies throughout the craton and we have encountered the presence of a ductile shear zone in the northern extremity of the presently established boundary of the Bundelkhand Craton. This ductile shear zone trends ~085 and exhibits a ~200 metres thick zone of ultramylonitised and mylonitised granitoids. This ductile shear zone extends throughout the archean crust of the Bundelkhand Craton and hence can be termed as a crustal scale shear zone. The name being assigned to this shear zone is Datia Shear Zone due to the presence of the exposures representing the core of the shear zone in proximity to the city of Datia, Madhya Pradesh, India.

The Datia Shear Zone (DtSZ) has characteristically outcrops of two major lithologies viz. Bundelkhand granites and Tonalite-Trondjemite-Granodiorite Gneisses, which show signatures of shearing under macro-, meso- and micro-scale observation. From the satellite imageries we have observed that rivers Betwa and Sindh follow the trend of the DtSZ showcasing sharp bending from their normal flow directions in the area towards the eastern and western ends of the DtSZ, which is a geomorphological expression of the presence of the DtSZ. Through detailed field-work, we have confirmed the extent of this DtSZ in the eastern, western, and central part of the northern BuC, and hence, presume that this DtSZ extends throughout the BuC. Evidences of Pegmatite vein intrusions along the ~E-W direction are common in the outcrops of the DtSZ which often show displacements and dragging across the shear fractures. A few younger shear zones (mainly trending in ~NE-SW and ~N-S directions) also dissect the ultramylonitic core of the identified shear zone at several occasions indicating that the ~E-W trending Datia Shear Zone was developed prior to the formation of the other intra-terrane shear zones in the Bundelkhand Craton.

Middle-lower crustal flow response to the India-Eurasia collision: structural evidence from the Chong Shan tectonic belt within the Sundaland block

Xiaoyu Chen[1]*, China University of Geosciences (Beijing) (xiaoyuchen@cugb.edu.cn)
Junlai Liu[2], China University of Geosciences (Beijing)
Yinchun Qi[3], China University of Geosciences (Beijing)

Abstract

The India-Eurasia collision since about 55Ma and the subsequent post-collision process have an important impact on the middle and lower crust activities, the formation and evolution of the crust structure in the Tibetan Plateau and its periphery. The lateral flow of the middle and lower crustal material in the Sundaland block has been widely accepted, but the characteristics, and mechanism of the crustal material flow are still widely disputed. Several models have been proposed to explain the response of the lateral collision zone in southeast Tibet, such as rigid block extrusion, middle and lower crust channel flow, and crust thickening. At the edge of the Sundaland block, there are several metamorphic complexes with Precambrian basement, most of which are developed along the ductile high strain zone. At the same time, the existence of metamorphic complexes in the Sundaland block, such as Ximeng, Bu Khang and Chong Shan complex, provides new important clues to explain the flow pattern of materials in Southeast Tibet during the Indo-Eurasian collision.

The Chong Shan complex is composed of A-type dome structure, the core of which is composed of deformed proterozoic high-grade metamorphic rocks, and the mantle of which is composed of Paleozoic and Mesozoic low-grade metamorphic rocks. The kinematic analysis reveals that the mantle rocks move in southeast relative to the core rocks.

The Chong Shan complex experienced three stages of progressive shear deformation in Cenozoic. The first stage was characterized by pure shear deformation accompanied by metamorphism, mainly by growth lineation and metamorphic foliation. The second stage of deformation is mainly simple shear related to the middle and lower crust flow, and is characterized by the development and formation of NW-SE stretching lineation, mylonitic foliation and A-type folding. The third stage of deformation was dominated by NE-SW shortening, accompanied by dome uplift and exhumation. The chronological data of the synshear granitic dike reveal that the shear occurred at 29-19Ma. During the extrusion of the Sundaland block from Oligocene to Miocene, the ductile deformation is not confined to the high strain zone at the boundary of the block, but also occurs in the interior of the block. We believe that the extrusion of Sundaland block is the result of the interaction of viscous flow and channel flow along the high strain zone.

Structural analysis of Riedel synthetic shears influenced by the thickness of the brittle layers: the lesson from analog modeling with PIV technique

Marilia Barbosa VENÂNCIO[1]*, UFRN (mariliavenancio@gmail.com)
Fernando César Alves da Silva[2], UFRN

Abstract

A strike-slip fault zone can develop subsidiary structures such as the Riedel shears. This study investigates the influence of stratigraphic layer thickness on the geometry and spatial arrangement of synthetic Riedel shears (R) within a strike-slip fault zone. Analog experiments were carried out in a sandbox apparatus with two stratigraphic layers, each made of materials with different rheological behaviors: a basal layer of quartz sand (QS) and a top layer of plaster powder (PP). While maintaining a constant stratigraphic package size (2.5 cm), experiments varied the thickness ratio of QS and PP layers (i – 2.3 and 0.2 cm; ii – 2.0 and 0.5 cm; and iii – 1.5 and 1.0 cm, respectively). The Particle Image Velocimetry (PIV) technique was employed to analyze the strain patterns and displacement on the surface. Results indicate that the thickness proportion of the layers controls structural architecture, influencing R-shears geometry. Using a displacement of 0.5 cm as a reference point, the experiment with a thin plaster powder layer (i) resulted in numerous synthetic R-shears, while thicker layers (ii and iii) resulted in fewer R fractures. The spacing between R-fractures was narrower in the experiment with a thin plaster powder layer (ranging from 0.2 cm to 2.4 cm) than those with thicker layers (ranging from 1.6 cm to 4.6 cm). The experiment with a thin plaster powder layer developed shorter R-shears, mainly measuring between 0.6 cm and 3.4 cm, whereas those with thicker layers produced longer ones, ranging from 3.9 cm to 15.6 cm. With further displacement (d = 1.0 to 1.5 cm), P-shears developed in experiments with a thicker PP layer, while R′ shears were well formed in the experiments, being more numerous and smaller in the model with a thin PP layer. The results emphasize that not only is the rheology a controlling factor in the fault zone architecture but also the proportion of the thickness of the brittle layers, which can shape the geometry and spatial arrangement of Riedel shears formed on a strike-slip fault zone.

Southern West African Craton Strain Field derived from integrated structural mapping approach : tectonic and kinematic significance of shear zones

Kalidou TRAORE[1]*, USTTB (kalidoutraore@yahoo.fr)
Dominique Chardon[2], GET, UPS, IRD
Séta Naba[3], UJKZ
Ousmane Wane[4], USTTB

Abstract

We have developed a mapping protocol to characterize the strain field of the Eburnean accretionary orogen (2.2-2.0 Ga) at the scale of the southern West African craton. Our approach combines field structural measurements extracted from geological maps and photointerpretation in order to map the regional tectonic fabric - an approximation of strain trajectories - and derive the mapping of shear zones.

The shear zones form an anastomosed fractal network, preferentially symmetrical over scales of tens to hundreds of km, which is indicative of dominant coaxial deformation regimes. Deformation is heterogeneous, transpressive and partitioned at all scales. Despite the documented deformation gradients, very large displacements (of several hundred km) appear to be lesser within the orogen. Overall, the strain field reflects the first-order lateral escape of the orogen in response to its collision with the adjoining Archean craton. The craton was largely deformed as a consequence of its thermal softening at the contact with the accretionary orogen, which may be explained by the delamination of its lithospheric mantle at the collision zone.

Structural mapping applied at the scale of Precambrian orogens as implemented in this work provides a relevant kinematic interpretation tool. It also shows that a characterization of the orogenic-scale shear zone network, completed by a limited number of field observations, allows constraining deformation-displacement relationships within and at the boundaries of the orogens and evaluating their significance in a global tectonic framework.

EXTERNAL VS. INTERNAL REFERENCES FOR KINEMATIC ANALYSIS OF A TRANSPRESSIVE SHEAR ZONE

SUSHMITA BHATTACHARJEE[1]*, GAUHATI UNIVERSITY, ASSAM, INDIA
(bhattacharjeesushmita98@gmail.com)
VASHKAR JIT MAHANTA[2], GAUHATI UNIVERSITY, ASSAM, INDIA
SURAJIT MISRA[3], GAUHATI UNIVERSITY, ASSAM, INDIA

Abstract

The kinematics of a shear zone is a primary requirement to study the deformational history of any terrane. Generally, kinematic study is done considering the external reference frame. However, there is some ambiguity when only an external reference frame is considered because the geometry of the deformed rocks is influenced by internally induced shears and material flows, considering the internal reference frame. Hence, vorticity and kinematics studied from internal reference frame is more suitable. A shear zone can be defined by external reference frames with the X, Y, and Z directions, where ‘X’ is the movement direction, ‘XY’ is the shear plane, and ‘Z’ is across the shear zone. Internally, the maximum elongation of any stretching or mineral lineation indicates the ‘X'’ axis of a strain ellipsoid, whereas ‘Y'’ is the intermediate, and ‘Z'’ is the shortening axis.

The present study focuses on the Barapani Shear Zone (BSZ), an intraterrane, multiply deformed shear zone present within the Meso-Proterozoic Shillong Group (SG) of rocks, located within the Shillong Plateau. The primary objective of this research is to study the asymmetric structures associated with the shear zone to comprehend the kinematics and deformational nature of the terrane. A detailed investigation reveals that the area underwent successive D1, D2, D3, and D4 events, resulting in preserved S1, S2, and S3 planar fabrics, with D4, evidenced by brittle deformation features. Generally, shear zones provide a finite kinematic and vorticity number; however, BSZ exhibits variable kinematic and vorticity numbers measured across different deformation zones. In this study both the external and internal reference frames have been considered to have better understanding about the kinematics and degree of rotation of the material lines. Subsequent analysis demonstrates that superposed transpressional tectonics dominated the D2 and D3 deformation episodes that played a significant role in the structural evolution of the plateau.

Fluid flow characteristics based on topological analysis of a fracture system in Sinseondae area, Geoje Island, Korea

Goeun KIM[1]*, Pukyong National University (gone1213@pukyong.ac.kr)
Jinhyeon SO[2], Pukyong National University
Young-Seog KIM[3], Pukyong National University

Abstract

The characteristics of fluid flow within bedrocks is controlled by discontinuities (fractures and faults) as well as permeabilities of rocks. Mineral-filled fractures and faults (veins) are good indicators for paleo-fluid flow characteristics, which can be applicable to a better understanding of future fluid behavior. Furthermore, new geological structures are commonly influenced by pre-existing structures. Therefore, to understand and evaluate the characteristics of fluid flow in bedrocks, it is important to analyze pre-existing structures including veins. The study area, located on Geoje Island in the southeastern part of the Korean Peninsula, consists of Cretaceous sedimentary rocks comprising shale and sandstone layers. This region has experienced multiple fluid infiltration events, leading to the development of various types of veins. First of all, we interpreted the developing history of fractures in the study area based on fracture geometries and cross-cutting relationships. Additionally, we conducted topological analysis of fractures and vein systems respect to the distance from the main fault. Based on the data, the following fracture development history was established: (1) the development of NE-SW striking reverse faults with high dips ; (2) the development of N-S striking tension fractures ; (3) the cutting of pre-existing fractures by low-angle NNW-SSE striking normal faults developed along bedding planes; (4) the cutting of the previous fractures by NNE-SSW to NE-SW striking left-lateral normal faults . Three mineral precipitation events are identified based on the mineral filling patterns: (1) calcite precipitation between stages 1 and 2; (2) epidote precipitation between stages 2 and 3; (3) secondary precipitation of calcite after stage 4. As a result of the topological analysis, it was observed that the number of connections per branch (CB) decreases as the distance from the fault core increased, with a total CB value ($0 \leq CB \leq 2$) of 1.82, showing a relatively high degree of connectivity. It indicates that fault is an important controlling factor to fluid flow. However, fluid flow characteristics are influenced not only by discontinuities but also by other physical and chemical factors, suggesting the need for comprehensive studies of fluid flow characteristics in the future.

Analysis of Subsurface Fault Systems Using Audio-Magnetotelluric Surveys in the Western Ilan Plain of Northeast Taiwan

Ping-Yu CHANG[1]*, National Central University (pingyuc@gmail.com)

Abstract

We employed the audio magnetotelluric (AMT) method to delineate subsurface resistivity structures associated with the western Ilan Plain, which emerged from the orogenic belt in northeastern Taiwan and is believed to be influenced by the opening Okinawa Trough. Our study focuses on how the later opening of the Okinawa Trough has impacted this previously compressional region. The results of the AMT surveys indicate that the area features a series of N-S trending fracture zones, in addition to the ENE-WSW normal fault systems. Comparing the AMT data with seismic reflection profiles, we discovered that the study area consists of normal fault systems that developed on the paleo-thrust fault, thrusting the Miocene Lushan slates onto the younger rock formations of the Hsuehshan groups. The normal fault systems are truncated by young strike-slip faults, modifying the relief of the rock basement in a recent stage of formation. The western part of the study area is dominated by left-lateral strike-slip faults, while the eastern part is dominated by right-lateral strike-slip faults. Our findings from the AMT resistivity images, along with the re-interpreted seismic profiles, provide new evidence of the tectonic evolution associated with the development of the Okinawa Trough system. The influences from the arc-continent collision may have extended into the western Ilan Plain.

Fractured feldspar clast as paleostress marker

Tridib Kumar MONDAL[1]*, Indian Statistical Institute (tridibkumarmondal@gmail.com)
Gourav Das[2], Indian Statistical Institute
Sirshendu Kumar Biswas[3], Indian Statistical Institute
Sourav Mondal[4], Indian Institute of Technology, Kharagpur

Abstract

The estimation of paleostress conditions in any structurally deformed terrain is important to understand the evolutionary history of that area. Many paleostress markers exist in nature that provide information on late-stage brittle deformation, such as tensile fractures and conjugate fractures. We study the possibility of using fractured feldspar clasts in deformed granite as a potential paleostress marker. The feldspar clasts, found within the Closepet Granite, Eastern Dharwar Craton, India, are systematically fractured. These fractures are near vertical, sub-parallel to each other, and strictly restricted within the clasts. We use the FEM (finite element method) tool to assess the state of stresses responsible for fracturing within the clasts. It was found that the tectonic stresses enhanced inside the clasts due to their higher rigidity than the surrounding matrix. This amplification of stresses inside the clasts is responsible for the formation of clast-restricted fracturing. The clasts are also rotated with respect to the applied stress direction, and we found that, within a range of ±24°, it is possible to form tensile fractures within the clasts. All these findings, along with the field observation, provide us with an E-W-directed paleostress orientation that was active during the Neoarchean time in the Eastern Dharwar Craton. This E-W directed paleostress orientation is also in a good agreement with the state of stresses revealed from the granitic plutons adjacent to the Closepet Granite. Therefore, we infer that fractured feldspar clasts can be used as reliable paleostress markers.

How good is your fracture model? Examining how interpreter experience and approaches affect fracture model variability.

Leila Evans[1]*, University of Strathclyde (leila.evans@strath.ac.uk)
Zoe Shipton[2], University of Strathclyde
Clare Bond[3], University of Aberdeen
Jen Roberts[4], University of Strathclyde
Namgwon Kim[5], University of Strathclyde

Abstract

Applied geoscience relies on a robust understanding of the structural regime and successfully developing structural models that are at the appropriate scale and level of detail for the problem at hand. But how good are we at developing structural models?

As humans, we each inherently hold different biases which are a product of our personal and professional experiences and backgrounds, areas of expertise, cognition and values. Therefore, we each bring a diversity of experience and approaches to geoscience activities such as fracture interpretation. Given that structural models form a critical part of geoscience outputs for a variety of industries across energy, resources and infrastructure, it is imperative to ensure we are generating robust interpretations. This can lead to improved safety, better decision making and ultimately helps to ensure project success.

Our study aims to characterise the variability in fracture interpretations made by geoscientists observing an aerial drone image of a fractured outcrop. We compare fracture data outputs (fracture density, network topology and orientation) from observations carried out by participants in a relatively short timeframe, to those from a more detailed set of observations. We are effectively comparing how “good” a set of observations carried out in a timeframe more closely aligned with common practice in a commercial setting are, with the outputs from a very detailed piece of mapping.

Previous experiments explored the variety of models that can be fit to a single 3D seismic image and showed that geoscientists’ experience and approaches impact the resulting structural models. Our experiment is the first to collect similar observations from outcrop data. By accounting for these biases and mitigating the uncertainties and issues generated, we can ensure positive outcomes to interpretational approaches. This can help develop better interpretation methods, inform how we arrange our teams and assurance processes and how we teach and communicate geoscience.

So, how good is your fracture model?

Exploring the significance of favourable and unfavourable structures in Orogenic gold deposits through a numerical modelling approach

SWARNENDU BHUYAN[1]*, IIT KHARAGPUR (sbhuyan@kgpian.iitkgp.ac.in)
Mruganka Kumar Panigrahi[2], IIT Kharagpur

Abstract

Archean greenstone-hosted lode gold deposits, referred to as mesothermal gold are popularly known as ‘orogenic gold’ and are characterized as quartz-dominated lode-type gold deposit systems where the source of ore fluid is supposed to be of metamorphogenic origin. The ‘Fault valve’ mechanism heavily rests on the metamorphogenic origin that is apparently caused by fluid pressurisation and rupture of the pre-existing fault. The fault-valve model commonly known as Sibson’s cycle needs an impervious seal referred to as the ‘seismic lid’ at the mid-crustal level and a pre-existing high-angle reverse fault that crosscuts the ‘seismic lid’ and is periodically reactivated. This high-angle reverse fault does not conform to the Andersonian theory of faulting. This study focuses on the pivotal role of fault orientation in fluid pressure evolution, introducing a distinction within structures as either 'favourable' or 'unfavourable’. The fault-valve mechanism is effective for unfavourably oriented (> 53 degree to σ1) low cohesion (0.6-0.85) faults that cause the build-up of fluid overpressure whereas a favourably oriented fault facilitates the channelization of overpressured fluids. The existence of favourable and unfavourable structures in worldwide gold deposits was validated by some gold provinces, although there has been a debate in the context of the Hutti gold deposit in the eastern Dharwar craton, S. India. To critically analyse the significance of favourable and unfavourable structures in the fault-valve model, the numerical simulation method proves to be the most effective. Among very few proposed numerical models on the fault-valve mechanism, Sheldon and Ord’s model appears to be an effective one. This model has certain limitations such as a pre-existing fault that is not exposed at the surface, a post-rupture fluid pressure value greater than the pre-rupturing value and so on. To overcome such limitations of the model, a modified 2D numerical model is implemented using COMSOL Multiphysics software with some changes including the fault being continuous and extending to the Earth's surface. Based on the simulation results, our findings indicate that fault orientation predominantly governs fluid migration rather than directly impacting fluid pressure build-up. A fault having an angle of 60 degree to σ1 may be designated as 'favourable,' while a low-angle fault with an angle of 30 degree may be labelled as an 'unfavourable' structure. The high-angle fault is not expected to be unfavourable thereby possibly preventing supralithostartic fluid pressure build-up and impeding the operation of Sibson’s cycle. Thus, the fault-valve mechanism vis-à-vis seismic pumping might not be operational, particularly for the Hutti deposit.

[Keynote] Illuminating fault zone structures in depth by dense seismic array

Haijiang Zhang[1]*, University of Science and Technology of China (zhang11@ustc.edu.cn)

Abstract

Fault zone structures play a very important role in controlling the rupture process of the earthquake, the propagation of seismic waves, and the distribution of local earthquakes. Therefore, it is important to illuminate detailed fault zone structures from near surface to greater depth. Here I will review the development of using local dense seismic array to determine fault zone properties and fault plane distributions.

By using surface waves extracted from continuous ambient noise data recorded by seismic array, ambient noise tomography can be used to determine three-dimensional (3D) shear wave velocity (Vs) model beneath the array. For fault zones with active seismicity, double-difference seismic tomography can be utilized to determine Vp, Vs, and Vp/Vs models of the fault zone. In addition, seismic anisotropy and attenuation models can also be determined by corresponding inversion methods. Joint inversion of body wave and surface wave data can also be used to further improve fault zone velocity models. Guided by fault surface trace, with fine velocity models we can further delineate the distribution of fault planes.

In addition to fault zone properties, we can also use seismic scattering imaging to determine the distribution of fault planes with earthquake waveforms following two strategies. The first strategy is to treat the earthquake sources as pseudo-active seismic sources with known locations and origin times. In this way, the Generalized Radon Transform can be used to determine discontinuous fault planes by using P-P or S-S scattered waves. The 2nd strategy is to use the interference between backpropagated P and S wavefields at an interface. In this way, source information is not needed.

100Ma of slip events in the core of the Highland Boundary Fault, Scotland: implications for earthquake slip.

Lucy McKay[1], University of Strathclyde (now at COWI UK)
Zoe SHIPTON[2]*, University of Strathclyde (zoe.shipton@strath.ac.uk)
Rebecca Lunn[3], University of Strathclyde
Billy Andrews[4], University of Strathclyde (now at Uni Plymouth)
Adrian Boyce[5], Scottish Universities Environmental Research Centre
Timothy Raub[6], University of St Andrews

Abstract

The Highland Boundary fault near Stonehaven, Scotland, provides a rare opportunity to study the internal fault structure of a well-exposed, along-strike section of an ancient plate boundary fault. As in many plate boundaries, serpentinite juxtaposes quartzo-feldspathic crustal rocks of distinct terranes. The Highland Boundary fault core is comprised of four structurally and chemically distinct clay-rich units that remain unmixed. Despite abundant evidence for internal strain, relatively intact clasts of wall rock and fragile microfossils are preserved within the clay gouge. The fault core clay minerology is consistent with a shallow, low-temperature authigenesis derived from shear-enhanced chemical reactions between wall rocks of contrasting chemistry during sinistral strike-slip. Using K–Ar isotopic dating of illitic fault rocks, coupled with X-ray diffraction and microstructural analyses we constrain, for the first time, timing of multiple illite-producing fault reactivation events on the HBF in the Carbniferous (348-314Ma), Permian (306-250Ma and Triassic (258-226Ma). Through detailed mapping, we demonstrate that the internal structure of the fault core varies in thickness and composition along-strike over centimetre- to metre- length scales. The observed structure is comparable to those of other major weak-cored plate boundaries (e.g. the San Andreas fault). Earthquake rupture mechanics critically depend on the physical properties of fault rock assemblages. For example, the more complex the fault geometry, the more energy has to be consumed at depth during an earthquake and the less energy reaches the surface. Therefore, models that investigate rupture propagation at active plate boundaries should incorporate, or else assess tolerance and sensitivity to, variable fault core thickness and composition.

Quantitative evaluation of fault connectivity and its petroleum significance based on topological analysis: a case study from the well H area, southern Sichuan Basin

jingru zhao[1]*, China University of Petroleum (East China) (zhaojingru_upc@163.com)
yangwen pei[2], China University of Petroleum (East China)
Qingqi Zhao[3], China University of Petroleum (East China)
zhengshuo miao[4], China University of Petroleum (East China)

Abstract

Due to the influence of multi-stage structural superposition, a large number of medium to small scale faults were developed in deep shale gas reservoir in the southern Sichuan Basin. Quantitative analysis and evaluation of fault network structures and plane connectivity are of great significance for deep shale gas exploration and development. On the basis of detailed delineation of medium to small scale faults in deep shale gas reservoir, this study conducted topological structural analysis and connectivity evaluation of fault networks in the well H area of southern Sichuan Basin. By integrating topological quantitative evaluation with the production data of shale gas wells, the controlling effects of fault network topology and plane connectivity on shale gas accumulation were discussed. This investigation indicates three aspects of new findings. (1) High level of spatial variation was observed in the distribution of fault nodes and branches in the well H area in southern Sichuan Basin. Their NE-SW oriented distribution, being in accordance with the strikes of folds, presents high concentration in the cores of three narrow anticlines and limited distribution in the three synclines, respectively. (2) There are significant differences in fault network connectivity in different structural domains in the well H area, with better connectivity in the anticlines than the synclines. The northern portion of the western anticline, the eastern anticline and the central anticline present good, medium and poor fault connectivity, respectively. In the eastern anticline, the northern portion presents relatively higher connectivity than the southern portion. (3) There is a significant correlation between the production data of shale gas and the topological connectivity of fault networks in the well H area. With increasing fault connectivity, the production of shale gas climbs up and then falls down, indicating that neither high connectivity nor low connectivity of fault networks benefits shale gas accumulation.

The Role of Thermal Buoyancy on the Permeable Faults: Insights from the Lattice Boltzmann Models

Soojung AN[1]*, Kangwon national university (ansj0603@kangwon.ac.kr)
Byung-Dal SO[2], Kangwon national univeristy

Abstract

Understanding the impact of thermal buoyancy on fluid flow within permeable faults is crucial for ascertaining the dynamics of subsurface fluid transport in geological formations. In this study, we employ the Lattice Boltzmann Method (LBM) to investigate the influence of thermal anomalies on porous flow within faults, focusing on the role of Rayleigh and Prandtl numbers. We examine the influence of positive thermal anomalies on the viscous flow within permeable faults in geological formations. Through numerical simulations, we analyze the thermal effects on fluid flow within porous media by varying the Rayleigh and Prandtl numbers, which represent the ratios of buoyancy to viscous forces and the relative importance of momentum and thermal diffusivity, respectively. By systematically varying these parameters, we investigate the resulting changes in Reynolds numbers, which characterize the flow regime and provide insights into the dynamics of the porous flow under thermal gradients. Our findings reveal that the average Reynolds numbers increase with the Rayleigh number, indicating a strengthening of the convective flow component driven by thermal buoyancy. Furthermore, we observe conditional dependencies of the Reynolds number on the Prandtl number, highlighting the significance of thermal diffusivity in modulating the kinematic response of porous flow to thermal anomalies. The implications of our results are significant for understanding the role of thermal effects on fluid flow dynamics in geological formations, particularly within permeable faults. The observed increase in Reynolds numbers with higher Rayleigh numbers underscores the enhanced convective heat transfer associated with thermal anomalies, which can influence processes such as groundwater flow, hydrocarbon migration, and geothermal reservoir engineering. Overall, our study provides valuable insights into the complex interplay between thermal effects and porous flow, elucidating the mechanisms governing fluid transport in geological formations under thermal gradients. These findings contribute to a better understanding of subsurface fluid dynamics and have implications for various fields, including geology, hydrology, and energy resource management.

The Orogenesis and Metamorphic Fabrics in the Western Pacific Subduction Zones since late-Miocene, the rock recored from strike-slip to collision

Gong-Ruei HO[1]*, Department of Geology, National Museum of Natural Science
(gongruei@gmail.com)

Abstract

The arc-continent collision in Western Pacific Subduction Zones is traditionally interpreted as a relatively continuous process with an invariant plate convergence vector since late Miocene. This steady convergence and the obliquity between the subducting continental margin and the plate boundary predict a propagating collision tectonic setting with a space-time equivalence along the developing orogen. More recently, detailed plate reconstruction and structural analysis suggest that the plate convergence changed from highly oblique to nearly orthogonal in the last 2 to 1 Ma. Oblique convergence, driven primarily by the northward motion of the Philippine Sea Plate wrt Eurasian, predicts a significant component of left-lateral, strike-slip shearing through Korea, Japan, Taiwan, and Philippine orogenic belts. A comprehensive analysis of available data helps to define this previously unrecognized zone of strike-slip deformation. In this study, we start from Taiwan and attempt to address the following questions: 1) The distribution of horizontal shear throughout the Western Pacific Subduction Zone; 2) The kinematics of deformation; 3) The age of deformation, and 4) Regional consistency between geological studies and plate reconstructions. To understand the strike-slip systems in the western Pacific Subduction Zones, we aim to study the orogenic belt in the eastern Central Range of Taiwan as a pioneer research and extend to the Sambagawa belt in Japan and the Philippines mobile belt. This study integrates previous studies, and the main details are listed as follows: 1) The strike-slip deformation, which ranges from 30 km in width and extends the 200 km length of the orogen, is characterized by a history of subhorizontal shearing. Evidence for high strain includes mylonitic fabrics, rotated fold axes, sheath folds, and rotated stretching lineations; 2) Microtectonics, including S-C fabrics, strain shadows and sigmoidal structures consistently indicate left-lateral shearing in D2 and transtensional deformation in D3; and 3) The syn-kinematic veins and fabrics showed an Ar-Ar age of 2-6 Ma in D2, and 1.1-1.5 Ma in D3.

ROOTLESS ORE DEPOSITS OF TIEN-SHAN

GENNADY ERMOLAEV[1]*, IMR (egs25@mail.ru)

Abstract

ERM0LAEV G.S.
ROOTLESS ORE DEPOSITS OF TIEN SHAN
Rootless ore deposits have been established in well-studied ore regions of Central Asia(Northern, Central and Southern Tien Shan). In-depth structural analysis and physical-mechanical (rheological) properties of rocks identified processes not associated with folding and faulting, but representing post-Alpine discontinuous block tectonic flow of rock masses, including ore. Within the Western Tien Shan(Eastern in China) industrial sites of non-ferrous, rare, noble and radioactive metals of various genetic and industrial types are known. Except for radioactive ones, all are located in pre-Mesozoic formations. The main part is confined to the contacts of the Mesozoic-Cenozoic and pre-Mesozoic complexes (Muruntau, Vysokovoltnoye, Zarmitan, Dzhizhikrut, Khaidarkan, Chonkoy, Kochbulak, Kalmakyr, Andash, Jerooy, etc.). Ore districts containing large industrial accumulations, such as Almalyk and Kyzylkum, are located at the end junctions of the Southern and Central Tien Shan. A similar situation is typical for other regions of the world: the Urals, the Cordillera, and also South Africa, where the largest ore district is located at the continent-ocean junction. This may indicate a rupture of ore-bearing structures in places of greatest accumulation of mineral matter, which is confirmed by the widespread development of faults that supposedly “control” the placement of ore fields and deposits. In Western Uzbekistan, industrial sites of gold, tungsten and uranium (Muruntau, Ingichke, Uchkuduk, etc.) are associated with approximately equal specific gravities (19 g/cm3), as well as zero values of magnetic anomalies Δ Ta and gravity field anomalies Δ g lok.,low (up to 2000m) altitudes and “island outcrops” of pre-Mesozoic formations against the background of the Mesozoic-Cenozoic.
Detailed structural studies have established that metallic mineralization is associated with isolated, rootless blocks of hard rocks contained in a mass of plastic strata and the morphostructure of the modern relief. Rigid formations - terranes, make up predominantly elevated parts of the relief, plastic ones correlate with the leveled part of it, the ore mineral complex occupies an intermediate position, located on the boundaries of the elevated and leveled relief. These are metasomatically altered sandstones, limestones, dolomites, granitoids, mafic rocks, volcanics, which have a blocky (rootless) structure with sharply changed parameters and surface configuration (indicating rupture-extension). By acting in reverse geodynamics (under compression conditions), it is possible to assemble broken (both laterally and vertically), often ore-bearing blocks into a single whole. Siltstone-schist (black shale) plastic, dynamic (inextricable) geomass (the main distribution is deep) is the driving force. It accommodates, or underlies and moves a wide variety of block structures of different ages over significant distances both vertically and horizontally, with the advantage of the horizontal component. In the process of movement and interaction of material composition with different rheological properties, melange complexes (shale or ophiolitic) are

formed, which mainly comprise the territory of Central Asia.

The rootless deposit is the result of not only the impact of mineralization processes on rocks, but also the subsequent processes of movement of blocks of ore-bearing rocks. The role of the transporter was played by plastic, thermodynamic silt-lithic shale geomass.

Abstract

The Bangladesh exclusive economic zone extends seaward into the northern portion of the Bay of Bengal, down to water depths of 2250 m. This area comprises the northern portion of the Bengal Fan, where sediment supply from the Ganges and Brahmaputra rivers has resulted in the accumulation of up to 20 km of shallow-marine, fluvio-deltaic and slope sediments during rapid tectonic subsidence since the late Miocene. The high sedimentation rates, along with the high organic matter content of the slope deposits, make this area favorable for the formation of natural gas from both microbial and thermogenic sources. Interpretation of multichannel seismic reflection profiles and modelling of the present-day gas hydrate stability zone (GHSZ) provide the first evidence for the occurrence of natural gas hydrates in this portion of the Bay of Bengal. Seismic indicators of gas hydrates, such as the Bottom-Simulating Reflectors (BSRs), and fluid flow, including seismic chimneys and other reflection anomalies, characterize the channel-levee and mass transport deposits (MTDs) sediments of the slope area. BSRs are located in water depths of 1300–1900 m and at depths below seafloor of 250–440 m. High seismic interval velocities (1920–1940 m/s) are visible above the BSRs, which can be explained by the presence of gas hydrate filling the pore space of shallow marine sediments. The theoretical base of the gas (methane) hydrate stability zone (BGHSZ) seems to lie at approximately the same depth as the observed BSRs. Some of the observed offsets between the BSR and the calculated BGHSZ may be explained by fluid flow through faults/fractures, causing localized heat-flow perturbations and/or changes in the hydrate-forming gas composition. In shallower areas, where the seafloor depth corresponds to the feather edge of the GHSZ, irregular BSRs and evidence for fluid flow correlates with the presence of MTDs (slumps), associated with recent events generating seafloor topography; here, the base GHSZ lies within tens of meters of seafloor and is considered to be

more sensitive to climate-driven factors that may change stability conditions, such as sea level variations and sedimentation rates. In such a setting, the excess pore-pressure caused by gas hydrate dissociation could have had a role in slope failure events.

Abstract

The 5.5 magnitude (Mw) earthquake in Pohang, South Korea in 2017 was one of the largest triggered earthquakes at an enhanced geothermal system (EGS) site. Faults that ruptured in Pohang were not identified by preliminary geological investigations or geophysical surveys, and the subsequent study of the fault rocks at the Pohang EGS site was limited to depths of 3790–3816 m. In this study, we present new observations of fault rocks from drill cuttings retrieved from the Pohang EGS. The drill cuttings obtained from 3256 to 3911 m contained “mud balls,” which showed a clay matrix with foliation and a cataclastic texture, indicating a typical fault gouge or breccia. Furthermore, the mud ball samples retrieved from depths of 3256 m and 3260 m contained black fragments. Scanning and transmission electron microscopy revealed that the black fragments consisted of glass-like material, which is indicative of frictional melting during coseismic slip (Jung et al., 2023). The presence of these black fragments suggests that at least one seismic event had occurred at the Pohang EGS site prior to the hydraulic stimulation test.

Abstract

We present the structural architecture and evolution of two main fault zones, which drove the formation of the southern part of the Alpine orogen (Ligurian Alps). The two fault zones encompass both the largest thrust (Monte Frontè thrust) and strike-slip (Horse Head Fault Zone) faults detected in this sector of the Alps. Faults have been studied through detailed structural mapping merging classic field-based survey (in the frame of the Albenga and Ormea sheets of the Carg projects) and Unmanned Aerial Vehicle (UAV)-based Digital Outcrop Model. Fault rocks have been characterized in terms of meso- and microstructure, texture, kinematics. The Monter Frontè thrust has been also characterized through thermometric measurements (synkinematic chlorite geothermometer and illite crystallinity index plus stable isotope and fluid inclusion microthemometry from calcite- and quarz-veins) and numerical simulations with the aim to investigate the thermal evolution during the deformation. Fault activity is dated in the Oligocene through the combination of thermochronometry (zircon (U-Th)/He dating) and stratigraphic relationships. Both fault system are part of a mega-shear zone with left lateral kinematics leading the bending of the the Ligurian Alps as part of the Western Alpine arc as accomplished through two consecutive, Late Oligocene and Early Miocene, stages driven by the combination of Adria rotation and the rollback of the Apennine subduction. Moreover, the thermal signature of the thrust zone (Monte Frontè thrust) indicates that the fault zone attained temperature higher than the wall rocks, with a ΔT of ~50 °C but with local input up to 150 °C. Isotopic signal of fluids indicates a local, proximal source localized in the wall rocks, rather than deep exotic fluids. We simulated the geological evolution with a suite of elasto-visco-plastic thermomechanical models using a 2-D finite difference code that reproduces the stress, strain, temperature, and pressure variations occurring within the thrust zone. Results indicate that shear heating during distributed cataclastic flow account for a moderate and persistent temperature increment (ΔT 5–30 °C), while transient higher temperature pulses (50–90 °C) are reproduced simulating coseismic slip along narrow slip planes. Integration of analytical data and numerical results supports the slow creeping frictional-viscous deformation as effective mechanism explaining the low-T part of the thermal history, whereas seismic deformation equivalent to moment magnitude Mw > 6.5–7.0 earthquakes

is required to fully account for the thermal signal, including the extreme peak temperature.

Heterogeneity of burial-related fracture networks and its effect on strata permeability: Insights from a volcano-sedimentary sequence in Wido Island, Korea

Seung-Ik Park[5], Department of Geology, Kyungpook National University

Abstract

This study aims to understand how heterogeneous spatial distribution of burial-related fracture networks controls strata permeability within a sedimentary basin. For this purpose, we examined a natural laboratory on the northern coast of Wido Island, Yellow Sea, where a Cretaceous lacustrine volcano-sedimentary sequence shows complex strata-bound fracture networks. We sampled the fracture networks on well-exposed low-angle bedding planes using the circular scanline method and analyzed them after unfolding to obtain their geometric and topological parameters. Our results show that the strata-bound fracture networks mainly consist of closely spaced NNW–SSE and ENE–WSW trending fracture sets along with NNE–SSW and WNW–ESE trending sets. Notably, the NNE–SSW and WNW–ESE trending fracture sets are concentrated in a pyroclastic unit cut by a listric strata-bound normal fault, reflecting the fault-induced strain. The mutually orthogonal fracture sets abut each other, likely indicating a local switch of intermediate and minimum principal stress axes during burial in the basin. The combination of mutually orthogonal fracture sets leads to high hydraulic connectivity at all stratigraphic positions because of the high proportions of Y-nodes. We highlight that orientations of bed-parallel permeability ellipse axes of the fracture networks differ depending on stratigraphic positions, indicating the localized fault-induced strain accommodation in addition to background fracturing during burial. Our findings demonstrate that burial-related fracture networks can promote heterogeneous layer-parallel flow migrations that are compartmentalized by strata boundaries.

Abstract

In the last decade, the development and popularization of remotely piloted aircraft systems (RPAS), digital photogrametric techniques and sensors for high-resolution mapping contributed to consolidate digital outcrop models (DOM) as part of the workflow in many geological studies. In the field of structural geology, there are many examples approaching geometric aspects and orientation of ruptile and ductile of geological structures and automatized extraction of discontinuities for rock mass quality (e.g., joints, faults, deformation bands). More recently, high-resolution images has permitted visualization and demarcation of discrete features directly on the DOMs. This scenario has opened new possibilities in the field of dynamic and kynematic analysis and in the understanding of stress-strain in the core and damage zones of fault systems. Topologic analysis derived from DOMs provides a unique opportunity to analyse fracture networks with the high sampling representativity necessary to unveil controls in the fluid flow of granular and fractured media. This case study presents results of a topological analysis performed in basalts from the Paraná-Etendeka Province at Southern Brazil. In this area, the lowermost basaltic lava flows constitute the Serra Geral Aquifer System (SGAS), that directly overlies aeolian sandstones that constitutes the Guarani Aquifer System (GAS). Almost 60% of the municipalities in the Rio Grande do Sul state, southern Brazil, has groundwater as the main water supply for human, industrial and agricultural uses. The water storage in basalts occurs in joints associated with fault zones and dykes. Large planes of joints were also analysed. Therefore, the quantitative analysis of patterns and behavior of the fractures can be of interest to integrate hydrogeological controls and groundwater productivity. This study used a basalt open-pit cut by two basaltic dykes to perform the data acquisition, which provided high-resolution pictures to generate a 3D digital outcrop model and orthophotos. Five sampling areas were used to perform a quantitative assessment of the nodes and branches to determine the degree of connectivity of the fracture system in the scope of topological analysis. Results showed that the rock mass presents dominance of the Y-type and X-type nodes and C-C branches. Connections per branch indicated high degree of connectivity with values ranging from 1.79 to 1.86. This scenario is favorable to fluid flow, if analysed independently. However, the topological pattern changes abruptly in the borders of dykes, where I-type and Y-type nodes and I-I and I-C branches dominate, becoming these zones potential flow barriers.

Damage Asymmetry and Earthquake Rupture Propagation

Young-Seog KIM[1]*, Pukyong University (ysk7909@pknu.ac.kr)
Jin-Hyuck Choi[2], Korea Institute of Geoscience and Mineral Resources
Kwangmin Jin[3], Korea Institute of Geoscience and Mineral Resources

Abstract

Fault damage zones composed of secondary deformation structures have helpfully been used to understand 3D fault architectures, fault behavior characteristics and fault evolutions. Damage zones divided into three main categories depending on purpose and concern of analysis; cross-fault damages, along-fault damages and around-tip damages. Detailed analyses of these fault damage zones with displacement distribution can contribute to understand fault scale, fault geometry, evolution pattern and fluid flow characteristics around natural faults. Thus, it has intensively studied for exploration and evaluation of potential water or oil reservoirs and mineral deposits.

However, recently, we are now applying the advanced knowledge about the fault damage zones to active fault evolution such as rupture propagation. The 2016 M L=5.8 Gyeongju, Korea, earthquake, the 1999 ML=7.3 Chi-Chi earthquake, Taiwan and the 2016 MW=7.8 Kaikoura, New Zealand, earthquake are good examples to apply these models. Although the Gyeongju earthquake did not generate any surface rupture, it is interpreted as the rupture on the linking fault between two main fault-segments along the Yangsan fault zone. For the Chi-Chi earthquake, along-strike variations in coseismic offsets along the Chelungpu fault also clearly displays the linkage relations of two fault segments. Although the rupture propagation pattern along the Hope fault and Kekerengu fault associated with the Kaikoura earthquake is much more complex, it clearly shows linkage pattern between two separated fault segments. Thus, if we carefully analyze the rupture propagation pattern and slip distribution along the fault ruptures, we could understand the characteristics of fault growth and evolution. This kind of study could contribute to assessing earthquake hazards and predicting the next potential ruptures.

Abstract

Unique exposures of active faults in Andalucía, southern Spain cutting through a variety of rock types and sediments provides a natural laboratory to study the interplay between fault geometry, active tectonic and host rock properties. We have studied the architecture and properties of three active faults in southern Spain, namely Padul, Baza, and Galera faults. Padul Fault is located in Granada Basin, while Baza and Galera faults are located in Gaudix-Baza basin. We have conducted several seasons of fieldwork, drone imaging, and in-situ and laboratory measurements of petrophysical and mechanical properties of host and fault rocks. The petrophysical and mechanical analyses include XRD and thin section studies, permeability, and elastic properties measurements. We have investigated both fault core and damage zone of these faults depending on the availability of outcrops in vertical (along fault height) and horizontal sections (along fault length). Our results show that the host rock mineral composition and properties influence the seismic behavior of faults and therefore their architecture and kinematics. This has significance for the fluid flow behavior of faults during the seismic cycles, which in turn results in diagenetic reactions between minerals within the fault zone and nearby host rock. The result of this study has implication for predicting the future earthquakes associated with these active faults in the studied area.

Abstract

This keynote presents a comprehensive summary of five years of research focusing on earthquake-related fault-fluid interactions in the Central Apennines, Italy, which are characterized by seismically active faults within an extensional tectonic setting. Our investigation employed a multidisciplinary and multiscale approach, integrating field and microstructural studies with analyses of carbon and oxygen stable isotopes, carbonate clumped isotopes, fluid inclusions, whole rock geochemistry, and U-Pb and U-Th dating. This approach aimed to elucidate the geochemical signature of syn-tectonic calcite mineralizations obtained from active normal faults. These mineralizations can be considered as fossil traces of past fluid flow in active faults. The examined faults include: (a) the Tre Monti Fault, potentially active during the 1915 Avezzano earthquake; (b) the Mt. Gorzano Fault, responsible for the 2016-2017 Amatrice earthquake; (c) the Val Roveto Fault, the most extensive fault in the central Apennines of Italy; and (d) the hydrocarbon-bearing Trisulti Fault. Our findings indicate that during seismic events, overpressured fluids were squeezed along the principal fault plane and its damage zones, likely facilitating fault slip. Co-seismic dilatancy facilitated the mixing of fluids from two primary crustal reservoirs: shallow meteoric-derived fluids and deep hydrothermal fluids. The results from the study mineralizations in active faults are compared with current geochemical monitoring of springs and groundwater before, during, and after earthquakes in the same region, to validate groundwater monitoring as a tool for earthquake prediction. Notably, the post-earthquake increase in fluid discharge is consistent with geological evidence suggesting the presence of co-seismically overpressured fluids within active faults and the upward migration of deep hydrothermal fluids towards shallower crustal levels. Future investigations will entail a detailed comparison of geochemical analyses of fault-related mineralizations with observed hydrochemical changes in groundwater to determine if the chemical changes observed presently in groundwater also manifested during past seismic events.

Geometric characterization of Baza and Galera active faults, Baza Basin, southern Spain

Ofelia Soledad SILIO[1]*, University of Oslo (ofelias@uio.no)
Anita Torabi[2], University of Oslo
Juan Francisco García Tortosa[3], Universidad de Jaén
Luc Girod[4], University of Oslo

Abstract

Fault geometric characterisation involves the study of attributes such as displacement, segment length, core thickness and damage zone width. These are used in scaling laws to predict fault growth and mechanics. However, there are challenges related to (i) limitations to access fault 3D structures; (ii) resolution limits of datasets; (iii) uncertainties and constrains of methodologies used to study faults and (iv) existence of specific-scale gaps in the fault global dataset. Moreover, there are less data available from active faults, although scaling laws for individual ruptures have been studied before. The objective of this work is to use drone imaging techniques to extend the visualization scope and approach 3D fault characterization in locations unreachable with conventional outcrop analysis.

The study area encompasses Baza and Galera faults, Granada Province, southern Spain. These two active faults are mainly normal and strike-slip faults, respectively, which extend along tens of kilometers. They originated in the basement and propagated through the poorly consolidated Miocene to Pliocene sedimentary rocks, representing a unique case study for the geometric analysis of modern faults.

Outcrop descriptions and structural measurements were carried out, together with drone imagery acquisition. Photos were processed using AGISoft Metashape Professional photogrammetry software. Field data were used as calibration points and faults were mapped based on color changes, strata dip changes, topographic features, fluvial channels distributions, rock alteration, among others. When possible, geometric attributes including strike, dip, length, displacement, fault core thickness and damage zone thickness, were measured on the virtual outcrop models with VRGeosciences software.

To the north, Baza fault core is formed by a single plane with a thicker clay smear. To the central and southern zone, displacement of the Baza fault is distributed among different splays and fault cores become narrower with a decreased proportion of clay smear. The strike of Baza fault is north-south in the northern and central segment and northwest-southeast along the southern sector. Inclinations are predominant to the east-northeast, ranging from 60° to 85°. Displacement measurements vary between a couple of centimetres to tens of metres offset across the fault planes. Fault core thickness range from 1cm for discrete planes to 8m for complex and clay-smear

structures.

In most localities, Galera fault exhibit striation that indicates sub-horizontal strike-slip displacement, affecting undeformed sub-parallel modern sediments. Strikes are scattered into two main families, one northeast-southwest and a second northwest-southeast oriented. Dip angles varies from 45° to 85°. When Galera fault experiments along-strike bending, it is possible to observe positive and negative flower structures, as a result of localized compression and extension, respectively. Fault zone thickness is delimited by flower structures, with scales varying from centimeters to decameters.

The application of drones allowed extending the scope of view of outcrop studies, therefore, increasing the accessibility. Drone imagery offers a bridge between conventional on-site outcrop survey that have limits in their reach, and satellite studies that suffer from relatively low resolution. The scope of the studies can therefore be extended, and features of different scales integrated in a single analysis.

Abstract

Complexity in the spatial organization of fault zone architecture, involving the fault core and the adjacent damage zones can influence the variation of mechanical properties along and across its strike. In this study, we integrate results from the investigations of excellent fault zone outcrops along scanlines from two separate basins. The first part involves active faulting in carbonate, evaporites and siliciclastic host rocks along ~30 km long Galera Fault (left-lateral normal fault) within Guadix-Baza Basin, SE Spain. The second part utilizes an almost continuous outcrop stretch of ~1500 m x ~350 m areal extent in Rio do Peixe Basin, NE Brazil. This outcrop exposes two major sets of deformation band (DB) fault zones oriented perpendicular to each other. The host rock in this outcrop comprises of siliciclastic braided-river system deposits, which was affected by rifting events during the Cretaceous.

Samples collected from active fault zone outcrops in SE Spain show that calcite cementation enhances the elastic behaviour, while increase in phyllosilicate content reduces the elastic property estimates relative to the adjacent host rocks. This has important implications in governing the locations of stable and unstable segments along the fault length in the subsequent earthquake cycles. In the siliciclastic outcrops of NE Brazil, fault zones are defined by the presence of high frequency of DBs. These DBs are more prevalent in the coarse-grained host rocks (which also show higher porosity)and show higher values of Young's Modulus and P-wave velocity (Vp). On the other hand, the less porous medium to fine-grained host rocks deform by forming fractures and constitute the damage zone of the fault. Apart from the grain-size distribution of the host rocks, the interaction of fault zones of various orientations also plays a crucial role in governing its overall architecture. Outcrops in SE Spain exhibiting fault sets of multiple orientations, display a comparatively wider damage zone. The interaction of the two perpendicular DB fault zones in NE Brazil influences the geomechanical property distribution of the fault and the host rocks. The modified estimate of Brittleness Index used in this study from samples collected in SE Spain, shows a direct relationship with the Vp of both the fault and the host rocks, revealing that the mineral assemblage of the fault as well as the adjacent host rocks controls the release of elastic strain during faulting.

Our results demonstrate that detailed outcrop investigations integrating structural, geomechanical and mineralogical analyses can help in delineating the multitude of factors influencing the geomechanical property distribution in fault zones. Insights from such outcrop studies can aid in better prediction of rock properties in active and fossil fault zones in the subsurface.

The Dauki fault zone architecture and its implications for the evolution of the Shillong Plateau, Meghalaya

Vinee SRIVASTAVA[1]*, IISER Bhopal (vinee@iiserb.ac.in)
Rikalave Raman Chabukdhara[2], IISER Bhopal

Abstract

The Dauki fault plays a crucial role in the Shillong Plateau uplift in the North-Eastern Himalaya based on previous tectonic-climate coupling studies. The upliftment of the Shillong Plateau commenced in Miocene and has been explained by various mechanisms. The most prevalent model of the Shillong uplift is that of a continental basement pop-up structure along two seismically active steep-reverse faults along its southern and northern edges by Bilham and England, (2001). As suggested the Shillong Plateau is separated from foredeep basin in south and bounded by the E-W trending Dauki Fault and the WNW-ESE trending Oldham Fault to the north. Geophysical and geomorphic based extensive studies have suggested strike-slip, normal as well as a reverse/thrust fault kinematics for the Dauki fault. However, the existing literature lacks structural and field evidences essential to constrain geometry and kinematics of the Dauki fault. Therefore, structural field mapping based on contemporary fault zone conceptual model was used to work out the geometry and kinematics of the Dauki fault. The Dauki fault was mapped along seven strike-perpendicular N-S transects along the frontal Shillong Plateau. Field observations indicates a partially preserved Dauki fault core and hanging wall damage zones in all seven traverses varying in thickness from ~1-3 km from east to west respectively. The Dauki hanging wall damage zone consists highly fractured and deformed sandstone, shale, and mafic Cretaceous rocks. The Dauki fault core preserved the highly pulverized gouge of same parent rocks. Footwall damage zone is either not exposed or preserved in patches along the six transects along the frontal Shillong Plateau. However, in the easternmost transect running parallel to N-S trending Umngot River section massive cross-bedded sandstones of Oligocene age Simsang Formation was exposed. Older Cretaceous rocks over younger Oligocene age Simsang Formation rock sequence confirms reverse sense of shear on the Dauki fault. In the absence of any displacement marker horizons and the diffused nature of the fault, it is difficult to conclude whether it is reverse or a thrust fault. However, based on the ~3 km width of outcrop of the fault zone we interpret it to be a gently-dipping, thrust fault. This is also consistent with the observations of uplifted terraces and growth of frontal topography south of the Shillong Plateau main topographic front. Our field observations are, however, not consistent with the pop-up hypothesis of the origin of the Shillong Plateau as that requires a Pre-Cambrian basement over Cenozoic fault contact along the Dauki reverse fault. It also suggests that more detailed structural work is required to constrain the deformation in the Shillong Plateau to constrain the models of its evolution.

Folarin Kolawole[3], Lamont-Doherty Earth Observatory, Columbia University,
Florent Boudzoumou[4], Marien Ngouabi University
Delvaux Damien[5], Department of Geology, Royal Museum for Central Africa

Abstract

The Congo basin and its surrounding orogens in the western Central African region had been experiencing several earthquakes, even though quite few studies had attempted to explain their occurrences. The link between the recent seismicity and known faults does not look straightforward. The analysis of seismic history of the onshore and offshore areas revealed that the earthquakes are occurring on pre-existing fault systems of the Congo Basin, its surroundings units, and along near-shore extensions of the oceanic transform faults. In addition, the western Central African passive margin is undergoing two principal stress regime, one which is a ENE-NE trending horizontal compression in a thrust regime, and the other which is a normal faulting regime. Using the slip tendency method, the application of these present stress regimes on the mapped pre-existing fault systems which are mostly high-angle strike-slip faults systems, suggest that it is difficult to reactivate these faults under a thrust faulting stress regime, but more easily in a normal faulting stress regime. As most of the earthquakes occur at upper-crustal depths, we propose three hypotheses: 1.) there might be a brittle shear zone at depth that is accommodating tectonic reactivation leading to seismogenic rupture, which could be achieved by landward stress transmission by oceanic transform faults; 2.) these earthquakes might be generated by plate uplift and gravitational collapse; 3.) some of the events may have been triggered by local anthropogenic stress perturbation. The second hypothesis is quite probable as the western Central African margin has experienced repeated episodes of tectonic uplift in the Cenozoic as recorded in the Congo Basin. A thorough seismic analysis of the western Central African margin would provide more insight into the most probable causative mechanism for the earthquakes.

Abstract

Faults are known to have a profound influence on both migration and storage of geofluids in the shallow crust. Due to their conducive, sealing, and/or combined barrier-conduct hydraulic behaviour, faults impact the modalities of fluid flow and accumulation according to the processes associated to their nucleation and growth, the geometry of the interacting fault segments, the strain rates they solve, the tectonic environment/s in which they form, and their diagenetic history. In this study, we carry out a structural survey on several 100's m- high cliffs exposing Jurassic – Cretaceous platform carbonates crosscut by WNW-striking, high-angle transtensional faults bounding the High Agri Valley Basin, eastward. This work involves the combination of field and digital outcrop structural analysis techniques to assess the variation of geometry, distribution, density, and intensity of both fractures and faults according to the host rock lithology and distance from the basin. Furthermore, we compute their multiscale length and height properties to obtain the input data for DFN modelling. Finally, we build multiple stochastic models of fracture networks at bed package (height: 5m), outcrop (height:50m) and reservoir scales (height: 500m). The goal is the assessment of variations of both fracture porosity and permeability, as well as the scaling factors for the horizontal permeability ellipses.

The results show a scale dependency of fracture and fault geometry over 3-order magnitude for the Cretaceous carbonates, and a scale independent geometry for the Jurassic carbonates. Data are interpreted according to the stratigraphic architecture of the carbonates, and hence the role exerted by efficient mechanical interfaces such as bed and bed-packages interfaces on the vertical propagation of fractures and small faults. The fracture stratigraphy exhibited in the field by the carbonates supports this interpretation. In fact, results of field circular scanline measurements are consistent with both fracture density, P20, and intensity, P21, characterized by similar trends in the Jurassic carbonates. Here the aforementioned mechanical interfaces promoted the vertical fault growth by linkage of pre-existing fractures, originally compartmentalized within single bed-packages, by localizing jointing at their extensional quadrants. Differently, contrasting results are achieved for the massive Cretaceous carbonates due to pronounced bed amalgamation. Furthermore, away from faults, the grain-supported carbonates such as grainstones and packstones show the highest P20 and P21 values due to the calcite rims coating the grains, which formed in marine-phreatic environments, and to the pervasive blocky cements that filled the pore space and formed in shallow freshwater-phreatic environment. In terms of fluid storage and migration properties, results after DFN modelling show the profound contribution provided by both strata-

bound and non-strata-bound fractures to fracture porosity, and by faults, to fracture permeability. Most of the DFN models show near isotropic horizontal permeability ellipses, which is consistent with the fractured and faulted carbonates behaving such as a porous-like medium for horizontal fluid flow. We note that the fault-parallel dominated flow tendencies are exhibited by geocellular volumes representative of the main basin-bounding fault zones.

Characteristics of fault zone structure and the relationship with hydrocarbon migration and accumulation: a case study of Qiongdongnan Basin, South China Sea

Yannan DU[1]*, China University of Petroleum (East China) (b20010011@s.upc.edu.cn)
Kongyou WU[2], China University of Petroleum (East China)
Yanying LI[3], China University of Petroleum (East China)

Abstract

Qiongdongnan Basin is a Cenozoic petroliferous basin in the northern South China Sea. Because it is located at the junction of the Eurasian plate, the Pacific Plate plate and the India Australia plate, it is jointly affected by multiphase stress, and a large number of extensional faults are developed. Faults are important elements that transport natural gas and form structural traps. A fault is a three-dimensional geological body with a certain width, and its internal structure has strong heterogeneity. This research is based on core characteristics and logging curve response characteristics to carry out structural identification and division of fault zone. The structural development model of fault zone is established. Through experimental testing of fault rock samples, the physical characteristics and diagenetic cementation were analyzed. The structural characteristics of fault zone in Qiongdongnan basin and its relationship with hydrocarbon migration and accumulation are discussed. The results show that: (1) Fault zone can be divided into fault core and damage zone, and deep and shallow resistivity, caliper, porosity logging curves have good response characteristics to the structural division of fault zone; (2) The structure of fault zone is not necessarily well developed, and its development degree is greatly affected by the lithology of country rock, structural stress and fault activity. The structural characteristics of the same fault are heterogeneous; (3) The transmission and sealing of fault zone to oil and gas depend on the development degree of each structural unit of the fault, physical property conditions, diagenesis and the "time-space" matching relationship. The incomplete structure of the fault zone is a transport type fault zone, and the transmission capacity is controlled by the fracture density and connectivity. The complete structure of the fault zone is a sealed fault zone, and the transmission capacity depends on the matching relationship between diagenesis, main generation and expulsion periods and fault activity periods.

Brittle Deformation History based on Kinematic Analysis in Igidae, SE Korea

[1]*, Pukyong National University. Geologic Structures and Geohazard Research group (eu1451@gmail.com)
[2], Pukyong National University. Division of Earth and Environmental System Sciences.

Abstract

The southeastern part of the Gyeongsang Basin in korea, composed of volcano sedimentary rocks of Cretaceous Yucheon Group, is characterized by the presence of several large faults on the Korean Peninsula including the Yangsan, Ulsan, Ilkwang, and Dongnae Faults. Understanding the characteristics and history of brittle deformation in the area is crucial for neotectonics and seismic hazard assessment. The kinematic analysis of faults, veins and dikes offers valuable insights into the deformation history and fault evolution of the area. Igidae area in Busan is one of the best place to understand the brittle deformation history and its relationship with large faults and regional tectonics. We collected structural dats through field surveys. Deformation events were analyzed from crosscutting relationship and kinematics of faults and fractures. The results indicate that the deformation history in Igidae is dominated by normal faulting with joints, veins, and dikes followed by multiple strike-slip events. Those multiple events were distinguished and analyzed based on fault geometry, fault connection, and fault displacement. The deformation events in the study area suggest that the normal faults with joints reactivated to strike-slip faults in the study area. The reactivation is mainly controlled by fault geometry, fault zone material and the orientation of stress. This will help to understand the overall tectonics of the area.

Fault reactivation and vein localization along dikes in granitic rock, Gyeongju, Southeast Korea

Sehyeon GWON[1]*, Korea Hydro & Nuclear Power Co., LTD. Central Research Institude
(sehyeon.gwon81@gmail.com)
Sambit Prasanajit Naik[2], Pukyong Nation University
Young-Seog Kim[3], Pukyong Nation University

Abstract

Veins associated with fault zones provide essential information on pore-fluid pressure and stress conditions at the time of vein formation. This study describes quartz-mineralized and fault gouge-infilled veins formed along the Cheongun fault segment in the Late Cretaceous to Early Paleogene granitic rocks, Gyeongju, Southeast Korea. We excavated two trenches across NNE-SSW-striking faults. In both trenches, the vertical separation of the unconformity between the granitic rocks and the Quaternary sediments and the observed striations on the fault planes indicate transpressional deformation along a reverse skrike-slip fault. Interestingly, vein networks are localized within the dikes along which the faults are reactivated with reverse-slip sense. Quartz veins are characterized by intense fracture networks within an andesitic dike. Fault gouge injection within a felsic dike shows that granular gouge materials are injected into fractures off the fault surface. The observed gouge injection and vein localization may imply fluid overpressure involved fracture propagation in the dikes and injection of the mineralized fluids or fluidized fault gouge from the fault zone. The structural analysis of the vein system indicates that the veins are formed under NE-SW-oriented maximum horizontal stress and NW-SE-oriented minimum horizontal stress. This study indicates that statistical analysis and 3D Mohr-circle reconstruction on fractures and veins can provide useful information to determine the magnitude of pore-fluid pressure and stress states associated with localized veins within dikes.

Structural heterogeneities in exhumed fault core: result from Great Glen Fault, Scotland

Namgwon KIM[1]*, University of Strathclyde (namgwon.kim@strath.ac.uk)
Zoe K Shipton[2], University of Strathclyde
Yannick Kremer[3], University of Strathclyde
Christopher D Jack[4], COWI

Abstract

A fault core accommodates most of the displacement within the fault zone, resulting in heterogeneous internal architecture governed by various geological factors. Heterogeneity in brittle structural discontinuities, including faults, fractures, and veins, will control the hydro-mechanical properties of the fault core that need to be considered for surface or near-surface engineering purposes. We use detailed structural and topological maps for the fault core of the Great Glen Fault (GGF) to elucidate the internal architecture and spatial relationships between fault core elements and brittle structural discontinuities controlling engineering properties. The GGF is one of the major NE–SW trending strike-slip faults in Scotland and cuts foliated protoliths. It exhibits a complex internal architecture developed through the multiple reactivation events and exhumation from the elastic-frictional regime. The fault core of GGF is exposed at the Torcastle area showing micaceous shear zones, faults and local dykes cutting foliated psammitic–pelitic gneiss and quartzite. The heterogeneous patterns of structural elements at the Torcastle outcrops define several fault-bounded structural domains. In several domains, NE–SW trending regional foliations are locally rotated by up to 90°. The faults and dykes tend to be subparallel to the adjacent foliations. The geometrical properties of fractures are highly variable, with local quartz and calcite infills, but they clearly relate to the local foliation trend and dyke distribution in each domain. The fractures can be subdivided into six types based on the distribution pattern and geometrical relationships with local faults and foliations. The distribution of X and Y node density indicates that a zone of highly rotated local foliations, and hence higher variability in fracture orientation and connectivity, is likely to represent a zone of lower mechanical stability. The results of this study highlight the structural heterogeneity related to the brittle deformation in the fault core and its relationships with pre-existing anisotropies, which have a predictable control on hydro-mechanical engineering properties.

Controls of deep strike-slip fault on fractures in the Tarim Basin, Northwest China: Insight from finite element numerical simulation

Yichen SONG[1]*, College of Geoscience, China University of Petroleum (Beijing)
(songyichen828@126.com)
Lianbo ZENG[2], College of Geoscience, China University of Petroleum (Beijing)

Abstract

The carbonate fractured-vuggy reservoir controlled by strike-slip faults is the main target for ultra-deep carbonate oil and gas exploration in the Tarim Basin, China. It is crucial to clarify the fault-related fracture distribution within the damage zone for guiding the exploration and development of ultra-deep oil and gas. In this study, a finite element numerical simulation method was employed to investigate the characteristics and development patterns of fault-related fractures in the fault damage zone with different structural styles in the Shunbei Oilfield, Tarim Basin. The simulation results were compared and validated with well-logging interpretations. In areas with multiple faults, fault stepovers exhibit the highest fracture density and widest damage zone. Within the pop-up structures of restraining stepovers, the fractures are concentrated near the sidewall reverse faults and the central uplift zone. Analysis of the stress state of rock fracturing reveals that these fractures belong to shear fractures, intersecting with the direction of the boundary faults at small angles (20-30°). In the pull-apart structures of releasing stepovers, the fractures are concentrated near the intersection of sidewall normal faults and opposite master faults, with the secondary concentration near the sidewall normal faults. These fractures are extensional fractures that intersect with the direction of the boundary faults at larger angles. In areas where a single fault is present, the fractures are shear fractures that intersect with the fault direction at small angles (20-30°). The highest fracture density occurs at the fault bend, followed by the fault tip. The simulated fracture density curve along the wellbore significantly correlates with conventional and gas-logging curves, confirming the accuracy of the simulation results. The research findings provide valuable reference for optimal well placement and fracturing operations in ultra-deep carbonate reservoirs within the Tarim Basin.

Quantitative characterization method of ultra-deep strike-slip fault damage zone based on facies-controlled seismic inversion

Lu LIU[1]*, China University of Petroleum(Beijing) (1789098232@qq.com)
Lianbo Zeng[2], China University of Petroleum(Beijing)

Abstract

The ultra-deep fault-controlled strike-slip fault damage zones are formed by fluid migration and dissolution along the fault-fracture system, which have the potential to bacome favorable reservoirs for oil and gas. The characterization of the spatial distribution and internal structure of the fault damage zones is of great significance for the screening of exploration targets. This study focuses on the ultra-deep strike-slip faults in carbonate formations with an average buried depth of more than 7500m in Fuman area of Tarim Basin. The drilling data indicates that there is a good correlation between P-wave impedance and porosity of fault damage zones in the study area, so a quantitative characterization method is established to calculate the porosity data volume by obtaining P-wave impedance data volume by facies-controlled seismic inversion. Firstly, using the constrained sparse spike inversion method, the first P-wave impedance seismic inversion is carried out based on the variation trend of P-wave impedance in multiple wells. This P-wave impedance data volume has the characteristics of longitudinal wave impedance variation which is consistent with that of the well, but lacks the trend of lateral variation. Three kinds of data volume are calibrated their threshold values from the drilling data and chosen to describe different components of the damage zone: the difference between the original seismic data and the median filtered seismic is used to describe the boundary of the whole damage zone, the fault distribution data obtained by CNN method is used to describe the fault and fracture system, and the residual impedance attribute is used to describe the shape of caves in the damage zone. We call these three data volumes facies and in each facies the P-wave impedance volume obtained from the first inversion is numerically replaced by the real impedance form wells. In this way, a facies-controlled low-frequency model is established through the combination of wells and seismic data. Finally, the model is used to constrain the second P-wave impedance inversion, and a new P-wave impedance data volume is obtained. Then the porosity volume is calculated through the fitting P-wave impedance-porosity calculation formula, which not only characterizes the structure of the strike-slip fault damage zone but also shows the porosity variation of different structures.

Structural characteristics of thrust system in the piedmont zone of middle part of Longmen Mountains during the Indosinian period

Na ZHENG[1]*, China University of Geosciences, Beijing (zhengna1999@163.com)
Fa Deng HE[2], China University of Geosciences, Beijing

Abstract

The Longmen Mountains tectonic belt is located at the boundary between the southeastern margin of the Qinghai-Tibet Plateau and the Sichuan Basin, and is divided into north, middle and south sections with Wolong-Huaiyuan and Beichuan-Anxian boundaries. Among them, the middle section of Longmen Mountains has the greatest variation of topographic gradient, which is one of the best places to reveal the geological structure of Longmen Mountains. During the Late Triassic Indosinian movement in Longmen Mountain, the preexisting normal faults in Longmen Mountain area reversed. In order to determine the Indosinian thrust system in the front and middle section of Longmen Mountain, the structure of the Indosinian thrust system in the piedmont zone middle section of Longmen Mountain was determined through field geological observation, combined with digital elevation and 3D seismic data, and a 3D geological model of the Indosinian thrust system was constructed. The results show that the Indosinian thrusts in the piedmont zone of middle part of Longmen Mountain are a series of reverse faults that tend to the NW and converge over the coal bearing strata of Xujiahe Formation. The front edge of the thrust belt is mainly involved in the deformation of the second and third members of the Xujiahe Formation, and the hanging wall of the fault develops into the Middle and Lower Triassic series. In addition, the thrust system of Longmen Mountain piedmont zone in the Indosinian period has a tendency to transfer from north to south, and the thrust table of imbricated thrust belt gradually decreases from north to south.

Earthquakes and neotectonics in cratonic Australia

Haibin YANG[1]*, Zhejiang University (haibin.yang@zju.edu.cn)
Mark Quigley[2], Melbourne Univerity
Schirin Sellmann[3], Melbourne University
Tamarah King[4], Geoscience Australia

Abstract

Australia is one of the most stable continents around the world with few earthquaekes. However, analysis of high-resolution digital elevation models indicates neotectonic fault-propagation fold traces on the nearly flat karst landscape that locally extend to lengths of >100 km, suggesting potential for hosting large (>7.3–7.5) moment magnitude earthquakes. Along-strike maximum displacements are not proportional to neotectonic fold surface trace length but are spatially associated with crust-scale electrical conductors identified in magnetotelluric surveys. Two major conductors penetrate from the upper crust to the uppermost mantle (at depths < 60 km) along crustal scale shear zones. Conductivity in the uppermost mantle shear zones is higher than conductivity at increased depth, suggesting fluid-enhanced enrichment with hydrogen and/or carbon. Lithospheric fluid localization associated with ancient slab subduction and/or hydrothermal alteration may have weakened pre-existing faults and enhanced neotectonic faulting in the Nullarbor Plain in South-Central Australia.

We further analyzed surface ruptures for 11 historical (1968–2018) moment magnitude (Mw) 4.7–6.6 reverse earthquakes in Australia using statistical techniques and compare their characteristics with magnetic, gravity, and stress trajectory data sets. Of the total combined (summative) length of all surface ruptures (~148 km), 133 km (90%) to 145 km (98%) align with the geophysical structure in the host basement rocks. Surface rupture length (SRL), maximum displacement (MD), and probability of surface rupture at a specified Mw are high compared with equivalent Mw earthquakes globally. This is attributed to (1) a steep cratonic crustal strength gradient at shallow depths, promoting shallow hypocenters (~1–6 km) and limiting downdip rupture widths (~1–8.5 km), and (2) favorably aligned crustal anisotropies (e.g., bedrock foliations, faults, fault intersections) that enhanced lateral rupture propagation and/or surface displacements. Combined (modeled and observed) MDs are in the middle third of the SRL with 68% probability and either the ≤33rd or ≥66th percentiles of SRL with 16% probability. MD occurs proximate to or directly within zones of enhanced fault geometric complexity (as evidenced from surface ruptures) in 8 of 11 earthquakes (73%). MD is approximated by 3.3 ± 1.6 (1σ) × AD (average displacement). S-transform analyses indicates that high-frequency slip maxima also coincide with fault geometric complexities, consistent with stress amplifications and enhanced slip variability due to geometric and kinematic interactions with neighboring faults. Rupture slip taper angles exhibit large variations (−90% to +380% with respect to the mean value) toward rupture termini and are steepest where ruptures terminate at obliquely oriented magnetic

lineaments and/or lithology changes. Incremental slip approximates AD between the 10th and 90th percentiles of the SRL. The average static stress drop of the studied earthquakes is 4.8 ± 2.8 MPa. A surface rupture classification scheme for cratonic stable regions is presented to describe the prevailing characteristics of intraplate earthquakes across diverse crustal structural-geophysical settings. New scaling relationships and suggestions for logic tree weights are provided to enhance probabilistic fault displacement hazard analyses for bedrock-dominated intraplate continental regions.

Active Son-Narmada-South Fault as major threat to dams in central India

VAIBHAVA SRIVASTAVA[1]*, Banaras Hindu University (vsrivastavabhu@gmail.com)

Abstract

The Son-Narmada-South Fault (SNSF) demarcates the southern limits of the Paleoproterozoic Mahakoshal Group of rocks in the Son river valley region of central India. Here, the two multi-phase deformed rock units namely the Mahakoshal Group and Archean Chhotanagpur Granite-Gneiss Complex (CGGC) rocks are at tectonic contact along the SNSF. The northern limit of the Mahakoshal Group is also at tectonic contact with the Middle- to Late- Proterozoic Vindhyan Supergroup. The Upper Vindhyans have remained practically undeformed and hence it is thought that this region of central India has not experienced tectonic disturbances since Late- Proterozoic therefore attained a tectonic stability. The myth was broken by 1997 Jabalpur earthquake in the vicinity of the SNSF and thereafter the studies carried out in the region started giving indications of the active tectonics prevalent in vicinity of SNSF. Using the structural analyses techniques the present study finds that the deformation patterns of the Precambrian rocks across the SNSF are not same even the two studied units namely Mahakoshal Group and the CGGC are located side-by-side in the Son valley region. This indicates that the two concerned rock units have been deformed elsewhere and now juxtaposed together along the SNSF suggesting huge strike-slip movements. The movement is still going on and hence posing a threat of possible earthquake in near future again along the SNSF. There are operational and upcoming dams and large reservoirs for hydropower generation lying close the SNSF hence the tectonic instability may affect them most and further intensify the possibility of severe disasters. Timely actions are therefore very much required for the greater safety.

Multi-phase non-coaxial orogenic growth: propagation of the Longmen Shan thrust belt on the eastern margin of the Tibetan Plateau

Zhicheng ZHOU[1]*, China University of Geosciences (Beijing) (zzcgeology@126.com)
Dan-ping Yan[2], China University of Geosciences (Beijing)
Liang Qiu[3], China University of Geosciences (Beijing)
Ruoyan Kong[4], China University of Geosciences (Beijing)
Huajie Song[5], China University of Geosciences (Beijing)
Dongzhi Xiao[6], China University of Geosciences (Beijing)
Xiaohan Lin[7], China University of Geosciences (Beijing)
Chao Du[8], China University of Geosciences (Beijing)
Fei Kong[9], China University of Geosciences (Beijing)

Abstract

Reconstructing the deformation sequence and strain history of the Longmen Shan thrust belt (LSTB) has significant implications for the growths of the SW Qinling orogenic belt and the Tibetan Plateau. However, the Mesozoic–Cenozoic propagation of the LSTB remains poorly understood owing to weak constraints on strain variations. We conducted a comprehensive structural investigation and made measurements of anisotropy of magnetic susceptibility along the entire LSTB. Magnetic fabrics are represented by prevalent layer-parallel shortening (LPS) fabrics, intersection lineation fabrics, and folding fabrics with magnetic lineations trending NE–SW, WSW–ENE, NW–SE, and N–S, corresponding to four compressional deformations. AMS results and structural analyses, revealed four phases of deformation (D1, D2, D3, and D4) that were characterized respectively by top-to-the-SSE thrusting in the northern LSTB at >219–164 Ma, top-to-the-SW thrusting in the central-northern LSTB at >201–164 Ma, top-to-the-SE thrusting of the LSTB at 125–5 Ma, and top-to-the-east thrusting at 5–0 Ma in the LSTB. D1, D3, and D4 LPS fabrics exhibit a strain evolution that progressed from incipient deformation to pencil structure to cleavage fabrics, corresponding to moderately oblate, prolate, and oblate strain ellipsoids, respectively. The intersection lineation fabrics imply a hinterland-ward progression from LPS fabrics to cleavage-controlled fabrics and non-coaxial superimposition of D2 on D1. Therefore, the early Mesozoic LSTB developed owing to the superimposition of D2 on D1 being non-coaxial, likely suggesting southward growth of the SW Qinling orogenic belt, whereas the modern LSTB was formed by the superimposition of D4 on D3, implying non-coaxial eastward growth of the Tibetan Plateau.

[Keynote] Surface Ruptures of the February 6, 2023 Earthquake Sequence, eastern Türkiye

Tim Kusky[1]*, China University of Geosciences, Wuhan (tkusky@gmail.com)
Jiannan Meng[2], China University of Geosciences, Wuhan
Walter Mooney[3], U.S. Geological Survey
Erdin Bozkurt[4], Middle East Technical University
Lu Wang[5], China University of Geosciences, Wihan

Abstract

Two powerful earthquakes struck eastern Türkiye on February 6th 2023, rupturing three active fault systems, including the Dead Sea fault zone (DSFZ), the East Anatolian fault zone (EAFZ) and the Çardak-Sürgü fault (Ç-SF). The DSFZ is the transform plate boundary between the Arabian and African plates, whereas the EAFZ is the transform plate boundary between the Arabian and Anatolian plates. The Feb. 6 2023 earthquake sequence activated both plate boundaries, providing a natural laboratory to study how fault ruptures are propagated from one plate boundary to another at triple junctions, and offering insight to how plates interact.

We present our first-hand field measurements of ground offsets and high resolution (centimeter level) drone-mapped determinations of surface ruptures taken 10-30 days after the first shock. The surface ruptures, liquefactions, massive landslides and dammed lakes caused by these earthquakes were clearly documented during our field work, and now available as public open-access databases (Meng et al., 2024 (10.1126/science.adj3770; doi.org/10.6084/m9.figshare.24872043). We present our data in raw form, and as vector files showing the new fault ruptures, but we refrain from classifying the fault systems into classical Riedel or other standard forms, as complimentary seismological studies. Ren et al., 2024 (10.1126/science.adi1519) show that some of the ruptures were super-shear, others sub-shear, and we do not wish to impose century-old assumptions of plane strain, homogenous isotropic media, and Andersonian stress fields to interpret this new data set. The geophysical, structural geology, and imaging communities can use these data to formulate new concepts in surface rupture in complex media during large earthquake events and their rupture properties and results through variable media with emerging concepts and technologies.

The initial rupture was on the Dead Sea fault zone (DSFZ), while the maximum displacements (around 47.5 kilometers away from the epicenter at the junction of the DSFZ and the EAFZ) and energy release (Mw 7.8) occurred 24 sec later when rupture transferred to the East Anatolian fault zone (EAFZ). Seven hours later, a Mw 4.5 aftershock at the junction of the EAFZ with the east-west striking Çardak-Sürgü fault (Ç-SF), was followed soon-after by the second large (Mw 7.5) earthquake, hinting at a possible causal relationship.

Our observations provide important data on surface deformation during large continental strike-slip earthquakes, rupture propagation mechanisms, and how slip may be transferred between complex fault systems. We also provide insight into how slip along linked fault systems accommodates global plate motions.

Hunting for an invisible Holocene fault beneath an urban region using historic aerial photos

Junjie REN[1]*, School of Earth Sciences and Resources, China University of Geosciences, Beijing (renjunjie@cugb.edu.cn)
Fei Guo[2], China Earthquake Networks Center
Kang Li[3], National Institute of Natural Hazards, Ministry of Emergency Management of China
Xiwei Xu[4], School of Earth Sciences and Resources, China University of Geosciences, Beijing

Abstract

A large earthquake in a city always causes a huge loss in the economy and big casualties. This type of large earthquake is related to Holocene faults generally with displaced landforms. Therefore, finding active faults beneath a city will be essential for disaster prevention and mitigation. In the urban active fault surveying project, the popular techniques are seismic reflection exploration and drilling which are expensive and time-consuming but include big uncertainties. In the middle part of the Datong Basin, the Shuiyu fault crosses the Yudong District of Datong City, north China. Urbanization in the past 20 years brought about dense buildings and cement roads that have erased the origin landforms and made the possibly visible fault trace invisible. Although the seismic reflection results show evidence of a potentially active fault beneath the Yudong District, the fault trace is hard to accurately determine, and the late Quaternary activity of the fault remains unclear. Here, we introduce the sterophotographic technique of old aerial photos taken in the1960s to reconstruct the original DEM data along the fault. We use trenching and radiocarbon dating to recover the paleoearthquake in the late Quaternary. Trenching results show at least five normal surface-rupturing events occurred in the late Quaternary along the Shuiyu fault, and the original DEM data indicate two or three clear scarps along the strike of the Shuiyu fault. The fault exposures in the foundation excavation of the buildings validate that the scarps are related to displaced terrace T3 by the Shuiyu fault. The height of the scarp and dating of terrace T3 indicates that the Shuiyu fault has a normal slip rate of about 0.12-0.21 mm/yr. Given the elapsed time of ~10 ka, the Shuiyu fault beneath the Yudong District will increase the risk of a large earthquake in the future. Besides, the old aerial photos before urbanization can provide unique clues for active faults beneath a city and make the invisible fault visible. With the development of urbanization, however, the potential earthquake will pose a high seismic risk to citizens and basic infrastructures.

Abstract

This report reviews, first, the challenges or opportunities brought by occurrence of extremely large earthquake events, the historical background of the approvals, funding status of relevant Chinese governmental departments, and also the main research contents for the projects of the urban active fault surveying, the large-scale mapping plan of active faults, the seismic risk assessment of active faults in the key earthquake monitoring and preventing areas, as well as the scientific investigations of the earthquake surface rupture zones of the major earthquakes occurred in past 20 years. Then, the significant progresses have been achieved since the implementation of those projects in the hidden active fault surveying and positioning technology under strong noise and weak signal conditions, fault-activity quantitative identifying technology, earthquake hazard assessment theory and method, multi-source data managing technology of active faults and a series of technical standards for active fault surveying. New theories, new methods and new concepts have also been established in the faulting behavior and great earthquake origin, the active fault avoidance, earthquake hazards prevention, earthquake monitoring and predicting, and they are the new dynamic uplifting model of the Qinghai-Tibet Plateau, multiple fault-segments-cascading rupture mechanism, earthquake rupturing localization characteristics and avoidance theory, and seismo-geological signatures for identifying M≧7.0 earthquake risk areas and their application in zoning an earthquake risk area. Finally, some scientific questions and problems that urgently need to be solved are put forward in active fault surveying and research, such as uncertainty of quantitative parameters of fault activity, multiple fault-segments-cascading rupture conditions and prediction of large/great earthquake magnitude, quantitative evolution process of the seismo-geological signatures for identifying M≧7.0 earthquake risk areas, simulation of strong ground motion and related earthquake disaster prediction based on 3D active fault model, and faulting resistance of major projects across active faults.

Abstract

The Gondwana rift basins of Peninsular India are situated close and parallel to the junctions in the suture zones between the Archean cratons such as Dharwar, Bastar, and Singbhum. There are four Gondwana rift basins of India represented by the E-W trending Satpura & Damodar Basins and NW-SE trending Pranhita-Godavari & Son-Mahanadi Basins. A combined analysis of gravity, magnetic, and Remote Sensing techniques to delineate the subsurface structures to trace the tectonic evolution of the basin. Landsat Remote sensing data, ground gravity, and Emag2 magnetic data were used to understand the surface and subsurface structures.

The Bouguer gravity anomaly map of the Gondwana rift basins of India and its adjoining area depicts prominent linear gravity low of 50mGal negative anomalies due to lower density Gondwana sediments. It shows a total anomaly variation of 148 mGal with a relative gravity low of 111 mGal and a high of 37 mGal. The EMAG2 magnetic anomaly map of the study area shows a variation of about 1773 nT with a low of -795 nT and a high of 978 nT. Landsat 8 Operational Land Imager (OLI) and Thermal Infrared Sensor (TIRS) C2 Level 1 Data of 30m resolution used for integration purposes.

The major structural trends show NNW–SSE from Pranhita-Godavari basin, ENE-WSW, and NW-SE from the Son-Mahanadi basin, NE–SW from the Satpura basin and it appears the different basins of the Damodar valley along with an E–W trending structures characterized by NW–SE Karanpura–Bokaro, NW–SE to NNE–SSW Jharia basin, NNW–SSE, and NNE–SSW Ranigunj basin.

Probabilities Seismic Hazard Modeling inferred from the newest fault slip rates and its effect on the Landslide Risks in the Eastern Tibet Region

Jia CHENG[1]*, China University of Geosciences, Beijing (jiacheng@cugb.edu.cn)
Xiwei Xu[2], China University of Geosciences, Beijing
Chong Xu[3], National Institute of Natural Hazards, Ministry of Emergency Management of China

Abstract

The Eastern Tibet Region (ETR) stands in the region where the crustal eastward extrusion of the Tibetan Plateau occurs. Tens of active strike-slip faults behave with high strike-slip rates to adjust this eastward extrusion of the crust. These active faults consist of the Xianshuihe fault zone, Litang fault zone, Lancangjiang fault zone, Baqing-Leiwuqi fault, Nujiang fault, Bianba-Luolong fault, Jiali fault, and other large strike-slip fault zones. Strong historical earthquakes frequently struck this region . These large-scale strike-slip faults all have earthquake risks of M7+. How to build a scientific and reasonable seismic hazard model for the eastern Tibetan Plateau is of great significance to the safety of both the local people and the major projects under construction and already constructed in western China.

In this study, we constructed a new seismic hazard model for the eastern Tibetan Plateau using the newest fault slip rates and considering the multi-segment possibilities and probabilities. First, we collected and analyzed the newest slip rate results from field works for the faults in the eastern Tibetan Plateau. Then, we built segmentation models for these faults according to DEM data and historical rupture behaviors. According to historical seismicity distribution and fault slip behaviors, we divided the ETR into eight seismic zones to obtain the Magnitude-Frequency Distribution (MFD) for different earthquake magnitudes in each zone. We also considered the multi-segment possibilities and probabilities for the active faults with clear segmentation and historical earthquake data in this region in the seismic hazard models. After that, we applied the taper Gutenberg-Richter distribution to convert the geodetic strain rates and the fault slip rates into fault seismic activity rates and background seismic activity rates. We calculated the Peak Ground-motion Acceleration (PGA) values for the ETA. Finally, we also predicted the landslide risks in the ETA in the PGA field.

Our results show that the PGA value is relatively lower around the middle section of the Xiaojiang fault, which is agree with the historical earthquakes occurrence pattern. The high probabilities of the multi-segment rupturing for the Xiaojiang fault are determined by the fault segment distribution based on the new geological mapping results. We obtained four fault areas with high risks of potential M7+ earthquake in the ETR, i.e., the Xianshuihe fault, the Jiali fault, the Jinshajiang fault, and the Litang fault. The predicted landslide risks show the high values occurring around the Jiali fault and the Xianshuihe fault.

Our results will enhance the application of regional geological field studies in earthquake risk analysis, and provide the preparedness for renew of the seismic hazard models.

Abstract

The Kongur Shan Extensional System (KSES), the largest E-W extensional system in the Pamir, is tectonically active with high rates of instrumental seismicity. However, its earthquake recurrence remains largely unknown, hampering the comprehensive understanding of regional seismic hazard and crustal kinematics. Here we investigate three paleoseismic sites in the northern KSES, including lacustrine seismites in the Muji Basin, surface ruptures of the Kongur Shan Fault, and an exposure of the eastern Muji Fault. Using multiple paleoseismic methods, we constrain recurrence intervals of Mw 6.5 ± 0.2 earthquakes at these sites. The seismites, as a regional record, indicate an aperiodic earthquake recurrence pattern, with two paleoearthquakes occurring over the past ~1000 years, at 720–683 and 1025–936 cal yr BP. The other two sites, with records spanning ~4800 and ~2700 years, reveal average intervals of 1400 ± 278 and 1125 ± 248 years on the Kongur Shan Fault and eastern Muji Fault, respectively. The long recurrence intervals contradict ~80–230 years estimated from slip rates of the two faults over a longer time span, which are ~2.2 and ~6.3 mm/yr, respectively. This inconsistency suggests irregular seismic recurrence behaviors of the two individual fault segments. Such irregular seismic recurrence behaviors, on both regional and individual fault scales, are potentially related to the low maturity and complex fault geometry of the northern KSES, as well as changes in surface loads in the region.

Abstract

Variability in earthquake-generating ruptures results in different seismic hazard implications and offers crucial insights into understanding causative factors such as fault geometry, the presence or absence of barriers restricting ruptures, time since the last earthquake, and the periodicity of seismic events. To comprehend the rupture variability, it is important to generate the past earthquake chronologies-data spanning for a longer duration which can assist in discerning the repeatability or randomness of the ruptures along individual faults. This study focused on two notables Himalayan earthquakes, the AD 1505 central Himalaya earthquake, and the AD1803 Gharwal earthquake, both pre-instrumental earthquakes, that occurred along the Central Seismic Gap (CSG)- a region believed to be seismically silent for hundreds of years. The long seismic quiescence in this region has led to the anticipation of a great earthquake in the near future. Despite the significance of the location of the AD1505 and AD1803 events in the CSG, there remains a lack of knowledge of its surface rupture extents, and thus in turn its magnitude. We excavated two paleoseismic trenches approximately 80 km apart in Gharwal Himalaya to establish earthquake chronology. Based on the preliminary earthquake chronology data from our trenches, and the correlation of probability density graphs of event chronologies from previous published trenches, we suggest a surface rupture of at least 110 km for the AD1505 earthquake and at least 98 km for the potential AD1803 event within the Delhi- Haridwar segment boundary.

Transient response of semi-elliptical hill with an elliptical tunnel under blasting and seismic loading

Hao Luo[1]*, School of Resources and Safety Engineering, Central South University (mingtao@csu.edu.cn)
Luo Hao[2], School of Resources and Safety Engineering, Central South University
Zhao Rui[3], School of Resources and Safety Engineering, Central South University
Xiang Gongliang[4], School of Resources and Safety Engineering, Central South University

Abstract

With the propagation of blasting and seismic stress waves, the structural discontinuities from the hill and the tunnel led to stress wave scattering, inducing dynamic stress concentration around the tunnel and surface displacement amplification effects of the hill. The focus of this study was the hitherto unexplored comparative analysis of transient response under blasting and seismic disturbances, which optimized the existing equivalent blasting wave to accurately characterize the engineering blasting stress wave, and the Ricker wavelet was introduced to characterize the seismic loading. The wave function expansion method based on the Mathieu function and angular Mathieu function half-range expansion method was jointly employed to obtain the exact mathematical solution for the steady-state response of the hill and tunnel. Subsequently, the Fourier transform and Duhamel integral were combined to derive the transient surface displacement of the hill and the transient dynamic stress concentration factor (DSCF) of the tunnel under the blasting and seismic loading. The differences in the transient response of the hill and tunnel under two types of loading were compared, and the effects of incident angle, the type and duration of loading, and the axis ratio of the hill and tunnel on transient DSCF and surface displacement were analyzed. The numerical results indicated that the spatial distribution of DSCF and surface displacement was mainly determined by the combination of the incident angle and axis ratio of the hill and tunnel, while the values of DSCF and surface displacement were mainly determined by the combination of duration and type of loading. Furthermore, earthquakes were prone to induce structural damage and exhibited a higher destructive capacity compared to blasting.

Morphotectonic studies and identification of active faults in Qazvin city up to a radius of 50 km from its center.

Maliheh Norouzi[1]*, Geological Survey and Mineral Exploration of Iran
(malihenorouzi0@gmail.com)

Abstract

Earthquakes that occur in densely populated cities are among the most dangerous natural disasters with potentially devastating effects on society and infrastructure across the globe. To better understand earthquakes, research in active tectonics aims at quantifying crustal deformation throughout the active fault's earthquake cycles by studying morphotectonics and stratigraphic evidence of recent and past earthquakes.

The underlying assumption in this approach is that a fault's current and previous seismic behavior is representative of its future behavior. Faults are seldom present in outcrops. However, even when they are, their occurrence is often limited to a cross-section, or the surface of the fault itself. Furthermore, such outcrops are commonly only exposed in either quarries or areas of high erosion or high seismic activity. On the contrary, in urban areas and intra-plate regions, the societal relevance of understanding the faults is higher; faults very rarely outcrop. This is where morphotectonics can play an important role. Constraining a fault's seismic behavior in such a manner requires high-resolution morphotectonics and stratigraphic records that enable us to resolve the spatial and temporal characteristics of co-, post-, and interseismic phases, ideally over multiple earthquake cycles. In this research, remote sensing studies and fieldwork led to the identification of active faults around the city. Also, the morphotectonics evidence indicates the existence of hidden faults in the city of Qazvin.

In the geological maps that have been published until today, no faults have been identified on the surface of Qazvin City, but this research indicates the existence of several active and young fault branches on the surface of Qazvin City.

Clastic dikes are the primary source of data used for paleoseismic interpretations. This research found clastic dikes several meters high related to historical earthquakes. This was while it is not seen in any article or scientific reference in Iran that a researcher has observed clastic dikes in Iran. This research has new results from the active tectonic knowledge of Qazvin City, which will be beneficial for future urban development and the preservation of the human and financial capital of this city.

New insight into the mechanism and evolution of HorseTail splay folds: A case study from the Huayingshan fold belt(South China)

Zhang-peng LIU[1]*, State Key Laboratory of Geological Processes and Mineral Resources, School of Earth Sciences and Resources, China University of Geosciences, Beijing 100083, China (thatjohnliu3390@gmail.com)
Liang Qiu[2], State Key Laboratory of Geological Processes and Mineral Resources, School of Earth Sciences and Resources, China University of Geosciences, Beijing 100083, China
Dan-Ping Yan[3], State Key Laboratory of Geological Processes and Mineral Resources, School of Earth Sciences and Resources, China University of Geosciences, Beijing 100083, China

Abstract

As the seismogenic fault of the Ms6.0 earthquake in Luxian County, China. the Huayingshan Fault bears great significance in seismic prevention due to the presence of the large urban area of Chongqing nearby. Analyzing its lithospheric structure and evolutionary formation mechanism is crucial in clarifying the tectonic history of the eastern Sichuan region. Many studies indicate that the Huayingshan fold belt is a typical Jura-type thin-skinned tectonic belt.

The fold-thrust belts are also considered closely associated with active tectonic earthquakes. The horsetail splay folds in research of the central-southern part of the Huayingshan fold belt have attracted widespread attention, and similar landforms are widely distributed in multiple countries. However, research on their formation mechanisms remains relatively weak. To better understand the mechanism evolution of the present-day landform of the Huayingshan horsetail splay folds. We utilize discrete element numerical simulation in the PFC2D software, based on the inferred regional geological structure of the Mesozoic and Cenozoic. We set the slope angle of the ramp and the depth of the detachment layer as variables, along with reasonable geological parameters. We obtained an extension sequence similar to the chronological results and profile fold topography results highly consistent with the actual geological background, We used the theory of fold linkage and combined it with the historical tectonic background to provide a reasonable explanation for the mechanism evolution of horsetail splay folds plane landforms. We hope that by studying the horsetail splay folds in Huayingshan as an example, we can provide important insights and new approaches into lithospheric structure and tectonic evolution processes for researchers in regions with similar landform units, contributing to global seismic research and disaster prevention efforts.

Abstract

Faults are the most important sources of seismicity worldwide, while the research on the recovery mechanisms of slip-surface strength or fault healing is scarce. We investigated the microstructures and nanostructures in fault rock of a seismogenic normal fault, hosted in chert-banded dolostones, from the Yuguang Basin South Margin Fault (YBSMF), northeast of the Shanxi graben system, North China. Also, high velocity shear experiments were conducted on the quartz-bearing dolomite fault gouge taken from the YBSMF. The behavior and its effects of nanoparticles during high-speed slipping are simulated by discrete element method (DEM). The fault slip surface exhibits a range of slip-related structures, including slickenlines, truncated clasts and nanoparticles/fragments. These nanoparticles are shaped into two forms, single spherulitic nanoparticles (size ranges from 50 to 300 nm) and agglomerated nanoparticles (size ranges from 300 to 500 nm). The textures of the gouge from high velocity experiments are characterized by grain comminution, R shear planes and localized deformation zone in the friction weakening stage. The slip surfaces of the gauge are characterized by mirror-like smooth surface and nanoparticle aggregates. Theoretical calculation results show that the temperature inside the gauge layer did not exceed 300 °C during the experiments. However, the microstructures present that the dolomite experienced thermal decomposition, indicating that the temperature at the asperity exceeds 550 ℃. Our microstructural investigations suggest the single spherulitic nanoparticles can be the result of thermal decomposition of dolomite along the major slip surface of the normal fault. Numerical simulation results from DEM present that the shear strength surges exponentially with the increasing volume percent of bonded nanoparticles. We suggest that the transformation from single spherulitic nanoparticles to agglomerated/bonded nanoparticles by sintering can result in the recovery of friction strength at the fault plane. The post-seismic strength recovery can partly attribute to formation of agglomerated nanoparticles.

Seismogenic structures of the 2022 M6.1 Lushan earthquake and M6.0 Maerkang earthquake sequence in western Sichuan, China

Chuanyou LI[1]*, Institute of Geology, China Earthquake Administration (chuanyou@ies.ac.cn)
Kai Sun[2], Institute of Geology, China Earthquake Administration
Junjie Li[3], Institute of Geology, China Earthquake Administration

Abstract

Both the Lushan Ms6.1 earthquake on June 1 and the Maerkang M6.0 earthquake swarms on June 10, 2022 occurred in the the eastern part of Bayan Har block west of Sichuan Province, where the NE-trending faults have dominated, and the structures are relatively complex. Among them, the Lushan Ms 6.1 magnitude earthquake occurred in the southwest section of the Longmenshan fault zone. Whether it was an aftershock of the 2013 Lushan magnitude 7.0 earthquake and whether it occurred in a seismic gap are the main points of contention. The Maerkang earthquake sequence occurred in the northwestern section of the Songgang fault. This fault has received little attention and been not well studied, therefore no consensus on its activity. In order to understand the cause of these two earthquakea, determine the seismogenic structure of the earthquake, and determine the future seismic trend, we conducted a field investigation of the geological structures, surface deformations and disaster distribution characteristics around the epicenter. The field observations of the Lushan M6.1 earthquake show that on the southeast side of the epicenter, the distribution of earthquake disasters including landslides and rockfalls were scattered and the sizes of landslides were also relatively small; whereas on the north west side of the epicenter the landslides and other earthquake disasters were densely distributed and showed big sizes, especially along the belt from north of Baoxing county to the east of Yanjing township. The field investigation combined with the results of the focal mechanism solution and the relocation of aftershocks, suggest that the seismogenic structure of this earthquake is a northwest-trending thrust fault between the Yanjing-Wulong fault and the Shuangshi-Dachuan fault, which is a small, secondary fault. The field investigation of the M6.0 earthquake sequence in Maerkang showed that the earthquake occurred in the northwestern section of the Songgang fault, which was an immature section with a complex structure. The surface deformation caused by the earthquake, such as building damage, ground fissures and landslides, is not distributed along the main fault showing a linear characteristics, but is arranged in a row along a belt located on the east side of the main fault and nearly parallel to it. Combined with the analysis of the results of relocation of aftershocks and focal mechanism solution, it can be concluded that the earthquake rupture did not occur along the main Songgang fault, but along the branch fault on the east. Above studies show that the Lushan M6.1 and Maerkang M6.0 earthquakes both occurred on secondary faults, which were the results of the unified movement of the Bayan Har block in the same tectonic environment.

3D modeling and seismic capablity assessment of the east margin fault of Daxing uplift in North China Plain

Zhengfang LI[1]*, Institute of Geology, China Earthquake Administration (lizhengfang07@163.com)
Bengang zhou[2], Institute of Geology,China Earthquake Administration
Yajing Zhang[3], Institute of Geology,China Earthquake Administration

Abstract

The east margin fault of Daxing Uplift is an important boundary fault in the North China Plain, which controls the development of Langgu secondary depression under the extensional tectonic background. The latest shallow seismic reflection profile and borehole data have found evidence of Holocene activity in the eastern margin of the Daxing Bulge, which has changed the conclusion in recent decades that there has been no activity since the late Quaternary, and has important application value for the seismic hazard risk survey in Beijing, and also poses a new challenge to the assessment of the upper limit of the maximum potential magnitude of the eastern margin of the Daxing Bulge. In this research, by collecting and organizing several shallow seismic geophysical profiles and deep seismic reflection profiles, a 3D model of the east margin fault of Daxing Uplift is constructed by using the 3D modeling software SKUA-GOCAD, which mainly includes: (1) 3D fault model and stratigraphic information map; (2) three-dimensional model diagram of fault distribution according to dip Angle; (3) Three-dimensional model diagram of fault distribution according to depth and three-dimensional map of small earthquake distribution. Finally, by using the structural analogy of the summer pad fault on the eastern margin of the Daxing uplift, the maximum potential magnitude induced by the Daxing fault is evaluated, and the following conclusions are drawn: (1) It is inferred in the research that the lower part of the fault on the eastern margin of the Daxing uplift is connected with the deep and shallow fault cutting the upper and lower crust interface and Moho surface, and it is a deep and shallow fault. (2) In this research, 15 shallow seismic geophysical profiles were collected and organized, and three-dimensional models of the east margin fault of Xiadian uplift according to strike, dip Angle and depth were constructed by using SKUA-GOCAD three-dimensional modeling software. (3) Based on the principle of structural analogy and the magnitude-fault rupture scale relationship obtained by predecessors for North China, this paper comprehensively estimates that strong earthquakes of magnitude M7.5 may be induced on the eastern margin of the Daxing uplift, and surmises that the eastern margin of the Daxing uplift still has the possibility of large earthquakes. This conclusion has important scientific guiding significance for earthquake disaster prevention and control in the Beijing area in North China Plain, and should be paid attention to and actively take prevention and avoidance measures.

Abstract

The Gyeongju Earthquake (Mw 5.8, on September 12, 2016) and Pohang Earthquake (Mw 5.4, on November 15, 2017) had a significant impact on Korea's geological and seismological researches, producing a wealth of research results. The series of earthquakes has generated a lot of fundamental research, but not much that is directly relevant to the public. In this study, we aim to cover both basic research and application. 1) We report on the Quaternary surface rupture (Gasan) at the southernmost end of the Yangsan Fault near two cities (Busan & Yangsan) (Active faulting behavior, Field observation). Based on this surface rupture's information with geotechnical database, 2) we analyze the seismic hazard assessment in the Busan metropolitan area (Earthquake hazard zonation, Data processing). Ultimately, 3) we provide data for practical preparedness against earthquake risk (Urban prevention strategies, Scene simulation).

1) Active faulting behavior (Field observation); Yangsan Fault is a major tectonic line in the southeastern Korean Peninsula that traverses major cities in the Yeongnam region, including Busan, Yangsan, Ulsan, and Gyeongju. Previous studies have reported numerous Quaternary fault sites associated with moderate to large-magnitude earthquakes along the fault. The surface rupture trace identified in this study at Gasan-ri, Yangsan, is located at the southernmost end of the Yangsan Fault and are very close to the Busan, the second largest city in South Korea. Two northeast-striking fault planes cut the alluvial fan deposits with 1 m vertical displacement in outcrop section. The OSL dating of the unconsolidated sediments indicates that the most recent earthquakes with surface rupture occurred after 111±7 ka, the late Pleistocene.

2) Earthquake hazard zonation (Data processing); Seismic hazard assessment for the Busan metropolitan area was conducted using the surface rupture evidence and geotechnical database. The moment magnitude estimated using the vertical displacement and the maximum displacement-moment magnitude empirical equation (Wells and Coppersmith, 1994) is 6.5. Based on the surface rupture point, a radius of 30 km from the epicenter was defined as the Busan metropolitan area for deterministic seismic hazard assessment. The site classification was determined based on the Korean domestic site classification of Sun (2010) using the bedrock depth and the average shear wave velocity up to 30 m depth extracted from the borehole data.

3) Urban prevention strategies (Scene simulation); If an earthquake of magnitude 6.5 occurs in Gasan in 2024, huge damage may occur in Mulgeum of Yangsan, Eco-Delta City of Busan where more than 560,000 people live. This result of seismic hazard assessment can be utilized for

developing earthquake disaster prevention plans and strategies as one of the earthquake disaster occurrence scenarios. Future studies should include additional research considering building codes, building structure, factors of fire occurrence, and emergency response planning for further quality improvement.

Mechanism analysis of underground powerhouse structure-stress-controlled collapse in fractured rock mass: microseismic monitoring and numerical investigation

Yuepeng SUN[1]*, State Key Laboratory of Hydraulics and Mountain River Engineering, Sichuan University (ypsun1997@163.com)
Nuwen Xu[2], State Key Laboratory of Hydraulics and Mountain River Engineering, Sichuan University
Biao Li[3], School of Geoscience and Technology, Southwest Petroleum University
Haoyu Mao[4], State Key Laboratory of Hydraulics and Mountain River Engineering, Sichuan University

Abstract

The stability of the surrounding rocks of large underground powerhouses is always emphasized during the construction process. The development of unfavorable rock mass structural planes such as fault will lead to large excavation deformation and obvious discontinuous deformation characteristics. An extremely intense collapse case observed in underground powerhouses in southwestern China was introduced as a case study. To understand the damage evolution mechanism in collapse, microscopic characterization of unloading damage evolution process of surrounding rock is carried out based on microseismic (MS) dynamic monitoring information. Second, to further reflect the characteristics of rock failure evolution and deformation response in the monitoring section, the digital panoramic borehole camera and acoustic wave test are arranged. The results show that the excavation unloading not only causes surrounding rock fracturing near the periphery of the cavern but also induces deep fracturing at a certain depth from the periphery of the cavern. Subsequently, based on numerical simulation and moment tensor inversion method, the evolution of the temporal distribution of the fine fracture type of the surrounding rock mass is clarified; For the evolution mechanism of the fault-slip collapse, many tensile fracture events occurred during the development stage, and a few shear fractures, corresponding to structure plane dislocation, occurred before the occurrence of the fault-slip collapse. The results provide a direct case history that will assist the prediction and support of fault-slip collapse disasters and contribute to excavation of deeply-buried caverns in the field.

The Characteristics of Geostress Field and Fault reactivation analysis Assessment in the Cucumber Mountain Area, southern Sichuan Basin

Zifan Zhu[1]*, China university of petroleum (East China) (anya187346068@163.com)
YangWen Pei[2], China University of Petroleum (East China)

Abstract

Due to the complex stress field and shale gas extraction, the faults in the Huanggua Mountain area are prone to reactivation, leading to incidents such as casing deformation and microseismic events. Therefore, accurately understanding the spatial distribution pattern of the stress field and evaluating the risk of fault reactivation are crucial for shale gas extraction. By comprehensively considering seismic data, logging data, and the spatial geometry of faults, numerical simulations of the stress field were conducted to ascertain its spatial distribution pattern. Based on the numerical simulation results, a novel method for evaluating fault reactivation was proposed, which combines differential matrices with the Coulomb-Mohr rupture criterion (fR=σn /τ), revealing the spatial distribution differences of fault reactivation risk along fault attitudes. Simultaneously, through the correlation analysis of horizontal wellbore deformation and microseismic data, the impact of fault reactivation on shale gas extraction was quantitatively evaluated. The research findings reveal that: (1) The stress distribution in the Huanggua Mountain area exhibits significant spatial variations, with the stress in the syncline zone being higher than that in the anticline zone, and the stress in the southwest region being higher than that in the northeast region, with the stress in thrust and back-thrust zones being higher than that in single thrust zones. (2) The risk of fault reactivation exhibits significant spatial variations and local high-value characteristics, gradually decreasing from north to south, but showing higher risk at areas of fault strike changes, connections, and overlaps. (3) There is a significant correlation between casing deformation and microseismic events with the risk of fault reactivation and the distribution of high shear stresses. With the increase in reactivation risk and shear stress, the probability and intensity of microseismic events and casing deformations also increase.

Unveiling the Hidden Dynamics: A Comprehensive Exploration of the Greater Himalayan Out-of-Sequence Thrust and Active Faults in the Sutlej River Section, India

RAJKUMAR GHOSH[1]*, DEPARTMENT OF EARTH SCIENCES, IIEST SHIBPUR, HOWRAH, WEST BENGAL, INDIA, 711103 (rajkumar.ghosh.2020@gmail.com)
ATIN KUMAR MITRA[2], DEPARTMENT OF EARTH SCIENCES, IIEST SHIBPUR, HOWRAH, WEST BENGAL, INDIA, 711103

Abstract

The Himalayan tectonics is composed of three major in-sequence foreland-propagating (southward) orogen-scale thrusts (MCT, MBT, and MFT), as well as North-to-Northeast-dipping Out-of-Sequence Thrusts (OOST) and additional back structures. Looks deeply into the unique structural pattern and intriguing dynamic tectonic setting of the Greater Himalayan Out-of-Sequence Thrust (GHOST) in the Sutlej River basin, from the Oligocene to the present. The Jhakri Thrust (JT)-Jeori Dislocation (JD)-Sarahan Thrust (ST)-Chaura Thrust (CT) system has recently been identified as a possible orogen-scale out-of-sequence thrust (OOST) in the proximal footwall of Main Central Thrust in NW Himalaya. The Jeori Dislocation (JD) and Sarahan Thrust (ST) are situated between the Main Central Thrust (MCT) and South Tibetan Detachment Zone (STDZ), but their age is similar to Himalayan Frontal Thrust (HFT) or Main Frontal Thrust (MFT) (<2.5 Ma).

Focuses on active thrust faults, including CT, which has a hanging wall exhumation rate of 4.82±0.55 mm/yr. and a footwall exhumation rate of 0.61±0.10 mm/yr. These geological data provide valuable insights into complex tectonic processes shaping Himalayan orogeny.

Emphasizes importance of understanding brittle-ductile style deformation processes, looks at multi-scale tectonics of the Greater Himalayan brittle-ductile style inside western Himalayan terrain. MCT reactivation was observed in setting of out-of-sequence faulting as late as the Pliocene. Perhaps a south-directed out-of-sequence fault disrupts upper plate of Himalayan orogen, overlapping (and cutting) pre-existing faults.

The fundamental approach includes of field observations, structural mapping, and geochronological analyses, which incorporate cutting-edge techniques spanning from outcrop-scale to microstructural analysis to provide a comprehensive picture of structural evolution. This section provides a detailed analysis of structural features of Greater Himalayan Out-of-Sequence Thrust, including fault geometry, fault-related folds (including intriguing box fold and micro-slip in the centre of box fold), and associated structures (irregular quartz vein with varying thickness) at various stages of symmetric and asymmetric shaped boudins, S-C fabrics (top-to-bottom shearing).

The emphasis is on identifying strain patterns and understanding the GHOST's kinematics. These geological correlations reconstruct tectonic history of Sutlej River segment, focusing on key episodes of deformation and metamorphism. In terms of broader implications, this section focuses

on contribution to understanding of Himalayan tectonics and potential implications for seismic hazard assessment in Jhakri (Nathpa area), Jeori, Sarahan, and Chaura regions. As a result, structural setting imposes numerous minor earthquakes (near Rampur areas) or release of stress energy in form of strain or fault-controlled hot springs over the area (along the right bank of the Sutlej river in Nathpa, near Jeori on Hindustan Tibet Road to Spiti valley) over geological time. The significance of structural pattern (box fold, kink fold, tension gases, S-C fabrics, Y-P planes, asymmetric boudins, and asymmetric quartz veins) and tectonic history of Greater Himalayan Out-of-sequence Thrust in Sutlej River section, as well as future research and exploration opportunities in this dynamic geological environment.

Deformation-Time Constraints on the South Tibetan Detachment System in the Cuona area, eastern Himalaya

Zhuo Tang[1], Institute of Geology, Chinese Academy of Geological Sciences
Hanwen DONG[2]*, Institute of Geology, Chinese Academy of Geological Sciences

Abstract

The South Tibet detachment system (STDS) is a set of stretched dissociation systems developed along the Himalayan orogenic belt, and its formation process is closely related to the uplift history and evolution process of the Himalayan orogenic belt, which is an important object for studying the tectonic deformation in the process of Indo-Eurasian collision and orogeny. Cuona Detachment (CD) is a ductile shear zone several kilometers wide in which a large number of different types of leucogranites develop, and on the basis of large-scale field mapping, two phases of leucogranites are identified in CD: early syn-tectonic leucogranites and late post-tectonic leucogranites. In this paper, zircon LA MC-ICP-MS U-Pb analysis tests were performed on three early leucogranites bodies and two late leucogranites bodies. Zircon U-Pb dating results showed that CD continued to be active at 20 Ma until it stopped around 14.8-16.5Ma. At the same time, combined with the results of previous research, the evolution process of STDS in the Cuona region and its difference along the orogenic belt were further explored. Along the Himalayan orogenic belt, the activity time of STDS in different regions showed obvious differences, and this paper believes that the STDS cessation time mainly shows a trend of gradually becoming younger from the western tectonic junction to the east (such as the Cuona area).

Constraining the evolution of shear zones in the Himalayan mid crust in Central Nepal: implications for the exhumation of the Himalayan metamorphic core

Rodolfo CAROSI[1]*, University of Turin (rodolfo.carosi@unito.it)
Chiara Montomoli[2], University of Turin
Salvatore Iaccarino[3], University of Turin

Abstract

The mid-crust of the Himalaya is exposed in the Greater Himalayan Sequence (GHS), one of the major tectonic units of the Himalayan belt cropping out for nearly ~ 2500 km along strike. GHS is regarded as coherent tectonic unit, bounded by the South Tibetan Detachment to the top and the Main Central Thrust to the bottom. Integrated studies by different techniques allowed to recognize several high-temperature shear zones in the core of the GHS, with top-to-the S/SW sense of shear (High Himalayan Discontinuity: HHD, (Montomoli et al., 2015) U-Th-Pb in situ monazite petrochronology provides ages older than the Main Central Thrust, along the same structural profile. Data on P-T evolution testify that these shear zones, acting for ~ 5-10 Ma, affected the tectono-metamorphic history of the belt and different P-T conditions have been recorded in the hanging-wall and footwall of the HHD. Burial and prograde metamorphisms in footwall rocks were linked to thrust sense movement along the HHD, while the hanging wall rocks were retrogressed and exhumed. This shear zone, running for nealry 1000 km , is documented in several sections of the belt. We present the results of some transects of the GHS in the Annapurna-Manaslu massif (Central Nepal). Close to the transition between sillimanite-bearing gneiss and kyanite-bearing gneiss, we identified a high-temperature ductile shear zone with kinematic indicators pointing to a top-to-the S sense of shear.

In situ U-Th-Pb analysis on monazite, joined with chemical compositional maps, on samples from the shear zone and its footwall provided ages ranging from ~ 8 to 43 Ma. The age of the HHD in central Nepal is constrained between ~ 28/27 and 17 Ma, in very good agreement with the ages of the HHD detected along strike in the GHS (Carosi et al., 2018). It is notably older than the Main Central Thrust along the same section (Catlos et al., 2001; Gibson et al., 2015) constrained at ~ 17-13 Ma.

The occurrence of the HHD in Central Nepal allows us to fill a gap in the recognition of the HHD in the Himalayan belt. Thus this study is a step towards a precise identification of the burial, assembly and exhumation mechanisms of the Himalayan metamorphic core.

[Keynote] Utilizing Multi-Mineral Multi-System Petrochronology to Unravel the Tectonic Development of the Himalaya

John COTTLE[1]*, University of California Santa Barbara (cottle@geol.ucsb.edu)
Kyle Larson[2], The University of British Columbia Okanagan

Abstract

Petrochronology, or the interpretation of isotopic dates in light of additional contextual data (e.g., microstructure, textures, trace element-, and isotope-geochemistry), is a key tool for understanding the timing and rates of orogenic events. The expansion (e.g. in situ Lu-Hf and Rb-Sr geochronology) and refinement (e.g. U-Th/Pb geochronology) of petrochronologic methods, as applied to the Himalayan orogenic system, has enabled the investigation of previously intractable geological problems, and the resolution of long-standing debates about the timing and duration of a range of geologic processes. In this presentation, some of the key recent advances in geochronologic instrumentation and analytical techniques will be highlighted, including 1) the application of in-situ Lu-Hf garnet geochronology combined with quantitative modeling to robustly interpret the geologic significance of garnet-based dates from metamorphic rocks; 2) Three-dimensional simultaneous imaging of U-Th/Pb, trace elements Sm-Nd isotopes in monazite and xenotime to unravel the complex history of melt formation and migration, and; 3) applications of a new generation of time-of-flight mass spectrometer to high-resolution (micron-scale) geochronology of a range of accessory minerals to document cryptic tectonothermal events. The presentation will conclude with a discussion of how the application of these, and other methods, has transformed our understanding of the processes that define the development of the metamorphic, magmatic, structural, and exhumation history of the Himalayan orogen.

The geodynamics of long-term convergence, Indian continental subduction and indentation at the India-Eurasia collision zone

Wouter Pieter SCHELLART[1]*, Vrije Universiteit Amsterdam (w.p.schellart@vu.nl)
Kai Xue[2], Vrije Universiteit Amsterdam
Arijit Laik[3], Vrije Universiteit Amsterdam
Vincent Strak[4], Vrije Universiteit Amsterdam

Abstract

Continent-continent collision is generally a relatively short-lived process, lasting up to max. several tens of Myr, as the convergence rate progressively decreases during the collision process. The short duration and decrease in convergence rate are thought to result from the reduction and eventual disappearance of the driving force during collision. The India-Eurasia collision, resulting in the largest mountain belt and plateau on Earth, the Himalaya and Tibet, respectively, are unusual in this respect, because relatively rapid India-Asia convergence (at 4-5 cm/yr) and mountain building have continued since the onset of collision at ~60-50 Ma. The collision is also unusual in that it has resulted in major indentation and northward advance of the collisional plate boundary, and major continental subduction of Indian lithosphere. Many previous studies consider an external driving force for the long-term convergence, continental subduction and Indian indentation. In this study, we investigate the mechanism(s) of the continued convergence, long-term continental subduction and long-term indentation of India into Asia using buoyancy-driven geodynamic models. We present results of time-evolving analogue experiments and numerical models performed in three-dimensional space to simulate the subduction and collision processes at the India-Eurasia-Sunda convergent boundary with different boundary conditions at the 660-km discontinuity. These include models that are confined to the upper mantle and models that incorporate a lower mantle reservoir. The results of both modelling techniques indicate that indentation and collisional plate boundary advance occur in all models, irrespective of the layering of the mantle, but is progressively enhanced for models with an increase in viscosity step at the 660 km discontinuity. Furthermore, both the analogue experiments and numerical simulations indicate that long-term convergence and continental subduction require subduction of slab material into the lower mantle, as the lower mantle slab segments provide the main drive for such convergence and continental subduction. Finally, our models suggest that the negative buoyancy force of both upper and lower mantle slab segments of the Sunda slab and the lower mantle Tethyan slab segment below the collision zone are the main driver of long-term convergence and continental subduction, while the combination of rollback-induced mantle flow of the Sunda slab and slab negative and positive buoyancy forces of the Sunda and India slabs, respectively, drives northward Indian indentation.

Abstract

Current models of the tectonics of the Eastern Himalayan Syntaxis in the Arunachal Pradesh of NE India project the Indus -Tsangpo suture along the NW-SE trending Tiding-Mayodiya-Tuting ophiolite belt. This ophiolite belt divides the region into a northeastern Lohit Plutonic Complex and associated metasediments and the southwestern block representing the Indian plate margin. The southwestern block is composed of gneiss, schists and volcano – sedimentary sequences of Proterozoic to Eocene age herein is called the Dibang Block.

Extensive fieldwork along with U-Pb, Lu-Hf and carbon lipid profile analysis and aided by published geochemical, isotopic and detrital zircon date leads to the conclusion that:

1. The Lohit plutonic complex consists of three generation of granitic magmatism represented by a. Late Jura-Early Cretaceous Gabbro-diorite complex with positive εHf formed contemporaneous with rifting of the Lhasa terrane from the Gondwanan margin b. Trodjhemite-Granodiorite-Hornblende-Biotite Granites with positive εHf and low initial Sr ratio of largely mid to late Cretaceous age formed by far field extension by subduction pull related to the subduction of Lhasa terrane along Bangong NuJiang Suture . c. Miocene S-type Leucogranite intruding both of the above granites which we relate to the post indentation rotation, oblique-slip faulting and transpression of the Lohit terrane and the Indian plate margin.

2. All the above granites show adakitic signature which for the Cretaceous granites formed by decompression melting in an extensional setting. The Miocene leucogranites were formed by post-convergence anatexis of crustal rocks in a manner analogous to the formation of Himalayan leucogranites.

3. None of these granites represent subduction related arc magmatism or correlate with the late Cretaceous-Eocene Gangdese batholith of Tibet. In our model, the Lohit Plutonic Complex represents the Central Lhasa block. The South Lhasa block terminates at the Namche Barwa syntaxis.

The Dibang Group is composed of volcano-sedimentary strata that overlie basement of the late Paleoproterozoic Bomdilla Gneiss dated at c.1750 Ma. On the basis of lithologic mapping, detrital zircon data, carbon lipid profile and published paleomagnetic data from the interbedded metavolcanic beds, we propose the entire sequence to be time equivalent to the Permian Gondwanan formations that occurs at the southern margin of our area that were deposited in several parallel rift bound basins. during the rifting of the Qiangthang terrain from the Gondwanan

margin. This Permian sequence forms the pre-rift base for the overlying Abor Volcanics of early Cretaceous age. The volcanics are interbedded with purple and green sandstones and shales, variously named Miri Quartzite, Yinkiong Formation and Hunli Formation and represent syn-rift sedimentation and volcanism related to the rifting of India and Australia in the Cretaceous. The overlying Dalbuing Formation with Eocene plant and shallow marine micro fossils represent post-rift sediments.

Geochemically, the mafic-ultramafic rocks of the Tiding-Mayodiya-Tuting ophiolite belt represent sub continental lithospheric mantle exhumed during extension of Gondwana, and do not represent an oceanic subduction zone or suture.

The Dibang Group is correlatable with the rocks of the Shillong Plateau and not with the lesser or Higher Himalayan rocks.

The Shillong - Mikir massif within the foreland of the Himalayan orogen, NE-India, is the largest active basement structure in the world. It now occupies a region which is subject to complex tectonic stress patterns on accounts of its location in the proximaty of the tri-junction of the Indian, the Eurasian, and the Burmese plates. The north-south collision between the Indian and Eurasian plates and east-west convergence between the Indian and the Burmese plates impart geologic and complex tectonic setting of the Shillong -Mikir massif. The northern part of the Shillong Plateau is overridden and compressed by the immense load of the Himalayan orogeny along the northeast dipping Main Central Thrust (MCT), Main Boundary Thrust (MBT) and Main Frontal Thrust (MFT) while its southern part is free from such compression and overridden by any load. In contrast, the Mikir Hills is overridden and compressed in the north by the enormous load of the Himalaya along the MCT, MBT and MFT while its south and southeast part is overridden and compressed by the Naga Hills along Halflong-Disang thrust. These two-block located in two such different tectonic regimes have experienced complicated tectonic regime and expected to experience different exhumation history.
To elucidate the exhumation history, Apatite Fission Track (AFT) ages were obtained for 15 samples out of which 08 ages are form Shillong Plateau and remaining 07 ages are from the Mikir Hills. Ages are analyzed combining with previously published ages. The ages in the Shillong Plataeu range between 33.7± 2.4 to 260.7 ± 38.5 Ma and in the Mikir Hills, it ranges between 64.0 ± 3.3 to 169.0 ± 8.8 Ma. Out of 08 AFT ages from the Shillong Plateau, 04 ages ranging between

33.7±2.4 and 91.4±6.2 Ma (With mean age 62.8±3.6 Ma) are from the middle of the Shillong Plateau i.e. from west of Shillong city and other four ages ranging between 119.1± 6.1 and 260.7± 38.5 Ma (With mean age 202.1 ± 22.6 Ma) are from the northern most part of the Shillong Plateau i.e north of Guwahati. In Mikir Massifs, the ages range between 64.0±3.3 and 169.0±8.8 Ma (With mean age = 104.5±9.8 Ma). Younging age pattern from northern edge (260.7 ± 38.5 Ma) to southern edge (8.6 ± 0.6 Ma) of the Shillong Plateau reflect that the southern edge was buried below closing temperature of AFT i.e. ~120 °C while the northern edge was over the 120 °C isotherm of AFT prior to Miocene time. In the other hand the Mikir Hills was exhuming slowly i.e. similar to the Guwahati region of Shillong Plateau.

Tectonic collision of Indian-Asian plates and the evolution of Himalaya foreland basin

KUN YU[1]*, China University of Mining and Technology (yukun@cumt.edu.cn)
Yiwen JU[2], University of Chinese Academy of Sciences
Bhupati Neupane[3], University of Chinese Academy of Sciences

Abstract

After continental collision of India-Asia plates in the Cenozoic, sediments deposited in the peripheral foreland basin were reworked and recycled in the southern margin of the Himalaya. A magnetostratigraphic and low-temperature thermochronology study of the post collision belt in Tansen Basin, central Himalaya was conducted to further constrain the age and evaluate the tectono-thermal history of the Himalayan fold-thrust belt in Nepal. The observed sequence of polarity zones correlates with the chron C7n1 to chron C6Bn1 in the Geomagnetic Polarity Time Scale spanning the time frame ca. 24 to 21.5 Ma. Detrital ZHe ages from the upper part of Bhainskati Formation and overlying lower to upper Dumri Formation range from ~126 to 7 Ma, with a dominant population of ~15-10 Ma in the Dumri Formation are spread across a range of eU values. This age range is younger than the proposed stratigraphic age of the host sediments and suggests substantial post-depositional Miocene thermal resetting of the ZHe system followed by relatively rapid cooling. The ZHe age pattern suggests an inverted age relationship, which is attributed to thermal metamorphism resulting from overthrusting by a hot nappe which is no longer preserved. This thermal effect however, is less apparent in outcropping coal measures of the underlying upper part of Bhainskati Formation, where vitrinite reflectance measurements suggest maximum post-depositional paleotemperatures attained were ~85-90°C. This study also indicated provenance change, after collisions of Indian-Asian plates, and exhumation history of the foreland basin in the central Himalaya since the early Miocene.

Abstract

Cenozoic closure of the Tethys Ocean in central Asia was associated with formation of an extensive zone of tectonic compressional deformations reaching the N margin of the Tibetan Plateau and beyond. One of the northernmost zones of compressional deformations is known from the NW part of the Qaidam Basin, located above the Tibetan Plateau in W China. Previous structural models for this zone, either based solely on surface field data and rather conceptual, or based on 2D seismic data with limited depth imaging, have suggested the presence of a rather simple thrust fault system rooted within the pre-Cenozoic (Meso-Paleozoic) basement and associated folds developed within the Paleogene-Neogene shallow water to terrestrial sedimentary succession of the Qaidam Basin. High-quality 3D seismic data acquired above the Jandingshan, Heiliangzi i Janbei anticlines in the NW Qaidam Basin proved that a much more complex model should be used to explain the structure and evolution of this compressional belt. The new model, supported by a balanced cross-section constructed using seismic data, consists of two main components: (1) thin-skinned thrusts detached within the Eocene evaporites, and (2) thick-skinned thrusts and backthrusts developed with the Meso-Paleozoic basement. Shallow growth strata precisely imaged by seismic data indicate very recent, Pliocene – Quaternary thrusting, uplift, and localized erosion. The proposed structural model also provides new clues about the origin of present-day salinity of numerous lakes located in the Qaidam Basin. At least partly this salinity might be related to erosion and redeposition of Eocene evaporites that were transported to the surface along recently active thin-skinned thrusts.

Seismic data used in this study was kindly provided by China National Petroleum Corporation (PetroChina) which is acknowledged with many thanks. IHS Markit is thanked for providing academic license of the Kingdom seismic interpretation software. This study was supported by statutory research funds of Institute of Geological Sciences, Polish Academy of Sciences.

Wedge-scale deformation in the Himalaya through time

Malay MUKUL[1]*, IIT Bombay (malaymukul@iitb.ac.in)

Abstract

The Himalayan boundary is wedge-shaped with a basal decollement or the Main Himalayan thrust (MHT). Transfer of slip along the MHT from the wedge backstop in the hinterland to the Himalayan foreland through time is the key to understanding Himalayan deformation from geological through decadal scales. Results from the Global Positioning System (GPS) measurements indicate that slip along the MHT is highest and aseismic in the Himalayan hinterland. The slip accumulates along the MHT as it climbs up section into the brittle regime from a ductile regime and is converted into shortening in the Lesser Himalayan Duplex. This also causes the maximum vertical uplift in the Himalayan wedge near the Lesser Himalayan Duplex indicating that the Himalayan wedge is currently sub-critical. Slip has been periodically transferred along MHT to the mountain front through time whenever the Himalayan wedge becomes critical. Slip has also been transferred forelandward from the locked region in out-of-sequence deformation thrusting. Out-of-sequence thrusts also appear to have ductile deformation signatures indicating prolonged out-of-sequence deformation in the frontal Himalayan wedge and change in deformation mechanisms in these faults possibly due to overburden removal in the wedge by erosion. Channel flow activity in the Higher Himalaya also operated out-of-sequence in the wedge to build taper in the sub-critical Himalayan wedge in the hinterland. Interseismic seismicity in the Himalaya is associated with the slip accumulation zone near the Lesser Himalayan Duplex. Great earthquakes are typically expected when the Himalayan wedge becomes critical and slip is transferred to the Himalayan front as evident from multiple palaeoseismic studies in the frontal Himalaya. In the hinterland, continued normal faulting and normal fault-related seismicity indicates that the wedge hinterland has been super-critical at times too. Such wedges typically develop into salients with multiple frontal imbricates forming a frontal schuppen belt without a well-defined Main Frontal thrust. Himalayan recesses have a well-defined Main Frontal thrust and may also have a hinterland rift in some cases. This work shows that the deformation in the Himalayan wedge varies through time and space but is consistent in terms of decollement tectonics and slip transfer along the MHT.

Spatial and temporal stress variations along a continental megathrust: case study of the Himalayan Main Central Thrust

Djordje GRUJIC[1]*, Dalhousie University (dgrujic@dal.ca)
Olivia Rolfe[2], Dalhousie University
Marianne Negrini[3], University of Otago
David Prior[4], University of Otago

Abstract

We investigate the internal deformational structure of an active continental megathrust exposing a full spectrum of active fault behaviours—from aseismic creep at depth to earthquakes creating surface ruptures. Himalayan thrusts, including the Main Central thrust (MCT), have collectively operated over broad ranges of pressure, temperature, and strain rates since the early Miocene. As all these structures merge into the Himalayan basal décollement, the Main Himalayan thrust (MHT), it can be safely assumed that the rocks now at the surface were within the MHT at the time of their deformation. Hence, they offer records of different behaviours along the megathrust.

The MCT in eastern Bhutan is a ductile shear zone extending up to four kilometres into the footwall block. First, we determined the metamorphic peak temperatures across the MCT by Raman spectroscopy of carbonaceous material (RSCM). We established the deformation temperatures by Ti-in-quartz thermobarometry and quartz c-axis textures. Thermal-kinematic history along the transit, for the period of interest, was derived by inverse modelling of the thermochronological datasets obtained by 40Ar/39Ar dating of muscovite, apatite fission-track dating, and (U-Th)/He dating in apatite and zircon (Grujic et al., 2020). From the optimal model, we obtained the Pressure-Temperature histories of the individual points across the shear zone, allowing accurate calculations of the flow stresses.

Further, microstructural and textural analyses of quartz mylonites from the MCT enabled us to quantitatively assess flow stress variations triggered by exhumation-induced pressure and temperature reductions. Notably, the flow stresses at the peak deformation temperatures were the same across the shear zone, but the strain rates decreased by two orders of magnitude from the core to the shear zone boundary. By the cessation of ductile shearing, flow stresses approached approximately 110 MPa. This allowed us to calculate the conditions for frictional slip reactivation of the brittle, seismogenic part of the megathrust.

Finally, microstructural observations under the Scanning Electron Microscope provide evidence that dissolution-precipitation creep accompanied by intergranular dilatation (aka microscale cavitation) was the dominant deformation mechanism during the final stages of ductile deformation.

Effects of structural position on the progressive evolution of internal shear zones from the Himalaya: Insights into orogenic wedge evolution

Pritam Ghosh[1], Indian Institute of Science Education Research (IISER) Kolkata; Department of Earth Sciences, Yonsei University, Seoul, South Korea.
Kathakali BHATTACHARYYA[2]*, Indian Institute of Science Education Research (IISER) Kolkata (kathakali@iiserkol.ac.in)

Abstract

We studied two internal shear zones, the Main Central thrust (MCT) and the Pelling-Munsiari thrust (PT), from the leading-edge to address how kinematic evolutionary paths of two successive internal shear zones vary along their transport direction due to varying structural positions. The rock parcel at the leading-edge exposures lies foreword of the Lesser Himalayan duplex (LHD) and, therefore, records the deformation signatures from trailing-edge locations during its progressive deformation. Hence, these rocks record the most complex and complete progressive deformation history. Structural analysis of the MCT and the PT reveals significant variation in thicknesses, deformation mechanisms, and strain partitioning from the trailing- to the leading-edge of the orogenic wedge.

The thickness-displacement plot signifies strain softening in all the exposed thrust zones, with leading-edge exposures exhibiting additional evidence of reaction and geometric softening. This is attributed to varying deformation conditions and mechanisms along the transport direction, due to decreasing overburden conditions, fault cutting up the section and concomitant erosion. Irrespective of their structural position within the orogenic wedge, exposures of internal thrusts record a non-steady, decelerating strain path. In the leading-edge exposures, the PT with greater connectivity with the immediate footwall duplex records a higher strain, higher translation, and higher pure shear component than the overlying MCT that does not have direct connectivity with the duplex. With a more complete deformation history, the leading-edge exposures of the MCT and the PT zones record a comparatively higher simple shear component and a higher strain than the trailing-edge exposures. We explain this as a result of the dominance of the less competent mylonite domain over the more competent protomylonite domain in the leading-edge exposures. Strain partitioning due to internal structural geometry, a manifestation of the varying deformation conditions along major shear zones, also plays a critical role in their kinematic evolution. This work demonstrates that the structural and kinematic behavior of shear zones associated with orogen-scale internal thrusts are intricately linked to their structural position and connectivity to footwall structures.

Magmatic and metamorphic evolution of the Late Cretaceous Muslim Bagh Ophiolite, western Pakistan: Implications for ridge subduction after subduction initiation

Masanari Arao[1], Tohoku University
Takeshi IMAYAMA[2]*, Okayama University of Science (t.imayama@gmail.com)
Yoshihiro Sawada[3], Shimane University
Koshi Yagi[4], Hiruzen Institute for Geology and Chronology
Rehanul Haq Siddiqui[5], Saindak Metals Limited
Dripta Dutta[6], Okayama University of Science

Abstract

The magmatic and metamorphic evolutions of the Muslim Bagh Ophiolite (MBO) can help understand the relationship among supra-subduction ophiolite, subduction initiation, and the former spreading centre in the forearc. Here, we investigated the whole-rock chemistry, mineral composition, P–T conditions, and K–Ar ages of the MBO and its associated units. The whole-rock and magmatic clinopyroxene compositions suggest that the MBO metabasites and tholeiitic basalts of the underlying Bagh Complex originated in a supra-subduction setting and mid-ocean ridges, respectively. Oceanic island basalts are also found in the Bibai Formation and the Bagh Complex. Metamorphic hornblendes in the MBO metabasites record low-pressure amphibolite-facies (partly granulite-facies) metamorphism, indicating a >50 ºC/km geothermal gradient. The K–Ar hornblende and plagioclase ages suggest contemporaneous high T/P metamorphism in the MBO and tholeiitic magmatism in the Bagh Complex at 78–77 Ma, implying that the heat source causing the high geothermal gradient could be due to orthogonal ridge subduction after subduction initiation in the forearc. Higher alkali content and Al values in the hornblende rims than in their cores suggest a pressure increase at high temperatures in a compressional setting. Our results, combined with those of the previous studies, demonstrate that the geothermal gradient in the MBO dropped from >50 ˚C/km at 80–72 Ma to 15–25 ˚C/km at approximately 65 Ma due to gradual steepening of the subducting slab, followed by the obduction of the MBO during the Late Cretaceous to Eocene period.

Neo-Tethyan subduction records in West Sulawesi, Indonesia

Xiaoran Zhang[1]*, Institute of Geology and Geophysics, Chinese Academy of Sciences (zxr627@163.com)
Shuiyue Xue[2], Institute of Geology and Geophysics, Chinese Academy of Sciences
Jinyu Xi[3], Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

The southeastern extension of the Neo-Tethyan arc system in SE Asia remains enigmatic mostly due to the lack of robust isotopic dating on arc magmatism in the Indonesian archipelago. Here, we report new detrital zircon U-Pb-Hf isotopic data from West Sulawesi to constrain its Cretaceous to Eocene magmatic tempo. We find that detrital zircons from West Sulawesi are dominated by ca. 105-80 Ma and ca. 70-45 Ma age populations with high positive εHf(t) values, suggesting derivation from juvenile sources with limited continental crustal contamination. Our new data, together with previous geological and geochemical investigations, support the existence of an Andean-type continental margin in West Sulawesi during mid-Cretaceous to Early Eocene times. More importantly, such a magmatic tempo of West Sulawesi and zircon Hf isotopic signatures agree well with those of Neo-Tethyan arcs in southern Lhasa and Sumatra, but contrasts with those of Paleo-Pacific subduction-related arcs in SE China, SE Vietnam, East Malaysia, and NW Borneo. Therefore, we propose that the Neo-Tethyan arc system may extend over 7500 km from southern Tibet to West Sulawesi, and that such huge an arc system with consistent magmatic flare-ups and lulls and may have played a vital role in global-scale plate reorganization and climate change.

Abstract

The Cenozoic growth of the Tibetan Plateau and the distribution of deformation across it are a consequence of India-Asia collision and continued convergence, which have implications for studies of continental intraplate deformation. The spatio-temporal development of Cenozoic deformation along the northern margin of the plateau is an important issue that can test various models of plateau growth. The northern Tibetan Plateau is bounded by the Cenozoic Qilian Shan thrust belt and the Haiyuan left-slip fault. In this study, we conducted geologic mapping, field observations, electron spin resonance dating, apatite- (U-Th)/He and fission track analysis, and analogue modelling in the Qilian Shan thrust belt to improve our understanding of the timing of brittle faulting, range exhumation, and intraplate deformation in the northern Tibetan Plateau. We document the first direct age constraints for Oligocene deformation within the central Qilian Shan via ESR dating, which correlates with AHe-AFT cooling ages in adjacent ranges. We demonstrate that the Qilian Shan thrust belt experienced Cenozoic two-phase growth history including Eocene-Oligocene fault-related uplift shortly after the India-Asia converge, and mid-Miocene regional overprinting deformation that reactivated the proximal thrust faults. This deformation pattern suggests the Qilian Shan thrust belt has experienced out-of-sequence development starting from the Eocene-Oligocene time and has persisted as the stationary northeastern boundary of the Himalayan-Tibetan Orogen throughout the Cenozoic. Analogue modelling results indicate that the Paleozoic Qilian suture systems acted as a pre-existing weakness to play a decisive role in controlling the lithospheric rheology, which therefore impacted the timing, pattern and strain distribution of Cenozoic intraplate deformation across the northern Tibetan Plateau.

Abstract

Strike-slip shear zones are important components in collisional orogens and play a key role in the tectonic evolution of the continental lithosphere. The Chongshan shear zone (CS-SZ) is an important hundred-kilometer-long continental scale strike-slip shear zone on the southeastern Tibetan plateau. To unravel its deformation history and processes, we examined a range of deformed rocks (e.g. granitic mylonite, mylonitic gneiss, quartz schist). The detailed field observations, microstructural, and EBSD texture analyses reveal that the CS-SZ experienced high-temperature (500–650 °C) deformation overprinted by a low-temperature (300–400 °C) deformation during the shearing and exhumation process. Kinematic vorticity data reveal that the Cenozoic ductile shearing on CS-SZ was characterized by general-shear deformation. The pure shear-dominated flow (79–55% pure shear) of the bulk deformation history has been overprinted by a later increase of simple shear up to a simple shear dominated flow (48–97% simple shear) during the latest increments of ductile deformation. The bulk strain rates of CS-SZ ranged from 3.4 × 10-16 to 3.8 × 10-12 s-1, while the northernmost region experienced higher differential stress (46 to 108 MPa) and higher strain rates (1.7 × 10-12 to 1.0 × 10-11 s-1). There are both sinistral and dextral kinematic senses in the northern segment of CS-SZ, but the southern segment is dominated by sinistral kinematics. The opposing shear senses in the northern segment could be explained by a large amount of pure shear during deformation. Our structural analyses, combined with published geochronology data, indicate that CS-SZ experienced rapid cooling between 19 Ma and 13 Ma, accompanied by the coeval exhumation of the metamorphic rocks.

Abstract

Quantifying deformation histories of the thrust faults within the Tibetan Plateau (TP) and its periphery can provide significant insight into the geodynamic mechanism of the formation of the Plateau. The Lancangjiang fault (LCJF) outcropped mainly along the Lancang (Mekong) River and is a NNW-SSE-striking regional thrust fault in the SE TP, which may have played an important role in accommodating the differential uplift in the SE TP. However, there is, to date, no precisely temporal constrains on the activity history of the LCJF due to poorly exposed fault trace and limited technique of brittle fault dating. Recent hydropower construction and drilling along the Langcang River excellently exposed the main fault zone of the LCJF at Quzhika village, east Tibet, providing a rare opportunity to study deformation histories of the LCJF by applying K-Ar dating of authigenic illite-bearing fault gouge.

The LCJF at Quzhika village strikes NNW-SSE to closely S-N and dips 60-85° NWW and juxtaposes the Triassic granite and dacite against the Jurassic fuchsia sandstone, siltstone and mudstone. The fault zone, exposed by the tunnel and borehole, is composed of the fuchsia and white fault gouge bands that outcrop as tectonic lenses, indicating thrust kinematic character of the LCJF. Two white fault gouge samples of the LCJF were collected from the borehole for clay mineralogical analysis and K-Ar dating. Oriented X-ray diffraction (XRD) analyses show that different clay size fractions of the fault gouge consist mainly of illite with tiny kaolinite. Random powder XRD analyses suggest that each fraction is comprised of 2M1 and 1Md/1M illite polytypes. Illite polytype quantification demonstrates that the components of 2M1 polytype relative to those of 1Md/1M one decrease from 22% to 3% with fractions decreasing. These results suggest that the finest fractions (<0.1 μm) are mainly composed of authigenic 1Md/1M illite. The apparent K-Ar ages also decrease from 12.8 ± 0.3 Ma to 3.4 ± 0.3 Ma with clay fractions decreasing. We interpret that the K-Ar dates for each fraction represent mixture ages comprised of the two-end member illite polytypes. Illite age analysis extracted the K-Ar ages of the pure authigenic 1Md/1M and 2M1 illite are 2.4 ± 1.3 Ma and 51.1 ± 11.3 Ma (2σ standard

errors), respectively. Integrated with thrust kinematic character of the LCJF, the Late Pliocene to Early Pleistocene K-Ar age for authigenic 1Md/1M illite represents the timing of brittle thrust deformation along the LCJF, coinciding with the Late Cenozoic rapid incision of the Lancang River. The K-Ar age (51.1 ± 11.3 Ma) for 2M1 illite is much younger than the crystallization and sedimentary ages of the host rock, which can represent syn-kinematically crystallized components resulting from the Early Cenozoic high temperature (>280 °C) ductile faulting associated with fluid flow of the LCJF. Integrated with previously published results, this study suggests that the TP and its periphery underwent quasi-contemporaneous tectonic compression deformation during the middle Eocene, likely caused by the combination of the hard collision of the Indo-Asia plates and intra-continental subduction of the terranes within the TP.

Abstract

The Xianshuihe-Anninghe-Xiaojiang Fault system (XAXFS) is an important lithospheric fault at the eastern boundary of the Chuandian block that plays a crucial role in understanding intro-continental deformation and lateral growth of the Tibetan Plateau (TP). The middle segment of the XAXFS that mainly consists of the Anninghe, Zemuhe, Shimian-Zhaojue Faults is characterized by brittle faulting with poorly geochronological age constraints on the timing of deformation yet. This study presents first attempt to integrate structural analyses with brittle fault dating and low-temperature thermochronology studies of the middle segment of the XAXFS, which could provide insight into the Cenozoic multiple-stage deformation and growth of the SE TP margin.

Structural analyses suggest that the Anninghe, Zemuhe, Shimian-Zhaojue Faults has experienced early phases of thrust deformation under NE-SW and nearly EW compression, respectively, followed by NW-SE transpressional deformation and NNW-SSE compressional strike-slip deformation. Isotopic dating techniques were carried out using K-Ar dating of authigenic illite-bearing fault gouge and calcite in-situ LA-MC-ICP-MS dating. The results show that the K-Ar age and the proportions of 2M1 illite relative to those of 1M/1Md illite decrease with size fractions decreasing. K-Ar ages for different fractions are mainly impacted by the physical mixture of detrital 2M1 and authigenic 1M/1Md illite, hence representing mixture ages. Based on illite age analysis, K-Ar ages of authigenic 1M/1Md illite were determined at ~50-28 Ma for the Anninghe, Zemuhe and Shimian-Zhaojue Faults, suggesting that the NE-SW compressional thrust deformation in the study area occurred at the Late Eocene-Early Oligocene. Meanwhile, LA-MC-ICPMS dating of syn-tectonic calcite slickenfibers from the Shimian-Zhaojue Fault yielded U-Pb age of ~8-4 Ma, showing the sinistral strike-slip deformation in the study area since the Latest

Miocene.
Low-temperature thermochronology analyses combined with thermal history modeling for the elevation profile of Xiaoxiang Mountain at the hanging wall of the Anninghe Fault suggest that the Xiaoxiang Mountain has underwent an extremely rapid cooling episode at ca. ~24-20 Ma with a mean rate of ~38 °C/Ma and a relatively rapid cooling episode at ca. ~20-13 Ma (~11 °C/Ma), followed by a protracted slow cooling episode since the late Miocene.
Integrating previously published results, we reconstructed three-stage Cenozoic deformation and growth of the SE TP margin. (1) During ~50-28 Ma, the far-field compressional force of the hard collision of Indo-Asia plates resulted in NE-SW compressional fold-and-thrust deformation and slow exhumation in the SE TP margin. (2) The SE TP margin underwent intense thrust faulting and uplifting during ~28-20 Ma due to E-W compression, which was likely attributed to the lateral horizontal compressional pressure resulted from the establishment of the present high elevation and flat topography in the central TP. (3) The SE TP margin experienced two-stage extrusion deformation since the early Miocene. During ~20-10 Ma, the study area experienced NW-SE transpressional deformation with the influence of sinistral strike-slip of Xianshuihe Fault. Since ~8 Ma, with the connection of the XAXFS, the present tectonic pattern of Chuandian block was established, resulting in the sinistral strike-slip deformation in the study area under NNW-SSE compression.

Mechanism for the Uplift of Gongga Shan in the Southeastern Tibetan Plateau Constrained by 3D Magnetotelluric Data

Feng JIANG[1]*, South China Sea Institute of Oceanology at Chinese Academy of Sciences (fengj.cn9@gmail.com)
Xiaobin Chen[2], National Institute of Natural Hazards, Ministry of Emergency Management of the P.R.C
Martyn Unsworth[3], University of Alberta

Abstract

The eastern margin of the Tibetan Plateau is characterized by a number of mountain ranges that include the Longmen Shan-Jingping Shan (LMS-JPS) orogenic belt. This is located on the boundary between the Songpan-Ganzi terrane and Yangtze craton which is part of the South China block. The region is tectonically active as shown by the 2008 Mw 7.9 Wenchuan earthquake that occurred in this region. On a regional scale, the mechanisms that have caused uplift are poorly understood. Gongga Shan is the highest mountain with a rapid uplift rate on the eastern margin of the Tibetan Plateau. Its distinct geomorphic characteristics very likely indicate a key factor at work for the lithospheric deformation in the eastern Tibetan Plateau. However, the mechanism for the uplift of Gongga Shan is unclear due to a lack of detailed geophysical studies. Inversion of an array of magnetotelluric data at 120 sites produced a 3D resistivity model that revealed that the Gongga Shan massif is characterized by a high resistivity upper crust underlain by a westward dipping resistor at middle crustal depths that is interpreted as the underthrust Yangtze Craton. A thin conductive layer is sandwiched between these two zones of high resistivity. This resistivity model is inconsistent with previously published geodynamic models. The new resistivity model strongly suggests that there is significant westward underthrusting of the Yangtze Craton beneath the Songpan-Ganzi terrane. Since the Songpan-Ganzi terrane presently is being extruded to the east (Wang and Shen, 2020), this study confirms that theSongpan-Ganzi terrane has been overthrust onto the basement of the YC and is the dominant cause for the uplift of Gongga Shan. This uplift has likely been enhanced by an oblique slip on the Xianshuihe Faults (Chen et al., 2016) in the southwest Songpan-Ganzi terrane.

Pulok Kumar Mukherjee[5], Formerly at Inter-University Accelerator Center, New Delhi-110067, India

Abstract

The South Tibetan Detachment System (STDS) is a well-studied peculiar syn-contractional Low Angle Normal Fault (LANF) that separates the sillimanite grade Greater Himalayan Sequence (GHS) gneiss from the low to unmetamorphosed Tethyan Himalayan Sequence. The deformation in the footwall GHS, as well as the relationship between the granitoids is well exposed along the Dhauliganga valley, NW India. Early Paleozoic gneissose granitoids intrude the high-grade mylonite-gneiss on the immediate footwall of the STDS. These granitoids possess U-Pb zircon ages ranging from 498.92 ± 2.7 Ma to 486.54 ± 1.1 Ma and are a part of an extensive Cambro–Ordovician (C–O) granite belt in the uppermost GHS straddling the STDS.

Six granitoid samples yielded Cenozoic ages and recorded zircon growths in two distinct phases: pulsative from Late Eocene to Early Oligocene, with Th/U ratios <0.045. The Upper Eocene to Lower Oligocene zircons show peaks at 33.99 ± 0.37 Ma, 30.53 ± 0.38 Ma, and 25.03 ± 0.43 Ma; and in the continuous mode from Middle Oligocene 23.68 ± 0.25 Ma to 13.30 ± 0.15 Ma in the Miocene, for nearly 10.0 myr. A few individual ages from leucosome also show growths around 36.8 Ma. Singular magmatic zircon rim growth records an age in the late Miocene 6.38 Ma (Th/U ratios 0.2). Most of these Cenozoic zircons represent typical metamorphic overgrowths on the Neoproterozoic and C–O magmatic cores portraying low Th/U ratios (0.09-0.05). These zircon growths reveal protracted Cenozoic metamorphic/magmatic activities along the STDS since the Late Eocene.

GHS granitoid along the STDS are observed to have undergone simultaneous high-grade metamorphism in the Late Eocene and Early Oligocene, leading to partial melting and various generations of leucosome. This early anatexis, in turn, might have triggered the initial reactivity of the STDS and, also consequently, led to the tectonic transition from its compressive tectonics to the extensional regime. This work attempts to constrain the tectonomagmatic activity along the STDS from the Eocene to the Miocene by correlating the deformed and undeformed leucogranitic and granitoids emplaced in the footwall of the STDS.

Abstract

The West Kunlun orogenic belt at the convergence of the Tarim Craton and the Tibetan Plateau encapsulates a comprehensive geological history documenting the subduction of the Paleo-Tethys and Tethys Oceans and the accretion of landmass and oceanic fragments from the Early Paleozoic to the Early Mesozoic. Hindered by the formidable natural conditions along the northern edge of the Tibetan Plateau, research has been limited, leading to a dearth of subsurface stratigraphic and chronological data and significant controversy over the evolutionary timeline and initiation of the orogenic process in this region.In pursuit of resolving these uncertainties, this study zeroes in on the West Kunlun foreland belt, examining Permian cores from well T1 in the Suget structural zone and Cretaceous and Jurassic cores from wells KD5 and KD101 in the Kedong structural zone. Leveraging advanced detrital zircon U-Pb dating techniques and integrating stratigraphic data, the research reconstructs the developmental history of the West Kunlun orogenic belt against the backdrop of Tethyan tectonics. The investigation reveals a critical Triassic period when the Tethys-Himalayan-Qiangtang block merged with the West Kunlun-Tarim block, followed by rapid uplift in the West Kunlun region during the Jurassic-Cretaceous periods.

All zircon samples showed peak ages around 430 Ma and 240 Ma, respectively corresponding to the final closure times of the Paleo-Tethys and the ancient Tethys Oceans. The youngest zircon ages in the Cretaceous and Jurassic samples are all in the Triassic, indicating a lack of effective volcanic activity records in the West Kunlun and nearby regions from the Triassic onward in the Mesozoic era. Correlation tests of the data show that the chronological data of zircon samples from the Cretaceous and Permian exhibit good similarity with previous studies of the Southern and Northern Kunlun blocks. However, the Jurassic samples show less similarity with the data from the South and North Kunlun blocks, but they display better similarity with previous data from the Tethys-Himalayan-Qiangtang area. This may indicate that the final plate collision between the Tethys-Himalayan-Qiangtang block and the Songpan-Ganzi-Southern and Northern Kunlun blocks was completed in the Triassic, between the Permian and Jurassic, and that there was a period of rapid uplift in the West Kunlun orogenic belt from the late Jurassic to the early Cretaceous.

This study furnishes new chronological evidence elucidating the closure events of the Proto-

Tethys and Paleo-Tethys Oceans, as well as the early developmental history of the West Kunlun orogenic belt. It enhances the comprehension of orogenic mechanisms and holds significant prescriptive value for guiding future hydrocarbon exploration efforts in the region.

EBSD-based microstructural characterization of the (ultra-) high pressure eclogite and retrogressed amphibolite from the Tso Morari Crystalline Complex in Ladakh, India

Dripta DUTTA[1]*, Okayama University of Science (dripta.dutta@gmail.com)
Takeshi Imayama[2], Research Institute of Frontier Science and Technology, Okayama University of Science, Okayama 7000005, Japan
Dyuti Prakash Sarkar[3], Department of Earth and Planetary Systems Science, Hiroshima University, Higashi Hiroshima 7398526, Japan

Abstract

Crystallographic preferred orientations (CPOs) of minerals are being widely used to identify the orientation relationships between the parent grains and their daughter crystals. These orientation relationships are used to trace the deformation mechanisms that affected the parent grains – now retrogressed to and replaced either partly or completely by the more stable daughter grains – at peak pressure conditions. Such breakdown of peak pressure minerals is often preserved in the exhumed (ultra-) high-pressure eclogites. We studied one such eclogite sample from the Tso Morari Crystalline Complex. The eclogite preserves symplectites with the coarse and euhedral omphacite grains either replaced partially along the periphery and transgranular fractures (Site 1) or completely (Site 2) by finer amphibole and plagioclase grains. A garnet amphibolite sample from the same locality is also studied to assess the dislocation creep-mediated deformation of the amphibole grains produced at a lower pressure than those of the eclogite. Though the samples are non-oriented, the shape-preferred orientations of omphacite and amphibole grains in the eclogite and amphibolite, respectively, are conspicuous. The jadeite contents of the omphacite grains range between 43-47%. The compositions of the plagioclase grains vary from albite to oligoclase. The amphibole grains of the eclogite are higher in Mg# values and Na content than those of the garnet amphibolite. Although the omphacite, amphibole, and plagioclase grains in the eclogite exhibit strong CPOs, the grain orientation spread values of omphacite are much lower than the rest. Therefore, the oriented growth of the omphacite grains likely produced their strong CPOs. The pole figures suggest the following crystallographic relationships between the phases: <001>Omp||<001>Amp, (100)Omp||(100)Amp, (010)Omp||(010)Amp, (110)Omp 30° to (110)Amp, and <100>Omp 30° to <100>Amp||<001>Pl. The low-angle misorientation axes (LAXs) of omphacite are mostly parallel to their <001> axes, and those of the amphibole grains mainly lie on the (100) planes with two maxima sub-parallel to <001> and <010> axes. Plagioclase LAXs from Site 1 are sub-parallel to the poles of (010) and (0-10), whereas those from Site 2 are not crystallographically controlled. The higher frequencies of the neighbour-pair misorientation angle distributions of amphibole and plagioclase than their respective random-pair and theoretical distributions at lower angles (10–30°) and point distributions of their CPOs suggest that their CPOs originated by inheritance. Interphase misorientation analysis also demonstrates statistically significant differences between the neighbour- and random-pair distributions for both omphacite-amphibole and omphacite-plagioclase pairs testifying to the influence of omphacite

CPOs on those of amphibole and plagioclase. Though characterized by point and girdle distributions, the amphibole CPOs from the garnet amphibolite are much weaker than those from the eclogite. The quartz grains are few and do not exhibit any preferred orientation. The distribution of the quartz LAXs implies activity of the high-T (>600°C) {m}<c+a> slip-system. In contrast, the amphibole LAXs are mostly sub-parallel to (100) poles, suggesting the dominance of (010)<001> slip-system activity (assuming tilt boundaries) and low-T (350-450°C) deformation.

NanogeoscienceA developing interdisciplinary

Yiwen JU[1]*, University of Chinese Academy of Sciences (juyw03@163.com)
Hongye Feng[2], University of Chinese Academy of Sciences

Abstract

Nanogeoscience is a highly comprehensive and overlapping subject, with combination of nanotechnology and geoscience. It will be a necessary way for the development of earth scienceIts research objects mainly include nanomaterials and nanopores, which are widely distributed on the earth so as to Planet and have diverse causes and obvious scale effects. To nanomaterials, researchers use various image analysis methods to observe their shape, size and aggregation model, also investigate the crystal structure of minerals and molecular structure of organic matter through all kinds of spectroscopy methods. To nanopores, researchers use image analysis, fluid invasion combined with numerical simulation methods, to characterize pore morphology, pore size distribution, connectivity and other characteristics Its function is closely related to the earth's supergene environment and resources. On the basis and framework of traditional geoscience research, the systematic research of nanogeoscience as a discipline is to solve the scientific problems about nanomaterials and nanopores in each sphere of the earth, such as formation, migration, aggregation and existence form of nanomaterials, as well as formation and evolution of nanopores. Consequently, it deepens the cognition of nanoscale characteristics of branches like mineralogy, petrology, structural geology, geochemistry as well as resources, disasters and environment. The emergence and development of nanogeoscience have brought human beings into a new level in understanding and transforming nature. It is the inevitable way for the development of the earth and planetary sciences. Related research has provided new theoretical basis for prevention and treatment of environmental pollution and geological disaster, mineral deposit exploration, resource development, new energy utilization, etc. Therefore, nanogeoscience has immeasurable scientific significance and application values.

The effect of inherited basement strike-slip structures on rift basin architecture: insights from analog modeling and PIV analysis

Marilia Barbosa VENÂNCIO[1]*, UFRN (mariliavenancio@gmail.com)
Fernando César Alves da Silva[2], UFRN

Abstract

Preexisting basement structures create zones of mechanical weakness that can influence the structural architecture, kinematic pattern, and deformation distribution of subsequent new structures within the basin on a crustal scale. This study investigates the impact of a preexisting basement shear zone on basin structural architecture through analog modeling. Sandbox experiments simulated the effects of structures developed during an early strike-slip event (D1) on the development of an orthogonal sedimentary basin undergoing extensional deformation (D2). The Particle Image Velocimetry (PIV) technique was employed to analyze the strain distribution on the surface and the vertical displacement. During the D1 event, subsidiary structures such as Riedel shears, Y fractures, and positive and negative flower structures were formed. Subsequent extensional deformation (D2) led to normal fault development, with orientations differing inside and outside the preexisting D1-related shear zone. Faults within the shear zone exhibited NE-SW to NW-SE orientations, while those faults outside were predominantly oriented N-S; also, faults within the shear zone had lower dip angles. During the nucleation, the first faults presented less strain intensity on the preexisting shear zone and thus were less developed, segmenting the sedimentary basin into two subbasins along the preexisting basement fabric. Internal faults displayed a discontinuous nucleation throughout the shear zone region, constrained by underlying structures. The basin exhibited a narrower width and deeper depocenter outside the inherited shear zone, whereas it widened with a shallower depocenter within the shear zone region. Syn-kinematic layer thickness decreased closer to the preexisting basement structure. Although the basin perimeter expanded near the shear zone, a direct association between the basin area and the preexisting shear zone was not feasible. An orthogonal crossline revealed a synclinal structure along the inherited shear zone. Overall, the results emphasize the significant role of inherited structural architecture in controlling fracturing, fault distribution, and basin evolution during rifting processes.

Abstract

Because small amounts of hydrogen can significantly decrease viscosity of nominally anhydrous minerals, different rheological models of continental lithosphere have been proposed based on vertically heterogeneous water distribution in the lower crust and upper mantle. Meanwhile, temperature is the controlling parameter of viscosity and thermal states of the continental lithosphere evolve with time. To examine the rheological evolution of a stable craton, we measured water content and fabrics of garnet granulite and peridotite xenoliths from the Udachnaya pipe in the Siberian craton. Using the Fourier transform infrared spectroscopy, water content in garnet granulite xenoliths were determined with clinopyroxene (334–977 ppm), garnet (23–149 ppm), and plagioclase (157–779 ppm). Mafic garnet granulite samples experienced pressures of 0.6–1.0 GPa and temperatures of 549–800 ºC using the Grt-Cpx Fe-Mg thermometer (TK88), which are consistently lower than equilibrium temperatures of 737–899 ºC from the REE-in-Grt-Cpx thermobarometer (TREE). Compared with pseudosection calculations, our samples experienced continuous cooling since the last granulite facies metamorphism at 1.8 Ga. On the other hand, garnet lherzolite xenoliths show heterogenous water content in olivine (34–166 ppm), orthopyroxene (32–126 ppm), clinopyroxene (83–166) and garnet (7–46 ppm). The calculated equilibrium temperature and pressure of the peridotite xenoliths vary from 846 to 1276 ºC and 4.0 to 5.2 GPa. This confirms the water content variation in olivine beneath the Udachnaya pipe from previous studies: low (20 ± 15 ppm H2O) at depths <130 km, but low to high (187 ± 135 ppm H2O) at depths >130 km due to mantle metasomatism.

Electron backscatter diffraction analysis revealed weak lattice-preferred orientation in clinopyroxene and plagioclase from mafic granulite xenoliths, and A-type olivine fabric in coarse-grained or protomylonitic peridotites but E-type olivine fabric in mylonitic peridotites. Assuming a strain rate of 10^-14 s^-1, we calculated the strength profile of the Siberian craton. The results indicate that water-poor olivine at depths of 74–170 km is about two orders of magnitude stronger than water-rich olivine at depth around 200 km, which can be attributed to the water-weakening effect at the base of the lithosphere. For mafic garnet granulites, if using TREE, the water-rich lower crust has the viscosity comparable with the underlying water-poor lithospheric mantle, no matter using flow laws of wet clinopyroxene or wet anorthite. When cooling down to TK88, clinopyroxene-controlled rheology will produce a stronger lower crust than the upper mantle, whereas plagioclase-controlled rheology still facilitates the mechanical coupling. The comparable effective viscosity of Udachnaya granulite and peridotite xenoliths is different from the “crème brûlée” or “jelly sandwich” models because the weak lower crust is water-rich and the upper

lithospheric mantle is water-poor. We named this strength profile as the “hot anchor” model of the cratonic lithosphere. By contrast, the present-day cold geotherm in the Siberian craton resulted in the water-rich and strong lower crust overlying the water-poor and strong lithospheric mantle, which is inferred as the “cold anchor” model. Transition from the “hot anchor” to “cold anchor” model explains the long-term crust-mantle coupling and stability of the Anabar tectonic province since the Neoarchean.

Microscale to mesoscale structures to constrain shear zone kinematics, a case study from the Shillong Plateau, NE India

SURAJIT MISRA[1]*, GAUHATI UNIVERSITY (misrasurajit@gmail.com)

Abstract

The shear zone kinematics are significant to determine micro-, meso- and regional scale tectonics of any terrane. Kinematics is generally derived from dominant structural elements such as foliation and lineation. Orientations of these elements are also significant to constrain vorticity numbers and kinematics with respect to the external and internal reference frames of any shear zone. These are simply recognized from ideal coaxial and non-coaxial shears rather than the general shears. It is more complex in a multiply deformed terrane like the Barapani Shear Zone (BSZ) an intracontinental deformation zone within the Shillong plateau. The lithology of the zone is dominantly phyllite that preserved evidence of intense shearing events and quartz vein intrusions.

The BSZ had experienced D1, D2, D3, and D4 events which are recorded as S1, S2, and S3 planar fabrics. The D1 was related to the E-W compression, which was followed by the D2 an oblique-sinistral strike-slip shearing along the NE-SW direction. Further, the zone was overprinted by an oblique-dextral strike-slip shearing along the E-W direction, and finally, the D4 was elastic-plastic deformation at locals. Orientations of these deformation-related fabric elements, vorticity numbers and their kinematics considering both the external and internal reference frames of the BSZ indicate that the superposed transpressional tectonics were majorly operated during the D2 and D3 events.

Microscopic Kinematic Indicators in the Achankovil Shear Zone, South India and its Tectonic Implications

Vikas Chandrasekharan[1], Oil & Natural Gas corporation Ltd (ONGC), KG-PG Basin, Godavari Bhavan, Rajahmundry, Andhrapradesh-533103, India.
Prasannakumar Vasudeva Kaimal[2], Department of Geology, University of Kerala, Trivandrum, Kerala- 695 581, India
Pratheesh PRABHAKARAN NAIR[3]*, Department of Geology, Central University of Kerala, Kasaragod, Kerala- 6713120, India (pratheeshp@cukerala.ac.in)

Abstract

The Achankovil shear zone (AKSZ), stretching approximately 120 km in a northwest-southeast direction across the states of Kerala and Tamil Nadu in Southern India, serves as a significant crustal boundary. It separates the Madurai block to the north, characterized by granulite facies, from the khondalite belt (Trivandrum block) to the south. A pronounced tectonic fabric oriented along the AKSZ is evident, marked by grain size reduction, enhanced flattening, elongation, and preferred orientation of constituent minerals, indicative of progressive strain. Mylonite and mylonitic patches, displaying numerous shear indicators, are prevalent along the shear zone's length. Despite significant attention to the AKSZ regarding metamorphic conditions and the correlation of Gondwanaland fragments, challenges persist in interpreting its geometry, tectono-metamorphic evolution, and movement characterization. This study aims to elucidate the geological and structural features of the AKSZ, with a focus on interpreting its kinematic and microstructural evolution through microfabric analyses. Crystallographic preferred orientation (CPO) of quartz, obtained via Electron Back Scatter Diffraction (EBSD), suggests deformation facilitated by diffusional creep, while mica, amphibole, and feldspars indicate plastic deformation via intracrystalline slip systems activation. All CPOs reflect fabric modifications due to reactivation during the tectono-thermal evolution of the AKSZ. The progressive evolution of mylonite signifies a transition in deformation mechanisms from dislocation creep to grain boundary sliding and ultimately to grain size-dependent diffusional flow in the study area. Kinematic indicators at meso- and microscopic scales predominantly indicate dextral shear sense, with a minor sinistral shearing component observed in microdomains. The occurrence of opposing shear senses is interpreted as a result of strain partitioning and/or AKSZ reactivation during the Pan-African period. Based on shear deformation characteristics, the AKSZ has been correlated with the dextral Axial shear zone of Madagascar, aiding in the correlation of Gondwanaland continental fragments. Tectonic models proposed for Pan-African orogenesis in South India must accommodate the prevalent dextral strike-slip shear movement observed throughout the AKSZ.

[Keynote] Multiscale modern structural geology in metamorphic basements: exploring processes from the map to the atomic scale

Michele Zucali[1]*, Università degli Studi di Milano (michele.zucali@unimi.it)

Abstract

Basement rocks that have undergone metamorphism are known to have diverse and complex tectono-metamorphic histories. These complexities can be observed at various levels, ranging from maps to microscopic scales. The trajectory maps of the rock's foliation reflect the tracking of finite strain features and metamorphic signatures, which are indicative of the rock's history.

Rocks can change their appearance and structure when they are subjected to metamorphic and strain conditions. This can lead to the development of different fabrics that can be classified into three categories: coronite, tectonite, and mylonite (CTM). The Degree of Fabric Evolution (DFE) determines which category the fabric belongs to, while the Degree of Reaction Progress (DRP) indicates how complete the metamorphic transformation is. A simple calculation shows that permuting DFE and DRP on an isotropic rock undergoing three metamorphic stages yields a thousand rock configurations. Do they correspond to rocks in the field?
We apply a procedure that integrates structural, petrological, lithostratigraphic, and, wherever possible, geochronological data while strongly maintaining the reference to the structural framework resolved by fieldwork activity. The procedure uses the DFE and DRP strategy to map rocks from map to microscale.

Quantitative estimation of concurrent deformation and metamorphism produces a matrix of rock types expected in a metamorphic terrain, which sheds light on the tectono-metamorphic evolution (Rock Matrix).

The evolution recorded by a specific rock type (e.g., granite) is mostly controlled by the evolution in space and time of chemical, shape, and crystallographic properties, which control the production of rocks that can record strong differences in the DFE (deformation gradients) and DRP (metamorphic transformation gradients).
The interplay of DFE and DRP produces the actual rock matrix. DFE and DRP can be mapped, and such maps lead to the sampling of the "right" samples for subsequent and more resolved analyses (e.g., geochronology, strain analysis, 3D quantitative imaging).

The efficacy of the combined method has been tested on various Alpine terrains, aiming at i) exploring the influence of thermal regimes, ii) studying the influence of inherited textures, DFE, bulk rock, and mineral compositions on DRP; iii) quantifying the 3D architecture of deformation and metamorphic transformation gradients; iv) individuating the critical thresholds making “strain rate” the dominant factor over metamorphic reactions.

New and very promising digital tools have been introduced nowadays. We need to make them a real advance in understanding tectonics and geodynamics through modern, solid, and quantitative structural geology.

Influence of salt diapir on the fault activity of subsalt units in salt-bearing fold-and-thrust belts: insight from natural example and numerical simulation

Wei WANG[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (wangwei09@outlook.com)
Hongwei Yin[2], Nanjing Univeristy
Shaowen Liu[3], Nanjing Univeristy
Dong Jia[4], Nanjing University

Abstract

Salt-bearing fold-and-thrust belts represent the deformation zone containing the salt layer, mainly between the mountain and the basin. The salt layer could make the deformation above and below it quite different, and the subsalt structure has a high risk of earthquakes and abundant potential for oil and gas. While previous studies mainly focus on the interaction between salt structures and suprasalt deformation, the relationship between salt structures and subsalt deformation is largely unrecognized. The Kuqa fold and thrust belt is associated with complex salt structures and abundant hydrocarbon sources. Changes in fold geometry and subsalt fault activity were investigated using parallel cross sections to reveal the effects of salt structures on along-strike variations in the subsalt structural wedge of the Kuqa fold-and-thrust belt. Results indicate that the pre-existing salt wall is the key factor driving along-strike variation because it acts as a weak zone influencing deformation propagation. Suprasalt structural variation results in different sediment depths which has a significant impact on subsalt fault activity. In the eastern segment, fault activity decreases from the hinterland to the basin. Conversely, due to the pre-existing salt wall and deep sedimentation near the hinterland in the western segment, the fault beneath the salt wall demonstrates maximum throw. The results reveal the connection between suprasalt and subsalt deformation and the role of a salt diapir in along-strike structural evolution variation in the subset structural wedge of the Kuqa fold and thrust belt. Then, numerical simulation is used to investigate the influence of salt structures on the evolution of salt-bearing fold-and-thrust belts, using salt diapirs as an example. A comprehensive and quantitative analysis of the relationship between salt structures with both suprasalt and subsalt deformation is presented, and the interaction between salt structures and subsalt deformation is addressed for the first time. Model results demonstrate the influence of salt diapir on the strain distribution during the deformation. The location of salt diapirs controls strain distribution during the deformation. Specifically, the salt diapir is the primary rupture surface for strain localization in the suprasalt units, and could produce two primary rupture surfaces in the subsalt units. In the suprasalt deformation, the salt diapir has a high priority to deformation as it acts as the primary rupture surface. The location of the salt diapir controls the structural geometry evolved from the salt diapir. Plug-fed thrust usually develops when the salt diapir is near the hinterland, while the source-fed thrust forms when near the foreland. Once the salt diapir initiates deformation, it tends to delay the deformation propagation to further structures in both total shortening and deformation rate. This effect fades as the distance from the salt diapir increases, and the fade rate also increase. Regarding subsalt

deformation, the salt diapir generates two primary rupture surfaces, and the distance between them could represent the impact range of the salt diapir. Faults tend to occur along the primary rupture surface. These faults have enhanced activities, while adjacent faults could be restrained.

Graphitic material in fault zones: Implications for tectono-thermal evolution and carbon cycle

Shuyun CAO[1]*, China University of Geosciences, Wuhan 430074, China (shuyun.cao@cug.edu.cn)
Meixia Lyu[2], China University of Geosciences, Wuhan 430074, China

Abstract

Graphite possesses characteristic mineral properties, including a layered structure and an exceptionally low friction coefficient. The irreversible graphitization process of amorphous carbonaceous materials with increasing temperature enables graphite to record metamorphic-deformation events. However, there remains a significant gap in our understanding of the formation of naturally deformed graphite-bearing rocks and their macroscopic to microstructural characteristics related to rock and mineral deformation, as well as their rheological weakening behavior and mechanisms. In this study, we focus on various types of metamorphic-deformation rocks in the shear zone or metamorphic massif, particularly graphite-bearing rocks and minerals. Leveraging detailed field observations, we employ optical microscopy (OM), scanning electron microscopy (SEM) with electron back-scattering diffraction (EBSD), cathodoluminescence (CL), Raman spectra, and carbon isotope mass spectrometry to conduct a comprehensive analysis of deformation macro-microscopic and submicroscopic structural features, mineral lattice preferred orientation (LPO), graphite Raman spectrum temperature, and the origin of carbon material. The results reveal deformed graphitic carbon-bearing rocks have experienced strong plastic to brittle deformation in medium-to low grade metamorphic rocks, accompanied by grain-size reduction, development of LPOs and micro-shear zones and slip-planes. The LPO patterns and mechanism of graphitic carbon present dislocation varieties from creep base <a>, rhomb <a> to prism <a> slip with temperature rise. According to the graphitic slip-planes, micro-shear zones with grain-size reduction and mylonitic foliation constituted by graphitic carbon minerals, we also propose that the development of fine-grained amorphous carbon plays an important role in rheological weakening of the whole rock during progressive ductile shearing.

Abstract

In the underground laboratory in Bedretto, an experiment is being planned to stimulate a fault zone and observe the induced seismic activity. The laboratory is located in a tunnel in the Swiss Alps and offers the possibility to access faults at a depth of c.a. 1km. This research aims to improve the understanding of earthquake processes and fault behavior. The experiment aligns with the broader goal of near-fault observatories worldwide, which aim to collect high-quality data from sensor networks placed close to active faults for a deeper understanding of earthquake mechanisms.

The success of the experiment depends on the identification and characterization of a suitable fault zone for controlled stimulation and close-up monitoring. A multidisciplinary approach has been employed to select the target fault zone. Geological mapping and remote sensing at the surface of the tunnel, borehole logging, and ground-penetrating radar in the tunnel and in boreholes have been used for data collection to assess the rock formations and identify potential faults. A specific fault zone, several meters wide has been chosen using a multi-parameter criterion. This fault is well-oriented within the existing stress field for potential reactivation. Laboratory tests on rock samples from the fault zone revealed specific properties, including a tendency to strengthening fault gouge under shearing forces and a complex flow path for injected fluids.

The comprehensive approach on fault selection addresses the heterogeneity of the rock formation within the fault zone and ensures a suitable target zone for controlled stimulation and detailed and close monitoring. The successful identification of the fault paves the way for the first experiment,

scheduled for spring 2024.

Abstract

Recently, a Quarternary fault was dicovered about 2 km southeast of the previously reported Yongdong fault. The purpose of this study is to understand the spatial distribution and the geometric & kinematic characteristics of the fault systems around this Quarternary fault location.

Based on the result of lineament analysis from remote sensing data (aerial photography, DEM & LIDAR), the NE-SW direction is the most dominant one, followed by the NNW-SSE to N-S and the NW-SE direction. The result is consistent with the result from the geological ground survey.

Left-lateral movement is mainly observed along the NE-SW striking faults with slight oblique slip, perceived through the lakes of slickenline (15 ~ 25º). This oblique slip is confirmed as result of weak transtension through Frohlich Triangle diagrams of win-tensor program. In addition, some right-lateral movement is also recognized along the NE faults. Left-lateral movement of the NE faults is confirmed at both the bedrock & the basal conglomerates and the boundary between these two rocks. Also, some right-lateral movement along the NE faults is observed in the basal conglomerates. These characteristics are consistent with the previously reported deformation history of the Yongdong fault during and after the formation of the Yongdong basin.

Along the NNW-SSE to N-S faults, left-lateral movement is mainly observed with slight oblique slip, perceived through the lakes of slickenline (15 ~ 25º). This oblique slip is confirmed as result of weak transpression through Frohlich Triangle diagrams of win-tensor program. This characteristic of the N-S trending faults is confirmed in quartz porphyry known to have intruded in the Late Cretaceous Period. The NE faults with right-lateral movement are cut and displaced sinistrally by the N-S faults or the accompanying subsidiary faults (NW-SE strike faults).

The fault systems in the study area is interpreted through the geometries, movement characteristics, relationship with the stratum and cross-cutting relationships as follows: 1) The NE

faults experienced right-lateral movement after left-lateral movement concerning the behavior of the Yongdong fault in Cretaceous Period 2) The N-S faults were developed cutting the NE faults with left-lateral movement after the quartz porphyry intrusion. 3) It is speculated that only sporadic distribution of the basal conglomerates (almost in the form of breccia) in this area away from the Yongdong basin is related to the transtensional component associated with the left-lateral movement along the NE faults.

This research was supported by a grant(2022-MOIS62-001(RS-2022-ND640011)) of National Disaster Risk Analysis and Management Technology in Earthquake funded by Ministry of Interior and Safety(MOIS, Korea).

Progressive evolution of a type II shear zone: the Ferriere-Mollières Shear Zone (Argentera Massif, Western Alps, Italy)

Matteo Simonetti[1]*, Servizio Geologico d'Italia - ISPRA (matteo.simonetti@isprambiente.it)
Rodolfo Carosi[2], Università di Torino
Chiara Montomoli[3], Università di Torino

Abstract

Shear zone behavior is mainly controlled by deformation regime, temperature, strain rate and rheology of the deformed rocks. If a gradient of strain is established across a shear zone, softening phenomena can cause a progressive localization of deformation toward the core, resulting in a constant thickness of the shear zone with increasing strain. In contrast, strain hardening may induce migration of deformation into the wall-rocks, causing an increase in shear zone thickness. In the Western Alps we studied a NW-SE striking steeply dipping km-scale shear zone, the Ferriere-Mollières Shear Zone (FMSZ), that cross-cuts Variscan migmatites in the Argentera External Crystalline Massif. The shear zone is characterized by a deformation gradient (Carosi et al., 2016), with strain increasing toward the center of the shear zone due to strain softening during Variscan retro-metamorphism. By combining structural and microstructural analyses with quartz fabric analysis, quartz palaeopiezometry and petrochronology, three main stages of shear zone development are recognized (Simonetti et al., 2021). Each stage is characterized by specific age, temperature and deformation regime. Stage I occurred between ~340 Ma and ~330 Ma under a temperature range of ~610 – 590° C with a prevalent (76%–65%) component of pure shear deformation; stage II occurred between ~ 330 and 320 Ma at temperatures between ~ 530 and 480° C with a decrease in the component of pure shear (73%–49%); stage III developed from ~320 to 300 Ma under temperature conditions between ~ 500 and 420° C with a prevalent component of simple shear (pure shear of 39%– 31%). Palaeopiezometry and microstructures revealed that during stage III alternation of cycles of brittle and ductile deformation occurred and they were triggered by fluids channelized in the active core of the structure.
The FMSZ is a new example of a strain-softening and long-lasting regional-scale shear zone, useful as a natural study area for future research about the complex processes operating in large-scale shear zones.

Abstract

Studies on the Gyeongsang Basin, SE Korea, are crucial for understanding the complex tectonic process occurring along the subduction zone between Eurasian and (paleo-)Pacific plates at the eastern margin of Asia since the Cretaceous. The Ulsan Block, located in the southeastern part of the Gyeongsang Basin and bordered by the Yangsan Fault to the west, has undergone multiple episodes of large fault movements and subduction-related igneous activities as the tectonic setting evolved. We have newly observed contractional structures that appear at various scales in the Ulsan Block. The block can be divided into eastern and western domains based on changes in stratal attitude and these domains are bounded by the Dongnae Fault, indicating their differential deformation histories. The stratal pattern in the western domain is delineated as a map-scale anticline with sub-horizontally W-plunging axis. This pattern is similar to that in the west of the Yangsan Fault, but is displaced about 38.2 km right-laterally by the strike-slip movement of the Yangsan Fault. On the other hand, the eastern domain shows a homoclinal structure dipping toward SE, except for the adjacent areas of intrusives. At the outcrop scale, numerous E-W trending folds and thrusts were observed in the western domain. Our findings, obtained from descriptive and kinematic analyses, paleostress reconstruction, and micro-scale observation, suggest that these contractional structures were formed by flexural-slip and/or buckling mechanisms under low P-T condition in the upper crust by N-S to NNE-SSW-trending horizontal compressional stress. Based on this geometric and kinematic similarity of structures on map, outcrop, and micro scales, observed structures in this study can be interpreted as a single structural assemblage, which is referred to as the ‘Ulsan Fold-and-Thrust Structure (UFTS)’. The dextral displacement of UFTS by the Yangsan Fault indicates that its formation was before the dextral movement of the fault, which is well-known to have occurred during the late Paleogene. This interpretation is supported by the cross-cutting relationship between fold-associated faults and felsic dikes and 73.3±0.54 Ma in zircon U-Pb age of the dikes. Considering the deposition age (103.6±2.5 Ma in zircon U-Pb) of the deformed sedimentary rock together, the formation timing of UFTS is constrained between 103.6 - 73.3 Ma. However, we do not yet know exactly what

causes the stress that formed UFTS. The UFTS may have been controlled by local stress field caused by movement of large fault zones or plutonism, and may be closely related to far-field stress field caused by regional tectonic event. This question is expected to be addressed by further detailed studies of the structures like UFTS formed in other areas of the Gyeongsang Basin.

Abstract

The Greater Himalayan Sequence (GHS) represents the metamorphic core of the Himalaya. The study of the GHS is particularly interesting since, due to its good exposure, it has often seen as a proxy for the middle-lower crust in orogenic settings. For a long time, the GHS has been often regarded as coherent, single tectonic unit. Recent findings, starting from field observations, down to microscale analysis, challenges this view. Indeed, nowadays most of the focus on the tectono-metamorphic evolution of the GHS is aimed to characterize how strain is accommodated within this "composite" unit, over the time.

In this contribution we report new data, combining field observations, microtectonics analysis, with pseudosection modelling and iterative thermodynamic modelling and monazite petrochonology, on the activity of high-temperature / low-pressure ductile shear zones, affecting garnet-sillimanite and cordierite-bearing anatectic paragneisses, in Eastern Nepal.

Field and microtectonics study highlighted how these shear zones are associated to a normal (both top-to-the-S and top-to-the-N) sense of shear. Mylonites were formed under upper amphibolite facies (c. 700°C) as testified by syn-kinematic mineral assemblage as well as quartz and feldspar dynamic recrystallization microstructures. Phase equilibria modelling (i.e., with the aid of P-T-X pseudosections) as well as iterative thermodynamic modelling, highlighted how sheared rocks experienced a "peak" pre-mylonitic stage in the medium-pressure, upper amphibolite-to granulite facies, under melt-bearing, conditions. This stage is followed by the mylonitic stage, which is associated to decompression and minor cooling.

Our multidisciplinary investigation highlights how strain was progressively localized within migmatitic terrain, following melt extraction, from the Oligocene down to Miocene. Possible consequences on the role of the detected HT-LP extensional shear zones on the exhumation and thinning of the GHS are presented.

Abstract

With the discovery of coesite relicts, diagnostic mineral assemblages (e.g., pure pyrope; the coexistence of jadeite with kyanite) and peculiar rocks occurrences (e.g., pyrope-bearing quartzite and whiteschist), testifying how the continental crust could be subducted down to mantle depth at ultra-high-pressure (UHP) conditions, the Dora-Maira massif (Southern Western Alps) has become a peculiar place for the Plate Tectonics.

Despite this globally wide recognition and importance, most of the focus and of the scientific interest, has been paid to the Southern portion of the Dora-Maira massif, specifically on the Brossasco-Isasca unit (BIU), where UHP was originally documented. The remaining, but still very consistent by extent, part of the massif is still largely unexplored from the geological point of view, including updated structural-geological mapping and modern tectono-metamorphic characterization. For these reasons, by decades, the Northern portion of the Dora-Maira has been regarded as a "monotonous" portion of the Western Alps, constituted by two continental-derived tectonic units, a structurally upper (largely) polycyclic basement unit and a lower monocyclic unit, affected respectively by Alpine eclogite and blueschist facies conditions. Recent findings, specifically the occurrence of a structurally thin, garnet-chloritoid-coesite-bearing tectonic unit, sandwiched among the two aforementioned basement units, opened new scientific puzzling and challenges.

In this contribution we report new data, starting from field observations coupled with microtectonics analysis, obtained from the ongoing geological mapping, at the scale of 1:50000 (Foglio 172 - Pinerolo), within the Italian national CARG (Geological CARtography) project. This project involves the creation of a database supplying more detailed geological and geothematic maps enabling cartographic data to be used for many different purposes, including research in Tectonics and beyond.

An updated geological map, coupled with new meso-and microstuctural observations is presented with the aim of discussing the internal architecture of the Norther Dora Maira massif and its relationships with the oceanic-derived units, located tectonically above it.

This research has been supported by the funds of the CARG – Project – Geological Map of Italy

Abstract

The distal parts of the preorogenic rock sequence in the Iberian Plate before its involvement in the Variscan orogeny were dominated by fine-grained detritics and lutites. During the Variscan event, this thick and monotonous rock sequence became the “slate belt” as the rocks developed a pervasive and strong tectonic fabric in relation to recumbent folding. Ongoing convergence resulted in the upright refolding of earlier folds. These folds were homoaxial with previous structures resulting in an overall strong linear fabric with fold axes subhorizontal and perpendicular to the overall E-W shortening direction.

The development of crystallographic and well as shape fabric in dominant metapelites imposes a strong mechanical anisotropy in slaty rocks. The homoaxial refolding and crenulation of this fabric affect bulk rock anisotropy by transforming an original planar anisotropy into a linear fabric. We use direct whole-rock measurements of CPO in slates by ESBD to constrain the physical properties of mineral aggregates. In combination with the modelling of their physical properties, we determine the bulk physical properties under various arrangements of minerals and fabrics.

Present-day crustal structure in the area has been surveyed using ambient noise from a seismic network deployed in and around most of the slate belt. Cross-correlation of seismic records in station pairs by seismic interferometry theory allows the extraction of velocity data in between stations. Rayleigh and Love dispersion measurements are used in ambient noise to extract vertically (Vsv) and horizontally (Vsh) polarized shear waves. When they differ, the solid medium is regarded as radially anisotropic (Vsv>Vsh is positive, Vsv<Vsh is negative). Our results show that in the NW Iberian upper crust, a strong positive radial anisotropy is preserved in the slate belt, contrasting with negative anisotropy on tectonic units on either side, the foreland fold and thrust belt to the E, the high-grade hinterland to the W.

Despite more recent tectonic events affecting the crust in NW Iberia, such as the Mesozoic extension giving rise to the opening of the Atlantic Ocean or the more recent alpine convergence, the crustal segment in the Variscan slate belt seems to preserve a subhorizontal fabric which cannot be related to these more recent events, where fracturing tends to produce vertical anisotropies. We suggest that this crustal fabric is related to the internal structure of the slate belt

as its appearance is restricted to the exposure at the surface of heavily folded slaty rocks.

Structure characteristics and its insights on shale gas exploration: an example from the Luzhou area, southern Sichuan Basin, China

zhengshuo MIAO[1]*, China University of Petroleum (East China) (miaozhengshuo@163.com)
Yangwen Pei[2], China University of Petroleum (East China)
Jingru Zhao[3], China University of Petroleum (East China)
Zifan Zhu[4], China University of Petroleum (East China)

Abstract

The southern Sichuan basin, a shale gas bearing area, presents great potential for increasing storage and production in the future. However, the structure characteristics and their control on shale reservoir quality have not been documented. Here the Luzhou area was selected as an example to study the structure characteristics and its insights on shale gas exploration in the southern Sichuan basin.

In this study, multiple methodologies, including 3D seismic interpretation, strain simulation, seismic attributes analysis, and fault system topology, were employed to investigate the fault characteristics, fault-fold spatial distribution and fault connectivity in the southern Sichuan basin. The quality and potentials of shale reservoirs were then evaluated.

In section view, different types of thrust fault were identified in the study area, including fore-thrust and back-thrust faults. Accordingly, the folds developed in the study area were divided into the anticlines in pop-up zones and the synclines in imbricate zones and stable zones. The strain simulation indicates that the fold of different types results in different level of reservoir damages, with high in the anticlines in pop-up zones, low in the synclines in stable zones, and intermediate in the synclines in imbricate zones. In plan view, two primary sets of faults, trending NNE and W-E, were interpreted based on 3D seismic attribute analysis. However, the two sets of faults present different distributions, with the NNE trending faults distributed throughout the study area and the W-E trending faults distributed primarily in the southwest portion. Based on fault topological analysis, the fault connectivity was quantitatively evaluated, demonstrating high level of variation in the study area. The anticlines in pop-up zones present high level of fault connectivity, whereas the synclines in stable zones present low level of fault connectivity. The synclines in imbricate zones present fault connectivity in between. By integrating the production data of shale gas wells in the study area, it is believed the high productive shale gas wells are primarily distributed within the synclines in imbricate zones with intermediate fault connectivity, which may provide important hints for the shale gas exploration in the Luzhou area in the future.

Structural diagenesis of deep-buried carbonates controlled by strike-slip faults: an example from the Sinian Dengying Formation in Central Sichuan Basin

Shangzi LIANG[1]*, Petroleum Exploration and Production Research Institute, SINOPEC, Beijing, China (liangsz.syky@sinopec.com)
Zhong Li[2], State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, China

Abstract

Fault-controlled structural diagenesis of carbonates has received increasingly attention mainly owing to its promising economic prospects for oil and gas exploration. The dissolution and mineral precipitation associated with faults can alter the reservoir properties. Therefore, faults that act as fluid migration channels and the relationship between faulting and fluid diagenesis should be further investigated. The Sinian Dengying Formation in Central Sichuan Basin provides an opportunity to combine structural analysis with petrographic and geochemical data to investigate the structural diagenesis of deep carbonates and clarify the related implications for the reservoir. Through core observation, thin section examination and cathodoluminescence analysis, the different phases of fracture-filling dolomite cements associated with the strike-slip faults were identified. According to the petrographic characteristics, typical samples are selected to conduct carbon and oxygen stable isotope analyses, fluid inclusions analysis and in-situ rare earth elements analysis, revealing the properties and sources of the mineral-deposit-forming fluid. Combining the deformation style of the strike-slip faults and the paragenetic sequence, the structural-fluid evolution history is deciphered, and structural diagenesis model is established. The research shows that four phases dolomite cements were developed in the Dengying reservoir. The earliest dolomite generation may have precipitated from mixing of meteoric water and seawater. The second and third phase of dolomite cements were formed during the middle–deep burial process, generated from modified seawater. The latest episode of dolomite cementation is related to regional hydrothermal activity. Beside dissolution occurred in the penecontemporaneous and hypergene stages, two-phase burial dissolutions developed in the Dengying Formation, which were related to hydrothermal fluid and hydrocarbon injection. Based on the study of in situ fluid–rock interaction records and burial–thermal history, it is believed that the burial dissolution–cementation of the Dengying reservoir was influenced by the fluid flows that were related to the four stages activity of the strike-slip faults.

Permeability structures of fault zones in low porosity carbonates

Fabrizio AGOSTA[1]*, University of Basilicata (fabrizio.agosta@unibas.it)

Abstract

In the brittle regime, fault zones in low porosity carbonates are characterized by a variety of deformation mechanisms and diagenetic processes, which might determine a profound effect on the time-space evolution of mineralization and fluid pathways within fractured reservoirs. Deformation associated to faulting of pre-existing structural heterogeneities, fault growth by linkage of neighboring segments, splaying of faults, and fault intersections may form localized fluid conduits for the infiltration of meteoric waters at depth and/or the upraise of deep and warm fluids toward the Earth's surface. As a result, the ingression of externally derived fluids into the fault zones can cause localized dissolution and/or mineralization of the carbonates, and modify the diagenetic history of fault rocks and of the encompassing fractured photoliths. Fluid circulation along carbonate fault zones can therefore form mineral deposits, produce hydrothermal activity, and affect groundwater integrity. For these reasons, extensive research is currently taking place on the analysis of surface analogs of subsurface fractured carbonate reservoirs. The results of this work are applied to industrial activities related geothermal energy production, secure storage of nuclear waste in the subsurface, CO2 confinement at depth, and groundwater management. A good understanding of the permeability structure associated to carbonate fault zones might be key to safely operate during production of renewable energy, CCS activities, and all types of operations related with the drilling of fractured carbonates at depth.

The present contribution summarizes the main outcomes of field-based geological investigations of low porosity carbonates exposed in the Mediterranean area. The fluid flow behavior of the outcropping high-angle fault zones is assessed by combining the results of field structural analysis with those obtained after petrophysical, rock physical, and geochemical investigations of carbonate samples, as well as with the outcomes of discrete fracture network modeling of geocellular volumes. Data are consistent with the carbonate fault zones rarely forming barriers or baffles to fluid flow in the subsurface. The fractured rock matrices often form localized or diffuse fluid conduits enhancing the along-fault flow. However, mineralization due to the ingression of externally-derived fluids might modify the permeability associated to carbonate fault zones. This process is very rare within faults in dolostone and dolomitic-rich rocks do not include any mineralization, whereas those in limestone are very often cemented by meteoric-derived fluids. As a consequence, cementation can reduce the fault-orthogonal permeability. Of course, any possible presence of clayish smears in the fault zones drastically inhibit the fluid flow. The overall permeability ellipsoid associated to fault zones in low porosity carbonates is therefore characterized by an oblate shape that sub-parallels the faults. The longer axes of the ellipsoid represent greater values of permeability associated to the fault-parallel fluid flow, which main localizes along the main slip surfaces and within the fractured carbonate around. Differently, the shortest axis of the ellipsoid represents the less conducive fluid behavior associated to the

comminuted and, possibly, cemented fault rocks, which may reduce the cross-fault permeability.

Phoebe Sleath[3], University of Aberdeen
Clare Bond[4], University of Aberdeen

Abstract

Starting points for understanding geomechanics and fluid-flow for faults and fault zones are clear descriptions of the geometry of these structures. But how well can we characterise geometry of faults and fault systems in the subsurface? Much of our understanding of faults, whether as individual structures or as arrays, comes from seismic imagery of structures have substantial displacements. Interpreted patterns of the displacements, charted by offsets of stratal reflectors, are widely used to test interpretations not only for the geometry and evolution of a fault but also for predicting its properties (e.g. shale-gouge ratio and derivatives thereof). This understanding is dominated by studies from normal faults – seismic imagery from thrust systems is generally poorer so that idealised conceptualisations are used to inform interpretational workflows – commonly applied to structures on regional cross-sections. These scales of application generally focus on large-displacement structures. However, when appraising candidate sites for subsurface geo-storage (e.g. for CO2 or rad waste), large faults are generally avoided. So potential risks to site integrity come from small faults. How well do we understand such structures and their geometric variability? What are the implications of different interpretations of small-displacement fault arrays for the initiation and early history of large-displacement fault systems?

Here we present combinations of, generally excellent, seismic imagery from 3D volumes, along with outcrop analogues to examine different workflows and approaches for mapping faults relevant to the scales and application to subsurface geostorage. These indicate that faults can initiate, in both extensional and contractional regimes, as distributed arrays confined to competent layers. We liken this to the patterns of fractures developed in packets of broken biscuits (crackers). All layers are faulted, but layers can have distinctly different fault patterns. The size of the early fault segments will be strongly controlled by the stratigraphic template. Deformation in incompetent layers can be distributed across shear zones and broader volumes of distributed strain/differential compaction. As recognised by others, complex localisation of faulting as they initiate and grow can result in complex architectures within fault zones. Seen in vertical profiles, as faults grow, they can link to create local segments with dip-directions counter to those on the segments within competent layers. In thrust systems, these counter-segments locally extend layering (apparent normal faulting); in normal faults the counter-segments show local reverse displacements. In plan-view, faults developed through the linkage of short segments will have sinuous traces. These results indicate that fault systems, once dismissed as being “minor

structures” in the context of regional cross-sections, can make complex patterns through stratigraphic multilayers. They precondition the geometry of large faults that may grow through further deformation, carrying the initial complexity in the architecture of larger fault zones. In recognising the likelihood of such complexity, interpreters should allow for significant uncertainty in their endeavours and for challenges in seismic interpretation, where structures, or parts thereof, may lie beyond the resolution of the imagery. Effective forecasting the complexity of fault zones may be enhanced by consideration of the stratigraphic template that host them.

Eugenio Carminati[6], Dipartimento di Scienze della Terra, Sapienza Università di Roma, Rome, Italy

Abstract

The NNE-striking, strike-slip Yangsan fault is one of the most seismically active faults in Korea (i.e., magnitude 5.1 and 5.8 earthquakes generated on September 12, 2016). Many past studies aimed at characterizing the structural architecture, micro- to nanostructures, and fault rock friction of the Yangsan fault; however, the origin and role of fluid circulation during the seismic cycles of this fault are still unknown. For this reason, we combined structural and microstructural analyses of calcite veins and slickenfibers sampled from three exposures along the Yangsan fault with stable carbon and oxygen isotopes to propose a first preliminary model of fluid circulation with implications on earthquake-related fault permeability. Results show that the Yangsan fault is characterized by both dextral and sinistral strike-slip kinematics, with both fault movements occurring during fluid flow within the fault zone. Slickenfibers are mostly localized along (1) the slip surfaces of competent, anastomosed rock lithons scattered within the strongly foliated clay-rich gouge in the fault cores and (2) along shear planes in the clay-rich gouge itself. Calcite veins occur within the anastomosed rock lithons in the fault core and in the fault damage zone consisting of volcanic and siliciclastic sedimentary rocks. Stable isotope data show that δ18O (VSMOW) values of both veins and slickenfibers range between +15‰ and +10‰. Both veins and slickenfibers show negative δ13C (VPDB) values. In particular, veins in the damage zone show more negative δ13C values than those of slickenfibers in the fault cores. Overall, the negative δ13C values suggest the circulation of meteoric-derived water both in the damage zone and in the fault core. Our results show that, although the low-permeability fault core is rich in sheared clays and shales, externally-derived meteoric fluids were able to circulate within it. Probably, these fluids were stored in the high-permeable (i.e., more fractured) damage zone and were further injected into slickenfibers (i.e., micro dilational jogs) during multiple seismic fault movements. Stable isotope data exclude the involvement of (1) locally derived, rock-buffered fluids, such as those from clay dehydration and (2) uprising hydrothermal fluids. We conclude that even low-permeable, clay-rich fault cores along strike-slip faults can act as conduits for the circulation of externally-derived meteoric fluids during seismic events, thus dismantling the paradigm of clay-rich gouge making faults completely impermeable to the circulation of external fluids. Further clumped stable isotope analyses are necessary to better constrain the fluid origin and validate the proposed fluid flow model and implications.

Multistage structural controls on hydrothermal vein system development in epithermal mineral deposits: A case study of the Tieluping Ag–Pb–Zn deposit, East Qinling, China

Xinming ZHANG[1]*, China University of Geosciences (Beijing) (zhangxmcugb@qq.com)
Da Zhang[2], China University of Geosciences (Beijing)
Xuan Wang[3], MNR Key Laboratory of Metallogeny and Mineral Assessment, Institute of Mineral Resources, Chinese Academy of Geological Sciences
Mingjian Yang[4], China University of Geosciences (Beijing)
Bojie Hu[5], China University of Geosciences (Beijing)
Songyan Liu[6], China University of Geosciences (Beijing)

Abstract

Epithermal deposits are formed by hydrothermal vein systems controlled by complex systems of brittle fractures. The development of these ore-controlling fractures results from the dynamic interplay of various structural factors, including paleostress regimes, fluid pressures, and pre-existing mechanical anisotropies in the rock mass. However, the nature of this interplay has not previously been described in detail. The Tieluping epithermal Ag–Pb–Zn deposit is situated on the western margin of the Xiong'ershan ore-concentration area and contains two groups of fracture-controlled N- and NE-striking veins. Here we systematically investigate the structural deformation and hydromechanical development of the Tieluping deposit. Ag–Pb–Zn mineralization is characterized by the superposition of multiple generations of mineralized hydrothermal quartz–siderite–pyrite (V1), quartz–ankerite–sphalerite–galena (V2), and quartz–calcite–fluorite (V3) veins. Our analysis of structural-deformation and fault-slip data reveals that the T1 stress tensor (σ1: 003/90; σ2: 183/00; σ3: 093/00; R = 0.50) during the formation of early V1 veins was characterized by sinistral shear and hybrid kinematics of NE-striking fractures and tensional kinematics of N-striking fractures. The subsequent formation of late V2 and V3 veins, including NE-striking hybrid (dip-slip offset) and tensional structures and N-striking dextral shear and hybrid structures, were controlled by the T2 stress tensor (σ1: 045/90; σ2: 221/00; σ3: 311/00; R = 0.77). Fluid inclusion petrography and microthermometric analysis suggest that epithermal mineralization in the Tieluping deposit was caused by mixing of magmatic fluids and meteoric water under hydrostatic conditions and occurred in the distal region of a porphyry–epithermal system in the Xiong'ershan ore-concentration area. These structural and fluid inclusion data were used as a basis to construct a quantitative 3-D Mohr circle to describe the dynamic evolution of ore-controlling fractures in the deposit. The results of the 3-D Mohr circle analysis suggest that differing multistage stress regimes and variable fluid pressure governed the reactivation of pre-existing cohesionless structural planes that controlled the emplacement of epithermal veins in the Tieluping deposit. Fluid pressure favored the widespread reactivation of pre-existing structural planes and provided tensional accommodation space for fluid mixing and mineral precipitation during epithermal mineralization. The quantitative 3-D Mohr circle method used to analyze the hydromechanical evolution of the Tieluping deposit successfully describes the formation and

evolution of the ore-controlling fracture system and gives insights into the development of epithermal deposits.

Abstract

In upper crustal fault zones, silica-bearing hydrothermal fluids may affect petrophysical and mechanical properties of rocks by modifying their texture and mineralogy with strong implications on geofluid storage and flow potential. It is, however, extremely difficult to predict the geometry of silicified rock volumes along and around fault zones as well as their textures and petrophysical properties in the subsurface and, therefore, well exposed outcrop analogues can provide important insights. The Kornos-Aghios Ioannis Fault (KAIF) on Lemnos Island (Greece) is a silicified extensional fault system active at shallow depth (<1 km) that, well exposed over 10 km length, juxtaposes Lower Miocene volcanic rocks against Middle Eocene to Lower Miocene turbidite sandstones. The fault zone structure consists of a m-thick fault core made up of silicified breccia, cataclasite and ultracataclasite and by fractured damage zones developed in silicified turbidite sandstone. In the footwall damage zones, this pervasively silicified sandstone locally contains crackle to mosaic breccia cemented by late stage quartz. Silicified and brecciated domains extend in the footwall for a maximum of 250 m and 80 m from the master fault, respectively, but their width strongly varies along-strike, it being greater at the fault tip. Fracture density and connectivity is higher in the silicified portions of the fault. Whole-rock X-ray diffraction data of representative samples show systematic changes in quartz content from the silicified fault core to the pristine host rock with maximum values >80 wt. % near the master fault plane and values between 40 and 50 wt. % where the host rock is not affected by silicification. Quartz content is inversely correlated with feldspar content. Oxygen isotopic composition of silica cements is in the range +7.0 ‰ < δ18O V-SMOW < +12.4 ‰ and fluid inclusion data indicate that silica precipitated from hydrothermal fluids with an average temperature of 170 ± 16 °C. Fluid inclusion and isotopic data from other hydrothermal minerals sampled in fault-related veins in the hanging wall (i.e. calcite, dolomite and barite) indicate similar temperatures (166 ± 17 °C) and the δ18O V-SMOW values of hydrothermal calcite vary between + 4.0 and + 23.0 ‰. Hydrothermal calcite

exhibits high Mn, Fe and REE contents (average ΣREE 94 ppm) and pronounced positive Eu anomalies. Our data support an evolutionary scenario in which deeply circulating meteoric fluids underwent thermal equilibration and trace element enrichment through fluid-rock interaction processes. Silica precipitation possibly occurred during their upward migration along fault zones due to a progressive decrease of silica solubility during cooling. Petrophysical analyses performed with an unsteady state gas permeameter and porosimeter suggest that the process of silica precipitation can strongly impact on petrophysical properties of faulted sandstone by decreasing matrix porosity from 12-14 % to 2-4 % and permeability from 1 to 0.001 mD.

Fluids and deformation processes at shallow subduction megathrust: hints from ancient analogues

Francesca REMITTI[1]*, Università di Modena e Reggio Emilia (francesca.remitti@unimore.it)

Abstract

Subduction megathrusts have been recognized for a long time as weak interplate faults that localize deformation under low shear stresses (<20 MPa) and active circulation of fluids. This is inferred from the small taper angles of overlying accretionary wedges, low surface heat flow, the distribution and nature of aftershock focal mechanisms, and geophysical measurements of high Vp/Vs. The weakness of megathrusts is ascribed to low-friction minerals and/or fluid overpressures which significantly lower the effective friction coefficient of megathrust faults. In particular, the shallow part of the subduction megathrust hosts several changes leading to progressive lithification of seafloor sediments at increasing P-T conditions, resulting in a shift from diffuse soft- sediment deformation to discrete faulting often characterized by diffuse veining. The widespread occurrence of fracture sets filled with mineral veins in ancient megathrust testifies to an active fluid circuit, cyclically subjected to pressure rises and drops and permeability changes related to fracturing and fracture healing by precipitation of hydrothermal minerals. Tectonic veins thus represent a valuable archive of information on both the stresses state and the physicochemical characteristics of fluids circulating in the fault zone through time. This presentation aims to explore two main aspects: (i) the impact of progressive lithification on deformation processes occurring in the shallow part of the megathrust, and (ii) the insights provided by tectonic veins into fluid pressure, fluid circulation, and stress distribution around shallow ancient megathrusts.

Deciphering fluid sources and pathways of hydrothermal Ba-F mineralisation in western Bastar craton, central India: Using mineral system approach by combining structure, fluid, Sr- and S-isotope geochemistry

Muduru Lachhana Dora[1]*, Geological Survey of India (muduru.dora@gsi.gov.in)
Sandip Kumar Roy[2], Geological Survey of India

Abstract

Hydrothermal vein-type Ba-F mineralization usually occurs in the vicinity of rift valleys, basement-cover unconformities, and large-scale crustal lineaments or fault systems. The study area is part of Western Bastar Craton (WBC), composed of ca. 2.5 Ga Tonalite-Trondhjemite-Granodiorite (TTG) suites, charnockite and mafic-ultramafics. These assemblages are intruded by 1.6 Ga Mul granite, overlain by Pranhita-Godavari (PG) cover sediments. Mineralization (Ba-F) is associated with numerous quartz veins along structural weak planes, i.e. faults, hosted in Mul granite. We combined field and laboratory studies using structural mapping, geochemistry, fluid inclusion, Sulfur, and Sr-Isotope geochemistry to characterize ore-forming processes and their pathways.

The regional NW-SE trending PG rifting provided pathways for fluid flow and ore formation along faults/fracture systems (F2 and F3 fault systems) in the host Mul granite of WBC. The F2 fault system, sympathetic to the PG rift, is deep-seated and contains mainly barites of magmatic origin besides the minor marine signature. The F3 cross faults, developed across the gneissic foliation of TTG gneisses and charnockites, can be traced to the PG basin's younger marine sediments, host barites of marine signature.

Petrography studies show barite is accompanied by galena, pyrite, fluorine and chalcopyrite. Sulfide-free (Brt-I), sulfide-bearing (Brt-II), and fluorite-associated barites (Brt-III) were observed in different assemblages. The fluid inclusion homogenization temperature (Th) ranges from 152°C to 310°C with a mean Th value of 201°C. Fluid inclusion and Sr-S isotope data suggest a bimodal evolution of the brine viz. the oxidative source forms sulfide-free high-salinity brine and reductive low-salinity sulfide-bearing aqueous fluid formed by interaction with reducing agent causing hydrothermal Ba-mineralization. The source for hydrotherms responsible for the formation of barite and galena in association with the quartz-barite vein is granitic magma. The 87Sr/86Sr isotopic ratios display two distinct arrays; one with lower 87Sr/86Sr of 0.706075-0.707791, having lower salinity, suggests the influence of Mesoproterozoic seawater. The second one, with higher 87Sr/86Sr of 0.71561-0.719785 and relatively higher salinity, indicates mixing hydrothermal solutions with the fluids formed in the continental areas generated in the rift valley. The combined 87Sr/86Sr and δ34S‰ data suggest mixing fluids from diverse sources, including magmatic, marine, and crustal fluids. Low 87Sr/86Sr (10‰) are indicative of alteration products of granite that were subsequently mixed with submarine hydrothermal fluid mobilized through the Mesoproterozoic PG rift system. The epigenetic-submarine hydrothermal vein-type barite

mineralization hosted in granite, WBC differs from VMS, Sedex, Carlin, or Orogenic-type barite deposits. The Ba ± F mineralization in the study area is a perspective for regional exploration and elsewhere in a similar geological milieu.

[Keynote] Reconstructing past fluid migrations in fold-and-thrust belts and forelands using geochemistry

Nicolas E Beaudoin[1]*, Université de Pau et des Pays de l'Adour (nicolas.beaudoin@univ-pau.fr)

Abstract

Orogenic forelands, either flexural foreland or broken foreland in style, host interactions between deformation and static or migrating fluids. Given their accessibility and dimensions, these areas are not only historic landmarks for structural geology, but they are also areas of prime interest for georesource exploration and geological storage, and loci of potential geohazards. Geochemical techniques applied on synkinematic mineralization in tectonic structures, along with direct measurements in fluid trapped in the crystals, can constrain the temperature, pressure, origin and pathways of fluids during deformation and allow the characterization of the past fluid system. This talk attempts at summarizing, through some selected studies of past fluid systems reconstructed at the scale of the orogenic foreland, the evolution of the fluids involved during deformation, with regards to the structural style. At first order, the past fluid system evolves in a similar way with respect to the considered stage of deformation, being rather closed to external fluids when deformation is bounded to mesoscale structure development, and opening to vertical flow when thrust and folds develop. In a more detailed view, it seems that the past fluid system evolves and distributes under the influence of the structural style, of the geometry of the major faults, and of the lithology of the sedimentary succession. The concept of geochemistry-assisted structural geology will be discussed through some cases studies where geochemistry of calcite veins helped refine sub-surface geometries and structural developments in orogenic forelands.

Scale-dependent fracture patterns and flow in low-enthalpy geothermal targets: the role of diagenesis and contingent nodes

Stephen Ernest Laubach[1]*, The University of Texas at Austin (steve.laubach@beg.utexas.edu)
Stephanie Forstner[2], The University of Texas at Austin

Abstract

Fracture patterns in rock strongly affect directions, magnitudes, and heterogeneities of both fluid flow and rock strength. Accurate and testable predictions of patterns are essential for understanding many societally important processes in the Earth and for effectively managing subsurface engineering operations. Chemical processes play a larger role in opening-mode fracture pattern development than has hitherto been appreciated. For fractures formed at depths of ~1–10 km and temperatures of 50–200 °C, new evidence shows chemical reactions are common and more diverse than previously recognized. We describe how viewing fracture formation and evolution from a chemical perspective helps to solve problems in fracture pattern analysis. We outline the main impediments to subsurface fracture pattern measurement and interpretation, assess implications of recent discoveries in fracture history reconstruction for process-based models of fracture and cement accumulation, review models of fracture cementation and chemically assisted fracture growth, and discuss promising paths for future work. Potential exists for basic scientific investigations to lead to progress on what has been one of the most refractory practical problems in subsurface science. Results suggest that progress in fracture interpretation and prediction can be made using observational, experimental, modeling, and theoretical approaches that view fracture patterns as the result of coupled mechanical and chemical processes. Developments have application for the energy transition.

Infiltration of illuvial clays along the near-surface slip zone

Youngbeom CHEON[1]*, Active Tectonics Research Center, Korea Institute of Geoscience and Mineral Resources (cheonyb@kigam.re.kr)
Hakyung LEE[2], Department of Geology and Research Institute of Natural Science, Gyeongsang National University
Chang-Min KIM[3], Department of Geology, Division of Geology and Geophysics
Raehee HAN[4], Department of Geology and Research Institute of Natural Science, Gyeongsang National University

Abstract

Illuvial clays are generally regarded as very fine deposit materials, which vertically migrate in water and accumulate in pore-like spaces without significant chemical and physical alteration. Here we present the nature of illuvial clays observed along paleoearthquake slip zones in near-surface regions, South Korea, based on outcrop to microscale structural observations and mineralogical investigations. Paleoearthquake ruptures distributed throughout the Korean peninsula are mainly characterized by a narrow slip zone (<3-cm-wide) in the basement depths, which branched into several narrower splays showing a bifurcation geometry within the overlying unconsolidated sedimentary strata. At the three studied sites (Oebuk, Songhak, and Geumam sites in the NNE−SSW-striking Gongju Fault Zone, central Korea), the specific slip zone in the basement rocks (granitic rocks) is mainly composed of the fault rocks (fault gouge and/or microbreccia), whereas the branched slip zones in the unconsolidated strata are expressed as the infiltration of illuvial clays without fault rocks. However, it is noted that the uppermost part of the slip zones in the basement rocks also contains the illuvial clays, which are intercalated within the fault rocks, showing a downward tapering geometry. Our structural and mineralogical findings show that the illuvial clays have a distinct texture and color but also mineralogy compared to the fault rocks. These features present that the narrow seismic slip zone propagated in near-surface regions, primarily showing a deformation mechanism of granular flow, can be an important permeability zone due to its dilation. We further need to consider the influence of infiltrating materials on subsequent earthquake slip events based on their mineralogical characteristics.

The mechanism and its geological significance of Mesozoic red sandstone bleaching in Luxi block, North China Craton

Li LI[1]*, China University of Petroleum (East China) (lili@upc.edu.cn)

Abstract

Red sandstone bleaching is of great significance for tracing the origin of reducing fluids and the fluid-rock interaction with subsurface sediments in the process of fluid escape. Based on the fieldwork data, XRD test and carbon and oxygen isotope test, this research systematic revealed the characteristics, mechanism and geological significance of bleached sandstone in Luxi block, North China Craton. Field observations found that the bleaching sandstone occurred along bed parallel layers and fractures in the Jurassic and Triassic red sandstone. The former is planar and diffuse along the layer and the latter is linear, branch shape, etc. along the fracture strike and planar on the profile. The XRD tests found that the mineral compositions of calcite and hematite in the Jurassic and Triassic bleached sandstones are different. The former has a high content of calcite and no hematite, while the latter has a low content of calcite and hematite. The mineral edge of the red sandstone is covered with a hematite coating in section, while the red coating on the mineral edge dissolved and partially dissolved after bleaching. Carbon and oxygen isotope tests show that the average value of δ13C in the Jurassic bleached sandstone is -4.04‰, and the average value of δ18O is -10.15‰. Although the carbon isotope values far from the fault are smaller than those near the fault, both of them are products of mantle-derived CO2 fluids reduction. While the average value of δ13C and δ18O of the Triassic bleached sandstone is of -2.70‰ and -13.64‰, respectively, heavy δ13C and light δ18O compared to the Jurassic bleached sandstone, indicating that the Triassic red sandstone is the reduction of hydrocarbon fluid. The fault is an important channel for the Mesozoic red bed bleaching and reducing fluids migration of the Luxi block. The Tan-Lu fault zone, the crustal detachment surface and the NW-trending detachment fault control the migration of the mantle-derived CO2 upward to the shallow surface, and the CO2 gas diffused along the bed parallel slipping surface and fractures produced by the NW trending detachment during the same period and reduced the Fe3+to Fe2+, resulting in the fluid-red sandstone interaction to bleach the Jurassic red sandstones. The Cicun fault is a channel for hydrocarbon migration from the Dongying sag, Bohai Bay Basin to the Luxi block, which led to the bleaching of the Triassic red sandstone by reducing the Fe3+to Fe2+. The geo-geochemical study reveals that there are two type of bleaching mechanism by reducing Fe3+to Fe2+ during mantle derived CO2- rock interaction and hydrocarbon- rock interaction in Mesozoic red sandstone of the Luxi block. The reducing fluid originates from the mantle and hydrocarbon in the Dongying sag, respectively, and the activities of the Tan-Lu fault zone and the regional faults in the Luxi block are closely related to the bleaching of red beds. The research implied that the northern part of Luxi block is a potential oil and gas exploration area.

Abstract

The Pohang earthquake (Mw 5.4) on November 15, 2017, caused significant property damage in Korea. The Korean Government Commission reported that the stimulation process of the Pohang Enhanced Geothermal System (EGS) project directly triggered the Pohang earthquake. The earthquake occurred when water was injected into PX-2 among two boreholes operated in the EGS project. The spatial distribution of aftershocks and foreshocks of the earthquake (Kim et al., 2018) indicates that the Pohang earthquake fault (the fault triggering the main shock) intersects the PX-2 borehole at a depth of approximately 3,800 m. The faulting event did not cause any surface rupture. This study aims to directly identify the fault that caused the earthquake by analyzing the cuttings retrieved from the PX-2.

The cuttings at depths between 3750 m and 3815 m of PX-2 contain an average of 60% mud balls. Mud balls are unconsolidated rock fragments that are wrapped in a thin layer of drilling mud and have a rounded shape. The cores of all the mud balls were identified to be composed of fault gouge or fault breccia fragments coated with drilling mud. Under polarized microscopy, the commonly observed clay-rich fault gouges show unique microstructural features formed in the brittle regime. At high magnification, mineral fragments are mainly composed of quartz, feldspar, and mafic minerals derived from granodiorite, the host rocks, with some minerals such as calcite and chlorite inferred to have been made during or after fault activities. In the matrix, alternating and distinctively separating bands, composed of dark brown to light brown and green clay mineral (probably mostly chlorite) layer and mafic mineral layer in thickness of tens of micrometers, form a unique foliation under open nicols. The foliation is regularly arranged as a whole, but the direction is rotated around large mineral fragments as a cataclastic flow. Based on these observations, it is concluded that the Pohang Earthquake occurred due to the reactivation of a large mature fault zone that has experienced repeated fault movements and injection of hydrothermal fluids during or after fault activity.

Abstract

Pseudotachylyte (PST), produced by frictional heating during seismic slip, provides information that is critical to understanding the physics of earthquakes. We present the results of occurrence, structural characteristics, scanning electron microscopic observation, geochemical and geochronological analysis of PSTs. The host rocks of these PSTs are granodiorite (Gyeongju, SHRIMP U-Pb zircon age, 75.0±1.5 Ma), biotite granite (Gyeonyju, SHRIMP U-Pb zircon age, 58.4±1.1 Ma; Maemul island, SHRIMP U-Pb zircon age, 68.1±1.2 Ma), and granitic gneiss (Jiri mountain, metamorphism age 1,860-1,900 Ma). These PSTs are presumed to have formed during the Eocene-Late Cretaceous. In these areas, PSTs and cataclasite, which are the products of brittle deformation under the shear stress regime, occur together along the fault zone. Cataclastic rocks are classified into non-foliated clast-supported and foliated clast-supported to matrix-supported cataclastite. PSTs are identified into four types based on the thickness and morphology in the field: single dike-, fault vein-, injection vein-, and brecciated-type PST. The single dyke-type PST, exposed on the coast of Gyeongju city, shows a variation of thickness from 15-40 centimeters along its strike and has an average thickness of 21 cm, which is the largest in the world, as far as we know. At a first glance it looks like a mafic dike, but it has a chemical composition almost identical to the wall rock of granodiorite. Also, it has many subrounded clasts which consist predominantly of quartz and feldspar and newly crystallized tiny grains (submicrometers to several micrometers in size). The feldspars and biotite are euhedral and some plagioclase grains show zoning. Flow structures and embayed clasts are also observed. The single dyke-type PST-bearing fault zone can be traced continuously over at least 1.5 km based on the data from the drilling sites and other outcrops. The fault vein-type PSTs, which is the most frequently produced in all study areas, occur as thin (as thick as 0.5-2 cm) layers generated on the fault surface, Embayed clasts, phenocryst with reaction rim, oxide droplets, amygdules, and flow structures are also observed. The smaller injection vein-type PSTs are also found along the fault vein-type PSTs in all study areas, and appear in a variety of shapes (bleb, lens, sigmoid, network, and breccia) based on field occurrence and vein geometry. The brecciated-type PST (1.2 m wide, >5 m long), which are much larger in width than single dyke-type PST, develop on the dilational jog of the dyke-type PST-bearing fault in the Gyeongju. The breccia and matrix components are the same as

the dyke-type PST, and characteristically, the chilled margin develops as the zone at the edge of the breccia. These breccias are similar to the autobrecciated rocks that often develop in highly viscous lava flows. All of these observations indicate the PSTs formed due to frictional melting of the wall rock minerals during fault slip related to strong seismic faulting events in the shallow depth of low temperature-low pressure. Further studies will be conducted to determine the age and mechanical aspect of the PSTs formation.

Abstract

A fault is a deformation structure where the both sides of a rock are displaced relative to each other due to slipping (shearing), and the area involving displacement develops structures through fracturing or pulverization. In the case of large-scale fault zones, they exhibit complex internal structures, which can serve as pathways or barriers for fluid movement. Generally, the influx and release of fluids within a fault zone can either cause repeated slipping during the seismic cycle or result from such slipping. Therefore, from a geological timescale, the movement and development of faults can be considered contemporaneous with fluid influx and specific stages of deformation. At this time, since the fluids entering the fault zone contain a significant amount of common lead, it is judged that utilizing this can constrain the timing of common lead influx, namely the movement timing of the fault. In this study, zircons were separated from the parent rock and fault gouge at major fault locations within the Korean Peninsula, and U-Pb dating was conducted. Before the U-Pb dating analysis, backscattered electron imaging and cathodoluminescence imaging were obtained to select appropriate analysis points and observe changes in the internal structure of zircons due to fluids. Observations of the internal structure of zircons revealed that zircons from fresh parent rocks showed oscillatory zoning structures typical of igneous rocks. However, zircons separated from the fault gouge showed the development of numerous microfractures due to fluid influx, along which formed or infiltrated microinclusions were observed. The U-Pb dating results for zircons from the unaffected parent rock mostly aligned on the concordia curve, indicating the crystallization age of the zircons. In contrast, U-Pb dating results for zircons separated from the fault gouge were characterized by discordant ages due to the influx of common lead. Utilizing these discordant ages caused by common lead is expected to be useful in constraining the timing of movement in basement faults in future studies.

Pressurization and injection of fault materials and fluids during the long-term seismic cycle, the intraplate Yangsan fault, SE Korea

Chang-Min KIM[1]*, Kangwon Nationl University (cmkim@kangwon.ac.kr)
Raehee HAN[2], Department of Geology and Research Institute of Natural Science, Gyeongsang National University
Sangwoo WOO[3], Institute of Geohazard Research, Pusan National University

Abstract

Fault zone processes during long-term cycles of seismicity in fault zones can provide key information for mitigating earthquake hazards in intraplate regions. To understand the fault zone processes during long-term seismic cycles in a granitic fault zone in SE Korea, we conducted an integrated methodological study combined with multiscale observations and analyses of the mineralogical properties of fault rocks, along with low- to high-velocity shear tests. A strike-slip fault zone that branches out from the main strand of the Yangsan Fault bounds Triassic and Jurassic granites. The fault zone consists of a <35 m-thick fault damage zone that is developed around a <1 m-thick fault core. The fault core contains breccia and clay-rich foliated gouge zones, which contain 43 wt.% clay minerals, including smectite (13.3 wt.%), illite (21.2 wt.%), and kaolinite (8.5 wt.%). The low- and high-velocity shear tests using foliated gouge taken from an outcrop show a low friction coefficient ($0.13 < \mu ss < 0.17$) and flash dilation of gouge material. Cross-cutting relationships among microstructures in the fault zone indicate the following sequence of events. (1) Pressurized fluid was vigorously injected along the fault zone. Notably, fluids from the wall rock invaded the densely packed, low-permeability gouge. (2) Fibrous calcite veins, which are perpendicular to the Y-shear direction of the fault, formed along foliation planes in the gouge. (3) Fluidized gouge material was injected into the damaged wall rock. These observations indicate the occurrence of cyclic coseismic and aseismic faulting during long-term seismic cycles in the intraplate granitic fault zone after the low-temperature formation of expanding clay minerals. Moreover, the shear tests show that mixed smectite/illite gouge can dilate instantaneously at a seismic slip rate (1.3 m/s) if the total displacement exceeds ~5 m. Our findings suggest that intraplate fault zones can behave unstably due to the cycle of long-term seismic events and the dynamic properties of fault core materials.

Three-dimensional structural and parametric models focused on finding the leads for different applications connected with energy acquisition in NW part of Poland.

Rafał Laskowicz[1]*, Polish Geological Institute – National Research Institute (PGI-NRI) (rlas@pgi.gov.pl)
Marcin Bolek[2], Polish Geological Institute – National Research Institute (PGI-NRI)
Jerzy Hadro[3], Polish Geological Institute – National Research Institute (PGI-NRI)
Jarosław Zacharski[4], Polish Geological Institute – National Research Institute (PGI-NRI)

Abstract

In the south-eastern part of the Central European Permian–Mesozoic Basins a 3D model was made covering an area of 27,000 km2 in the NW part of Poland. Data derived from 103 deep boreholes, 781 surface 2D seismic surveys and 3 3D images were used, as well as archival maps. Coverage of the area by geophysical and seismic surveys is uneven. Geophysical reconnaissance is concentrated around reservoir zones leaving other parts of the area only partially recognized. This results in holes that are difficult to interpret. Due to the large number of studies stored in analog phaorma, in order not to lose a large number of data contained in them, a method of recovering seismic data from paper printouts was tested and applied. These data were scanned and, after appropriate graphic processing, imported into the interpretation project in the form of 2D seismic profiles (SGY format) - this enabled the seismic interpretation from the southern part of the area to be completed. In the course of analyzing the thickness distribution of the basic elements of the separated petroleum systems, verification of information from deep boreholes was performed for consistency of stratigraphy in individual boreholes. Consolidation of scattered data in a single platform gave the opportunity to verify data originally prepared in different standards, from different sources and from different period. Interpretations in the time domain were carried out and the results were converted into depth obtaining the final models in the depth domain. Preparation of a consistent fault model verified by images from selected seismic materials mainly in 2D and the course of fault traces on archival maps led to an unambiguous three-dimensional image of dislocation sequences. The deep geological structure was detailed and hydrocarbon prospective horizons were selected for which structural and thickness models were prepared. Spatial models of the distribution of selected lithological, petrophysical and geochemical parameters on the lithostratigraphic framework (porosity, Vshale, TOC) were developed. A preliminary quantitative assessment of Carboniferous, Red Bedrock, Main Dolomite and Lower Jurassic petroleum systems was performed.

The compiled data integration originally focused on identifying hydrocarbon prospects. Due to the wide range of analyses performed and the integration of all the data produced so far, it allows the analysis of structures in terms of the multifaceted use of deep structures for substance storage and energy extraction.

Landform Evolution of the Brahmaputra, Padma and Meghna interfluve, Bengal Basin, Bangladesh – A Pedological Approach

Zahidul BARI[1], Jahangirnagar University
Md. Sharif Hossain KHAN[2]*, Jahangirnagar University (sha@juniv.edu)
Khalil R. CHOWDHURY[3], Jahangirnagar University

Abstract

Soil archives the changes since the deposition of its parent materials, hence pedological study is very important to assess the soil-landform evolution of an area. The capital city Dhaka lies within the central part of the Bengal Basin, which hosts the Quaternary Madhapur Tract, is an interfluve of Brahmaputra, Padma, and Meghna rivers. A comprehensive landform evolution of Madhupur Tract is yet to be done. Hence a pedological approach in conjunction with alluvial/fluvial morphology has been employed to assess the soil-landform evolution in the central part of the Bengal Basin. The study is based on soil-geomorphic map, detailed field investigation, and soil-chronoassociation. A soil-geomorphic map has been prepared using soil resource maps, toposheets and satellite images, delineating thirteen (13) distinct soil-geomorphic units within the research area. Based on pedogenic characteristics, particularly solum thickness, ped development, and cutan development in the B-horizons of soil profiles across various soil-geomorphic units, as well as considering the ages of the soils and published proxy ages from the area, a five-membered soil chronoassociation (QGSD1 to QGSD5) has been developed to elucidate the evolution of the soils and the concurrent development of the landform in the area under investigation. The tentative assigned ages of the soil chronoassociation (QGSD1 to QGSD5) are <500 yr., 0.5-3 ka, 3-7 ka, 14-18 ka and >18 ka, respectively.

Soil-chronoassociation member QGSD5 occupies the top of the local catena on the Madhupur Tract. QGSD4 and QGSD3 soils stand the middle position of the local catena representing the older floodplain, while QGSD2 and QGSD1 are situated at the lower relief of the local catena, indicating the young floodplain. This hierarchy determines the areas of active sedimentation, pedogenesis, and erosion. The final phase of the terrace formation on the Madhupur Tract with QGSD5 soil-chronoassociation member was accomplished during >18 ka (LGM) under subhumid-semiarid climate when sea level regression entrenched the rivers of Bengal low land. During a period between 14 to <18 ka, onset of humid monsoon climate leads the deposition of older Flood plain soils parent material (QGSD4); later during 3-7 ka sea level transgression/oscillation deposits the QGSD3 soils parent materials. Around 0.5-3 ka leads recent phase of soil formation of QGSD2 member. In QGSD1, active sedimentation is going on and at the very initial phase of pedogenic processes.

Fluvial morphology particularly stream initiation, confluence, stream straightness, stream offsetting/bending help identify nine lineaments/faults, namely Kaliganga, Dhaleshwari,

Bongshai, Jhinai, Madhupur east, Madhupur west, Bhaluka, Jaina and Tongi-Narsindi. These lineaments separated the different soil-geomorphic units in the area and have played a significant role in shaping the relief (local catena) and soils of the study area. Therefore, the study has a broader implication to understand the landform evolution and active tectonics of the central part of the Bengal Basin.

Active fault mapping, structural framework, kinematics, and segmentation – An appraisal of the Chittagong Coastal Fault along the outer Indo-Burman Ranges

Md. Sakawat Hossain[1]*, Jahangirnagar University (sakawat@juniv.edu)
Dilruba Yesmin Shetu[2], Jahangirnagar University
Md. Sharif Hossain Khan[3], Jahangirnagar University

Abstract

Large-scale active faults along or close to the convergent plate boundary are complex systems whose growth, structural framework, kinematic, and segmentation are still not well understood. However, it is important to understand these complex fault systems as all the devastating earthquakes and associated geohazards that occur on Earth's surface are generated by these seismogenic faults. These kinds of faults also act as the major conduits for different types of geofluids (e.g., hydrocarbon, magma, etc). Therefore, proper mapping of these complex fault systems and determining the attributes, kinematic model, structural framework, and segmentation not only help to appropriate seismic hazard assessment but also unveil their significance as subsurface conduits. The goal of this research is to map the Chittagong Coastal Fault (CCF), which traverses along the western edge of the outer Indo-Burman Ranges (IBR) and close proximity to the Indo-Burmese plate boundary and to quantify tectonic geomorphology using evidence derived from both at the surface (e.g., surface geology, and geomorphology), as well as in the subsurface (e.g., wireline log, gravity, and seismic). Integration of data sets from the surface, subsurface, and remote sensing have provided the necessary information to understand all processes leading to the growth, extent, geometry, kinematics, and segmentation of the CCF.

The CCF fault system has been studied along the western flank of four prominent anticlinal structures (from north to south: Sitakund, Maheshkhali, Inani, and Dakhin Nhila) situated at the western edge of the Chittagong-Tripura Fold Belt (CTFB). Surface geology, fault attributes, and geomorphology were observed in the field. Field evidence of abrupt change in topography and bedding attitude, dragging, bending, shortening, and visible displacements of beds, domino structures, small-scale recumbent fold, and shear joints suggest high tectonic stress and the presence of a major thrust fault system with dextral strike-slip component. The recorded fault traces along the western flank of the four anticlines are extrapolated and merged together, which form a single fault of approximately 350 km long. The fault map clearly shows that CCF runs parallel to the east coast of Bangladesh, continues inland northward along the Bangladesh-India (Tripura) border, and finally terminates into the Sylhet Fault. The net displacement of the fault has been quantified based on the field outcrop observation and 2D seismic sections, which is about 1150 m. With roughly 1.1 km of net displacement and 350 km length, the CCF, in general, complies with the existing fault length-displacement models. Evidence derived from the surface geology, tectonic geomorphology, historical seismic record, and recent geodetic measurements

suggest that the CCF is an active fault, and possibly segmented into four parts. All observations imply that a seismogenic gap exists in the northern two segments of the CCF. Finally, the interdisciplinary approaches of this study which integrate different data sets from field observations, and structural, geomorphological, geophysical, and remote sensing studies have enabled to elucidate the structural framework, kinematics, segmentation, and length-displacement model of the CCF, which presently accommodating approximately E-W convergence in the eastern Bangladesh, and poses a potential threat of a major earthquake.

Slab tear and its corresponding crustal deformation of subducted Indian lithosphere in the Eastern Himalayan Syntaxis region

Bo ZHANG[1]*, Peking University (geozhangbo@pku.edu.cn)
Ziqing Li[2], Peking University

Abstract

The southeastern Tibetan Plateau is currently experiencing active southeastward extrusion and rotation around the Eastern Himalayan Syntaxis (EHS) due to the ongoing collision between the Indo-Eurasian continents. This tectonic activity is evident through a series of N-S-striking, NW-SE-striking, and NE-SW-striking ductile strike-slip shear zones/faults in Tibet and the Indochina Block. These geological features play a crucial role in investigating the relationship between Cenozoic crustal deformation and the lithospheric evolution of the Tibetan Plateau. However, the kinematics, linkages, and developmental patterns of these shear zones along their strike remain inadequately understood. This lack of information has led to the formulation of poorly evaluated formation mechanisms, particularly in terms of along-strike geometry variation and linkages, such as the concepts of continuum rotation deformation and discrete extrusion tectonics. Two potential outcomes are predicted: a clockwise rotation around the EHS along the curved strike-slip shear system or southeastward extrusion of related blocks along two conjugated strike-slip shear zones/faults. Therefore, it is crucial to explore the along-strike geometry and linkage of individual strike-slip shear zones/faults to gain essential insights into understanding and evaluating these two proposed mechanisms/models. In this contribution, our investigation focuses on the structures, geometries, kinematics, and thermochronological data to constrain the formation and evolution of the regional-scale dextral strike-slip ductile shear zone system. Our new findings indicate that these dextral shearing zones, delineates a curved regional-scale dextral strike-slip zone system around the EHS region. This observation aligns with the current tracks of GPS and FPD (fast polarization direction) and contradicts the features of a conjugated strike-slip shear system dominating extension tectonics, which initiated nearly simultaneously along a straight strike. These characteristics suggest that the initiation, movement, and linkage of the curved dextral strike-slip shearing are significantly influenced by continuum rotation deformation, driven by slab tear of subducted Indian Plate beneath the EHS region, rather than discrete extrusion tectonics.

Investigating the relative roles of structural and mechanical (lithology, bed thickness) controls in fracturing in frontal thrust sheets: Insights from fracture characterization and attribute study, Eastern Himalaya, Sikkim

Ammu J.K.[1], Indian Institution of Science Education and Research (IISER) Kolkata
Kathakali BHATTACHARYYA[2]*, Indian Institute of Science Education Research (IISER) Kolkata (kathakali@iiserkol.ac.in)

Abstract

We investigate the partitioning of fracture modes, their temporal evolution, and the competing effects of structural distance from the fault and mechanical anisotropies (lithology and bed thickness) on their intensity, density, orientation, mode, length, and spacing within ~3.4 km of the frontal-most exposure of the Ramgarh thrust (RT) sheet from the Sikkim-Himalayan fold thrust belt (FTB). Shear (~88%) fracture with slickenlines are better exposed than joints with plumose structures due to their favorable relative orientations with the outcrop bearing and bedding. Detailed structural analysis reveals coexisting shear fractures (~59%) and joints (~41%), emphasizing the necessity of such studies in mountainous terranes with limited outcrops to avoid under-representation of a particular mode. Fracturing initiated with low-angle, shear fractures that progressed to high-angle, shear (~44%), and extension (~56%) fractures. This study, for the first time, reveals that lithology has the most dominant control on fracture density, followed by bed thickness and structural distance in the frontal thrust sheet of the Himalayan FTB. However, lithology does not partition fracture mode and angularity. Also, structural distance effects the temporal evolution, intensity, and angularity of fractures, but not their mode. Although mechanical discontinuities constrain fracture lengths irrespective of their mode and angularity, structural distance dominantly controls fracture network evolution close to the fault.

Petrotectonic framework of the Siwalik Group in northern part of the Chitwan Dun Valley, Central Nepal

Niraj Singh Thakuri[1]*, Tribhuvan University (niraj.thakuri444@gmail.com)

Abstract

The present field, detailed petrography and modal analysis of representative 38 sandstone thin section have been carried out to determine petrotectonic setting of rocks of the Siwalik Group in Narayangadh-Lothar area, northeast Chitwan Dun Valley. Lithostratigraphically, the study area consists of the Lower Siwalik, the Middle Siwalik and the Upper Siwalik in ascending order. From bottom to top, it is lithologically characterized by light to dark grey mudstone, variegated mudstone, and fine-grained sandstone. Light to dark grey siltstone, salt, and pepper appearance sandstone, pebbly sandstone, and clast to matrix-supported conglomerate. The QtFL (Qt, total quart; F, Feldspar; L, lithic grains) petrofacies indicates most of the sandstones of the Siwalik Group were derived from recycled orogen provenance. Petrographically, the sandstone of the Siwalik Group delineates different microfacies including mainly sub-litherenites to sub-arkose with minor quartz-arenite, litharenite, feldspathic-litharenite, and lithic-arkose. The increasing proportion of biotite and feldspar and decreasing textural maturity of mineralogy in sandstone from the Lower Siwalik to sandstone of the Middle Siwalik indicates the tectonic unstability, shifting of block provenance from low grade to high grade and earlier sedimentation of detrital grains in the Lower Siwalik sandstones from the distant block provenance respectively. The abundance of monocrystalline quartz grains are common in sandstone of both the Siwalik Group units shows the igneous intrusion in related block provenance. The provenance of the sandstones of the Lower Siwalik and the Middle Siwalik was from mixed type sources, most probable from the Lesser Himalaya and the Higher Himalaya.

Miocene paleo-elevation constraints in the Tibetan Plateau: constraints of deuterium isotope from the Greater Himalayan Complex

Wentao GUO[1]*, School of Earth and Space Sciences, Peking University (2421872153@qq.com)
Bo Zhang[2], School of Earth and Space Sciences, Peking University

Abstract

The study of the Tibet Plateau is an important focus in the field of earth science, and the uplifting history and mechanism of the plateau are important and fundamental issues. By studying the paleo-elevation, the surface uplift can be reflected, the uplift mechanism can be tested, and the uplift history of the plateau can be reconstructed. However, the Tibetan Plateau has a large number of blocks with different uplifting properties, and different paleo-elevation records can only explain the uplifting history of a single block. Consequently, we require a great amount of paleo-elevation data in different regions to reflect the complete uplifting history of the Tibetan Plateau.

A paleo-elevation estimate by means of stable isotope for the Tibetan Plateau is presented based on mica in mylonitic gneiss from the Greater Himalayan Complex in the footwall of the STDS in the northern Yadong area. Using microstructures, hydrogen isotope geochemistry, zircon U-Pb ages, and 40Ar/39Ar chronology of mica, we find that atmospheric fluids in this area infiltrated into STDS footwall and interacted with water-bearing silicate minerals during the deformation (~ 16-11 Ma). For paleo-elevation recovery, we refer to the stable isotope composition of paleo-atmospheric fluids from mica in mylonitic gneiss and the $\delta^{18}O$ values of near-sea level atmospheric precipitation in similar ages calculated from the autogenic carbonates in the Siwalik foreland basin at low altitudes. The difference of $\delta^{18}O$ is $-13.95\pm0.60‰$, and the paleo-elevation is 4982±214m calculated by the global isotope decline rate ($\delta^{18}O$: -2.8 ‰/km) in middle and low latitudes areas. This paleo-elevation estimate indicates that the high topography of the Himalayan orogenic belt during the Miocene has prevented the migration of moist air mass from the south to the north, resulting in a northward rain shadow, which led to the aridity of the northern Tibetan Plateau.

Bo Zhang[2], Peking University

Abstract

In Cenozoic, after the closure of the Neo-Tethys Ocean, the lithosphere of the Indian continent continued to subduct below Asia, resulting in the widespread development of alkaline, potassium, and adakitic rocks and metal deposits in the southeastern Tibet Plateau since the Eocene, which is explained as a result of the removal of the lithospheric mantle. This study compiled geochronological and geochemical data of magmatic rocks in Cenozoic collision orogeny in the southeastern Tibet Plateau, and analyzed their relationship with spatial and temporal evolution. The results of geochronology show that the age in the north shows an east-west zoning but with shorter activity period, while in the south, the age becomes younger near the shear zone and the overall period is longer. Major and trace elements indicate that the southern part of southeastern Tibet Plateau has a wider range of alkaline and potassium rock types compared to the northern part. According to Sr-Nd and zircon Hf isotopes, the contribution of mantle derived materials to the source region of granitic magma in the north is significantly greater than that in the south, while the basaltic magma source region in the north shows sustained depletion and corresponding enrichment in the south. Overall, this phenomenon may suggest the addition of depleted components in the north and strong crust mantle interactions in the south. Geophysical observations indicate that as the thickness of the crust decreases from north to south, the range of the asthenosphere mantle increases, indicating differential lithospheric removal between north and south in the southeastern Tibet Plateau. This may provide space for the southward movement of hot mantle flow and ultimately affect surface processes in the region such as the activity, connection of shear zones and block rotation.

New lithostructural map of the Doropo region, northeast Côte d'Ivoire: insight from structural and aeromagnetic data

ZIANDJEDE HERVE SIAGNE[1]*, INSTITUT NATIONAL POLYTECHNIQUE FELIX HOUPHOUET-BOIGNY (siagneh@gmail.com)
Tahar AÏFA[2], Université de Rennes 1
Alain Nicaise KOUAMELAN[3], Université Félix Houphouët-Boigny
Wilfried DIGBEU[4], Université de Man

Abstract

This study, performed in the Doropo region (northeastern Côte d'Ivoire) in the Paleoproterozoic domain (southern part of the WAC), aims to produce a detailed lithostructural map of this area. The geology of this region is less known due to the thick lateritic overburden and the scarcity of outcrops. Recent airborne geophysical data (aeromagnetic) integrated with field structural and lithological observations allowed to distinguish several lithologies including biotite granite, gneissic and migmatitic granite, granodiorite, tonalite, gabbro, amphibolite, rhyolite and dolerite. Filtering techniques of derivatives, upward continuation, tilt, analytical signal, spectral analysis and 3D Euler deconvolution showed the presence of faults, shear zones and intrusions. The structural analysis revealed four deformation events (D1-D4): (i) D1 is a N–S compression marked by E-W foliation (S1), conjugate NE-SW and NW-SE sinistral and dextral shears, respectively, as well as F1 folds with E-W axial planes; (ii) D2 is a major transpressive phase characterized by an intense NE-SW foliation (S2), E-W dextral shear zones, a weakly dipping stretching L2 lineation plunging N-E, and NE-SW faults; (iii) D3 is a NE-SW compressional phase generated NW-SE foliation (S3) with ~E-W shears, and NW-SE axial plane F3 folds; (iv) D4 is a late, rather brittle phase characterized by brittle structures (faults, fractures, etc.) and the emplacement of NE-SW and NW-SE dolerite dykes. This tectonic evolution demonstrates that the Doropo region was subject to ductile and then brittle deformations. Furthermore, we suggest that the geodynamic model which could have prevailed in the Doropo region occurred in an oceanic arc collisional tectonic context.

Zhiliang Shi[4], Sinopec petroleum exploration and production research institute

Abstract

The formation of tectonic fracture is a product of regional tectonic stress on stratum. How to carry out quantitative prediction of fractures from the perspective of origin has always been a difficult problem and challenge in the industry. On the basis of structural interpretation of seismic data, this study utilized finite element numerical simulation methods, by simulating the distribution of stress fields during different fracturing periods, a mathematical relationship between fracture density and stress field parameters is constructed based on Hooke's law, elasticity theory, rock strain energy theory, and fracture surface energy theory. Transform the stress field simulation results into fracture density prediction results, ultimately achieving the goal of quantitatively predicting the spatial distribution of fractures. Taking the deep carbonate reservoir of Feixianguan Formation in Puguang Gas Field as an example, the fracture prediction results show that the developed fractures in the target interval are the superimposed products of the Late Hercynian and Late Himalayan periods. Among them, the Late Hercynian period mainly developed northeast oriented fractures, while the Late Himalayan period mainly developed northwest oriented fractures. In areas close to faults and folds, the maximum density of fracture development can reach 4.5 fractures/m, and there is a significant negative correlation between fracture density and distance from the fault. This method can supplement and constrain small-scale fractures, which cannot be predicted by geophysical methods. Meanwhile, it is of great significance to connect the geological modeling, characterization of fault damage zone, and numerical simulation of gas reservoirs.

Internal characteristics and main influencing factors of buried hill faults in the south Fault zone of Zhu III sub-basin, Pearl River Mouth Basin, China

zedong LIU[1]*, China University of Petroleum (zedongliu2023@outlook.com)
kongyou Wu[2], China University of Petroleum

Abstract

Background: The buried hill with oil and gas shows in the work area is controlled by faults, and no large karst caves have been developed. The reservoir is mainly of fracture type, so whether the fracture zones around the faults are developed or not and their distribution ranges are great influenced on the favorable reservoirs.

Methods: (1) Using Landmark software to make structural interpretation and MOVE software to recover the history of structural evolution. (2) Through the observation of cores combined with the preference of logging curves (sonic differential time, resistivity, natural gamma, density, etc.) to establish a model of the faults (fault core + fracture zones). Then use the likelihoods and curvature attributes to portray the fault structure. (3) In addition to the qualitative description of the influence of lithology and burial depth on the internal structure by means of coring and logging, we focus on exploring the influence of fault activity (fault distance, fault activity intensity, etc.) on the development of the internal structure.

Results: (1) We obtained the planar and spatial distribution characteristics of strata and faults in the work area, and drew the structural evolution diagrams. (2) The "binary structure" of the basement location faults is generally developed with both fault cores and fracture zones, and the fault cores have structural Breccia developed, and the fracture zones have network fractures developed. The density, acoustic time difference and natural gamma values of the fault core are slightly larger than those of the fracture zone, and the RTC curve of the fault core is flat, and the curve of the fracture zone part of the curve varies drastically. (3) The maximum likelihood attribute and curvature attribute show that the fracture zones in the deep part of the fault are wider than those in the shallow part, and the fracture zones are more developed in the stress-concentrated parts of the fault such as turning, convergence, and bifurcation. (4) The paleo fall and fault activity rate of the Cenozoic are calculated isometrically on the strike, and show that the thicknesses of the fault cores and the fracture zones are positively correlated with the strength of the fault activity.

Abstract

Multiple superimposed tectonic activities often occur in nature. Many studies have shown that there is mutual influence between multiple superimposed tectonic activities, and the importance of each tectonic activity during basin formation and evolution varies. In this study, physical simulation experiments were conducted to explore the mechanism of Central Africa Bongor Basin's superimposed evolution through two rifting events and one reversal event models. In the experimental design, steel plates were used to simulate rigid basement in the crust; silicone gel was used to represent the overlying soft layer; and quartz sand was used to simulate sedimentary strata. This model aims to reveal the dynamic process of rift basin formation and evolution. It is found that the initial morphology of the basin is mainly controlled by the first rifting event, laying a framework for the basic morphology of the basin. The subsequent second rifting event carried out further topographic transformation on this basis, but its influence on the basin's morphology was relatively weak. In contrast, later reversal events did not have a significant impact on the overall structure of the basin, highlighting the decisive role of early rifting events in basin evolution. The physical simulation results of this study provide intuitive experimental support for understanding the formation and evolution process of Bongor basin in Central Africa, also similar rift basins. The results also highlight the dominant role played by early rifting in the development history of the rift basin.

Abstract

As a significant part of Himalaya-Tethys tectonic domain and the largest Mesozoic marine oil-bearing basin in China, the Qiangtang basin has experienced complex tectonic evolution. Despite significant efforts and extensive thermochronological research, including apatite and zircon fission track as well as (U-Th)/He analyses, controversies persist regarding the Qiangtang Basin's uplift and exhumation processes since Cretaceous. Here we summarize all available thermochronological data from the Qiangtang basin. The data reveal a pattern where older ages are concentrated in the central Qiangtang terrane, gradually becoming younger southward and northward. Regional thermal history reconstruction reveal three periods of rapid cooling stages: Early Cretaceous (140-100Ma), Paleocene-Eocene (65-45Ma) and late Oligocene (25Ma), and exhumation's initiation time progressively decreases from the center towards the south and the north. The exhumation history coincides with hydrocarbon accumulation. The first exhumation event is in response to the Lhasa-Qiangtang terrane collision. The main faults and folds are basically formed during 180-140Ma, which provides good conditions both for trap and migration of the late Jurassic hydrocarbon accumulation. The second and third exhumation events may be contributed to the collision between Indian and Asian plates and the Indian plate's subsequent continuous northward subduction, which corresponds to the destruction or secondary accumulation of oil and gas since the Cenozoic, forming the present complex tectonic pattern and affecting the distribution of ancient reservoirs.

Zircon U-Pb geochronology of the weathering crust from Permian Maokou Formation, Western Hubei Province and its indication for Emeishan volcanic activity

Yaxian GAO[1]*, Key Laboratory of Tectonics and Petroleum Resources, China University of Geosciences, Ministry of Education, Wuhan 430074, China (Gyx@cug.edu.cn)
Xiang GE[2], Key Laboratory of Tectonics and Petroleum Resources, China University of Geosciences, Ministry of Education, Wuhan 430074, China
Chuanbo SHEN[3], Key Laboratory of Tectonics and Petroleum Resources, China University of Geosciences, Ministry of Education, Wuhan 430074, China

Abstract

The Dongwu movement during the Permian is one important tectonic event in South China Block. Because of different regional tectonic settings, various stratigraphic contact relationship, such as disconformity, conformity and unconformity, exits in different geological areas. The nature, timing and dimension of the Dongwu movement is still under controversy. The weathering crust section at the top of the Permian Maokou Formation in Lianziya, northern margin of the Yangtze plate, is an ideal object for determining the nature of the Dongwu movement. In order to find out the provenance of the weathering crust and provide new evidence of chronology for the Dongwu movement, the zircon U-Pb chronology, whole-rock major elements, trace elements and rare-earth elements analysis were conducted.

The results of geochemical analysis show that the claystones characterized by medium SiO2 content (average 42.54%) and enriched in light rare earth elements with weak negative Eu anomaly, presenting uniformity with the previous results of Emeishan Large Igneous Provinces. Combined with the published data of Emeishan basalts, the enrichment trend of major and trace elements and rare earth elements in samples displaying similar geochemical characteristics of Emeishan high Ti basalts. The LA-ICP-MS zircon U-Pb isotopic dating reveals that the weathering crust was formed during ~263Ma-259 Ma, which is consistent with the formation age of the Large Igneous Province(~263-257 Ma). The results show that the Emeishan basalts provide the source for the formation of weathering crust, and the continuous formation time of the Lianziya weathering crust indicates and constrains the time of the Dongwu movement. It is also a response to the Emeishan Large Igneous Province.

Development Characteristics and Formation Evolution of Cambrian Strike-Slip Faults in the Gaoshiti-Moxi Area, Sichuan Basin, SW China

Ruifeng Wang[1]*, China University of Petroleum(East China) (rfengwang@163.com)
Yangwen Pei[2], China University of Petroleum(East China)
Qingqi Zhao[3], China University of Petroleum(East China)
Zhengshuo Miao[4], China University of Petroleum(East China)

Abstract

Gaoshiti-Moxi area is located in Sichuan Basin, and its Cambrian strata contains rich oil and gas. However, the development of strike-slip faults is complex and diverse due to multi-stage structural superposition, which limits the progress of oil and gas exploration and development. Therefore, based on high-precision three-dimensional seismic data and drilling data, the development characteristics and formation and evolution process of Cambrian strike-slip faults are determined by using seismic attribute calculation, detailed structural interpretation, and analysis of the episodes of faulting. Through ant tracking technology and detailed interpretation of strike-slip faults, the geometric characteristics of strike-slip faults are defined. The faults in the Gaoshiti-Moxi area exhibit two common styles: highly steep vertical structures and flower-like formations, and they show significant variations in fault displacement across different horizons, with most terminating in the Cambrian system. On the plane, three groups of faults trend predominantly in the EW, NE, and NW directions, and there are three typical combination styles of horsetail structures, conjugate shear structures and en echelon structures. By analyzing the activity, nature and geometric characteristics of strike-slip faults in the Gaoshiti-Moxi area, the formation and evolution of strike-slip faults in the Gaoshiti-Moxi area can be divided into Caledonian, Hercynian and Indosinian-Yanshanian periods. Research indicates that during the Sinian period, the Gaoshiti-Moxi area experienced basement faults trending predominantly in the EW and NE directions, which control the tectonic evolution of the overlying layers. During the Caledonian period, the Gaoshiti-Moxi area was under the dynamic setting characterized by NE-trending oblique tension due to the influence of ground fissure activity and cratonic rifting. Under this background, the basement fault generated a tensional torsional strike-slip fault in the Cambrian strata, distributed along the near EW, NW and NE directions, with significant fault displacement and strong activity, and terminated in the Cambrian. During the Hercynian period, affected by Emei mantle plume and Emei volcanic activity, the Gaoshiti-Moxi area was in the dynamic background of NNE extension. Some of the strike-slip faults formed during the Caledonian period were reactivated to form Hercynian faults, which extended from the Cambrian to the Permian, mainly in the near EW and NE directions, with less activity. During the Indosinian-Yanshanian period, the Gaoshiti-Moxi area underwent NW compression. The deformation generated in the Cambrian overlying strata is transmitted to the Cambrian through the plastic layer, forming a large number of secondary faults, which are widely distributed in proximity to the Caledonian and Hercynian strike-slip faults.

Lihua YANG[7], State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University

Abstract

Fluid diapirs are widespread in the northern South China Sea (SCS), are significant indicators of the existence and distribution of hydrocarbons and natural gas hydrates and are of great petroleum geological significance. Based on high-precision 3D seismic and drilling data, this paper analyses the tectonic features and genetic mechanism of a fluid diapir zone in the northern SCS, and a development model of fluid diapirs is proposed herein. Studies have revealed that the northern SCS large-scale fluid diapir zone is located within a concealed structural transition zone, which is consistent with the spatial distribution location and direction of a concealed structural transition zone and that the formation of a fluid diapir zone is strongly influenced by the structural transition zone. Fluid diapirs are large continuously spreading bright reflection zones in shallow surface layers and are downwards converging high-variance ribbons in middle and shallow layers, all of which are spreading in a NW-NNW orientation on the plane. The profile shows a conical or mushroom-shaped shape that converges from shallow to deep, with a height of approximately 7 km, and is characterized by a compound gas chimney fuzzy zone. The main body of the concealed structural transition zone is a slope structure and is flanked by large-scale NW-NNW-oriented fault systems. Minor en echelon spreading NW-NNW-oriented faults and fractures are developed within the structural transition zone and are soft linkages that match well with the distribution direction and location of the fluid diapirs. On the profile, the overall display is a composite flower-like structure dispersed from deep to shallow, which belongs to a large strike-slip fault zone with a tectonic transformation effect. A comprehensive analysis suggests that the formation and development of the structural transition zone are mainly controlled by preexisting structures in the basement and that minor faults, fractures, and slope zones within the structural transition zone serve as dominant pathways for the migration of deep overpressure fluids and gas hydrates. Consequently, the concealed structural transition zone provides favorable conditions for fluid

diapirs to develop. Moreover, the stratigraphic overpressure systems mainly caused by gas generation provided the main driving force for the formation of fluid diapirs. Obviously, the development location, distribution direction, formation, and evolution of the northern SCS fluid diapirs are jointly controlled by internal minor faults and fractures of the Eocene-Miocene structural transition zone and the overpressure of the rifting period after the Pliocene. The main development period of the northern SCS large-scale fluid diapirs was the second phase of the Dongsha Movement. During the exploration of gas hydrates and hydrocarbons in the PRMB, it is essential to consider the mutually restricting relationships between fluid diapir structures and gas hydrates and hydrocarbons.

The impact of fracture development patterns under tectonic influence on hydrocarbon productivity in the Bozi-Dabei region

GUANNAN ZHONG[1]*, zhongguannan0612@163.com (zhongguannan0612@163.com)
[2], zhongguannan0612@163.com

Abstract

The Bozi-Dabei region is located in the western part of the Kelasu tectonic belt in the Kuqa depression. Under the joint control of the Tianshan orogeny and the rotation of the Tarim plate, the tectonic system undergoes passive strike-slip and thrust imbricate fan tectonic system that cut through the basement on the basis of thrust, resulting in complex fracture development under structural control. Based on the latest seismic, outcrop surveys, core and imaging logging data, the development characteristics of fractures at different structural positions were studied. The strain situation of faults and their surrounding areas under the influence of different horizontal forces, rock types, fault dip angles, and distance from the fault plane were simulated using Comsol finite element software. The development patterns of structural fractures under different control factors were analyzed. Based on the above research, the distribution pattern of fractures was systematically summarized and analyzed from a geological perspective. At the same time, from a geometric perspective, parameters such as fracture density, fracture opening, fracture length, fracture morphology, maximum geostress direction, and the angle between fracture strike were considered as the research objects. Through the CRITIC weight method, a set of fracture development evaluation standards was studied and formed. Finally, a mechanism model was established to study the impact of reservoirs on production capacity under different fracture development evaluation standards, in order to guide the subsequent development of oil and gas reservoirs in the Bozi-Dabei area.

Characteristics of the Meso-Cenozoic fracture system in the Xihu Sag and its control of the basin

Jinhang Zheng[1]*, China University of Petroleum,Qingdao,China (770593515@qq.com)
Zhiping Wu[2], China University of Petroleum,Qingdao,China

Abstract

The Xihu Depression is in the eastern depression of the East China Sea shelf basin, controlled by the tectonic domain of the Pacific Ocean, the Tethys-Himalayan tectonic domain and the deep crust-mantle action, and has experienced the tectonic evolution process with multiple phases, multiple dynamics, and multiple natures. The basement of the Cenozoic basin in the Xihu Depression is not a flat plate, and the pre-existing basement fractures affect the tectonic structure of the Cenozoic basin. The evolution of the Cenozoic basin has gone through the stage of cleavage and tensioning and extrusion reversal, and there are three sets of basement pre-existing fractures, cleavage and tensioning fractures, as well as the reversal of extrusion and fracture systems. The basement pre-existing fracture system mainly consists of NW-directed fractures, which cut deeply into the basement downward, and most of them do not cut through T30 upward; the rift-tension fracture system consists of NE-directed and NS-directed fractures, which cut downward to the basement, and most of them terminate at T21 upward; the reversed extrusion fracture system consists of longitudinal tensile, transverse tensile, and inverse fractures generated by extrusion, and the transverse tensile fracture develops in the period between T10 and T30, which is suspended above the rift-tension fracture system, and the transverse tensile fracture develops in the period between T10 and T30. Transverse tension fractures are developed between T10 and T30, hanging over the fracture system, longitudinal tension fractures can cut up to T12, and reverse fractures are mostly developed in the wings of the backslope, cutting up to T12.

The NW-directed basement fractures were resurrected to a certain extent in the Cenozoic, which played a transforming and regulating role in the Cenozoic basin, leading to the north-south zoning and segmentation of the slope zone and inversion zone; the NE-directed fracture activity rate was large during the depositional period of the former Pinghu Formation and the vertical activity was stronger than that of the NS-directed faults, and the near-NS-directed fracture activity rate during the depositional period of the Pinghu Formation was large, reflecting the tendency of the shift from NE to near-NS, and the spreading of depositional centers was controlled by fracture activities, which also experienced the shift from NE to near-NS. The spreading of the sedimentary center was controlled by the fracture activity, which also experienced the change from NE to NS direction. The change of the subduction direction of the Pacific plate from NNW to NWW is the main reason for the change of the extension stress direction of the Xihu depression. The extrusion of the Miocene Longjing movement led to the development of the central backslope belt, and the number of longitudinal and transverse tension fractures associated with the formation process correlates well with the fold amplitude of the central backslope belt.

Characteristics of Unconformity and its Control on Buried Hill Hydrocarbon Reservoirs: A Case Study from the Qiongdongnan Basin, South China Sea

Yanying LI[1]*, China University of Petroleum (East China) (b18010016@s.upc.edu.cn)
Kongyou WU[2], China University of Petroleum (East China)
Yannan DU[3], China University of Petroleum (East China)

Abstract

The T60 unconformity in the Qiongdongdong Basin, as the boundary between the Paleocene and Neocene, witnessed the transition of a faulted basin into a depression basin, and the T100 unconformity, as the basement unconformity, is clearly manifested in the whole basin, and the basin began to develop gradually above it. After years of hydrocarbon exploration, the work in non-structural traps has achieved significant results in Qiongdongnan Basin, and the buried hill hydrocarbon reservoirs have gradually become the focus of offshore oil and gas exploration, but the insufficient study of the structural characteristics and distribution range of the unconformity restricts the development of the exploration. This study combined the seismic data interpretation and logging identification technology to conduct a comprehensive study on the unconformities of T60 and 100, in order to explore the role of the unconformity structure in hydrocarbon formation. This work is crucial for guiding the evaluation of the unconformity reservoirs and the deployment of exploration. The research has three outcomes. (1) The T60 unconformity structure is intact, the thickness of weathered clay layer is 3-6m, the T100 unconformity weathered clay layer can reach a thickness of 8m, and the thickness of weathered clay is negatively correlated with the thickness of the leached layer. (2) The unconformity structure plays a controlling role in hydrocarbon formation in the area. The upper and lower layers of the structure can be the storage spaces or migration channels for oil and gas, and the weathered clay layer with a thickness of over 3m can seal natural gas. (3) The reservoir formation model in the Yacheng area can be summarized as "dual source hydrocarbon supply, composite stepped transport, and structural + stratigraphic trap hydrocarbon accumulation".

The in situ stress field and microscale controlling factors in the Bozhong depression, Bohai Bay Basin

Guanjie ZHANG[1]*, School of Earth Resources, China University of Geosciences, Wuhan 430074, China (zgj199688@163.com)
Jingshou LIU[2], School of Earth Resources, China University of Geosciences, Wuhan 430074, China
Chuanbo SHEN[3], School of Earth Resources, China University of Geosciences, Wuhan 430074, China

Abstract

To ensure the effectiveness of fracturing treatment and improve the production metamorphic basement reservoirs of individual wells, it is important to accurately predict the in situ stress distribution to prevent the collapse of horizontal wells. under similar structural environments, microscopic factors, such as reservoir and petrophysical characteristics, are often the key factors that affect reservoir fracturing differences and drilling design in same well areas. Therefore, we need to clarified the in situ stress characteristics of metamorphic basement reservoirs and microscale controlling factors. Here, we have determined the three-dimensional distribution of in situ stress in the Bozhong depression, Bohai Bay Basin through the finite element numerical simulation method and revealed the influencing Factors. By establishing a maetamorphic basement reservoir heterogeneity model and a geomechanical heterogeneity model and with the finite element method, the 3D distribution of maetamorphic basement reservoir in situ stress can be predicted, and the effects of the maetamorphic basement reservoir rock density, clay content, rock acoustic velocity and mechanical properties on the in situ stress can be clarified. The results show that: The in situ stress of Bozhong depression, Bohai Bay Basin is generally normal fault type. The horizontal maximum principal stress is between 105-130 MPa, and the horizontal maximum principal stress is between 80-105 MPa, the horizontal stress difference (Δσ) is between 15-25 MPa, and horizontal principal stress difference coefficient (Kh) is between 0.31-0.44 MPa. The clay content is found to be negatively correlated with the Δσ and Kh. The relationships between rock density and Δσ and Kh feature a two-stage pattern. Acoustic velocity has a great influence on Δσ and Kh, but the effects of P-waves and S-waves on Δσ and Kh are different. Rock mechanics parameters has a great influence on Kh, and a little influence on Δσ.

GEOLOGICAL ANALYSIS OF THE DEVONIAN COMPLEX IN THE SOUTHERN PART OF THE CASPIAN BASIN (KAZAKHSTAN)

Aliya ABILGAZIYEVA[1]*, Yessenov University (aliya-abilgaz@mail.ru)
Araibek Zhiyengaliyev[2], Atyrau Oil and Gas University named after S.Utebayev
Sofia Nursultanova[3], Atyrau Oil and Gas University named after S.Utebayev
Yerassyl Anepiya[4], Atyrau Oil and Gas University named after S.Utebayev

Abstract

In recent years, a new stage of research has emerged, focusing on the study and assessment of the oil and gas potential of Paleozoic deposits in the Caspian Basin at significant depths. This stage is characterized by increased interest in deep-lying Paleozoic sediments. In addition to the more accessible lateral parts, structural-tectonic and spatial models of the deeper inner parts of the Caspian Basin have been investigated. This new stage has been made possible by improved technical means and new methods of processing and interpreting geological and geophysical data.

The study of deep-seated sediments in the Caspian Basin, including the Devonian complex, has attracted attention due to their regional distribution, diverse lithologic-facies composition of sections, high differentiation, and unique variety of accumulation conditions, leading to the development of models of Paleozoic sedimentation. This paper reviews various geological and geophysical methods for studying the areas adjacent to the southern and southeastern parts of the Caspian Basin rim.

The results of a comparative analysis of drilling data, seismic surveys, and complexing of potential field data for the Paleozoic complex of the southern part of the Caspian Basin allow us to make positive forecasts for the discovery of significant hydrocarbon accumulations at great depths.

Integrating data obtained from different methods contributes to the formation of more accurate ideas about the geological structure and oil and gas potential of the Caspian Basin. Further studies and integrated data analysis will allow us to deepen our understanding of sedimentation processes, structural features, and conditions of formation of hydrocarbon deposits in this region. The importance of such studies lies not only in their practical significance for the exploration industry but also in expanding theoretical knowledge of the geological history and development of the Caspian Basin in the Paleozoic.

Characterization of the Deformation and Formation Evolution of Mud Diapir Structure in the Rel Del Rey Basin, Niger Delta

Jixin ZHANG[1]*, China University of Petroleum (2019017@sdipct.edu.cn)
Yangwen Pei[2], China University of Petroleum(East China)
Yixin Yu[3], China University of Petroleum, Beijing

Abstract

The Rel Del Rey Basin in the northeastern Niger Delta underwent by multiple phases of tectonic superposition evolution, resulting in the large-scale development of mud diapir structure in the Akata Formation mudstones. This process had a significant impact on the formation of traps, reservoir development, and the migration of oil and gas, which are elements crucial to petroleum accumulation. However, there is still controversy over the mechanisms and stages of mud diapir formation and evolution in this area. To address this issue, this study collected seismic and well logging data and conducted balanced cross-section restoration alongside physical simulation experiments. The experimental results precisely identified the deformation characteristics of mud diapir structures and variations in surrounding strata thickness, thus uncovering the evolutionary processes of mud diapirs along with their controlling factors. The results show that: (1) The mud diapir structure mainly experienced three evolutionary stages: the initial depositional-weak activity period before the middle Oligocene, the strong uplift activity period in the Late Oligocene-Middle Eocene, and the weak activity-overall burial period from the Pliocene to the present, and the basin is characterized by the multi-phase activation of the orthogonal faults. (2) The development of the mud diapir structure was influenced by gravity sliding and differential loading of the overlying strata, in addition to the Atlantic Transform Fault in the southeastern part of the basin and the sub-mud basement rupture. (3) Influenced by the mud diapir structure and the development of faults at the top, the main reservoir in Agbada Formation often develops backslope, broken backslope and fracture block closure at the top of the mud diapir structure, and also develops the lithological shield closure at the periphery of the mud diapir structure, which provides a good place for the gathering of hydrocarbons. In addition, the flanks of the mud diapir structure and the related faults can be used as good oil and gas transportation channels, which are favorable for the oil and gas generated from the hydrocarbon source rocks of the Akata Formation to be transported to the reservoirs of the Agbada Formation.

The development characteristics and genetic mechanisms of inversion tectonics in the northern part of the Yinggehai Basin

qingbo WU[1]*, China University of Petroleum (East China) (W17864205620@163.com)
zhiping wu[2], China University of Petroleum (East China)

Abstract

The Yinggehai Basin is a Cenozoic sedimentary basin developed in the western region of the northern continental shelf of the South China Sea. It is located at the intersection of the Eurasian Plate, Pacific Plate, and Indo Australian Plate. Affected by the activity of the Red River fault zone, it is generally distributed in a NW diamond shape, and has undergone multiple important tectonic movements in the Cenozoic Era, resulting in the development of inversion tectonics in the region. Its northern region covers the Hanoi area and the Lingao area. The latest three-dimensional seismic data and drilling data indicate that the northern region of the Yinggehai Basin experienced a significant tectonic inversion process in the Neogene. The Hanoi area in the northern part of the research area has developed three types of positive inversion structural styles: propagation type, back thrust fault type and fold type, with the inversion time of the Late Miocene. According to the recovery of the balanced profile, its positive inversion lateral compression rate is 14.15 percent. The Lingao area in the southern part of the research area only develops fold type positive inversion structural styles, with the inversion time of the Middle Miocene and a lateral compression rate of 2.57 percent. Compared with the Hanoi area, it has the characteristics of earlier inversion time and lower inversion intensity. The northern part of the Yinggehai Basin is located in the NW-SE to nearly NS trending transition section of the Red River fault zone, with a tectonic inversion time of the Middle to Late Miocene, corresponding to the left-right transition stage of the Red River fault zone. It is inferred that the pressure increasing effect of the fault bending section is the main factor leading to the inversion process.

Analysis of effects of activities of Zahedan and Nosratabad faults on deformation and displacement dikes into zahedan poloton.(southeast of iran))

Zahra IRANI[1]*, Golestan.gu.ac.ir (zahrairani136464@gmail.com)
Aliasghar Moridi[2], Geology Department of sistan and Balochistan
Habib Biyabangard [3], Geology Department of sistan and Balochistan

Abstract

Dikes are keys for realize geological problems, using of this structure help us to understand the regional tectonics. Zahedan granitoid (part of the granitoed Zahedan - Saravan)is located between two faults, Nosratabad and Zahedan in the southeast of Iran that interrupted by anumerous dikes that petrogherphcaly are within the granodiorite to diorite ,these faults belong to fault system East with approximate N-S along a strike-slip action. Activities of these fault make a shear zone in this area . granitoid and dikes are informed by the activities of them. These dikes injected into pre-existing crack that are created by fualts (Zahedan and Nosratabad) activities. Evidences of activities of fault are seen in two scale macroscopic and microscopic.These structures parallel extensions and cross layers in some area. lakhshak poloton is a part of this set located in tip of the zahedan fault . Dikes that injected into Lakhshak poloton
are mainly diorite and granodiorite in composition and consist of plagioclase, biotite, hornblende and quartz.
The deformation evidences are quartz microboudines, mica fish (especially in biotite), and fractures in minerals, inflation in quartz, asymmetric porphyroclasts, preferred orientation and rotation of minerals. These
evidences show that the dikes suffered from brittle to ductile deformation.the microscopic evidencese are seen in Satellite Images and fild.

A Preliminary Study on the Sediment Source of the Maérzheng Formation in the Southern Margin of the East Kunlun Region, China

Lei PEI[1]*, 18810552917 (peilei.1989@163.com)

Abstract

The Buqingshan tectonic mélange played an important role in the tectonic mélange of the southern margin of the East Kunlun. It was formed during the long-term subduction of the Tethys oceanic lithosphere plate from south to north during the Early Paleozoic to Late Paleozoic. Seven different types of rock blocks of the tectonic mélange have been identified within the Buqingshan tectonic mélange zone. The rock blocks mainly include Haerguole ophiolite, Delisitan ophiolite, Delisitan granodiorite, Gerizhuotuo dacite and tuff, combination of limestone and basalt and lower Permian Maérzheng Formation. In order to study the sedimentary source and sedimentary tectonic setting of the lower Permian Maérzheng Formation in the southern margin of East Kunlun, we conducted a detailed study on the sedimentary stratigraphic division, sedimentary environmentand detrital zircon U-Pb geochronology were taken for the Lower Permian Maérzheng Formation in Gerizhuotuo area in the southern margin of East Kunlun. The results indicate that the Maérzheng Formation is a turbidite series formed in a semi deep-sea to deep-sea environment on a continental slope. Detrital zircon U-Pb age spectrum can be clearly divided into two main age spectrum: Early Paleozoic and Neoproterozoicand two secondary age spectrum: Paleoproterozoic and Mesoproterozoic. The main age spectra are 396-573 Ma and 727-947 Ma, respectively, with peak ages of 421 Ma and 862 Ma. The secondary age spectra are 1117-1993 Ma and 2319-3063 Ma, respectively, with no significant peak age. This study suggests that the sedimentary source of the Maérzheng Formation in the southern margin of the East Kunlun are relatively complex, indicating the characteristics of joint supply of sedimentary sources from multiple times including the Early Paleozoic, Neoproterozoic, Mesoproterozoic and Proterozoic. The Early Paleozoic and Neoproterozoic magmatic rocks in the East Kunlun orogenic belt provide about 60-65% of its sediment sources, while the ancient metamorphic basement provides only about 30-35% of its sedimentary debris for Maérzheng formation. Combined with previous data, we suggest that Maérzheng Formation formed in extensional system related to the passive continental margin tectonic setting.

Tectonic significance of the Early Paleozoic ophiolite in the Central East Kunlun orogenic beltChina

Wei DU[1], chang'an university
Lei Pei[2]*, chang'an university (Peile.1989@163.com)

Abstract

The ophiotes are fragments of oceanic ithospheres that provide abundant evidence for studying the evolution history of ancient oceanic and continental margin basins. The latest research results on ophiolites in orogenic belts indicate that they are mostly formed in the tectonic environment of oceanic subduction zones (SSZ type) and oceanic spreading ridge (MORB type).

The East Kunlun orogenic belt is located in the northern part of the Qinghai Tibet Plateau and is a composite continental orogenic belt that has undergone multiple tectonic movements. Previous studies on the chronology and geochemistry of the Central East Kunlun orogenic belt ophiolite have been conducted. There are still controversies regarding the tectonic environment and magmatic source. Along Central Eastern Kunlun zone, the ophiolites in Xiarihamu and Dagele areas are composed of serpentinized dunite, gabbro, and eclogites. Based on the previous studies of petrological and geochemical characteristics, it is inferred that the original rock of eclogite is basalt.

The MgO, SiO2, and TiO2 contents of eclogite are 5.58% to 8.63%, 46.79% to 51.10%, and 1.06% to 1.30%, respectively, which are equivalent to island arc calcium alkaline basalt. The SiO2 and MgO contents of gabbro are 45.54% to 49.49% and 6.51% to 13.59%, respectively. The Al2O3 content is relatively high, ranging from 12.44% to 19.37%. The SiO2 content of serpentinite dunite ranges from 39.87% to 41.82%, while the MgO content ranges from 28.53% to 35.95%. The content of TiO2, CaO, and Al2O3 is relatively low, ranging from 0.11% to 0.56%, 1.32% to 4.15%, and 1.48% to 4.30%, respectively. The geochemistry of trace elements shows rocks are relatively enriched in large ion lithophilic elements such as Rb, Sr, U, while depleted in Zr, Hf, Ta, Nb, Ti, suggesting that they were formed in an island arc environment. In addition, the Th/Yb, Th/Nb, and Hf/Th ratios of eclogite and gabbro are 0.12 to10.11, 0.11 to 2.58, and 0.22 to 3.89, respectively, indicating the characteristics of island arc basalt. In the discrimination diagram of Zr/Y-Zr, Ti/100-Zr-3Y, MnO-TiO2-P2O5 structures, the sample points all fall into the area of the island arc. The above results indicate that the ophiolites in the Xiarihamu and Dagele areas are SSZ type.

Combining this achievement with previous data, the early Silurian island arc type granite belt within the Central Eastern Kunlun zone proves the subduction of oceanic crust and island arc magmatic activity during this period. The Late Ordovician Early Silurian marine volcanic rocks were formed in a back arc basin environment. The basic rock veins exposed in the Central Eastern Kunlun tectonic zone represent the latest magmatic record of oceanic crust subduction. The ages of the ringed granite and monzonite formed in the continental collision, the metamorphic ages of the amphibolite facies, and the metamorphic ages of the eclogite are all between 411.1 to 437.6

Ma, reflecting the final closure of the East Kunlun Ocean Basin in the early Middle Silurian.

Boundary effects in the evolution of the deformation and stress field of southern Andean plateau, southern central Andes (26°30´–27°30´S)

Rodrigo QUIROGA[1]*, IANIGLA-Conicet-Argentina (rquirogo@gmail.com)
Laura Giambiagi[2], IANIGLA-Conicet-Argentina
Andres Echaurren[3], IANIGLA-Conicet-Argentina

Manfred Strecker[7], Institut für Geowissenschaften, Universität Potsdam

Abstract

We present a study in the southern Puna region in the southern central Andes (26°30´–27°30´S), aiming to explore the late Cenozoic evolution of the deformation and tectonic stress field during the uplift of the southern border of this plateau. The results correspond to structural field-observations, U-Pb ages, reduced paleostress tensors obtained from fault-slip data, and balanced geologic cross-section. We compare the compression directions from the paleostress analysis with field observations that can help identifying the age of the different deformational events, considering the absolute and relative ages of deformed and non-deformed stratigraphic units and cross-cutting relations between the analyzed faults.

Integrating the data here presented with previously published geologic information, we propose a structural conceptual model that document the spatio-temporal evolution of the deformation and predominant stress field model over the past 24 million years, separated in four stages.

Stage 1, in the late Oligocene to middle Miocene, the region experienced east-west compression and thrust-faulting with an E-W orientation; Stage 2 from middle to late Miocene, a transition to thrust-faulting/strike-slip deformation is observed, while Stage 3, from late Miocene to early Pliocene, showed a further shift in the stress field, resulting in a combination of strike-slip and thrust-faulting; finally, stage 4, from late Pliocene to Quaternary, featured a dominance of strike-slip regime.

Our results show that the type of stress field in each stage is associated with the orogen's internal structural anisotropies, like the nature of the structural systems on each morphoteconic units defined in the southern central andes, and its evolution in the space and time. Vertical stress magnitudes increased due to cortical thickening and topographic uplift of the plateau, and varies in magnitude across the borders, creating topographic gradients. Horizontal stress variations occurred by rotations caused mainly by an edge effect resulting from the growth of the plateau and transference of gravitational potential energy, while it reaches a critical crustal thickness and elevation. This leads to a transfer of compression from high-lying areas to lower regions. The southernmost Puna region shows no significant evidence of normal faulting, suggesting it isn't undergoing orogenic collapse within a regional tensional stress regime, differing from observations in the Altiplano to the north, as well as in the Tibetan plateau.

Fractal Dimension Analysis in Breccias of the Colombian Emerald Belts

Camilo Andrés BETANCUR[1]*, Center of Technological Development of the Colombian Emerald (cabetancura@unal.edu.co)
Andreas Kammer[2], Universidad Nacional de Colombia
Javier Toloza[3], Center of Technological Development of the Colombian Emerald

Abstract

This study analyzes the fractal dimension in the breccias of Colombia's emerald belts through the analysis of 2506 rock fragments (880 from the eastern belt and 1626 from the western belt). Fractal dimension analysis was applied to investigate the size distribution of the clasts (Ds), revealing the geometric complexity of the breccias, which is related to the mechanical energy to which the rocks were subjected. Additionally, the fractal dimension of the roughness of the breccias (Dr) was calculated, indicating the interaction of the fragments with the surrounding hydrothermal fluids. The results show that the western emerald belt (WEB) exhibits higher fractal dimension values in the size distribution of the clasts (Ds), suggesting generally higher mechanical energy than the eastern emerald belt. Furthermore, in this belt, the interaction of fluids with the host rock fragments is low, resulting in a lower fractal dimension of roughness. This is consistent with a compressive structural style, where hydrothermal fluids are restricted to shear zones and fold axes. On the other hand, the eastern emerald belt (EEB) shows a higher fractal dimension of roughness (Dr), indicating a more significant interaction of the fragments with hydrothermal fluids, attributable to an extensive structural style, where hydrothermal fluids flow pervasively over the entire rock, altering the edges of the fragments, generating more complex geometries than in the WEB.

The ‘fault-controlled-fluid’ diapir in Yinggehai Basin : a new understanding based on OBN data

Chenxi Chen Ma[1]*, China University of Petroleum(East China) (1701050219@s.upc.edu.cn)
Wu Zhi Ping[2], China University of Petroleum (East China)

Abstract

Diapir is an important hydrocarbon bearing structure in Yinggehai Basin. In the past, due to the limitation of seismic and drilling data, people 's understanding of its internal structure, formation process and genetic type is not clear, which largely restricts the in-depth development of hydrocarbon exploration in diapir structure in Yinggehai Basin. Based on the analysis of 3D seismic data collected by OBN (Ocean Bottom Node) in DF1-1 diapir zone, it is shown that the diapir is obviously different from mud diapir, salt diapir and magmatic diapir, which are mainly manifested in the following aspects : (1) OBN seismic data show that the diapir core is not a blank or messy reflection of mud, salt diapir or magmatic diapir core, but has a good layered structure, continuous seismic reflection axis and corresponding extension relationship with surrounding strata. (2) Different from other diapirs, there is no obvious boundary interval between the core of Dongfang 1-1 diapir and the surrounding rock, and the existence of diapirs does not cause severe deformation of the surrounding rock. (3) The mud diapir, salt diapir or magmatic diapir zone is characterized by fuzzy anomalies such as salt bodies, mud mounds and magmas, while the Dongfang 1-1 diapir zone is characterized by multi-stage, overlapping and communicating. There are three sets of fault systems in the NS, NE and NW (NWW) directions, with a large number of faults and high density. (4) There is no deep parent rock or root zone similar to gypsum rock salt pillow, mud source layer or deep magma chamber in Dongfang 1-1 diapir. (5) The distribution of diapirs in the Yinggehai Basin reflects the ' orderliness ' under the control of faults. The diapirs are distributed along the nearly NS-trending tension-shear faults formed during the dextral strike-slip period, and are mostly developed at the intersection of active faults in each stageIn addition, it is worth noting that the abnormally high homogenization temperature of fluid inclusions, the rapid increase in the evolution of clay minerals, the development of hydrothermal minerals such as ankerite and siderite cements, and the enrichment of mantle-derived CO2 and other non-hydrocarbon gases also record the activity of upward invasion of deep thermal fluids from the diapir zone. Therefore, a new understanding that the diapir in the Yinggehai Basin is a ' fault-controlled fluid diapir ' is proposed. It is a deformation structure of the dome (or later collapse) formed by the upward flow of the pressure relief zone formed by the deep high-temperature and high-pressure gas and liquid fluids along the fault fracture zone. The new understanding of " fault-controlled-fluid " diapirs has broken through the restricted area where diapirs can only accumulate at the top and wings. The good stratification characteristics make it also have reservoir-forming conditions inside, which can form multi-layer floor gas reservoirs. This has important guiding significance for deepening and expanding oil and gas exploration in the diapir area of Yinggehai Basin.

New understanding of the evolution and structural deformation of the northern Neuquén Andes (37-38°S)

Lucía JAGOE[1]*, IDEAN (CONICET - Universidad de Buenos Aires) (lu.jagoe@gmail.com)
Martín Miguel Turienzo[2], Instituto Geológico del Sur (INGEOSUR, UNS-CONICET), Departamento de Geología, Universidad Nacional del Sur, Bahía Blanca, Argentina.
Lucía Sagripanti[3], IDEAN (CONICET - Universidad de Buenos Aires)
Natalia Paola Sánchez[4], Instituto Geológico del Sur (INGEOSUR, UNS-CONICET), Departamento de Geología, Universidad Nacional del Sur, Bahía Blanca, Argentina.

Abstract

The Guañacos Fold and Thrust Belt (FTB), located in the northern Neuquén Andes (37°-38°S; 70°30′-71°10′ W), exposes Oligo-Miocene volcaniclastic sequences corresponding to the Cura Mallín Formation. This unit outcrops on both the Chilean and Argentinean flanks of the Andean Cordillera, extending between 37° and 38° S. It encompasses a lower volcanic member and an upper sedimentary member, defined in Chile and correlated in Argentina, reaching a total thickness of up to 3000 meters. The tectonic setting during the deposition of the Cura Mallín Formation is a matter of debate. Two main hypotheses exist in the recent literature regarding this: a) syn-extensional deposition of the Cura Mallín Formation, starting at ~28 Ma, associated with a regional extension phase responsible for creating a series of intra-arc rift basins along the continental margin between 33° and 45° S. This hypothesis is based on the interpretation of a seismic line with limited resolution, where the investigators identified a basin-bounding normal fault that subsequently underwent inversion in a late-Miocene compressional stage. Hypothesis b) states a strata deposition in a compressional regime with horizontal shortening and vertical thickening, grounded in interpreted growth strata near folds and reverse faults.

This work contributes to the interpretation of the evolution of the Cura Mallín Formation with a new structural model carried out on the Guañacos FTB, where we conducted a comprehensive field mapping, identifying and documenting the spatial distribution of geological structures and the orientation of the bedding planes. Analysis of the collected data resulted in a detailed geological map and two balanced cross-sections that included the upper parts of the sedimentary member. We interpreted the deformation style of the Cura Mallín Formation in this portion of the orogen as thin-skin, with no evidence supporting either syn-extensional or syn-compressional deposition of the layers. We also calculated the shortening associated with the uplift and deformation of these sequences, obtaining results between 8,5 and 9,5 km, which we consider reasonable given the regional values provided in previous works. Furthermore, our new U/Pb ages for the Cura Mallín Formation of 15,42 ± 0,15 Ma are consistent with recent work that suggests a younger age for the formation and hence, its deformation. Hereby, our results are consistent with the post-depositional deformation occurring in the late Miocene already postulated in previous works. These findings contribute to the growing body of evidence suggesting younger deformation for these sequences, revising the previously proposed evolutionary context for the Oligocene-Miocene period in the Andes at these latitudes.

Thermokinematic 2D restoration of the Marañón Fold and Thrust Belt in the Andes along the Puchca Valley, Perú.

CRISTIAN MIGUEL MACHACA SARDON[1]*, Universidade de São Paulo (cristian.machaca@usp.br)
GINALDO ADEMAR DA CRUZ CAMPANHA[2], Universidade de São Paulo

Abstract

The Marañón Fold and Thrust Belt (MFTB) spans from northern to central Peru, the research area is located in the Puchca Valley, Huari province. The basement is composed of schists and gneiss of the Marañón complex, the Mesozoic sedimentary rocks (sandstones, mudstones, and limestones) are the most common, however, our focus lies on the Tithonian and the Berriasian because they are important to generate structures in the research area. Structurally the Tithonian and the Berriasian rocks play an important role as a detachment level, that is because are composed of black shales and carbon layers which are perfect for developing faults overlying upper Cretaceous sedimentary rocks.

Previous research on the evolution of the MFTB used structural models based on outdated geological data. Currently, the Peruvian Geological Survey (INGEMMET) is updating these maps, it has new maps at a scale of 1:50 000, in areas of more structural complexity, high-resolution maps at a scale of 1:10 000 were constructed, and this new data is useful to research the evolution of the Peruvian Andes across the MFTB.

The present research is supported by a geometric analysis to construct a geological balanced cross-section, low-temperature thermochronology, and a sedimentary analysis showing the stratigraphic variations. Currently, the study is focused on developing a thermokinematic model for the geological balanced cross sections of the MFTB, whose geometry of the structures suggests mainly a thin skin style. At the same time, towards the east, the reactivation of previous normal faults is clearer than in the west area, which suggests a thick skin tectonic, the shortening estimated is around 30 to 35% at least.

New Understanding of Late Mesozoic Structural Deformation in the South Yellow Sea Basin and Its Significance for Oil and Gas Exploration

Huang ZHEN[1]*, Tianjin Branch of CNOOC (China) Co., Ltd (huangzhen2@cnooc.com.cn)
Lv dingyou[2], Tianjin Branch of CNOOC (China) Co., Ltd
Yang haifeng[3], Tianjin Branch of CNOOC (China) Co., Ltd
Yang bo[4], Tianjin Branch of CNOOC (China) Co., Ltd
Wu qingxun[5], Tianjin Branch of CNOOC (China) Co., Ltd

Abstract

The South Yellow Sea Basin has undergone multiple cycles of tectonic evolution, with strong stratigraphic deformation and extremely complex structures. The overall quality of seismic data is poor, and there is relatively little research on the late Mesozoic tectonic deformation, resulting in unclear understanding of the tectonic deformation mechanism. Traditionally, it is believed that due to the strong compression and transformation during the Indosinian period, it is difficult to form large-scale oil and gas preservation, which has constrained the pace of oil and gas exploration in this area.

Based on gravity data, magnetic data, seismic data, drilling data, and outcrop data, we conducted regional tectonic stress, tectonic evolution history, numerical simulation, physical simulation, and structural deformation analysis, forming the following innovative understanding:

Firstly, it is proposed for the first time that the South Yellow Sea Basin underwent east-west compression deformation in the Late Mesozoic era. A large number of north-south trending wide and gentle anticlines and thrust fault systems can be identified on seismic profiles, and a series of north-south trending faults can be clearly identified on seismic variance slices. Analysis of apatite fission data suggests that this type of fault was formed during the Late Mesozoic era.

Secondly, innovate the establishment of a tectonic deformation mechanism under two periods of conjugate compression forces, pointing out the existence of two periods of compression in the South Yellow Sea Basin, namely the Indosinian north-south and early Yanshanian east-west directions.Based on Ha isotope analysis of intrusive granite, it was first discovered that there is a rigid crystalline basement of the Archean in the South Yellow Sea, which has inherent stability advantages. The rigid crystalline basement of the Archean provides a stress barrier for the development of stable zones.The Silurian mudstone with a thickness of about 1500 meters and the Cambrian gypsum provide a plastic medium for the detachment system. The detachment layer exhibits a structural decoupling phenomenon, providing a dual guarantee for the structural stability below the detachment layer.The compression deformation pattern during the Mesozoic era in the South Yellow Sea is characterized by "strong in the west and weak in the east, strong in the north and weak in the south, and strong in the upper and weak in the lower". It is clear that the central uplift and the thrust zone are structurally stable, which is conducive to the preservation of natural gas in the Cambrian and Sinian systems.

The above understanding has changed the traditional understanding that the preservation conditions of the Lower Yangtze Plate are poor, clarified the advantageous preservation zone of

oil and gas in the South Yellow Sea Basin, guided the implementation of a number of large-scale structural traps in the central uplift, improved the structural development history of the South Yellow Sea Basin, and pointed out the next exploration direction in the area.

Effect of tectonic extrusion on the physical properties of clastic reservoirs: Based on physical simulation experiments

Yumeng Song[1]*, China University of Petroleum (East China) (1945476894@qq.com)
Liqiang Zhang[2], 15194507095
Yiming Yan[3], 15194507095

Abstract

Tectonic action plays an important role in the formation and evolution of extrusion basins, and tectonic processes affect the quality of reservoirs by affecting the settlement rate, burial rate, fracture development and other factors of the basin. Although the deep high-quality clastic reservoir has a large burial depth, its reservoir physical properties are still good, which is closely related to the relationship between tectonic movements. Therefore, in order to quantitatively study the influence of lateral compression caused by tectonic movement on the pore evolution of reservoirs, diagenetic physical simulation experiments were carried out. By controlling a single variable in a way that: The quartz sandstone with the same grain size, sorting and rounding was used to adjust the lateral extrusion stress of different sizes under the same temperature conditions, and the vertical compaction was pressurized to the same depth, so as to explore the evolution law of reservoir pores and reveal the influence process of tectonic stress on the physical properties of the reservoir. The results show that there is a certain functional relationship between the change of reservoir porosity and the vertical compaction stress: With the increase of lateral compression stress, the relationship between reservoir porosity and vertical compaction stress gradually changes from exponential to linear, and the slope of linear relationship decreases gradually. That is, with the increase of tectonic stress, the decline rate of reservoir pores gradually slows down, and the existence of tectonic stress will hinder the continuation of vertical compaction to a certain extent, which has a certain improvement effect on the preservation of reservoir pores. Therefore, this study clarifies the mechanism of extrusion on the formation and evolution of deep reservoirs, and has a positive effect on the evaluation and prediction of deep high-quality reservoirs in extrusion basins.

Early Cretaceous lithospheric thinning of the North China craton: Insights from mantle-derived mafic dyke swarms in Jiaodong peninsula

Lei JI[1]*, China University of Geosciences (Beijing) (lji@email.cugb.edu.cn)
Junlai LIU[2], China University of Geosciences (Beijing)
Jun DENG[3], China University of Geosciences (Beijing)
Jinlong NI[4], Shandong University of Science and Technology
Xiaoyu CHEN[5], China University of Geosciences (Beijing)

Abstract

The coupling/decoupling relationships between shallow, crustal and deep, lithospheric mantle tectono-magmatic activities during lithospheric thinning and destruction of cratons remain hotly debated in the last decade. Multidisciplinary studies were done on non-deformed mantle-derived mafic dyke swarms in southern Jiaodong peninsula, southeastern North China craton (NCC) to explore the crustal and lithospheric mantle responses to regional tectonic extension. LA-ICP-MS zircon U-Pb age dating of the dykes gives consistent ages of 122-121 Ma indicating intensive magmatism at the mantle depth around 122 Ma due to large-scale tectonic extension of regional lithospheric mantle. The dykes show island arc basalt-like trace element patterns and enriched Sr-Nd isotope composition, which is indicative of their enriched lithospheric mantle sources. Anisotropy of magnetic susceptibility (AMS) analysis of dykes with different orientations reveals a systemic variation in dihedral angles between dyke walls and magnetic foliations. Geometrically, the magnetic foliations rotate counterclockwise relatively to the dyke walls for most dykes striking NW–N, while clockwise rotation is dominant for the dykes of NE–E orientations. The WNW-ESE (297 ± 5°) oriented extension resulted in the dextral shearing for the former and sinistral shearing for the later during magma emplacement along crustal fractures. Combined with analysis of regional tectono-magmatic events, we show that the Jiaodong lithosphere experienced two stages of Early Cretaceous tectonic evolution, i.e., an early stage (135-122 Ma) lithospheric thinning characterized by large-scale tectonic extension of the crust and limited magmatic activities of crustal sources, and a late stage (122-108 Ma) lithospheric root collapse dominated by intensive tectonic extension and magmatism in the lithospheric mantle level. The decoupling crust-mantle evolution during lithospheric thinning and destruction of the NCC is accompanied by the changes in direction of Early Cretaceous tectonic extension from E-W direction to ESE-WNW direction, which may relate to coeval subduction direction change of the Paleo-Pacific plate underneath the Eurasian plate.

Neotectonics, geochemical dispersion processes and mineral exploration: linking basement and surface in regions of cover

Ignacio Gonzalez-Alvarez[1]*, CSIRO (The Commonwealth Scientific and Industrial Research Organisation) (ignacio.gonzalez-alvarez@csiro.au)
Carmen Krapf[2], Geological Survey of South Australia

Abstract

Detection of mineral system footprints in regions under thick cover is challenging. The difficulties are enhanced in regions with low-relief landscapes that are deeply weathered. This is also widely the case in Australia where >80% of the surface and subsurface is characterised by transported cover and/or deeply and intensely weathered profiles.

Geochemical dispersion/concentration processes throughout cover units can be efficient in a variety of geological-cover contexts. These processes can produce near surface geochemical anomalies in the landscape, that may be an expression of a mineral system within basement rock units at depth.
Basement structures in Earth's crust are a well-recognised conduit for fluid flow, which can result in the formation of a large variety of mineral deposits. Therefore, identifying basement structures that may be associated with mineral deposit formation has become an important part of exploration protocols and prospectivity assessments.

The possible link between neotectonics and geochemical dispersion processes should be carefully considered when studying landscape geochemistry in areas with thick overburden. Soil or surface landscape units should be selectively sampled in relation to surface structures that are linked to main basement structures that could have been reactivated through time and therefore maintain a direct geochemical link between the basement and the surface.

This study discusses that in areas of deep cover, neotectonics/reactivation surface landscape features have the highest prospectivity to detect deep basement geochemical signatures at surface. This approach may have a critical impact in mineral exploration under cover in similar landscape contexts around the world, such as regions in Australia, West Africa, India, China and Brazil.

Abstract

Among the various methodological approaches used to study landforms, the morphometric analysis of the drainage network is a valuable tool for understanding geomorphological responses to lithological, tectonic, and climatic constraints. By processing and interpreting a set of geomorphic parameters that describe the topographic, hydrographic, and geometric characteristics of the drainage basin and its sub-basins, it is possible to infer landscape evolution at a local and regional scale. This study proposes a detailed morphometric analysis of the Côa River drainage network, situated on the left bank of the Douro River (northeast Portugal). Geomorphologically, the drainage area under consideration is located on the northwestern edge of the Iberian Meseta, an extensive and polygenic Cenozoic planation surface with regional significance, cutting a metasedimentary and granitic substrate. After producing a detailed Digital Elevation Model of the study area, several geospatial tools were used to process the following geomorphic parameters for the Côa River drainage basin and its sub-basins: the longitudinal profiles of the main watercourses, the channel slope gradient and the normalised channel slope index, together with the identification/characterisation of the respective knickpoints/knickzones, and the bifurcation ratio; the elongation ratio and the asymmetry factor; the swath profiles; the curve and hypsometric integral, the transversal topographic symmetry factor, and the width-height relationship from the main watercourse valley. The results obtained for the Côa River longitudinal profile indicate the presence of convex segments and some knickpoints in the lower half (towards and close to the confluence with the Douro River), highlighting an imbalance associated with a rapid lowering of the local baseline level (defined by the Douro River), as well as to lithological variations (schists/phyllites vs. quartzites/granites) and the presence of local geological structures (fractures). The less evolved sub-basins from the downstream sectors, even maintaining a global concavity in their longitudinal profile, present more significant asymmetry and disturbances from the initial linear trend, indicating a transient response of the profile and a higher imbalance that they must be analysed in the context of the Douro River regional evolution. Thus, in evolutionary terms, the Côa River drainage network was mainly affected by regional factors related to the capture of the “Upper Douro” (endorheic) by the “Lower Douro” (exoreic Atlantic drainage) and the subsequent

rapid fluvial incision under the influence of Plio-Quaternary climatic and environmental variability, as well as by local factors such as the interference of lithological variability and pre-existing geological fractures. Differentiated tectonic uplifts of the substrate between the downstream, central, and upstream sectors of the Côa River basin, with a magnitude of accumulated vertical linear movements around ~0.29-0.15 mm/year, have accompanied this fluvial incision during the last ~2.4-1.6 Ma. Furthermore, some phases of tectonic quiescence and rate variations in the fluvial incision, conditioned by the rapid Pleistocene climate oscillations, are expressed in the regularisation/stability of the main watercourses' longitudinal profiles. These tectonic constraints agree with previous studies on other geological evidence for the Iberian Meseta in northeast Portugal.

The history of the most typical world's great rivers: the evolution of the Yangtze and Yellow rivers controlled by the Himalayan orogeny

Liankang YANG[1]*, Ministry of Natural Resources (15646568081@163.com)

Abstract

In 1963, the author discovered the earliest sediments of the Yellow River - the lower Wuquan gravel layer in Lanzhou, Gansu (2.5 Ma?), the largest visible thickness of the loess (315m), and the most complete profile of the river's evolution (for 2.5 Ma?). In 1981-84, for the first time in human history, he spent 1,111 days on foot to survey the whole course of the Yellow River and the Yangtze, discovered the highest terrace (1250m above the current river bottom), the largest number of terraces (>32 terraces), the longest mountainous river's section (the Yangtze 4500 km; the Yellow 3500 km), the deepest vertical karst (622 m) of the world, etc. and published "The formation of the Yellow River" and "The formation of the Yangtze River" at the 14th INQUA. Since 1992, the author has examined the world's other great rivers with > 5,000 km long (Nile, Amazon, Mississippi, Ob, Yenisei), other longest or famous rivers on six continents (Volga, Murray-Darling, Danube, Rhine, etc.). "The developmental history of global longest rivers" was presented at GSC, AGS, and IAG, and successfully refuted the arguments in "Pre-Miocene birth of the Yangtze River" (PNAS 2013.4) at 33 IGC and in Li Jijun's papers about the formation of the Yellow River. This article further confirmed that the history of the Yangtze and Yellow River is controlled by the Himalayan orogeny which uplifts the world's highest Mt. Himalayas and Qinghai-Tibet plateau, making it the world's most typical one.

Full-length Hiking Expedition along the Yellow River and Yangtze River, Discovery of Their earliest Sedimentary Layer, and Confirmation of a Complete Developmental Historical Profile

Liankang YANG[1]*, Ministry of Natural Resources (15646568081@163.com)

Abstract

There are seven rivers in the world that exceed 5,000 km in length. From 1981 to 1984, the author embarked on a 1,111-day full-length survey of the Yellow River and the Yangtze River on foot to investigate their earliest sediments and complete historical profiles, marking a significant milestone in human history.

Wuquan Mt. in Lanzhou City, Gansu Province, located 2,200 km from the Yellow River's source, contains a Conglomerate. On December 23, 1963, the author and their group discovered that this conglomerate is divided into two parts: the lower part consists of alluvial material with rounded pebbles of granite and quartzite from the upper reaches of the Yellow River. Furthermore, at Fanjiaping west of Wuquan Mt., the conglomerate layer is distinct from the underlying red strata and contains limestone pebbles with *Verbeekina* from the Western Qinling Mt at its base, providing conclusive evidence of the Yellow River's connection to the Western Qinling Mt, challenging previous beliefs(Yang- Bian, 1936).

During a 750-day survey of the Yangtze River, the author identified the world's highest terrace at 1250m above the current river bottom. This discovery resolved the historical development survey conducted by the Three Gorges Geomorphology Team from 1958 to 1960 and revealed the Wangbuding section of the conglomerate containing Hengduanshanghyrax .gen.nov., representing the most complete section of the Jinsha River in the upper reaches of the Yangtze River, dating back to the Pliocene.

The author has investigated and studied major rivers around the world, and the above methods have played a crucial role.

Danxia Landform research in China: Tectonic significance, fracture mechanisms and controlling factors

Fang REN[1]*, Chinese Academy of Geological Sciences (546615019@qq.com)
Zhinxin Pan[2], Hainan University

Abstract

Danxia landform is a kind of erosional landform featuring steep cliff slopes, which mainly developed from continental sandy conglomerate .However, the control factors of of Danxia landform is still controversial. In this study, the surface process and landform morphology of Danxia Landform development are studied through a large amount of data analysis, and it is believed that tectonic factors had extensive influence on the development of Danxia Landform morphology.Through GIS-based remote sensing image interpretation,field geological surveys and regional tectonic settings to study the morphological mechanism of the Danxia Landform. Field data including faults and bedding directions (strike and dip),and kinematic characteristics are analyzed. Field verification for the geomorphological characteristics obtained by remote sensing and DEM data analysis are carried out. The results show that not only the tectonic fractures have great immpact on the formatinon of Danxia steep cliffs, but only tectonic fracture-controlled groundwater erosion has been playing important role in Danxia geomorphology development. The development of Danxia Landform is the unity of time- space, and the result of the joint action of internal and external forces. Tectonic control and water erosion play a crucial role in the formation of Danxia Landform. West Pacific Plate subduction processes and deep earth processes lead to the corresponding surface processes in South China block in the East Asian Continental Margin, which are recorded in the Danxia geomorphology. Geomorphic evolutionary trends and climate change in Danxia red beds basins in the south China block show similarities, thus is the reason that Danxia landform is widely distributed in South China.

Controls of tectono-pluviometric forcing on landscape dynamics and seismicity in Java

Manoj Joseph Mathew[1], Department of Geography, Geology and the Environment, Kingston University, London, United Kingdom
Benjamin SAUTTER[2]*, UBS (benjamin.sautter@univ-ubs.fr)
David Menier[3], Geo-Ocean UMR CNRS 6538, Université Bretagne Sud, 56017 Vannes Cedex, France
Franto Novico[4], Research Center for Geological Disaster, National Research and Innovation Agency, Indonesia
Numair Ahmed Siddiqui[5], Department of Geosciences

Abstract

The quasiperiodic frequency of seismicity in rapidly deforming terrains located at plate boundaries is concentrated along faults that are loaded at consistently uniform rates and stochastic signals emanated from such deformation are manifest as non-linear geomorphic phenomena. The island of Java presents a key case-in-point, where, seismicity, deformation and exhumation are driven by steady relative plate motion. However, there remains a paucity of information regarding geomorphic response of the landscape to these tectonic forcing. Here, through a systemic morphotectonic analysis, we show that intrinsic mechanisms govern extrinsic surface processes and pluviometry in Java than have hitherto been perceived or documented. Owing to tectono-climatic forcing, variations in the behaviour of power-law scaling between catchment area and channel slope reveals methodical, large-scale landscape transience, and reorganization of basin geometry and flow line topology. In Java, topographic dissection by disequilibrated streams that demonstrate amplified averaged specific stream power, non-lithologic knickpoints and discrete convexities in channel profiles shows the transmission of transient incisional signals through the river network. Conclusive evidences garnered from our results emphasize the role of progressive tectonic deformation along inherited basement faults in landscape instability and disequilibrium within the island of Java. These NW-SE and NE-SW striking conjugate faults are responsible for differential subsidence and uplift across the island. They function as major conduits/pathways for fluid migration that results in immense isostatic disequilibrium, as is the case with the Lusi mud volcano in east Java. Our results highlight the aggregation of significant geomorphic anomalies along the major Flores Back Arc Thrust Fault and the Cretaceous suture zone. The implication is that present-day crustal motions, which generate topography, influence pluviometry, induce seismicity and instigate geomorphic landscape dynamics are facilitated by long-lasting convergence accommodated by the reactivation of intrinsic basement structures such as faults and suture zones.

Relationship between development periods of coastal sand dunes and climate-environmental factors

Min HAN[1]*, Korea Institute of Geoscience and Mineral Resources (hanmin@kigam.re.kr)
Jin Cheul Kim[2], Korea Institute of Geoscience and Mineral Resources
Dong Yoon Yang[3], Korea Institute of Geoscience and Mineral Resources

Abstract

To confirm the relationship between the development of coastal dunes and climate-environmental changes, this study classified the activation periods using optically stimulated luminescence (OSL) dating for major coastal dunes on the west coast of the Korean Peninsula (Taean Chollipo, Seocheon Dasari, and Gochang Sabanri dune). The results from these dunes were compared with those from previous studies to establish a broad understanding of coastal dune development in East Asia. Sedimentation rates were calculated for the three dunes, and their development periods were classified five main periods during mid to late Holocene: <0.1, 0.2~0.5, 1.2~2.0, 2.5~3.2, and 5.5~6.5 ka. These results were compared with temperature anomaly curves and drift ice indices during the Holocene, and it was confirmed that the development of dunes became prominent during the global cooling events and the enhanced East Asian winter monsoon. In addition, it was suggested that increased human activities contributed to the most recent dune development. This study showed how coastal sand dunes can be evaluated as important indicators of global climate change. These results improved our understanding of how paleoclimate changes affected environmental conditions in East Asia and how coastal dune development periods can be used to reconstruct paleo-environmental conditions. As further studies, we plan to compare the development periods of dunes around East Asia and identify other climate factors.

Decadal and Millennium Scale Gully Expansion Rates, Mthatha, Eastern Cape, South Africa

Debbie Claassen[1]*, Council for Geoscience (debclaassen@gmail.com)
Bastien Linol[2], Nelson Mandela University
Greg Botha[3], University of KwaZulu-Natal

Abstract

Widespread dispersive sequences comprised of colluvium and pedogenic sediments of the Late Quaternary Masotcheni Formation, mantle valley slopes of the rural eastern hinterland of South Africa. These formations are highly susceptible to erosive gullying and extensively scar the landscape. These features exert a substantial impact on environmental health, sustainable socio-economic growth, and infrastructure development in the region. Yet, current studies lack integrated qualitative and quantitative investigations aimed at holistically assessing the influence of both the static and dynamic natural and anthropogenic factors on the temporal erosion rates and evolution of gullies over the decadal and millennium-scale.

The study undertook erosion inventory mapping, detailed pedogenic logging, optical stimulated optical luminescence (OSL) sampling and analysis, multi-temporal study, statistical testing of natural and anthropogenic static erosion drivers, and a near-century temporal investigation of dynamic drivers that included the calculation of gully expansion rates with the aim of investigating how erosion rates fluctuate in response to the temporal variations of drivers.

Gully inventory mapping revealed 1762 erosional features occupying 2.3% or 2579 ha of the study area. Logging across numerous gullies identified 7 laterally consistent paleosols. The normalized gully density and frequency Chi-square test results indicate a statistically significant relationship between the occurrence of gullies and the regolith lithology, slope characteristics, land use, drainage densities, and topographic wetness indexes. The spatial examination of 25 gullies over an 82-year period between 1938-2020 revealed an average gully expansion rate (AGER) of 0.61 m y-1, an AGER of 0.2 m y-1, and an average headcut erosion growth rate of 1.03 m y-1. Erosional features showed an average annual areal increase of 2.8%. The multi-temporal mapping of the Ngwevana Gully across 12 time slices showed systematic fluctuation in the average annual growth percentages, with the largest growth occurring between 1938 and 1948 at 3.98%, and the lowest occurring between 2003-2005 at 0.66%. OSL dating results revealed a chronological sequence for each of the paleosol layers. Minimum burial ages for the oldest and thickest basal paleosol unit ranged from 117±18 ka to 147±12 ka, with the youngest uppermost paleosol dated at 1.3±0.2 ka. Additional accretion pulses occurred at 93±8 ka; 64±18 to 70±3 ka; 43±3 ka and 27±6 and 10±1 ka.

The integrated assessment of drivers revealed that the temporal promotion or suppression of

erosion rates in the last century is the consequence of the complex interaction between dynamic drivers, at specific times in the region. Rapid expansions are directly linked to large-scale flooding events, particularly during drier climate cycles. Periods of increased erosion are exacerbated by invasive dryland agricultural practices, inappropriate land use, and haphazard settlement and infrastructure development compounded by the legacy of Apartheid settlement laws. Findings indicate that although static conditioning factors play a significant role in the location and initiation of gullies, once established, their areal expansion is predominantly driven by dynamic drivers. OSL results show that transgressive and regressive Marine Isotope Stages (MIS) drove long-term depositional and erosional events in relation to alternating warm and cool periods in Earth's paleoclimate from MIS 5e.

Pascale LAHOGUE[6], Royal Museum for Central Africa, Tervuren, Belgium

Abstract

The Republic of Congo, located in Central Africa, stands out for its remarkable karstic potential, concentrated in the foreland of the West-Congo belt. This region encompasses a vast expanse of carbonate rocks stretching from Gabon to Angola, through the Republic of Congo (RC) and the Democratic Republic of Congo (DRC). In the Republic of Congo, these formations are found in the southwest, covering approximately 10% of its total area, which extends over 342,000 km^2.

The karst of the carbonate formations in the foreland of the West-Congo belt in the Republic of Congo (RC) is significant due to several distinctive features: the abundance of discovered cavities, the presence of tectonic structures, concretions, as well as the faunal and archaeological richness, and the variety of observed karstic morphologies (Adam et al., 1966; Adam, 1969; Bede and Lanfranchi, 1978).

In the context of geomorphological study to better characterize this karst, the region of Madingou has undergone several explorations involving optical satellite image analysis and processing of a Digital Elevation Model (DEM). These investigations have revealed a profusion of conical hills, either isolated or in clusters, emerging from the limestone plain of the Niari River. This represents a typical example of cone karst, primarily encountered in tropical zones (Salomon, 2006; Gilli, 2011). The evolution and structuring of the Madingou cone karst are closely linked to the progressive lowering and widening over time of the Niari River plain, the main watercourse draining this karst, as well as the discharge of its various tributaries. According to Grund's classification (Grund, 1914), the Madingou cone karst is categorized as mature to old, suggesting a low preservation of numerous underground conduits.

Tackling Mediterranean Hurricanes through artificial intelligence in a near-future climate projection

Giovanni SCARDINO[1]*, University of Bari (giovanni.scardino@uniba.it)
Alok Kushababa[2], IUSS Pavia
Gaetano Sabato[3], University of Bari
Marco Borzì[4], University of Catania
Andrea Cannata[5], University of Catania
Giovanni Scicchitano[6], University of Bari

Abstract

Mediterranean Hurricanes (known as 'medicanes') are extreme weather systems that cause damage along the Mediterranean coasts. These events are intensifying, and future climate projections show increasingly stronger events than now. Medicane effects are reflected in the high storm surge and coastal flooding that enhance coastal erosion and cause infrastructure damages and casualties. These issues are also intensified by ongoing climate changes, which are determining a global sea-level rise. To address these issues, multi-observation platforms could be used integrating modern techniques of deep learning. Deep learning models allow us to automatically analyze a large amount of data related to the effects of medicanes and sea-level rise. The main parameters of medicanes are usually correlated to mean sea-level pressure, sea surface temperature, significant wave height, and wind speed. On the other hand, sea-level rise is determining coastal flooding and shorelinre retreat, which cause damage to the infrastructure and changes in land use. All these parameters can be assessed from numerical climate models and satellite observations. Furthermore, in-situ data from field surveys could be used to calibrate numerical models and satellite data for target coastal areas. In this work, a Convolutional Neural Network was developed by applying sliding convolutional filters to 1-D inputs in Matlab environment, in order to assess the vulnerability connected to medicane impact in a framework of future sea-level rise. Here, datasets of meteo-marine parameters from satellite, Copernicus, ERA5 numerical models, morpho-topographical data from LiDAR surveys have been used for the training and validation of the Convolutional Neural Network. The 1-D inputs are represented by vectors where mean sea-level pressure, sea surface temperature, significant wave height, sea-level rise, and wind speed are reported for the medicanes that occurred in the last decades. Regional technical maps and morpho-topographical data have been considered to extract the landforms and areas occupied by buildings and infrastructures, in order to assess the exposure in the most vulnerable areas. The predictions of Convolutional Neural Network provide an output of the hurricane track and the coastal areas prone to be impacted by storm waves in a given future scenario. For each coastal area, the vulnerability degree is automatically assessed, and the exposure is automatically highlighted through the polygons representing the infrastructures affected by sea-level rise and medicane impact. These findings are particularly useful for multiplatform observation systems to continuously monitor medicane impacts in conjunction with flooding related to future sea-level rise.

Climate change versus anthropic induced reactivation of slow-moving landslides in temperate environments

Mihai Niculiță[1]*, Alexandru Ioan Cuza University of Iași (mihai.niculita@uaic.ro)

Abstract

Slow-moving landslides are among the most widespread urban ones that act as natural hazards. In Romania, major cities and rural areas developed since the medieval period on slow-moving landslides. Historically, traditional building materials and technology assured resilience to the communities for landslide reactivations induced by climate. After the Industrial Revolution, new building materials, technologies, and urban sprawl triggered reactivations. In the contemporaneous context in which climate changes can overlay anthropic-induced changes is very important to assess which of the two is the most important or if both overlay. We investigate this situation for the entire Romania using the EGMS dataset and show that sometimes anthropic-induced hydrological changes might be more important for slow-moving landslide reactivations than climate changes. Actually, for the Romanian territory, climate changes in general mean a decrease in overall precipitation although the intensities might increase. We also investigate the future changes in winter precipitation which actually might exacerbate the anthropic changes effects. The EGMS dataset allowed us to identify the slow-moving landslides that show a progressive increase in deformations and we assigned the factors that most probably were involved. Through correlations, we computed future trends and simulated increases in both climate and anthropic changes. The modeling shows that the worst-case scenario regarding the slow-moving landslide reactivations is due to both climate changes and anthropic changes, a situation that requires rethinking structural measures needed to increase resilience.

Dirk Balzer[8], Federal Institute for Geosciences and Natural Resources (BGR)
Marie Bredal[9], Norges Geologiske Undersokelse (NGU)

Abstract

The archipelago of Svalbard is one of the fastest warming arctic regions and the temperature increase is more than twice the global average during the last 50 years. Its cryospheric landscapes are adversely affected by increasing temperatures and changing precipitation trends, leading to glacial retreat, permafrost degradation, and associated slope destabilization.

To study the relationship between mass movements and climate warming in a natural environment with negligible human influence, the Forkastningsfjellet coastal ridge was investigated. The west-facing slope was affected by a huge postglacial rock slide and shows a relatively well known litho-structural composition and deformation history.

Field mapping, bathymetrical surveys, GPS- and temperature measurements were performed to reveal the controlling factors, deformation rates and mechanisms that drive the rock slope instability. Four successive UAV surveys acquired between 2019 and 2023 document the spatio-temporal development of the landscape.

The Forkastningsfjellet coastline is characterized by a postglacial rock slide of 100.000.000 m3 that is dissected in 17 slide blocks of different size. After a quiescence of at least 80 years, as indicated by aerial photography covering this period, a 175.000 m^3 rock slide in August 2016 concluded a period of stability at the coastal cliff face. A back-analysis of the rock slide revealed that slope instability initiated along a pre-existing listric block fault that was inherited from the postglacial Forkastnings-fjellet rock slide. Slope failure was attributed to a strength decrease of weak Jurassic shales, permafrost degradation and increasing water pressures. Since this event, we documented rapid surface alterations mainly driven by thermokarst processes.

Thermokarst-driven settlements, sinkhole and subsurface channel formation in combination with redirection of surface water runoff finally lead to a second rock slide event (volume ~700.000 m^3) in November 2022. dGPS data revealed the highest displacements on the block that failed and acceleration was detected on that block in the previous measurements. Again, a reactivation of an older pre-existing sliding plane governed the failure. Drone-based visual observation of the main scarp documents the cryogenic-structural setting and evidences thermo-erosional gullying and permafrost thaw inducing rock mass dilation and slope failure.

The findings show that unfavourable litho-structural settings and climate warming correlated permafrost thaw and increasing water availability are likely first order controls on the stability of the rock slopes. Based on climate projections, an increase in rock slide activity and erosive mass transfer is expected in the future. Moreover, there is the possibility that larger segments of the post-glacial rock slide could be reactivated. Therefore, continued monitoring of Forkastningsfjellet is necessary, as the adjacent blocks to the south are large and could cause dangerous displacement waves in case of rapid failure.

Sunil Kumar DE[4], Department of Geography, School of Human and Environmental Sciences, North-Eastern Hill University, Shillong – 793022, Meghalaya, India

Abstract

The present study examines the complex interplay between short-term climate change impacts from 1981–2021 and the frequency of landslides in the highly susceptible terrain of South Sikkim, India. The analysis of 265 landslides identified through the Google Earth platform and field investigation varied in size and magnitude between 1989 and 2022, revealing a heightened vulnerability in the region. Geological mapping and GIS analysis indicate the significant influence of diverse rock formations, tectonic activities, and river courses on slope instability. The climate of Namchi and Ravong is highly dynamic, as noticeable in the instrumental data of the NASA (LaRC) POWER Project. Mann-Kendall analysis carried out on this data indicates a noteworthy upward trajectory in temperature and precipitation, a clear signal of the impact of climate change. Correlating landslide events with climatic variables underscores the pivotal role of heavy rainfall, especially in lower elevation zones, as a predominant trigger for landslides. Human activities, particularly infrastructure development and road construction, are identified as exacerbating factors for slope instability. Moreover, the Scanning Electron Microscope (SEM) results have been used to ascertain the microscale characteristics of soil and rock types that have the potential to fail. These SEM results reveal intricate material properties influencing landslide susceptibility. According to numerical data of the failures, there was a 44% increase in the occurrence of new landslides, 2% of slides were reactivated, 3% experienced expansion, 10% began shrinking, 21% remained dormant, and 19% stabilized between 2019 and 2021-22, highlighting the growing concern of this issue. A detailed numerical and analytical finding may contribute to evolving a standard database for informed decision-making on local development issues and formulating an effective risk mitigation strategy in similarly intricate environments elsewhere.

Mauro Soldati[7], Department of Chemical and Geological Sciences, University of Modena and Reggio Emilia, Via Campi 103, 41125 Modena, Italy

Abstract

In mountain environments, landslide activity can be enhanced by extreme events that are becoming more frequent and intense in relation to climate change. A notable example of this occurred in May 2023, when the Emilia-Romagna region in Northern Italy experienced exceptionally heavy rainfall. In numerous mountain basins, rainfall events surpassed historical records, leading to the activation of approximately 60 thousand landslides, resulting in loss of lives and significant economic damages. In this context, comprehending the response of slope dynamics to the evolving rainfall patterns under climate change becomes paramount to provide clues for landslide risk mitigation and adaptation actions. Starting from these premises, this paper shows the outputs of a study aimed at deciphering the response of the slope dynamic to environmental and climate changes in a pilot area of the Modena Apennines (Emilia-Romagna Region) providing insights for landslide risk forecasting and prevention. The analysis involved the study of landslides in selected study sites through an interdisciplinary approach combining proximal and remote sensing techniques with field surveys. The complementarity of different methods and techniques and the synergistic use of the data collected was crucial for the recognition and monitoring of hillslope processes. In this study, data from Interferometric Synthetic Aperture Radar (InSAR) technique, Global Navigation Satellite Systems (GNSS) surveys, traditional topography, Uncrewed Aerial Vehicles (UAVs) photogrammetry, and terrestrial laser scanning were used. Historical aerial photos and high-resolution satellite images were also analysed. All data collected were organized in a multitemporal perspective and implemented in a Geographic Information System (GIS) environment.
The research focused on selected study sites located in the Scoltenna Stream catchment which shows a remarkable number of active and dormant landslides of different types and sizes, serving as exemplary cases of slow-moving landslides of the Northern Apennines. The most frequent are

slow-moving earth slides and earth flows affecting clayey terrains. The latter show a significant propensity to slope instability, related to their poor mechanical resistance and the presence of groundwater, and can be quite easily remobilized, especially in relation to intense precipitation.
The research let to detect the state of activity of the earth flows / earth slides and monitor their evolution through time. The integrated methodological approach enabled to identify centimetric displacements and highlighted that the most significant displacements through time occur at the foot of the landslides, and can be possibly related to extreme rainfall events. Furthermore, this study showed how the integration of different remote and proximal sensing techniques can be beneficial in supporting investigation of slope dynamics in clayey terrains and their response to extreme weather conditions.

Abstract

River bank falls of Anavilhanas extreme events in Negro river, Amazon state, Brazil
Alves, N. * & Rodrigues,C.**
* UEA Universidade Estadual do Amazonas (nsalves@uea.edu.br)
**USP Universidade de São Paulo (cleidrig@usp.br)
River bank falls are seasonal common processes in most Amazon rivers, particularly in white water rivers with sedimentary beds, such as the Amazon River. This process occurs mainly in two periods throughout the annual hydrological cycle, during the maximum and minimum water levels, promoting social and economic risks in Amazon riverside communities. The Anavilhanas Fluvial Complex, located in the lower Rio Negro region, is considered a particular anabranches river pattern with a predominance of channels of different sizes, sandy bars, and islands limited by functional natural levées with internal lakes. The Anavilhanas Complex has a silt-clay composition and holocenic phytostability in their morphology, despite the river presents high annual rates of stream power, river flow (35 499 m3 s-1) and a high average of annual water level amplitude. In 2023, the Negro River reached its lowest extreme water level registered of 12.70 m and many of its tributaries dried up, affecting the security and mobility of the local communities. During this event, was observed a significant increase in the number of river bank falls and mass movements, including in the islands of the complex, an uncommon phenomenon in this reach of the Negro River. This study evaluated the increase in these mass movements known as “terras caídas” and their relationship with the extreme low precipitation rates recorded in 2023, that was linked to the oceanic-atmospheric phenomenon El Niño. Field work was carried out in the months of October 2023 and January 2024 during the extremes of low levels water in Anavilhanas Complex. Daily data of water level of the Negro River in Manaus have been monitored since 1902, and, for this period, the maximum water level occurred in 2021 (30.02m) and the minimum in 2023 (12.70 m). During the event of lowest water level period of 2023, the Negro River observed a sudden drop of 10.94m only in August. Considering that in their more frequent hydrologic annual regimes, the river takes around four months to reach the lowest water level, this rapid and intense descent appears to have been the main trigger to the increase of frequence of mass movements observed. This appears to be caused mainly related to the following interconnected factors: a greater lag between the speed of descent of the piezometric level compared to water level of the channel; changes of internal resistance forces in the sediments with saturation or drying; increase in hydrostatic pressure of sediments of the islands and river banks; and exfiltration processes in the sediments. This scenario is coherent to the study conducted by Alves (2013) that considers that the occurrence of ‘terras caídas’ because of the rapid descent of

water during the lowest water level periods. In 2023, the frequence of these processes increased, creating new instability and risk zones to riverside communities.

Abstract

Villages and towns in mountainous areas of Hubei province, with complex geological conditions, abundant rainfall, and urbanized development, these areas are often affected by landslides, which pose a great threat to the safety of people's lives and property. Conducting risk analysis and assessment of landslides is an effective means to reduce landslide-caused casualties and economic losses. Therefore, the research on landslide risk assessment at the village scale has become a new challenge and is also urgently required by local governments for risk management.

In this study, we explored a framework for a detailed survey and quantitative risk assessment of landslides at the village scale. We took Jingyang town as the study area, which has the landform Characteristics of a U-shaped Canyon located in the reservoir. Firstly, we surveyed the rock cliffs at the top, the deposit in the middle, and the reservoir-affected slopes at the axis of the canyon, by using unmanned aerial photography, field ground survey, drilling and geophysical exploration and other technical methods. Then, based on physical and mechanical models considered rainfall, loss empirical formulas, and other landslide risk assessment models, we attempted to quantify landslide risk at different locations in Jingyang town. The local government can use them for risk management, and urban planning.

Impacts of rainfall-triggered landslides in New Zealand: déjà vu all over again

Martin Brook[1]*, University of Auckland (m.brook@auckland.ac.nz)
Matt Cook[2], University of Auckland
Chris Nicoll[3], University of Auckland
Murry Cave[4], Gisborne District Council
Ariane Pola[5], University of Auckland

Abstract

Land surface changes resulting from human activities have emerged as a factor of equal, if not greater importance than climate change in affecting landslide occurrence in New Zealand. Indeed, land use changes mean that the landscape becomes less resilient to the impacts of severe rainstorms, and any climate change. Two examples of this are provided here, from Auckland and Gisborne, cities on New Zealand's North Island. In Auckland, two severe rainstorms in early 2023 (the "Auckland Anniversary Storm" and Cyclone Gabrielle), caused thousands of landslides that damaged houses, infrastructure, and caused fatalities. Many of the damaged houses were constructed in areas exposed to known, existing landslide hazards. Such areas include steep slopes, consisting of weak, Miocene-age weathered rock, residual soils and colluvium. However, irrespective of the known landslide hazard, the prevailing planning legislation allowed development in these areas. In Gisborne, rainfall-triggered landslides have also been a particular issue over the last half-decade, including from Cyclone Gabrielle. An interferometric synthetic aperture radar (InSAR) monitoring programme has been implemented in recent years to identify vulnerable slopes and track slope deformation. Using Sentinel-1 imagery, the pattern of slope deformation across Gisborne's steepland periphery was determined. The InSAR slope deformation time series data shows a coincidence with rainfall and also with seasonal changes, due to shrink-swell of expansive soils. Also, clear evidence exists of the impacts of land use change on slope failure, including tree removal, loading of slopes by construction activity, and installation of unconsented, inadequate retaining walls. Together with existing planning legislation issues, improving landslide resilience in New Zealand cities remains a challenge, despite scientific efforts.

Sea level rise and the ‘hidden’ landslides on the NW coast of Malta

Mauro SOLDATI[1]*, University of Modena and Reggio Emilia (soldati@unimore.it)
Stefano Devoto[2], University of Trieste
Mariacristina Prampolini[3], CNR-ISMAR

Abstract

Bathymetric surveys revealed landslide deposits on the seafloor surrounding the NW coast of the Island of Malta (Central Mediterranean Sea), thus raising questions as to their relations with emerged landslide bodies occurring along the coast and the timing of their development. The aim of this paper provide an overview on Maltese emerged and submerged landslides, and to chronologically constrain their evolution in the frame of post-glacial climate changes. Detailed geomorphological mapping showed a clear continuity between emerged and submerged deposits. Cosmogenic nuclide dating of samples collected from head scarps of two coastal block slides extending below the sea level revealed the oldest detachments as occurring ca. 21 kyr ago, i.e. during the Last Glacial Maximum (LGM). At that time the sea level was about 130 m lower than the current one in the Mediterranean region. This makes it clear that the investigated landslides occurred in a subaerial environment, being possibly accelerated when sea level reached the landslide toes during post-glacial marine transgression. The latter has progressively submerged and hidden at least two third of the landslide deposits. Based on geomorphological observations, this is likely to have applied not only to the dated landslides, but to all those occurring along the investigated coastal stretch.

Late Quaternary slip rate of the strike-slip faults on the eastern margin of the Qaidam Basin and its implication on the northeastern margin of the Tibetan Plateau

Guodong BAO[1]*, Institute of Geology, China Earthquake Administration (baoguodong@ies.ac.cn)
Zhikun Ren[2], Institute of Geology, China Earthquake Administration
Jinrui Liu[3], Institute of Geology, China Earthquake Administration
Guanghao Ha[4], Institute of Geology, China Earthquake Administration
Haomin Ji[5], Institute of Geology, China Earthquake Administration
Lei Wang[6], Institute of Geology, China Earthquake Administration

Abstract

The Qaidam Basin, the largest Cenozoic basin on the northeastern margin of the Tibetan Plateau, is an ideal region for studying regional tectonic deformation. Nevertheless, the mismatch between shortening and the elevation of the eastern basin remains unresolved. The shortening strain in the Qaidam Basin decreases from exceeding 48% in the west to 1% in the east, yet the elevation difference between its eastern edge and the west is minimal. We speculate that the structural deformation on the eastern edge of the basin might not primarily involve compressional shortening. Additionally, the tectonic evolution process of the eastern edge of the Qaidam Basin since the late Quaternary remains unclear.

To address these issues, during field investigations, we identified four active strike-slip faults—two north-west to south-east dextral faults and two east-west sinistral faults. We determined their slip rates using drone-based topography and OSL dating techniques. For the NW-SE Xiariha fault, north to south slip rates are: 1.39 +0.51/-0.34 mm/yr, 1.19 +0.15/-0.14 mm/yr, and 0.9 +0.19/-0.16 mm/yr. The Yingdeerkang fault slips at 1.01 +0.17/-0.13 mm/yr. The E-W Reshui-Taosituohe fault, from west to east, slips at 0.95 +0.22/-0.19 mm/yr and 1.20 +0.11/-0.09 mm/yr. The Taosituohenan fault, west to east, slips at 0.83 +0.36/-0.23 mm/yr and 1.21 +0.43/-0.25 mm/yr. The Taosituohenan fault's exposure revealed a paleoseismic recurrence interval of 3000 years.

Before 16 Ma, Qaidam Basin may have been connected to Gonghe-Qinghai Basin. Around 16 Ma, activation of the Elashan Fault separated Qaidam Basin from Gonghe-Qinghai Basin, closing its drainage system. It intersected with the East Kunlun Fault, leading to compressional uplift and northwestward extension, resulting in the two active strike-slip fault sets. The deformation at the eastern margin is primarily attributed to the initial development of these faults. Ongoing tectonic forces fractured bedrock along southeastern basin perimeters. Examining the strike-slip fault distribution along the northeastern margin of the Tibetan Plateau reveals an eastward "wave-like" trend in slip rates, indicating ongoing structural deformation influenced by distinct geological blocks and detachment layers in the upper crust.

Spatial Distribution and Regional Tectonic Significance of the Newly Discovered Kalawenguquan Fault in the Interior of the Tian Shan

Zhongtai HE[1]*, Institute of Geology, China Earthquake Administration (hezhongtai@126.com)
Xingao Li[2], National Institute of Natural Hazards, Ministry of Emergency Management of China

Abstract

Quantifying the geometrical and kinematic aspects of faults within the Tian Shan is crucial in investigating tectonic deformation patterns in the region. Through remote sensing image analysis using GF-7 data and field geological surveys, we determined the geometric distribution and fault properties of the Kalawenguquan fault. The newly discovered Kalawenguquan fault spans over 400 kilometers and mainly strikes in the ENE direction, with some localized segments in the NE direction. The fault plane dips southward at angles ranging from 60° to 85°. The Kalawenguquan fault is a recently discovered Holocene active fault in the Tian Shan and is a thrust and left-lateral strike-slip fault. Based on the geological survey findings and sediment dating data from the late Quaternary period, the Kalawenguquan fault has a vertical sliding rate of approximately 0.32 mm/a, as determined through Monte Carlo simulations. The left-lateral strike-slip rate was calculated to be 0.5-1.3 mm/a. We detected that at least two paleoseismic events have occurred in the fault since 4.7 ± 0.7 ka. The active faults in the Tian Shan suggest that the mountain absorbs crustal deformations within the region. Strain is uniformly distributed in the Tian Shan region. The high incision rate of rivers in the Tian Shan supports our results.

Optimization of InSAR based coseismic slip modeling for moderate earthquakes accounting for fore-aftershock sequence

Lejun LU[1]*, School of Earth Sciences and Engineering, Sun Yat-sen University (lulj8@mail2.sysu.edu.cn)
Yu ZHOU[2], School of Earth Sciences and Engineering, Sun Yat-sen University

Abstract

Determination of coseismic slip distribution for moderate (moment magnitude, Mw < 6.5) earthquakes is challenging as the commonly-used interferometric synthetic aperture radar (InSAR) technique is unable to separate mainshock and fore-aftershocks due to its limited temporal resolution. In this study, we propose a new method of optimizing coseismic slip modeling by removing fore-aftershock contributions using earthquake relocation data and empirical earthquake source scaling relationships. The method is tested with a series of synthetic fore-main-aftershock sequences, through which we demonstrate that our method can largely recover the real slip distribution of the mainshock. The synthetic tests show that if the moment release by fore-aftershocks is <= 10% of the mainshock moment release, fore-aftershock corrections are necessary to improve the accuracy of coseismic slip model. We also test the proposed method with the 2021 Mw 6.3 northern Thessaly, Greece earthquake sequence, in which case we have independent InSAR measurements for both the mainshock and aftershocks. We successfully obtain the slip distribution of the mainshock from the main-aftershock-mixed InSAR measurements, and the result is highly consistent with that derived from the mainshock-only InSAR data. We also evaluate the robustness of the method using the northern Thessaly sequence through a series of tests, showing that the proposed method makes significant improvements even if the earthquake relocation error reaches 5 km. In the end, we apply the method to re-investigate the 2021 Mw 6.0 Yangbi earthquake sequence and find that previous studies may have overestimated the coseismic slip by 25% and the total seismic moment by 18%.

Field and UAV surveys of the northern Xainza rift, south-central Tibet: EW extension rates and earthquake hazard assessment

Marie-Luce CHEVALIER[1]*, Chinese Academy of Geological Sciences, Institute of Geology (mlchevalier@hotmail.com)
Ziqi Fang[2], Chinese Academy of Geological Sciences, Institute of Geology
Jiawei Pan[3], Chinese Academy of Geological Sciences, Institute of Geology

Shenqiang Chen[5], Chinese Academy of Geological Sciences, Institute of Geology
Junyi Wang[6], Institute of Tibetan Plateau Research, Beijing, China
Lin Ding[7], Institute of Tibetan Plateau Research, Beijing, China

Abstract

The presence of ~NS-trending rifts within the Tibetan Plateau attests that it is undergoing ~EW extension coevally with the ongoing ~NS shortening due to the India/Asia collision. In southern Tibet, the cumulative extension rate, distributed across seven main rifts over ~1,000 km, has been shown to amount to about half of the shortening rate across the Himalayas. Quantifying late Quaternary extension rates across the south Tibetan rifts is essential to understand Tibetan deformation and to discuss the high plateau evolution during the later stages of continental collision. Extension rates along the prominent Yadong-Gulu rift (YGR) appear to increase northwards from <1 mm/yr south of the Yarlung Zangbo suture, to 1.3 ± 0.3 mm/yr in the central part of the rift, and 3 to 6 mm/yr farther north, likely as a result of dextral slip along the nearby Beng Co fault. Limited data however, makes it uncertain whether such a northward increase also occurs along other rifts. Assuming a ~1.3 mm/yr rate across each of the rifts yields a total late Quaternary extension rate of 9 ± 2 mm/yr across southern Tibet, similar to early inferences and consistent with current geodetic results.

Here, combining detailed UAV surveys from two alluvial surfaces that are vertically offset up to 75 m by the Xainza normal fault, with last interglacial (~120 ka) to late Holocene (~6 ka) ages, we test whether rates along the northern Xainza rift, just west of YGR, also vary along strike. Because the northern Xainza fault merges with the Gyaring Co dextral fault to the north, as does the YGR with the Beng Co fault, we aim to test the inference of a comparable, northward rate increase along the rifts in the Lhasa terrane. We also acquired a high-resolution UAV Digital Elevation Model along the still well preserved 1934 M7 Xainza earthquake surface rupture, reputed to have locally produced ~4-5 m horizontal, and ~1.5 m vertical co-seismic offsets.

Abstract

The upper crust of the southeastern margin of the Tibetan Plateau is currently rotating clockwise around the eastern Himalayan syntaxis, and its deformation shifted from being concentrated on large strike-slip faults before the early Miocene to the current mainly diffusely distributed on internal secondary faults. The deformation characteristics of the Sichuan-Yunnan block have significantly changed during this transformation, and deformation patterns in its local areas are also different or even opposite from current macro movements due to internal structural complexity. For example, the Red River fault, the southwest boundary of the Sichuan-Yunnan block, had been a recognized significant tectonic boundary fault before the change of its kinematic properties, with left-lateral strike-slip displacements up to 500-1000 km. After transforming into a dextral strike-slip fault, its horizontal slip rate has been gradually decreased to < 2 mm/a. However, different from the right-lateral strike-slip of the middle and southern segments, its northern segment has been a typical normal fault since the late Quaternary with relatively high seismic activity, and its movement was opposite to the direction of macro rotation deformation.

The Chenghai fault is located at the junction of two tectonic boundary faults, the Lijiang-Xiaojinhe fault and the northern segment of the Red River Fault. The clear normal fault landforms, e.g. graben basins, and a series of water systems offset by horizontal slip of faults were well preserved along the Chenghai fault, showing that its kinematic properties have changed significantly influenced by these two faults. As a significant participant in regional tectonic evolution, the structural deformation of the Chenghai fault should record valuable regional evolution information. In addition, the Chenghai fault generated the Chenghai M 73/4 earthquake in 1515 and the Qina Ms 6.0 earthquake in 2001. However, dense vegetation along the fault makes it difficult to obtain its surface deformation characteristics and the distribution of small-scale horizontal offset, resulting in its misty kinematic properties, roughly determined geometric distribution, and the highly controversial rupture parameters of the Yongsheng earthquake in 1515.

In this study, we used LiDAR technology, which can penetrate vegetation to obtain high-resolution surface topography data, to map the Chenghai fault within 120 km. Combined with

Google satellite images and field investigations, we determined that the Chenghai fault is composed of four secondary faults with a simple geometric structure. Discontinuously exposed surface rupture, e.g. fault scarps and valleys, and densely distributed linear landforms, e.g. water systems and ridges, with sinistral offset were preserved along the S2-S4. 102 offsets below 30 m obtained along the S2 and S3 were statistically analyzed, and the calculated results of the cumulative offset probability density (COPD) revealed that both S2 and S3 have a characteristic displacement of ~6 m and they may rupture as a united segment or cascade rupture as different rupture segments in each large earthquake, and thus the magnitude of Yongsheng earthquake is estimated at 7.6. Finally, based on this study, the tectonic evolution and deformation characteristics of the Dali subblock and Sichuan-Yunnan block, where the Chenghai fault is located, are discussed.

Global basic landform mapping using 30-meter DEM for geologic and geomorphic research

Xingyu Zhou[1]*, School of Geography, Nanjing Normal University (xyzhou@nnu.edu.cn)
Xin Yang[2], School of Geography, Nanjing Normal University
Sijin Li[3], School of Geography, Nanjing Normal University
Yang Chen[4], School of Geography, Nanjing Normal University
Guoan Tang[5], School of Geography, Nanjing Normal University

Abstract

Landforms are complex compositions of endogenic and exogenic forces, recording the traces of tectonic activities, climate changes, material transfer and other incidents. Landform classification and mapping provides basic and critical surface evidence for geomorphological studies. Our team Geomorphology Working Group, which is a group of Deep-Time Digital Earth (DDE) Big Science Program, roots in landform classification and mapping for several years.

The development of earth observation technologies, especially the emergence of 1-arcsecond open Digital Elevation Models (DEMs), has brought opportunities of more detailed and highly accurate landform maps than before. However, the explosive boom of data volume and wide array of landforms on our planet also challenge the evolution of global landform mapping.

Previous studies often utilized local relief and slope as key indicators in basic landform classification. These indicators were commonly calculated by windows, resulting in coarse boundaries, mistaken scatters and serious uncertainty when classifying landforms in large scale. To overcome above problems, we revisit landforms as indivisible elements, and introduced a novel framework, which emphasizes the integrity and continuity of landforms, based on morphology. In this framework, two improved indicators, accumulated slope (AS) and mountain uplift index (MUI), were proposed to replace classical slope and local relief for a more precise result. AS reduces slope variation inside plains but enlarges its increase at transition zones, showing effective delineations of plains. Meanwhile, MUI takes each mountain rather than a window as a computed unit, quantifying mountain relief in a more reasonable way. At last, our team crossed the gap of 30-meter resolution in global landform classification, and published our mapping result, Global Basic Landform Units (GBLU). GBLU presents global basic landforms with unprecedented precision and details, while it indicates a fantastic performance in identifying sand dunes as well.

GBLU is available at DDE Geomorphology platform (https://geomorph.deep-time.org) now and free for personal studies. GBLU serve as a resource, which is able to inspire a deep understanding of morphologic characteristics, spatial distribution and evolutionary process, for scholars, supporting their research in geomorphology, geology and other fields.

Quantitative Assessment on Relative Tectonic Activity along Western Mae Chan Fault Zone, Northern Thailand

PICHAWUT MANOPKAWEE[1]*, DEPARTMENT OF GEOLOGICAL SCIENCES, FACULTY OF SCIENCE, CHAING MAI UNIVERSITY (pichawut.m@cmu.ac.th)
YANNAWAT NGERNLUMYONG[2], DEPARTMENT OF GEOLOGICAL SCIENCES, FACULTY OF SCIENCE, CHIANG MAI UNIVERSITY
WEERAKORN SATHAPORNPIBOON[3], DEPARTMENT OF GEOLOGICAL SCIENCES, FACULTY OF SCIENCE, CHAING MAI UNIVERSITY

Abstract

Mae Chan Fault Zone (MCFZ) is one of the active fault zones in mainland Southeast Asia that cuts across northern Thailand and continues to Laos PDR. Despite fault activeness, the records of recent earthquakes represent that the frequency and magnitude of earthquakes across MCFZ are significantly lesser than those of the surrounding regions. The use of morphotectonic analysis has been proven to successfully evaluate the relative tectonic activity of drainage systems and geomorphic expressions in numerous tectonically active regions worldwide. In this research, the Western Mae Chan Fault Zone (WMCFZ) is an ideal natural laboratory to explore the spatial adjustment of landscape to differential relative rock uplift and long-term tectonic deformation because lithologic and climatic conditions are relatively uniform. We delineated the fault lines from the remote sensing technique of Sentinel-2 band combinations and the topographic expressions from the 12.5 m resolution digital elevation model (DEM). We also extracted 70 low-order channels developed along WMCFZ in order to analyze the spatial variation of topography and evaluate the tectonic activity using geomorphic indices, including the hypsometric integral (HI) and hypsometric curve (HC), the normalized stream length-gradient index (SL/K), the elongation ratio (Re), the drainage basin asymmetrical factor (AF), the mountain front sinuosity (Smf), and the valley floor width-to-height ratio (VF). The combination of these geomorphic factors and field observations of deflected streams and ridges, active mountain front, and triangular facets helps indicate the relative indices of active tectonics (RIAT). Our findings revealed that the lineament detection from the remote sensing technique on DEM indicates the NW-SE direction of WMCFZ. The analysis of the geomorphic indices showed that the overall tectonic activity in the WMCFZ is relatively moderate. The high tectonic activity was found in large watersheds in the west of the study site: Nam Mae Mao, Huai San, Nam Mae Chai, and Nam Mae Sao, and some elongated watersheds in the east: Klong Hahu, Nam Mae Chan, and Klong Mae Chan Noi. The low tectonic activity is distributed in a few watersheds in the east. Our analysis on RIAT was consistent with the paleo-faulting events along WMCFZ based on C14 AMS, OSL, and TL ages, the spatial patterns of lineament density on granitic rock, and the steepness of longitudinal profiles. Our study provided insight into the fact that the long-term tectonic deformation along this fault zone has sculpted the modern landscape. The use of geomorphic indices can be an effective tool to evaluate spatial variation in tectonic activity on the geomorphic evolution of the WMCFZ.

Abstract

Restraining or releasing bends, which distinguish the fault geometry and undergo structural transformation, are widespread along the strike-slip faults. However, it is still unclear how to quantitatively allocate the components of strike-slip and thrust slip, and how to transform and coordinate the strain within the stepover or fault bend area. We target the left-step Wulan segment along the right-lateral strike-slip Elashan fault, which holds both strike-slip and thrust branch faults, and use a suite of high-resolution topography data, including DEMs generated from GF-7 stereo pairs of satellite images, and uncrewed aerial vehicle (UAV)-derived DEMs, to interpret its fine geometry and fault slip characteristics. Furthermore, by dating multi-level measurable offset landforms using optically stimulated luminescence (OSL) and cosmogenic isotope dating methods, we conclude that the geometrically straight main branch fault is characterized by strike-slip and the average slip rates since 16 ka was constrained to be 2.7 ± 0.2 mm/yr. In contrast, The geometrically curved Dongshan branch fault is mainly characterized by reverse, and 6 sets of displace-age data were employed to obtain the incremental slip rates and analyze the fault paleoslip based on the "MCMC-incr_slip_rates. py" program proposed by Zinke et al. (2017). The results indicate that there are no significant temporal variations during the last 60 ka and a constant vertical slip rate can reach 0.35 ± 0.02 mm/yr. This study emphasizes that there are positive flower structures developed in the restraining bend of strike-slip faults and the thrust branch fault bears a significant strain component.

Abstract

Determining the age of abandoned alluvial surfaces is a key component in quantifying landscape evolution processes, tectonic activity, and paleo-climate conditions. However, the dating of such landforms is often limited by the resources required, field accessibility, availability of dating material and analytical complexities in the dating techniques employed. To help address these limitations, we employ a new and complementary approach for dating abandoned alluvial surfaces that uses landscape evolution models to reconstruct the post-abandonment development of incision gullies. The approach presented uses high-resolution topographic data to: (1) Measure gully profiles and their drainage area; (2) Locally calibrate the parameters of an applicable model describing the incision of multiple gullies incision into a surface with an a-priori known age; (3) Apply the calibrated model to compute the duration of incision required to form observed gully profiles on nearby alluvial surfaces with unknown ages. This approach was tested on a set of previously dated late - mid Pleistocene alluvial terraces in the hyper-arid Negev desert (southern Israel). Model parameters calibrated for gullies incised into a previously dated 70 ka surface were within the typical range reported elsewhere for arid regions. Modeled incision durations for gullies on nearby late Pleistocene (34 and 70 ka) terraces were within 10% of their independently obtained surface-ages. In contrast, modeled incision duration for gullies on an older surface previously dated to 230-539 ka, were grossly underestimated at <120 ka, an underestimation that is associated with documented temporal changes in tectonic/climatic boundary conditions that violate the assumptions that underlie the proposed approach. We also present application of this approach used to constrain temporal variability in lateral slip rates across the eastern termination of the Altyn Tagh fault since 52 ka. Accordingly, we propose morphologic dating of gully incision as a new and effective approach for constraining the age of alluvial surfaces. As with other geologic dating approaches – the validity of the landform ages obtained hinges on the validity of the underlying assumptions employed and scales with the robustness of the geologic framework used for their interpretation.

Large-scale Traps Development and Hydrocarbon Accumulation along Transition Surfaces in Lacustrine Basin

Zhanlong Yang[1]*, Northwest Branch, Research Institute of Petroleum Exploration and Development, PetroChina (yang_zl@petrochina.com.cn)

Abstract

For the purpose to systematically analyze the occurrence of “small and multiple” trap groups and then conclude large-scale traps occurrence and hydrocarbon accumulation of lacustrine basins, it is proposed that various transition surfaces controlled by different geological factors such as tectonic activities and climate change are the keys to reflect the evolution of a basin, and the relationship between various transition surfaces in lacustrine basin was established. Structural style, sedimentation, geochemical feature, biogenetic species and abundance of a lake/basin have undergone significant change due to tectonic activity and climate change during lake basin evolution. The changing of these relevant factors are complement with the occurrence of different traps and accumulation of hydrocarbon. In a lacustrine basin, it is mainly developed the structural transition surface dominated by unconformity formed by the changing of tectonic movement, the sedimentary transition surface dominated by lithological differences caused by the cycle of sedimentary system and the bio-transition surface and geochemical transition surface dominated by the change of biota species in different stratification of water bodies. Different types of transition surface control the development of structural, stratigraphic, lithological, diagenesis and physical properties traps respectively. The identification and analysis of various transition surfaces is comprehensive important to understanding the occurrence of large-scale traps and accumulation of hydrocarbon in lacustrine basins.

Abstract

The northeastern margin of the Tibetan Plateau has witnessed intense tectonic deformation since the Neogene, leading to the development of numerous large-scale strike-slip faults and secondary fault systems, triggering multiple major earthquakes. This has garnered considerable attention from researchers investigating the seismic hazard associated with these large strike-slip faults. However, the seismic risk posed by complex fault systems, such as those composed of secondary faults, prevalent in areas like the eastern margin of the Qaidam Basin, should not be underestimated. Previous studies have delved into strain distribution along strike-slip faults in this region, yet the precise contribution of the eastern margin of the Qaidam Basin to the overall strain remains unclear. This study is based on the high-precision digital elevation model obtained through drone mapping technology, which identifies three active faults on the eastern margin of the Qaidam Basin: the Xiariha Fault (XRHF) and Yingdeerkang Fault (YKF) are NW-SE strike dextra faults, whereas the Reshui-Taosituohe Fault (RTF) is a nearly east-west strike sinistral fault. This study discusses the seismic hazard and strain distribution in the region based on those strike-slip faults on the eastern margin of the Qaidam Basin.

High-precision displacement measurements of landforms were conducted using Monte Carlo simulations, and optically stimulated luminescence dating was employed to constrain the ages of landforms. We have respectively selected two research points to preliminarily estimate the slip rates of the NW-SE trending dextral strike-slip faults: XRHF ranging from 1.12±0.07 to 1.68±0.12 mm/yr, and YKF ranging from 0.99±0.06 to 2.29±0.13 mm/yr. Additionally, trench excavations constrained paleoseismic events for RTF at 714-1,792 yr BP and at 700 ± 18 yr BP, indicating a recurrence interval of approximately 1000 years for paleoseismic events.

Together these faults possibly form a complex cross-fault system along the southeastern edge of the basin, heightening seismic risk. Compared to recent seismic events triggered by complex fault systems (e.g., the 2019 Mw7.1 Ridgecrest earthquake sequence), we hypothesize that the fault system on the eastern margin of the Qaidam Basin might evolve into a complex cross-fault system following subsequent seismic activities. Deformation in the western part of the northeastern Tibetan Plateau is driven by slip on the Altyn Tagh Fault and Qaidam Basin compression. The central part experiences slip on the East Kunlun Fault, along with secondary faults, shortening, and block rotation. The eastern part primarily experiences slip along the Haiyuan Fault.

Coseismic deformation of the 1976 Ms 7.3 Chaldiran earthquake in eastern Turkey measured by satellite imagery, in comparison with field measurements

Yu ZHOU[1]*, School of Earth Sciences and Engineering, Sun Yat-sen University
(zhouyu36@mail.sysu.edu.cn)
Lejun Lu[2], School of Earth Sciences and Engineering, Sun Yat-sen University

Abstract

Large continental earthquakes are infrequent, but they are important for understanding active tectonics. Many pre-1990, magnitude greater than 7 earthquakes have not been well documented due to a lack of data. The declassification of KeyHole (KH) imagery provides opportunities for investigating those historical events. In this study, we present new geodetic observations of surface deformation from the 1976/11/24 Ms 7.3 Chaldiran earthquake in eastern Turkey. We use various historical KH imagery and modern Pleiades stereo imagery to determine the coseismic deformation, providing new constraints on the 1976 rupture. Based on the image measurements, we resolve the coseismic slip at depth. The inverted slip from a simple elastic dislocation model, ~ 4.0 m at shallow depths of the Hidirmentes segment, is larger than the surface displacement, around 3 m from previous field surveys, suggesting that the coseismic deformation is a combination of slip on the primary fault with 30±16% off-fault deformation. We also measure cumulative offsets at two sites with well-preserved features, and find a constant ratio of horizontal to vertical offsets throughout the past few earthquake cycles. Both the observed constant slip ratio in this study and offset clusters from previous field measurements support that the Chaldiran fault exhibits a characteristic slip behaviour in the late Quaternary. By combining all the geodetic and geological observations in the broader region, we also present a brief analysis of the slip rate of the Chaldiran fault.

Coseismic slip distribution of the 2023 earthquake doublet in Turkey and Syria from joint inversion of Sentinel-1 and Sentinel-2 data: An iterative modeling method for mapping large earthquake deformation

Jianlong Chen[1]*, Sun Yat-sen University (chenjlong25@mail2.sysu.edu.cn)
Yu Zhou[2], Sun Yat-sen University

Abstract

Interferometric synthetic aperture radar (InSAR) decorrelation that creates great challenges to phase unwrapping has been a critical issue for mapping large earthquake deformation. Some studies have proposed a “remove-and-return model” solution to tackle this problem, but it has not been fully validated yet, and therefore has rarely been applied to real earthquake scenarios. In this study, we use the 2023 Mw 7.8 and 7.6 earthquake doublet in Turkey and Syria as a case example to develop an iterative modeling method for InSAR-based coseismic mapping. We first derive surface deformation fields using Sentinel-1 offset tracking and Sentinel-2 optical image correlation, and invert them for an initial coseismic slip model, based on which we simulate InSAR coseismic phase measurements. We then remove the simulated phase from the actual Sentinel-1 phase and conduct unwrapping. The simulated phase is added back to the unwrapped phase to produce the final phase measurements. Comparing to the commonly-used unwrapping method, our proposed approach can significantly improve coherence and reduce phase gradients, enabling accurate InSAR measurements. Combining InSAR, offset tracking and optical image correlation, we implement a joint inversion to obtain an optimal coseismic slip model. Our model shows that slip on the Çardak Fault is concentrated on a ~100 km segment; to both ends, slip suddenly diminished. On the contrary, rupture on the East Anatolian Fault Zone propagated much longer as its geometry is fairly smooth. The iterative coseismic modeling method is proven efficient and can be easily applied to other continental earthquakes.

Long-term influence of seismic activity on hot spring observation

Tian LEI[1]*, China Earthquake Networks Center (tian12lei@126.com)
Zhou Zhihua[2], China Earthquake Networks Center
Zang Yang[3], China Earthquake Networks Center

Abstract

The underground fluid is the most sensitive medium in the crust. The slight change of the water temperature in the underground fluid may reflect the tectonic activity in the process of earthquake preparation. The hot spring, as the most important manifestation of the deep upwelling of the underground fluid, is also one of the most convenient means to characterize the change of the underground structure. In the practice of earthquake monitoring and prediction for many years, a large number of hot springs have been observed, and Litang hot spring is the representative of these springs.

Since the observation of Litang Hot spring in 1975, it has shown serval times of low water temperature anomalies before several earthquakes of magnitude 7 or above occurred around. It showed a decrease for about 0.5-3℃ before the earthquake, and then the low value lasts until the main earthquake. The temperature of Litang showed a step-like decline because of the six main earthquakes.

The reason for this phenomenon is that the channel of the hot flow upwelling in Litang hot spring changes. Litang hot spring is a mixed hot spring by hydrogeochemical result. Before the earthquake occurred, the accumulation of crustal stress caused changes in the surrounding geological structure, resulting in the reduction of the hot flow upwelling channel, which led to the increase of the mixing proportion of cold water. However, before the main earthquake, the stress accumulation time was long, the fault was in a locked state, the channel was relatively stable, and the water temperature was continuously low, so the water temperature of Litang would drop in a stepped shape before these main earthquakes.

Application of geological and geomorphological data in ground motion simulation

Jiangyi LI[1]*, Institute of Geology, China Earthquake Administration (lijiangyi@ies.ac.cn)
Bengang Zhou[2], Institute of Geology, China Earthquake Administration

Abstract

The Tianshan Mountains are one of the most active seismic regions on the Chinese mainland, as testified by the occurrence of 15 earthquakes of M ≥ 7 leading to surface rupture. The Kalawenguquan fault is known to be the northern edge of the Nalati fault and controls the northwestern edge of the Yultuz Basin (an internal block of the Tianshan Mountains). This left-lateral strike-slip fault has an average strike of N64°E and dips 60–80° to the south. The results of high-resolution remote sensing image interpretation, geological field surveys, geomorphological surveys, drone aerial surveys, trench excavation, and the dating of trench samples with the radiocarbon-14 dating method provides fault parameters for ground-motion simulation. The geological and geomorphological results revealed that the southwestern segment of the F1-3 fault is the most active, and there is a high seismic risk of large earthquakes on this fault in the future. Therefore, we set the largest asperity to be in this location and the smallest asperity to be at the epicenter of the 2007 Tekesi MS 5.9 earthquake.

Based on this source model and a multi-scheme simulation, we used different modeling parameters to design a logic tree. We calculate all the combinations of each scheme using the stochastic finite-fault method to analyze the impact of different site locations on the simulation of near-field large earthquakes, and obtained the minimum, average, maximum, and 50th-, 84th-, and 95th-percentile PGA values and response spectrums. The results showed that the response spectra of the sites located on the hanging wall of the fault were higher than those of sites located on the footwall. Ground motion simulations wherein the site was located near the asperities were greater than when the site was located further away from the asperities. Further, when the site is located on a smaller asperity and has a certain distance from the largest asperity, the simulation results are greater. Our results revealed that the geological and geomorphological data have great effects on the near-field ground motion simulation. Therefore, our study highlights the relevance of determining the source model based on geological and geomorphological data to obtain a reasonable evaluation for near-field strong ground motion simulations at major infrastructures.

A study on high-resolution 3D seismic velocity structure in southern Sichuan basin, China, using a local temporary network

Yang ZANG[1]*, China Earthquake Networks Center (zangyang@seis.ac.cn)
Lingyuan MENG[2], China Earthquake Networks Center
Yanyan Han[3], China Earthquake Networks Center

Abstract

Induced seismic activity is becoming more and more severe in recent years near the southeast of the Sichuan basin, China, as the rapid development of Shale Gas exploitation around the local area. An MS 5.7 earthquake occurred near Xingwen County on 16 December 2018 within the Sichuan basin which is the largest hydraulic fracturing (HF) earthquake in China to date and caused ground motions intense enough to be felt, triggered landslides, caused 50 million in direct economic losses, injuries, and resulted in the first fatalities. Besides, 8 MS≥5.0 earthquakes have occurred Southeast of the Sichuan basin since 2018 supposedly either caused by HF operation or induced by wastewater disposal, where seismic activity has been low historically. The tomoDD double-difference tomography method has been applied to get the high-resolution three-dimensional structures and accurate locations of small earthquakes in the study area, taking advantage of 21 mobile stations' temporary network. Combined with the inverted structure and events' location data, along with the local geological structural information, we better understood the seismogenic structures of some moderate to strong earthquakes that occurred in the Sichuan basin. This study can help to establish a suitable regulation controlling system for the safe development of shale gas resources in the Southeast of the Sichuan basin as there is no one yet to date.

Relationship between seabed geomorphology and flexural subsidence in the Sibari and Corigliano basin (Southern Italy)

Nora Markezic[1]*, National Institute of Oceanography and Applied Geophysics (nmarkezic@ogs.it)
Silvia Ceramicola[2], Institute of Oceanography and Applied Geophysics
Emanuele Forte[3], Institute of Oceanography and Applied Geophysics

Abstract

Complex tectonic settings often exhibit particular spatial patterns of seabed morphologies reflecting the deep on-going processes and dynamics. This is the case of the Ionian Calabrian margin, part of the active Calabrian subduction zone, whose accretionary wedge is migrating and thus represents a seismic hazard. The area has undergone a km-uplift scale over the last 1Ma and it is deeply incised by several submarine canyon systems.

The north-eastern sector of the Calabrian margin, i.e. the Sibari and Corigliano Basins, whose formation can be linked to the Neogene-Quaternary evolution of the Gulf, exhibits a peculiar spatial pattern of seabed geomorphologies with different geometries.

We hypothesize that the observed geomorphology and evidence from sub-bottom data, are related to the subsidence that this area is experiencing, which is controlled by the downward flexure of the lithosphere in response to thrust accommodation and loading. Tectonics may have locally enhanced subsidence in the examined near-coastal area.

Seismic data at different resolution integrated with bathymetry data have revealed the presence of multiple stages of submarine landslides as well as aggrading submarine gullies testifying the ongoing activity in this area.

Coupling the seafloor expression to deep tectonic processes where active tectonics is occurring, is crucial for determining the potential geohazards of near-coastal areas. We present new information about on mapped geomorphologies with particular emphasis on their spatial constraints and evolution.

Application of Acoustic Classification for Seabed Characteristics of Spratly Islands in the South China Sea

Yin Hsuan Liao[1]*, National Taiwan University (b02208008@gmail.com)
Ho Han Hsu[2], Institute of Oceanography, National Taiwan University, Taipei, Taiwan
Tzu Ting Chen[3], Woods Hole Oceanographic Institution, Falmouth, MA, United States
Char Shine Liu[4], Ocean Center, National Taiwan University, Taipei, Taiwan
Yu Huang Chen[5], Institute of Oceanography, National Taiwan University, Taipei, Taiwan
Liwen Chen[6], National Academy of Marine Research, Ocean Affair Council, Taiwan

Abstract

The Spratly Islands, located in the southern region of the South China Sea, consist of numerous atolls, reefs, shoals, and small islets. The seabed morphology of the islands exhibits marked disparities both within and outside the atolls encompassed by coral reefs, which are consolidated calcium carbonate platforms. Concurrently, being one of the largest marginal seas in the Western Pacific Ocean, the South China Sea receives substantial sediment influx from adjacent continental rivers. In this study, we analyzed different geophysical data collected near Tizard Bank, a partially submerged atoll within the Spratly Islands. These geophysical data, coupled with sediment sampling, facilitated a comprehensive assessment of the topography and classification of the seabed of the Spratly Islands. Based on the results, we developed a method to classify the nature of the seabed that complies with the S-101 encoding standards for the electronic navigational chart (ENC), established by the International Hydrographic Organization (IHO). High-resolution multibeam echo sounding (MBES) bathymetric data, backscatter data, and sub-bottom profiles were acquired to study seabed characteristics. Moreover, through gravity coring and Shipek grab, 33 seabed sediment samples were retrieved and analyzed to validate the geophysical data interpretation. The bathymetric data reveal that the interior of Tizard Bank predominantly features water depths of less than 100 meters, with coral reefs and shallow shoals covering the area. The seabed outside the atoll descends steeply, interconnected by numerous submarine channels, with depths exceeding 2,500 meters between atolls. Analysis of backscatter imagery obtained via MBES reveals the highest backscatter intensity within Tizard Bank, indicating elevated hardness and roughness within the atoll, which also shows high amplitude reflectors on the seafloor in sub-bottom profiles. Conversely, backscatter intensity is heightened within the submarine channels outside the atoll, diminishing as seabed depth increases seaward. Results from seabed sediment analysis demonstrate that the seabed within Tizard Bank primarily comprises coral and coarse-grained foraminiferal sand (<5 phi). In contrast, the exterior seabed sediment exhibits significantly finer particles (6-8 phi), with grain size diminishing towards the atoll. The wide surface data collected by MBES, combined with the sub-bottom profiles on survey lines, finally verified by actual seabed sediment sample analysis, classify the nature of the seabed features in the study area. By application of multiple geophysical acoustic data near Tizard Bank, we develop a method of wide surface seabed characteristics classification for the electronic navigational chart, and provide a deeper understanding of depositional environments and sedimentation processes within

the Spratly Islands and the broader South China Sea.

Investigation of the genesis and development of the late Pleistocene paleosols for the reconstruction of the geomorphic evolution of the loess deposits near Gorgan, Iran

Sahar MALEKI[1]*, Geological Survey of Iran (sahar.maleki@ut.ac.ir)
Farhad Khormali[2], Gorgan University of Agricultural Sciences and Natural Resources
Faezeh Shahpouri[3], Phd student of Isfahan university

Abstract

During the last glacial-interglacial cycle, wet periods that reduced dust sources resulted in the expansion of loess deposits in northern Iran. These loess sediments formed and developed the Saad Abad loess-soil microtexture sequence, which contains an old soil with moderate evolution. To understand the genesis and development of the landscape in the study area, located on the northern slopes of the Alborz Mountain range in Golestan province, we selected the site based on the exposure of the old soil in the wall after field visits. We sampled every horizon and at 5 cm intervals from the wall. We described the particle size distribution, magnetic susceptibility, morphology, micromorphology, mineralogy and calcium carbonate equivalent (CCE) characteristics in detail. The old soil, associated with the last interglacial period, is an ABk horizon with moderate evolution, which underwent carbonate leaching from surface horizons, decreased soil-forming processes, and reduced humidity. This old soil likely formed during secondary sedimentation intervals. Loess in Saad-Abad is classified as clay loam due to the high clay content, averaging 35%. Many of the collected samples have no particles larger than 200 micrometers, while smaller particles comprise a very large proportion. The loess particles deposited on the slopes of the Alborz mountains are considerably smaller. The presence of various forms of calcium carbonate aggregates, high values of magnetic susceptibility χlf and χfd% in this old soil indicate a period of heavy rainfall during its formation. The values of χfd% for the Bw horizon of the modern soil are about 10.14% and for the old soil between 5.67% and 13.59%. The strong correlation between χlf and χfd% suggests that the super-paramagnetic minerals produced by pedogenic processes are the main cause of the increase in magnetic susceptibility. The highest value of χfd% equal to 13.59% was observed in the old soil, which implies that pedogenic processes in this soil are stronger than in other modern soils. Based on the similarity of the patterns of magnetic susceptibility and particle size distribution and the assumption that the formation of the ABk horizon in Saad Abad coincided with the Bt horizon (1-3) in Toshan and Bk (p1) in Mubarak Abad; the different degrees of soil formation indicate an increase in humidity from east to west and from north to south in the current period and the last interglacial period. Therefore, we infer that the climate gradient of the late Pleistocene was similar to the present one. Consequently, the old loess and soil in Saad Abad, like the stratigraphy of other study areas, show a cyclic pattern.

Identification and classification of the Salehyeh wetland sediments and assessment of possible contamination markers (toxic elements)

Nayerehsadat BAYAT GHIASI[1]*, Geological Survey of Iran (na_bayat60@yahoo.com)
Sahar Maleki[2], Geological Survey of Iran
mehdi tahmasebi jam[3], Geological Survey of Iran
Reza Shahbazi[4], Geological Survey of Iran

Abstract

Wetlands are among the most vital and irreplaceable ecosystems on Earth. Salihiya wetland, located near the capital city in Alborz province, is one of the most significant wetlands in Iran. This wetland hosts a variety of migratory birds annually and contributes to the regulation of the local climate. Moreover, it provides habitat for many animals and serves as a natural attraction for visitors. The main objective of this research was to examine the sedimentological, geochemical and environmental features of this wetland and to evaluate the influence of anthropogenic activities on its contamination by heavy elements. Soil texture analyses indicated that the dominant soil texture in the wetland was silty and silty clay. The soil electrical conductivity in the eastern and northeastern parts of the wetland, the sulfate content in the east and the calcium carbonate content in the western and southwestern parts of the wetland were higher than in other areas. The total water hardness was also greater in the eastern and northeastern parts of the lagoon than in other regions. The investigation of heavy metals revealed the predominance of human activities over geogenetic factors in causing wetland pollution. High concentrations of iron, titanium, vanadium, aluminum, beryllium and cobalt were dispersed throughout the lagoon environment, while bismuth was enriched in the western and southwestern parts, chromium and zinc in the center, copper in the east, manganese in the east and nickel in the northwest. These patterns were associated with the activities of factories, industries, agriculture, road transport and mining. The modified degree of contamination index showed the high degree of contamination of the lagoon by chromium, manganese, vanadium, barium, zinc and cobalt. The enrichment factor was also very high for vanadium, Ba, Mn, P, Y. The geoaccumulation index values of these elements exceeded the standard value, indicating the pollution of the wetland environment.

Understanding the Long-Term Impacts of Human Activities and Climate Change on the Krishna-Godavari Delta through Remote Sensing

RESHMA KADAKATH NARANTHATTA[1]*, NATIONAL CENTRE FOR COASTAL RESEARCH (reshmarechu16@gmail.com)
MANI MURALI RAJAGOPAL[2], CSIR NATIONAL INSTITUTE OF OCEANOGRAPHY
SANTHOSH KUMAR SAKTHIVEL[3], CSIR NATIONAL INSTITUTE OF OCEANOGRAPHY

Abstract

Deltas, characterized as dynamic ecosystems, play a vital role in global biodiversity and carbon cycling, and function as economic hubs. Despite their significance, global delta systems face imminent threats from a combination of natural and human-induced activities. Upstream damming of rivers disrupts the essential flow of water and sediment crucial for deltaic sustainability. Moreover, the impact intensifies with local exploration of oil, gas, and groundwater, contributing to subsidence, wetland loss, and accelerated erosion. This study focuses on a long-term understanding of the Krishna-Godavari delta, the second-largest delta in India, to assess its response to the impacts of climate change and human-induced activities. By utilizing remote sensing technologies and incorporating both optical and microwave satellite data, parameters such as land use pattern, ground deformation, and shoreline of the twin delta were assessed. The methodologies employed in this study encompassed the utilization of the maximum likelihood supervised classification approach to analyze land use changes. For assessing shoreline changes, the study employed the Net Shoreline Movement statistical analysis. Additionally, the Rate of deformation was determined through Short Baseline Interferometric analysis. The analysis reveals a substantial and abrupt increase in urbanization from 96.90 km2 to 325.63 km2 in Godavari and 13 km2 to 114 km2 in Krishna over the past 48 years. Increasing urbanization exerts pressure on the delta ecosystem through land conversion, and groundwater exploration, leading to urban-induced subsidence (upto-10mm/yr.) at various locations of the delta. High Erosion (-320m to -781m) near the river mouths of the delta was estimated from 1973 to 2014. The pronounced erosion identified poses a significant threat, rendering the delta more susceptible to the impacts of climate change. In parallel, mangrove restoration initiatives within the coastal zones of this delta have led to an increase in mangrove cover, contributing to enhanced stability along the coastal area. Despite the positive influence of mangrove restoration on coastal stability, the cumulative impacts of high erosion, subsidence, and urbanization underscore the vulnerability of the Krishna-Godavari delta in the face of climate change scenarios. This study emphasizes the critical need for integrated and sustainable coastal management practices to mitigate the adverse effects of urbanization, subsidence, and erosion, thereby safeguarding the ecological integrity and resilience of the Krishna-Godavari delta against evolving
environmental challenges.

Tectonic Segmentation along the Himalayan Arc from Geomorphic Analysis and its implication on the Strength of the underthrusting Indian Lithosphere

Raj Sunil KANDREGULA[1]*, CSIR-National Geophysical Research Institute
(krsunil17@gmail.com)
Pavankumar Gayatri[2], CSIR-National Geophysical Research Institute
Ajay Manglik[3], CSIR-National Geophysical Research Institute

Abstract

The Himalayan collision belt presents a complex geological scenario where the underthrusting Indian plate exhibits segmentation along its arc. This segmentation, marked by variations in the angle of underthrusting of the Indian mantle lithosphere (IML) and its northern limit beneath Tibet, is intricately linked to pre-existing transverse tectonic fabric in the Ganga foreland basin. These structural variations hint at changes in the mechanical properties of adjacent blocks, likely reflected in spatial variations in topography and related parameters. To delve into this phenomenon, an extensive analysis was conducted, combining the study of the normalized river channel steepness index (ksn) with key factors such as the width of the Ganga foreland basin vis-à-vis disposition of major thrust faults and Bouguer gravity anomaly. The results support a linkage between the spatial variability in the ksn and the segmentation of the Indian plate. This analysis delineated six distinct sectors within the Himalaya, mirroring sectors identified through independent studies based on the GPS studies, analysis of topography and Bouguer gravity anomaly data. Furthermore, significant deviations in high ksn pockets from the arc-parallel distribution were attributed to the transverse tectonic fabric of the Indian plate in the Ganga-Brahmaputra plains. Importantly, the integrated findings shed light on the mechanical strength of various lithospheric sectors, identifying regions like the Kashmir - Himachal and the eastern part of Arunachal as possessing mechanically strong lithosphere, in contrast to the central-eastern Nepal sector which exhibits lithospheric weakness. This comprehensive analysis highlights the linkage between the tectonic segmentation, topographic variations, and lithospheric mechanical properties in the Himalayan region, offering valuable insights for understanding its seismic hazard potential.

The climate-tectonic interplay in Ladakh, NW Himalaya (India)-Records during the Quaternary Period

Binita PHARTIYAL [1]*, Birbal Sahni Institute of Palaeosciences, Lucknow
(binita_phartiyal@bsip.res.in)
Debarati Nag[2], Department of Geology Savitribai Phule Pune University, Pune, India
Priyanka Joshi[3], Agharkar Research Institute, Pune, India

Abstract

In the complexity of the Himalayan system lies Ladakh-a cold arid high-altitude desert. It is the part of the NW Trans Himalaya exhibiting a cold desert environment being the rain shadow area of the India Summer Monsoon. The region is sensitive to environmental changes where a little perturbation may lead to massive sediment production, erosion, and sedimentation resulting in dynamic evolution of the landform development and evolution of the area. This sector offers a rich platform for Quaternary palaeoclimatic studies. It is also tectonically very active due to its vicinity to the Karakorum fault and the Indus suture zone. It is well established that the monsoonal precipitation over the Indian subcontinent is largely controlled by the thermal gradient between the Tibetan Plateau and the Indian subcontinent and is highly variable with contrasting precipitation patterns seen from east to west and north to south, especially over Himalaya. This has contributed significantly to the varied geomorphology of different sectors of the Himalaya. The bulk of the precipitation over Ladakh and Karakoram regions is received as snow between November-April which is crucial to replenish and maintain the water budget of the ten major rivers originating from the Himalaya and Tibetan Plateau area and catering to almost 20% of the world's population. However recent uprising trends in flash floods induced by abrupt and intense precipitation events in the high-altitude Himalaya are becoming worrisome. A spatial variation exists in the studied records and to understand this concurrent variability it is very important to have good knowledge of past variability. Thus, strategically as well as critically placed Ladakh region provides an opportunity to unravel the signatures of palaeoclimate and neo-tectonics preserved in these Quaternary deposits and their relation with the regional and global climate and morpho-sedimentary.

This paper discusses the sediment archive record of the cold arid altitude desert of India i.e., Ladakh- to understand the overall geomorphological evolution in view of both exogenic as well as endogenic forcings. The entire region displays a wonderful play of tectonics in its multiple levels of terraces and the recurrence of soft sediment deformation structures in its sediments. Studies suggest that the Indus Valley has undergone tectonic disturbances, which are seen in the deformed lacustrine sediments moreover the palaeolakes have been formed due to the damming of the rivers by different landslides (either due to seismic disturbances or abrupt monsoon years) at different periods in the past. Several lake sediments (paleo and proglacial) from the Ladakh range and the Indus Valley were studied with a multi-proxy approach for recording the climate. A composite picture of the Late Quaternary from Ladakh is sought and a higher resolution picture since LGM

shows several prominent arid phases intervened by comparatively warmer conditions.
This mid-latitude, high-altitude cold desertic region aptly known as the roof of the world has a very good archive of sediments that are preserved along the river valleys which would answer questions of climatic perturbations, geomorphological evolution, and tectonics and thus hold key to the understanding of several climate uncertainties.

Tectonic landforms and Morphometric analysis of the frontal part of the Belt of Schuppen: Focus on Naga Thrust

SENTISENLA JAMIR[1]*, NAGALAND UNIVERSITY (sentisenla123@gmail.com)
KHAYINGSHING LUIREI[2], WADIA INSTITUDE OF HIMALAYAN GEOLOGY
GLENN T THONG[3], NAGALAND UNIVERSITY

Abstract

The Belt of Schuppen (BoS) which trends NE-SW in the western part of the Indo-Myanmar ranges, represents a tectonically active zone. Development of landforms suggests recent tectonic activity in the BoS, particularly along the Naga Thrust (NT). The mountain front is defined by the NT. The current study is an attempt to establish neotectonic activity in the study area using structural and morphotectonic features, through field observations and analysis of morphometric parameters with the help of Digital Elevation Models and Google Earth Imagery. Multiple levels of strath terraces, incised bedrocks, nature of the mountain front are important morphotectonic features. Structural features include the development of duplex structures in the BoS and swing in strike of the bedrock that resulted in curved mountain front. The study area, situated in the western part of the BoS, is divided into 15 sub-basins. Morphometric analysis of 15 third order and above sub-basins were carried out. Asymmetric factor (AF) values indicate tilting of all the sub-basins. Mountain front sinuosity (Smf) values of the study area ranges from 1.06 to 1.26, which indicates a tectonically active front. Steepness index (Ksn) and valley floor width to height ratio (Vf) for Dzüdza River were also determined. Several knickpoints were noted which are located in the proximity of major thrusts, viz., Disang Thrust, Piphema Thrust, Sanis Chongliyimsen Thrust and Naga Thrust. Numerous normal faults and folds are developed in the bedrock. The Naga Thrust appears as an emergent thrust in the field, with abrupt contact between the bedrock and Quaternary deposits. Multiple fluvial terrace levels (T1 at 221 m asl, T2 at 224 m asl, T3 at 227 m asl and T4 at 255 m asl) are developed along the Dzüdza River. The presence of paleochannels depicts shifting of streams, tilted fluvial deposits, and deformed sediments, which suggest later phases of tectonic activity.

Multi-phase drainage rearrangement in response to geodynamic mechanism transition in southeastern Tibet

YONG ZHENG[1]*, Institute of Geology, Chinese Academy of Geological Sciences (zygeology@163.com)

Abstract

Fluvial systems react rapidly to tectonic events and therefore paleo-drainage changes are often used to shed light on the tectonogeomorphic evolution of an area. There are several large-scale rivers of southeastern Tibet characterized by particular geometries, which indicates changes in river patterns due to river capture and drainage direction reversal. Among them, the Dadu River abruptly shifts from south- to east-flowing forming a ~90° bend, and the upper Yangtze River abruptly shifts from southeast- to northeast-flowing forming a ~110° bend. Here we report our identification, based on detrital zircon U-Pb age distribution, of a range of fluvial sands left by the paleo-Dadu River. Cosmogenic 10Be and 26Al burial dating provides burial ages for these fluvial sands and indicates that reorganization of the Dadu drainage completed within the last 0.6 Ma. Additionally, using the low-temperature thermochronology, we have dated the rerouting and formation of the Great Bend of the upper Yangtze River in the Miocene. We hypothesize that the Miocene river capture was caused by geodynamic mechanism transition. During this period, the regional fault systems started to shift from pure strike-slip faulting activities to transpressional faulting. Because enhanced river incision since Quaternary in the southeastern margin of the Tibetan Plateau occurred mainly within a narrow region between the Sichuan Basin and the Eastern Himalayan Syntaxis, we attributed the river rerouting during this period to an episode of widespread extensional deformation superimposed above middle- to upper-crustal flexure.

Abstract

The dynamic interplay of spatio-temporal stress variations within the Ganga-Brahmaputra plains has instigated the formation of numerous neotectonically induced geomorphic features along the Himalayan foothills. Notably, the investigation into the terminal fans and soft sediment deformation structures in the Indo-Gangetic plains and the paleopedological records in the Brahmaputra basin offers significant insights into recent tectonic movements. The distribution of terminal fans in the Ganga plain reveals three distinct episodes of basin segmentation during the past 10 ka. The earliest segmentation occurred roughly between 9,000 and 7,000 years ago, succeeded by faulting episodes from 6 ka to 2 ka and 1 ka to 0.7 ka. The peak of faulting activity transpired during the second stage, constituting approximately 70% of the total faulting events. The formation of shallow sub-surface faulting facilitated sediment accumulation, while sediment supply for fan development was spurred by fluvial sediment discharge during various climatic epochs. Notably, larger fans tended to develop during wet climatic periods. The presence of shallow sub-surface deformation structures along basement faults suggests ongoing neotectonic activity and the propagation of secondary faults. Holocene sediment records from the Brahmaputra plain mirror the intense tectonic activity observed in the Ganga plain during the Holocene, indicating significant sediment redistribution. Soil classification in the Brahmaputra Plain reveals four sub-categories based on age, with the oldest soils occurring along the Brahmaputra Arc. These older soils developed during the early to mid-Holocene along the Brahmaputra Arc within a compressional regime between the Naga Thrust and the Himalayan Frontal Thrust (HFT). This is supported by the closeness of the Naga Hills and the Himalayan Frontal Thrust at the center of the valley than at the periphery. Similarly, the distribution of alluvial fans and Naga Hill piedmonts also suggest that the older deposits occur along the central region. These findings from the sediment distributions in the Brahmaputra valley indicate that the intense compression between the Naga Thrust and the HFT uplifted the Brahmaputra Arc. The younger sediments in the valley were derived from the erosion of the older soils along the arc. In summary, the Ganga and Brahmaputra plains showcase consistent patterns of neotectonic activity, highlighting their regional importance in unraveling the broader geological dynamics of the Himalayan foothills.

Mangroves ecosystem metamorphosis impacted by climate change in Indus Delta

Ping YIN[1]*, Qingdao Institute of Marine Geology,China Geological Survey
(yinping@mail.cgs.gov.cn)
Jingpeng Liu[2], Qingdao Institute of Marine Geology,China Geological Survey
Yuqing Tian[3], Qingdao Institute of Marine Geology,China Geological Survey

Abstract

Mangroves are salt-tolerant woody plants growing in the intertidal zones of tropical and subtropical regions, playing a significant role in cementing coastal berms, controlling wind and waves, purifying water quality and regulating climate. They also play an irreplaceable role in protecting biodiversity and maintaining the ecological balance of coastal zones. The Indus Delta is home to 95% of Pakistan's mangroves, making it the largest dry-climate mangroves, as well as the seventh largest mangrove forest in the world. Integrated Earth Observation on the Indus River delta revealed the spatial and temporal changes of mangroves, corresponding to climate changes and anthropogenic impacts, geo-information based risk assessment and management strategy study provide scientific supports for coastal ecosystem restoration and wetland protection in the future. Over the past 30 years, mangroves in the Indus Delta have changed significantly in spatial composition and distribution with an overall trend of increasing then decreasing. Mangroves in the west of the present Indus estuary showed an overall growth trend while to the east of estuary generally show a trend of increasing then decreasing during the same time frame. Landscape pattern index shows that mangrove fragmentation was decreasing and mangrove was growing more concentrated, ecosystem connectivity and aggregation index is increasing in most areas west of the present Indus River estuary.

Coastal erosion due to climate change, rising sea levels and reduced sediment input from the Indus River is the major factor contributing to the widespread loss of mangrove habitats. Sea level near Karachi increased at a rate of 1.1 mm/yr, increasing eastward to 1.9 mm/yr, the rise of sea level is positively correlated with the rate of coastal erosion, over the past half century, Indus Delta has lost approximately 3,750 km^2 land under the continuous influence of sea level rise and coastal erosion. In addition to coastal erosion squeezing living space, sea level rise can also lead to stronger wave action, higher tides and more intense storm surges, all of which further increase coastal vulnerability and exacerbate mangrove decline.

The abandoned tributary channels and tidal branches undergo long-term dynamic adjustment, the reconstruction of the geomorphic balance of the delta is accompanied by the adjustment of the mangrove ecosystem. The Indus River main tributary channels located near Karachi was abandoned in the middle of 19th century, afterwards large river channels and tidal channels are filled and tend to be consistent with the elevation of the tidal flat, and secondary tidal channels with shallow depth and small width are developed, which is conducive to the stable expansion of the mangrove body system. On the southeast side of the delta near India, the overall elevation is

low, and the lack of sediment supplementation, strong tidal currents and waves brought by the southwest monsoon have widened and deepened the tidal channels, which is not conducive to the growth of mangroves and leads to the erosion of mangroves at the edge of the tidal channel.

Quaternary Tectonism and Channel Migration in the Banas River, Western India M.R. Resmi and Manisha Gupta

Resmi M.R[1]*, Banasthali Vidyapith (resmiarun.mr@gmail.com)
Manisha Gupta[2], Banasthali Vidyapith

Abstract

The Banas drainage basin in central Rajasthan displays asymmetry in nature, particularly in relation to the 6th order Banas River channel (highest order). In the southeastern segment of the Banas River catchment, near to the Mej River sub-basin in the Chambal catchment, the channel's minimum distance from the watershed is merely 7 km. This characteristic is ascribed to the migration of the Banas watershed, estimated at 25-30 km, from its original position along the Vindhyan hills to its present location. From our present study, it is evident the southward shifting of Banas River has occurred in the past. This shift is a consequence of the superposition of the Mej river system and its headward erosion within the Banas system, influenced by neotectonism. Consequently, a portion of the Banas catchment has been annexed by the Chambal River system. Given the dynamic nature of the Mej river system, there exists a potential for future piracy and beheading of a significant segment of the Banas River. In addition, the tectonic activity in and around Banas River can be attribute to reactivation of Great Boundary Fault (GBF). Ultimately, we can correlate the reactivation of GBF is due to Himalayan Tectonics and Indian plate motion.

Sediment characteristics and carbon stock in mangroves of Mahanadi delta in western Bay of Bengal

KAKOLI BANERJEE[1]*, Central University of Odisha (banerjee.kakoli@yahoo.com)
Pramod Kumar Bindhani[2], Central university of Odisha
G Jayanti Reddy[3], Central University of Odisha

Abstract

Mangrove forests, one of the most important ecosystems, provide a range of ecosystem services in carbon cycle, coastal protection, fisheries habitat and water filtration. The physical, chemical, and biological properties of mangrove sediment vary widely depending on the forest site, which is a result of the intricate interactions between biotic and abiotic factors. We present a case study conducted at four different mangrove sites investigating the diversity changes in mangrove species (*Avicennia marina*, *A. officinalis*, *Excoecaria agallocha*, and *Rhizophora mucronata*) in relation to sediment properties. The present research work is an attempt to understand the carbon storage capacity of mangrove forest of Odisha coast at Bhitarkanika Wildlife Sanctuary in Mahanadi delta in western Bay of Bengal during 2017-2022 in these 4 different dominant mangroves. We found that sediment parameters such as temperature, pH, electrical conductivity (EC), bulk density (BD), soil organic carbon (SOC), available nitrogen, phosphorus, potassium, and soil texture were significantly correlated with the Importance Value Index (IVI) of the selected mangrove species. The diversity of mangrove species was found significantly higher at sites with higher levels of SOC and BD. A significant variation was observed between station vs depth and season vs depth ($p<0.05$) which proves that carbon deposition in mangrove sediment is highly dependent on soil quality as well as variation in temperature and rainfall w.r.t season and station respectively. The present study has proved the inefficiency of high saline sediment to store carbon which actually leads to stunted mangrove vegetation. Year–wise trend of AGB shows the dominancy of *Excoecaria agallocha* > *A. officinalis* > *Avicennia marina* > *Rhizophora mucronata*. Analysis of variance computed between species, between stations and between seasons as well as species vs station showed remarkable variation ($p<0.05$) proving the reason for varied distribution of the selected species in the study area. AGC is almost a replica of AGB which proves that highest biomass and carbon was observed at areas with low salinity and high pH due to freshwater discharge. Regression equations plotted for AGB and AGC values for the selected species showed significant relation (R2= 1) proving the fact that with increase in AGB, AGC increases. This suggests that mangrove conservation efforts should focus on maintaining or increasing the levels of these sediment properties. Overall, findings of this study have important implications for the conservation of mangrove forests in the existing deltaic ecosystem. By understanding the relationship between mangrove diversity, carbon stock and sediment properties, we can develop more effective management strategies for these valuable deltaic ecosystems prone to cyclonic depressions, which are the carbon sinks in the changing era of climate.

Sustainable Habitability of the Mountain Valley Systems under Emergent climatic transition: A case of the Himalaya

Satish Jagdeo SANGODE[1]*, Savitribai Phule Pune University (sangode@rediffmail.com)

Abstract

A range of mountain valley architectures broadly classified into Outer, Lesser and Higher Himalayas show variable denudational and depositional fronts that are rapidly converging due to climate change and thus interfere with the habitability at higher rates in this densely populated South Asian region. The complex combination of natural as well as anthropogenic effects have laid to new phase of landform evolution demanding recognition of new stable/metastable surfaces under the altered weather conditions for safer habitability. The frequent changes in sediment mass to slope gradient ratios are triggered by; i) altered weather conditions due to climate change, ii) the effect of tectonics, iii) changes in basin fill conditions and iii) altered pathways of sediment mass transfer; demands cautious human intervention. Accounting for the scope of extreme events such as cloud burst, snow/rock avalanches, glacial serge and GLOFs, a synergy of defining the stable/metastable surfaces amongst these valleys is essential and the uncertainties can be reduced using systematic studies in individual valley basins. Adopting case study from NW Himalaya (viz., Dun valleys in Outer Himalaya, Chandra valley in Higher Himalaya; Leh and Pangong-Tangtse valleys in Trans Himalaya) a first order approach has been produced here to evaluate the dominating processes, their magnitudes and scaling.

Based on the parameters suggested by Sangode et al (2021) ‘the convergence and divergence of the denudational front (Dw) with depositional front (S), advancements of lateral valley denudation front (Lw) and the changes in base levels (bn) under constant valley-accommodation-space; efforts are made to develop the approach of finding stable and metastable surfaces. A guideline for database with parametric inputs is suggested for the long- term predictions with variable rates of denudation, basin fill and sediment transfer under tectonically active and stable valley conditions over this hugely characteristic region of the earth.

The Ganga Plain rupture cyclicity deduced from the terminal fans; and its coherency with the Himalayan earthquake cycles

PITAMBAR PATI[1]*, IIT ROORKEE (pitambar.pati@es.iitr.ac.in)

Abstract

The Himalaya has been seismo-tectonically active since its inception. As the Ganga plain is coupled and segmented with the Himalayas, its tectonics are mainly controlled by the Himalayan tectonics. Minor surface rupture and displacement allow the fluvial system to form terminal fans on the down-thrown block of the fault. Hence, terminal fans are promising tectono-geomorphic markers in the Ganga plain, extensively used for mapping active faults. Forty-five Holocene terminal fans mapped from the Ganga plain are spatially well distributed throughout and temporally clustered. The temporal clustering of these geomorphic features suggests episodic rupture of the Ganga plain, which is propelled by the Himalayan tectonics. A total of six tectonic episodes have been identified in the Ganga plain based on the temporal clustering of the terminal fans. The average recurrence interval of these rupturing events has been calculated to be 681±66 years. This recurrence interval closely matches the recurrence interval of large earthquakes in the Himalayan Arch proposed by Gupta and Gahalaut (2014), which is about 750 years. Other studies on the recurrence interval of large earthquakes from different parts of the Himalayan region do not match the Ganga plain rupture cyclicity. The Ganga Plain rupture during the 2015 Nepal earthquake supports a necessary topographic requirement for forming terminal fans.

The enigmatic Sarasvati River: Unravelling the mystery through space and time-A multidisciplinary approach

HARSH TEWARI[1]*, GEOLOGICAL SURVEY OF INDIA (harsh.tewari@gsi.gov.in)
Manoj Kumar Shukla[2], GEOLOGICAL SURVEY OF INDIA
Deepali Kapoor[3], GEOLOGICAL SURVEY OF INDIA
Sanjiv Kumar[4], GEOLOGICAL SURVEY OF INDIA
Maloy Kumar Bhowmic[5], GEOLOGICAL SURVEY OF INDIA
Chandrabadan Tiwari[6], GEOLOGICAL SURVEY OF INDIA
Rajesh Chaturvedi[7], GEOLOGICAL SURVEY OF INDIA

Abstract

Sarasvati, a legendary river mentioned in ancient Indian texts, believed to be flowing in parts of NW India has captivated the interest of academicians from various disciplines for centuries due to its linkage with the term "lost river" and its generous portrayal in the ancient Indian scriptures like Rigveda. The exact course and geographical extent of the Sarasvati River remains a subject of debate. Extensive evidence from diverse fields supports the existence of a high-energy palaeo fluvial system in Northwestern India during Late Pleistocene - Holocene period. A comprehensive study employing multi-disciplinary approach viz. remote sensing, geochronology, sedimentology (grain size, heavy mineral and SEM analysis), geochemical (XRF and XRD) studies as well as geophysical investigations, has been undertaken to shed light on the spatial and temporal evolution of the palaeo Sarasvati River system.

Using temporal multi-sensor satellite data, such as Landsat TM, MSS, Resourcesat AWIFS and ESA Sentinel, a comprehensive palaeochannel map of the Sarasvati River system comprising three major palaeochannels viz. Satluj palaeochannel, Yamunanagar Kurukshetra Shutrana palaeochannel (YKSP) and Drishadwati palaeochannel, having combined length of approximately 2000 km was delineated from Himalayan foothills to Arabian sea. For the first time, this palaeochannel system was ground validated and sampled to unravel its temporal evolution and provenance. Geophysical survey (Vertical Electrical Sounding) and topographic profiles made across the palaeochannels on DEM data also confirms the existence of palaeochannels. The upstream extension of YKSP and its connectivity with Yamuna River was also established using geophysical survey.

Based on OSL dates (64 samples), collected from critical locations, the authors conclude that the Sarasvati fluvial system was active from at least 45,000 years BP to 10,000 years BP. Striking similarity in the sediments collected from palaeochannels and present-day perennial rivers viz. Satluj and Yamuna was also observed. Analysis viz. XRD (50 samples), XRF (93 samples), heavy mineral speciation (57 samples), SEM analysis of quartz grains (20 samples) confirmed that Satluj and Yamuna River supplied higher Himalayan sediments and glacial melt water to Sarasvati River system. Ephemeral rivers originating from the piedmont zone and Outer Himalayas, in the Yamuna-Satluj interfluve, also contributed to its discharge and now flow as misfit rivers inside wide palaeo-valleys. Based on the above inferences, spatio-temporal evolutionary model of the

Sarasvati paleo-fluvial system has been generated.
The beginning of the Holocene period played a critical role in the ultimate disappearance of the Sarasvati fluvial system due to the shifting of both the perennial sources of this fluvial system i.e the eastward shift of the Yamuna River, probably after 13,000 years BP, and the westward shift of the Satluj River after 10,000 years BP. This phenomenon of drainage reorganisation of mighty Sarasvati River system during the Late Quaternary may be related primarily to upliftment of tectonic mountain belts of Outer Himalayas and climate change. The present study involving multi-disciplinary approach has contributed significantly to our understanding of the evolution and demise of the ancient Sarasvati River system which is also applicable to folded mountain belts in other parts of the world.

Comparative analysis of sea level changes along the South Sea coast in South Korea during the Holocene Thermal Maximum

Jeogyun KIM[1], Pukyong National University
Baekyeong SO[2], Samgang Cultural Heritage Researcher
Hankyo SEO[3], Korea Social Science Institute
Ayoung KIM[4], PUKYONG NATIONAL UNIVERSITY
JUNGHYUNG RYU[5]*, PUKYONG NATIONAL UNIVERSITY (jryu@pknu.ac.kr)

Abstract

The Holocene Thermal Maximum (HTM), a period of peak temperatures during the mid-Holocene between 9,000 and 5,000 years ago, brought warmer conditions to South Korea. This warming event led to notable changes in the coastal landscape and human activities. However, the lack of well-defined transgressive shoreline and comprehensive geological evidence limits our understanding of historical sea level variations and their impacts on coastal environments. This study aims to estimate past shoreline movements through a multiproxy approach, including geological, geomorphological, microfossil, and archaeological analyses. Multiple long cores were extracted from the southwest to the southeast along the coast of the South Sea, encompassing various estuarine environments such as the Nakdong, Nam, and Hwang Rivers. Geological and geomorphological data indicate a significant oceanic transgression occurred around 7,000 BP, resulting in a strong saline water incursion, identified approximately 41 km inland from the South Sea. This finding corresponds to the presence of acorn pits and shell mounds, which serve as important archaeological evidence for past sea levels due to their implications regarding past human behavior, environmental conditions, and the proximity of ancient communities to water sources. During the HTM period, the coastline likely retreated significantly inland, forming wide ranges of brackish and saline environments along the coast until around 5,000 BP. This study reveals that the inland movement of coastlines during the HTM had a significant impact on the habitats, diets, and behaviors of ancient peoples.

Kuanchuanpu biota – An early Cambrian Orsten-type Lagerstätte yielding the earliest ecdysozoan body fossils

Huaqiao ZHANG[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing, China (hqzhang@nigpas.ac.cn)
Yunhuan LIU[2], School of Earth Science and Resources, Chang'an University, Xi'an, China

Abstract

Ecdysozoans refer to a group of protostomes that regularly moult their cuticles during growth, and their modern representatives include Scalidophora (Kinorhyncha, Loricifera, and Priapulida), Nematoida (Nematoda and Nematomorpha), and Panarthropoda (Tardigrada, Onychophora, and Arthropoda). Molecular clock estimates indicate that ecdysozoans may have diverged in the Ediacaran Period or Cryogenian Period, but it was not until the earliest Cambrian Period (ca. 538.8 million years ago) when ecdysozoans first appeared in the fossil record, as represented by *Treptichnus pedum*, a putative priapulid trace fossil. Unambiguous ecdysozoan body fossils, however, first appeared in the early Fortunian (ca. 536.4–531.8 million years ago) Kuanchuanpu biota in northern Sichuan and southern Shaanxi Provinces, South China. The key bed yielding abundant soft-bodied fossils falls within the small shelly fossil *Anabarites trisulcatus-Protohertzina anabarica* Assemblage Zone, and has an estimated age of about 535 million years old. In the past decade, we processed rock samples of more than 10 tons from the key bed through acetic acid maceration, and recovered relatively abundant and diverse ecdysozoan body fossils, including several crown-group cycloneuralian species (e.g., *Eopriapulites* and *Eokinorhynchus*), a total-group ecdysozoan taxon *Saccorhytus*, a total-group ecdysozoan fossil embryo *Saccus*, and introvert musculature of scalidophoran animals. All these fossils are three-dimensionally phosphatized and microscopic in size, and they are preserved in a manner similar to the Orsten-type fossils from the Furongian of southern Sweden. Most are preserved as cuticular remains, some have a digestive tract, and only very rarely can the muscles be preserved. Our analysis shows that *Saccorhytus* is a bag-shaped ecdysozoan and not the earliest deuterostome. The bag-shaped body of *Saccorhytus* indicates that the last common ancestor of the Ecdysozoa may be bag-shaped rather than vermiform. The introvert musculature of scalidophoran animals indicates that priapulid-like introvert musculature may have diverged by the early Fortunian. The Kuanchuanpu biota represents an early Cambrian Orsten-type Lagerstätte. It yields the earliest ecdysozoan body fossils, and provides key insights into the origin and early diversification of the Ecdysozoa, the most speciose and ecologically successful animal lineage on Earth.

Adaptive specialization of hexactinellid sponges from the early Cambrian black shales of southern China

Hao YUN[1]*, Northwest University (steven6886@126.com)
Cui LUO[2], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Dorte JANUSSEN[3], Senckenberg Research Institute and Nature Museum
Xingliang ZHANG[4], Northwest University
Joachim REITNER[5], Göttingen Academy of Sciences and Humanities in Lower Saxony

Abstract

Black shales are mostly deposited in dysoxic to anoxic marine environments that inhospitable to most benthic animals. However, flourishing sponge communities dominated by diverse hexactinellids were discovered from the early Cambrian black shales (Niutitang, Shuijingtuo, Hetang, and Huangboling formations; Stages 2 to 4) in the South China block, reflecting an intriguing pattern of adaptive evolution. The adaptive specialization of these sponges is well revealed by two articulated fossil species: Sanshapentella tentoriformis Yun et al., 2022 and Hyalosinica archaica Mehl and Reitner, 1993. The S. tentoriformis has a unique dendriform body that composed of a columnar trunk and multiple conical high projections; each projection is framed by a quadripod-shaped dermal pentactine spicules. This body shape likely reflects a consequence of adaptation that help enlarging the surface area-volume ratio and then maintaining an effective using of oxygen and a low energy cost in the hypoxic condition. The H. archaica possesses an ovoid main body and an impressive long, rope-like stalk, representing the oldest extinct taxon that took advantage of a long root tuft/stalk to elevate the main body above the sediment surface. The long root tuft links Hyalosinica to a series of fossil and recent sponge taxa and indicates a parallel evolution within the Hexactinellida in response to two types of special environmental pressures: 1) frequent currents from different directions and 2) dysoxia. Furthermore, different morphological groups of sponge bodies are discerned from 15 Cambrian hexactinellid genera. The common bodies, including ovoid and cylindrical shapes, are characterized with a relatively smooth wall and mostly a conspicuous osculum at the top (represented by Diagoniella, Protospongia, and Triticispongia). Some cylindrical bodies have an uneven body wall that characterized by numerous small, circular parietal gaps (represented by Hintzespongia) and/or a serrated oscular margin (represented by Lantianospongia). The above-mentioned dendriform (and tent-like) S. tentoriformis and long stalk-bearing H. archaica represent the most uncommon body shapes within the Cambrian sponge communities. Generally, the ovoid and cylindrical bodies were adapted to a large spectrum of environments and thus are ‘one size fits all’ in the adaptive evolution. However, the uncommon bodies, such as Lantianospongia, Hyalosinica, and Sanshapentella, are restricted to black shales, indicating that they are adaptive morphological specializations in response to the inhospitable, oxygen-deficient environments.

Phosphatised calcified cyanobacteria at the terminal Ediacaran and the earliest Cambrian transition stage: Response to the paleoenvironment

Xiao MIN[1]*, Chengdu Center, China Geological Survey (Geosciences Innovation Center of Southwest China) (360446872@qq.com)

Abstract

Calcified cyanobacteria were only sporadically discovered in the Neoproterozoic and did not appear widely until the early Paleozoic. It is proved that the abundance of calcified cyanobacteria is related to the change of atmospheric CO2 level and the calcium carbonate saturation of seawater. Description and systematic research of phosphatized calcified cyanobacteria in the Cambrian is rare, even though some phosphatized materials were reported. A variety of phosphatised calcified cyanobacteria recovered from the terminal Ediacaran Gaojiashan and early Cambrian Terreneuvian Kuanchuanpu biota fill a major gap in the fossil record of calcified cyanobacteria during this transitional period. Calcified cyanobacteria share some similarities in composition and phosphatised preservation style. Thus, research on phosphatised calcified cyanobacteria of the Kuanchuanpu and Gaojiashan biota around the Precambrian–Cambrian boundary sheds new light on the mechanisms of calcification and phosphatisation in cyanobacteria. Based on the morphological variations of Girvanella in these two biotas, three preservation modes, which may not be discernible in thin sections, were recognized. These different preservation modes should result from different degrees of calcification and phosphatisation, instead of evolution. The continuity in the evolution of calcified cyanobacteria and changes in marine chemical conditions indicate that atmospheric CO2 levels may have risen to approximately 10 times present atmospheric level (PAL) after 551 Ma, during the critical period of the Precambrian–Cambrian transition.

Cambrian small skeletal fossil bioprovinces and their application to test paleogeographic models

Michael STEINER[1]*, Shandong University of Science and Technology (Michael.Steiner@FU-Berlin.de)

Abstract

The transition from the Neoproterozoic to the Cambrian period marked a significant era of restructuring and innovation across the Earth's geosphere, hydrosphere, and biosphere. The Cambrian "explosion" witnessed a bioradiation of metazoans, leading to the abrupt appearance of various metazoan bauplans within a brief 20-million-year span of time in the fossil record. This biotic revolution was characterized by a remarkable increase in disparity, with a somewhat moderate rise in metazoan diversity. Despite numerous hypotheses attempting to explain the Cambrian Bioradiation, a consensus has not yet been achieved.

Understanding the causes behind this event necessitates a deeper exploration of sedimentological, geochemical, paleontological, environmental, and tectonic aspects during the Precambrian-Cambrian transition. Astronomical, geophysical, and geotectonic factors are believed to have played a pivotal role in the Cambrian Bioradiation, yet detailed information on these aspects lags behind other geoscience subjects related to this event. Factors such as the geotectonic regime, specific paleogeographic configurations with larger supercontinents or deep ocean barriers, are likely to have exerted influential effects on the biotic development during the Ediacaran-Cambrian period.

Geographic speciation emerges as a crucial mechanism in metazoan evolution, alongside competitive speciation and polyploidy. The division of the gene pool by a geographic barrier, like deep oceanic basins, which has the most impact on benthic fauna, is a prerequisite for speciation and diversification. Therefore, reconstructing the paleogeography and biogeography of the Ediacaran and early Cambrian becomes paramount for a comprehensive understanding of the Cambrian Bioradiation.

Regrettably, the paleogeography of the Ediacaran to early Cambrian remains insufficiently constrained. Recent reconstructions highlight considerable uncertainties in the positions of smaller continental blocks and terrains, with only larger continents showing robust data consistency (e.g. Gondwana). Small terrains impacted by later orogenies (such as the Central Asian Orogeny Belt-CAOB) and more generally by remagnetization events add complexity due to vague hypotheses about the paleogeographic positions of the microcontinents.

To address these uncertainties, Small Skeletal Fossil (SSF) occurrence data for different Cambrian intervals were compiled, and hierarchical cluster analysis was conducted to determine fauna

similarities in different tectonic or geographic sub-regions. Categorizing the SSF fauna into 11 larger provinces facilitated discussions on paleobiogeographic relationships, allowing for a comparison with existing paleogeographic models based on paleomagnetic data.

The results provided a more precise paleogeographic reconstruction for smaller tectonic blocks, especially those undergoing collisional events. The paleobiogeographic reconstruction based on SSFs contributed to the development of a hypothesis for the early Cambrian Ocean circulation pattern, aligned with constraints from modern ocean circulation patterns. This method serves as an independent toolkit to test the validity of existing paleogeographic models in deep time, less susceptible to tectonic and thermal overprinting.

Chronology of the Ediacaran-Cambrian BoundaryDiscussion with new data from Aksu area of Xinjiang Province, China

Ben YANG[1]*, Institute of Geology, Chinese Academy of Geological Sciences
(yangben8@foxmail.com)

Abstract

GSSP of the Ediacaran-Cambrian Boundary is currently set at the Fortune Head section in Newfoundland of Canada, indexed by the first appearance datum (FAD) of the trace fossil Treptichnus pedum. The Ediacaran- lower Cambrian deposits in this section are composed with siliciclastic sediments preserving no δC13 isotope value and missing the earliest record of body fossils (small shelly fossils or acritarchs etc.). In addition, the FAD of Treptichnus pedum in global sections varied in the lower Cambrian strata. These problems have been challenging the section as a GSSP. Studies are discussing on reassessing the current section or selecting other potential sections for the boundary though most of them has similar problems. Here we make a preliminary discussion on the global correlation of Ediacaran- Cambrian Boundary with new data from the Aksu region of Xinjiang Province in China. The Aksu areas, lying in the northwestern part of the Tarim Block, preserves a set of sections with the earliest small shelly fossils (Protohertzina anabarica, Protohertzina unguliformis, Anabarites trisulcatus, etc.), acritarchs, trace fossils in the basal Cambrian Yuertusi Formation, also δC13 isotope data around the Ediacaran-Cambrian boundary (possibly correlated to the boundary of Yuertusi and underlying Qigebulaq formations). Our data demonstrates a consistence among different types of the data. Comparing with other known sections, here, the data diversity and resolution show potential to overcome the problems discussed above. It is possible to fix a point at sections of the Aksu area for the chronological correlation of the Ediacaran-Cambrian Boundary.

3D morphologies of the early Cambrian Chengjiang arthropods

Yu LIU[1]*, Yunnan Key Laboratory for Palaeobiology, Yunnan University (zac.liu@126.com)
Xianguang Hou[2], Yunnan Key Laboratory for Palaeobiology, Yunnan University
Dayou Zhai[3], Yunnan Key Laboratory for Palaeobiology, Yunnan University
Huijuan Mai[4], Yunnan Key Laboratory for Palaeobiology, Yunnan University

Abstract

The “Cambrian Explosion”, or “Cambrian Radiation”, represents one of the most important events in the evolution of metazoans. Evidence of this event has been found in various Lagerstätten from all over the world, among which the Chengjiang Biota located in Yuxi, Yunnan Province, China provides unparallel fossils of over 300 species from the early Cambrian. More than 80 Chengjiang species belong to the most abundant animal group throughout the entire geological time —the Arthropoda. Knowing the exact morphologies of the early Cambrian arthropods is fundamental for understanding their evolutionary history and ecological traits, which then reflect the co-evolution of these widespread animals and the environment they used to live in. For a long time, due to limitations of methods, researchers have been able to extract only little information, mostly from the surface of the fossils. Little has been known about the important soft-body structures on the ventral side of the Chengjiang arthropods. In recent years, our team has conducted in-depth research on various Chengjiang arthropods from multiple perspectives such as 3D morphology, ontogeny, and phylogeny by using micro-CT scanning, computer-based 3D rendering, and virtual anatomical dissection techniques. New information that had been ignored in previous studies has now been discovered, and certain progress has been made. As a representative of our team, I will talk about these new developments, and provide prospects for the next step of this kind of research.

Ventral Morphology and Their Ecological Implications of Two Xandarellids from Chengjiang Biota, China

Maoyin ZHANG[1]*, Yunnan University (maoyin_zhang@163.com)
Xianguang Hou[2], Yunnan Key Laboratory for Palaeobiology, Yunnan University
Huijuan Mai[3], Yunnan Key Laboratory for Palaeobiology, Yunnan University
Michel Schmidt[4], Yunnan Key Laboratory for Palaeobiology, Yunnan University
Javier Ortega-Hernández[5], Harvard University
Yu Liu[6], Yunnan Key Laboratory for Palaeobiology, Yunnan University

Abstract

Xandarellida, a group of Artiopoda from Cambrian Lagerstätten, is characterized with a broad shape of the exoskeleton dorsally, and a pair of compound eyes followed by a pair of antennae and a series of similar post-antennal appendages ventrally. More morphological details remain ambiguous. The ecological inferences that Xandarellids with large compound eyes are likely to be predators or scavengers do not seem insufficient and still remain controversial. Phylogenetically, the relationships between artiopods and other euarthropods, such as Total-group Mandibulata and Total-group Chelicerata, are still under debate. Phylogenetic relationships among species within this taxon are also uncertain. An explanation for these is that, most artiopods are known with very limited morphological details pertaining to key structures such as the head organization and the biramous appendages. In the present study, we employed X-ray computed tomography to reveal the ventral morphology of two xandarellid species, *Xandarella spectaculum* and *Cindarella eucalla* from the Chengjiang Biota. Key structures including the head organization, trunk limbs and mismatch between tergites and ventral trunk limbs are demonstrated in detail here. We further carried out phylogenetic analyses using both parsimony and MrBayes inferences. Our results suggest that, 1) xandarellids are closely related to naraoiids; 2) xandarellids may not be predators or scavengers, but rather particle feeders that used to live near the sea floor in shallow waters.

Spatially and temporally dynamic marine redox state through late Ediacaran-early Cambrian: evidence from carbonate I/Ca proxy

Ruliang HE[1]*, Northwest University (rulianghe@nwu.edu.cn)
Chao Chang[2], Northwest University
Hao Yun[3], Northwest University
Wei Liu[4], Northwest University
Xingliang Zhang[5], Northwest University

Abstract

Ediacaran-Cambrian witnessed the bio-diversification from the appearance of earliest metazoans to Cambrian Explosion. The increased oxygenation state of marine-atmosphere system has commonly been considered as a primary environmental trigger. However, growing evidence of geochemical proxies and numeric models has questioned the unidirectional shift of marine redox state during this interval, highlighting a spatiotemporally dynamic redox condition during Ediacaran to Cambrian. To address this issue, we report new I/Ca data, a local redox proxy, from Ediacaran-Cambrian carbonate successions of different depositional environments in Tarim Basin and South China. In Tarim Basin, comparing to the relatively low I/Ca background of Ediacaran, high I/Ca ratios up to 2-4μmol/mol, comparable to I/Ca in the modern well-oxygenated waters, are observed at the Yuertusi Formation of early Cambrian, coincident with the occurrence of small shelly fossils (SSFs). For South China cores, the overall I/Ca values of early Cambrian are comparable to the background of Ediacaran (< 1μmol/mol) with transient I/Ca pulses observed, suggesting a generally oxygen-depleted condition in the upper ocean. Some high I/Ca values are observed in Yanjiahe Formation South China, but they are suspectable to the contamination from apatite, suggested by a positive correlation between I/Ca and P content. Our results suggest the overall marine O2 content may still be relatively low in Ediacaran-early Cambrian; oxygenation pulses could have occurred both in Tarim Basin and South China, but such oxygenation events are temporally inconsistent and spatially heterogenous, probably associated with their own local oceanographic settings. The spatiotemporally dynamic redox condition could be a major feature of the Ediacaran-early Cambrian ocean that nurtured the Cambrian Explosion.

The anterior sclerite in early arthropods

Mengxiao YU[1]*, Yunnan University (ymx720@126.com)
Yu Liu[2], Yunnan Key Laboratory for Palaeobiology, Yunnan University
Xianguang Hou[3], Yunnan Key Laboratory for Palaeobiology, Yunnan University
Huijuan Mai[4], Yunnan Key Laboratory for Palaeobiology, Yunnan University

Abstract

The so-called “arthropod head problem” is a highly debated topic in the studies of arthropod evolution. This “problem” mainly deals with the alignment of head segments across various groups. The anteriormost head segment of euarthropods is often called “anterior sclerite” which, in our view, only refers to the tergite of that segment. The anterior sclerite has been considered as a derivative of the dorsal plate in the anterior region of radiodonts. Despite suggestions of its homology and neurological origin across these groups, the precise morphology and evolutionary significance of this structure remains ambiguous. This is mainly because of the flattened preservation of the fossils, which didn’t allow in-depth investigations along the direction of fossil compression. Due to the recent advances in technology, such as microtomography and computer-based 3D rendering techniques, our team has been able to observe and reconstruct the ventral organization of the head in various early arthropods from the early Cambrian Chengjiang biota. By comparing the new data from several arthropod species from Chengjiang, we propose that the anterior sclerite has a more intimate relationship with the visual system than previously thought. After inherited from radiodonts, the anterior sclerite remains as a separate structure in several euarthropod groups, but becomes part of the head via a fusion mechanism in various euarthropod lineages.

María Gabriela Suárez[14], University of Zürich

Abstract

Earth's Palaeozoic marine environments were undoubtedly dramatically impacted by the evolution and global radiation of trilobites, an extremely diverse extinct euarthropod group that occupied almost all marine ecological niches. However, the processes by which trilobites dispersed and diversified around the globe in the early Palaeozoic remain unclear, amplified by aspects such as incomplete understanding of the biogeographical occurrences of different trilobite groups and underlying uncertainty around geographical reconstructions (e.g., biologically-informative regions, plate reconstruction models). We introduce an international working group ('TriBE: Trilobite Biogeography and Ecology') of primarily early-career researchers established to drive forward research on trilobite biogeography and dispersal, and their links to ecological mode. We present reconstructed trilobite biogeographical patterns accompanying their initial global radiation from the early to late Cambrian. We used biogeographical data collected by the working group members and data retrieved from the Paleobiology and Geobiodiversity Databases to analyse trilobite biogeography. We used the published Cambrian phylogenetic tree of 107 species with tip-dating (representing most of the Cambrian trilobite families) by Paterson et al. (2019) and conducted biogeographic analyses using the R package BioGeoBEARS to reconstruct ancestral area relationship. The results of the BioGeoBEARS analysis inform on Cambrian trilobite ancestral geographical ranges, infer the number and type of allopatric evolutionary events, and reveal the connectivities of different regions during this crucial stage of euarthropod evolution. These data will then be applied, in addition to occurrence, ecological (e.g., life habit, diet), and environmental information, to broad-scale analyses exploring dispersal mechanisms and patterns in the Cambrian and later Palaeozoic using sophisticated network analyses. The TriBE working group is thereby elucidating the enigmatic and foundational dispersion of trilobites in the

Palaeozoic, the underlying causes of their biogeographical ranges, and their varied and extensive impact on early global ecosystems.

Abstract

Macrofossils of late Ediacaran age are increasingly recognised to include representatives of stem and crown group metazoan phyla, but robust fossil evidence for Ediacaran Porifera has proven elusive. Here we describe a new Ediacaran macrofossil genus, comprising two distinct species, from the late Ediacaran Aar Member (~548 Ma) of the Nama Group of southern Namibia. The two new taxa, which are globular and bowl-shaped respectively, can reach at least 40 cm in size, are often preserved three-dimensionally, and exhibit surface impressions of a grid of sub-divided quadrate boxes that covers the entire body. Preservation of some specimens in the assemblage with regions showing entirely smooth surfaces (lacking the grid, which often occurs on sub-millimetric surface veneers), and wrinkling, suggests that these taxa possessed a smooth and flexible internal membrane. Such specimens find comparison with a number of similar smooth, three-dimensional, bag-like structures preserved in sandstones in other global localities. The grid impressions are interpreted to indicate the presence of a non-mineralized organic exoskeleton comprised of cruciform skeletal elements, similar to that seen in several biomineralized Cambrian hexactinellids. Reappraisal of late Ediacaran candidate sponges and earliest Cambrian sponge spicules supports the suggestion that spiculogenesis evolved prior to the evolution of biomineralization, and is consistent with the independent acquisition of biomineralization amongst the major poriferan clades. The Namibian specimens provide a new search image for fossil sponges prior to the evolution of mineralized spicules, and suggest that the fossil record of late Ediacaran sponges may be far more diverse than previously recognised.

Systematics of the Redlichiidae (Redlichiida, Trilobita) and related groups

Zhixin SUN[1]*, Nanjing Institute of Geology and Palaeontology, CAS (zxsun@nigpas.ac.cn)
Fangchen ZHAO[2], Nanjing Institute of Geology and Palaeontology, CAS

Abstract

As an exemplification of primitive trilobites, redlichioids and related groups from the early Cambrian is important for understanding the origin and early evolution of trilobites. Here, we suggest a revised systematics of Redlichiidae Poulsen 1927 and related taxa based on types and new materials from South China. The new systematics through phylogenetic analysis indicates that Redlichiidae s. l. is indeed nonmonophyletic, and many groups previously placed under this superfamily (such as Saukiandidae Hupé 1953, Menneraspidae Pokrovskaya 1959, Metadoxididae Whitehouse 1939, Kueichowiodae Liu 1965 and Mayiellidae Chang 1966) are reassigned to other clades. The Yinitidae Hupé 1953 s. l. do not constitute a monophyletic group in our analyses, and most genera previously belonged to this family are reassigned to Longduiidae Zhang & Qian 1980, Drepanopygidae Lu 1961 and Yiliangellinae Zhang & Lin 1980 (?Gigantopygidae). Longduiidae and Drepanopygidae was nested within the ‘corynexochids’ clade, and Yinitidae s. s. are possible annectant forms between Redlichioidea s. s. and stem ‘corynexochids’ such as the Edelsteinaspididae Hupé 1953 and Jakutidae Suvorova 1959. In addition, our new systematics suggest that ‘ellipsocephaloids’ should not be included in the Redlichiidae s. s., and favor a relationship between this group and Paradoxidoidea. Although the considerable uncertainty across phylogenetic analysis, these results imply that early trilobites require a new high-level classification scheme.

Ediacaran chronostratigraphy: falling into place or falling into pieces?

Dmitrii GRAZHDANKIN[1]*, Northwest University, Xi'an, China (f6oeoua@mac.com)

Abstract

The prospect of subdivision of the Ediacaran System into chronostratigraphic units that would represent globally recognisable intervals of geological time and serve as references in narratives about biosphere evolution is tremendously appealing, but hardly any pattern is discernible in the distribution of fossil taxa. Ediacaran chronostratigraphy is currently in a state of ferment, stirred by the addition of new geochemical and geochronological data as well as controversial interpretations of fossils. It appears that biotic evolution proceeded in mostly anoxic environments, and was punctuated by episodic oxygenation, global-scale euxinia, and alkalinity events. It is generally accepted that the Ediacaran macro-organisms were “normal” aerobic metazoans; however, recent evidence from Siberia suggests that not only were these organisms tolerant of anoxic conditions, but they also had the capacity to function anaerobically. The implications are sobering: the late Ediacaran increase in ecological and morphological complexity does not represent an expansion of aerobic metabolism. Recent discoveries continue to challenge the existing orthodoxies. Previous studies have separated late Ediacaran palaeocommunities into three taxonomically distinct assemblages. Known as the Avalon-, White Sea- and Nama-type biotas, these benthic communities were arguably adapted to different specific yet-unknown environmental conditions and were the subject to different taphonomic processes. Hydrodynamics, water depth, sedimentation rates, and/or substrate heterogeneities have been suggested as potential factors that could determine taxonomic composition and structure of the Ediacaran communities; however, it has been difficult to explain the absence of Ediacaran fossils in lithofacies that are otherwise fossiliferous. What is usually overlooked is the relative position of chemocline. Although persistent widespread anoxic conditions are generally assumed to be lethal to benthic Ediacaran communities, studies in the Khatyspyt lagerstätte of Arctic Siberia have demonstrated that anoxia might have driven ecological differentiation of organisms, and that heterogeneous and dynamic redox landscapes were far more significant in early animal evolution than hitherto appreciated. More important is that the preservation of Ediacaran soft tissues via authigenic precipitation of micrite cements in the Khatyspyt lagerstätte appears to be controlled by the relative position of redox chemocline, whereas the disappearance of the fossils in the Khatyspyt Formation correlates with the stepwise oxygenation of the water column. So taphonomy and palaeoecology both matter for the Ediacaran chronostratigraphy – but to a surprising extent in a positive and constructive way. Eventually, there may be no simple correlation between the Ediacaran biotic evolution and the geological record of environmental perturbations; but it seems increasingly possible that the Ediacaran macro-organisms disappeared from the geological record as a consequence of progressive oxygenation, providing strong evidential basis in support of the “Cheshire cat” model. The observed patterns of Ediacaran fossil distribution most likely mirror the the episodes of basin-scale authigenic cementation of the sediment during alkalinity events

triggered by redox fluctuations in Ediacaran habitats. Perhaps those glued to their computer screens laboriously correlating peaks and plateaus on carbon isotope variation curves should emerge blinking into sunlight where the emerging Ediacaran palaeobiology awaits our exploration. Preservation of arthropods and microbes in Cambrian Orsten Lagerstätten

Jonathan POPLE[1], University of Lausanne
Pierre GUERIAU[2], University of Lausanne
Allison DALEY[3]*, University of Lausanne (allison.daley@unil.ch)

Abstract

The Upper Cambrian Orsten locality in Sweden has yielded abundant microscopic arthropods phosphatically preserved in exquisite 3-dimensional detail, revealing much about their anatomy, systematics, and ontogeny, and providing a window into Cambrian meiobenthic faunas which are usually absent from the more common Burgess Shale-Type Lagerstätten. However, despite this exquisite quality of preservation, the Orsten is highly selective in the range of sizes, tissues, and taxa preserved and almost only yields hollow carcasses of cuticle-bearing metazoans smaller than 1-2 mm. The reasons for this selectivity and the processes that led to the exceptional preservation of these organisms have yet to be elucidated. Combining synchrotron radiation X-ray microtomography (SR-µCT) with scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDX), we undertook a taphonomic examination of over 60 bivalved phosphatocopine arthropods that we collected from an Upper Cambrian Alum Shale outcrop in the Kinnekülle region of Västergötland, Sweden. Shield valves are extremely well preserved in all specimens, and soft tissues within the valves are preserved in a third of specimens but restricted to small individuals (length < 350 µm). These soft tissues include the external cuticle of the body and the appendages, and a grade of taphonomic states was observed ranging from highly detailed and complete external cuticle, through various stages of disarticulation and loss of cuticular detail, to indistinct masses of globules reproducing only broad anatomical features.

SR-µCT and SEM results show that no internal anatomical structures can be distinguished within the internal space of the body and appendages of the Orsten phosphatocopines. Instead, spherical phosphatic globules partially fill the cuticle, sometimes creating near-complete pseudomorphs of external anatomical structures and appendages. These globules are hollow or less dense at their core, and in any given specimen they have a narrow diameter size range averaging between 2 and 5 µm depending on the specimen. The size, morphology, and spatial distribution of these globules lead us to propose that they represent autolithified and minerally overgrown bacteria preserved inside the cuticle, and that these bacteria were intricately associated with the phosphatisation process. We also observed highly localized filamentous structures interpreted as bacterial biofilms, which also indicate that bacterial activity was taking place in the immediate proximity of decaying arthropod carcasses. These observations provide direct evidence for the involvement of internal and external microbial activity in Orsten-type preservation and allow for a step-by-step reconstruction of phosphatization processes.

Taxonomic revision of Dickinsonia Sprigg

Nikita SOZONOV[1]*, The Trofimuk Institute of petroleum Geology and Geophysics SB RAS (n.sozonov@g.nsu.ru)
Natalia Bykova[2], The Trofimuk Institute of petroleum Geology and Geophysics SB RAS
Nikolay Bobkov[3], The Trofimuk Institute of petroleum Geology and Geophysics SB RAS
Dmitriy Grazhdankin[4], The Trofimuk Institute of petroleum Geology and Geophysics SB RAS

Abstract

This study presents a comprehensive analysis of the genus Dickinsonia, a prominent member of the Ediacaran biota, aimed at refining its taxonomy and deepening our understanding of its ecology and evolution. A total of nine species of Dickinsonia have been described, of which six remained valid until recently: D. costata, D. tenuis, D. lissa, D. brachina, D. menneri and D. rex. Initially described based on a few specimens, these species gradually become increasingly difficult to distinguish from each other as material accumulates. Thus, determining the species identity of many individuals might be difficult due to the lack of clear diagnostic characters, especially for small-sized individuals. A similar fate befell the Dickinsonia population, discovered in the Konovalovka Member of the Cherny Kamen Formation cropping out along the Sylvitsa river in the Central Urals. The Central Ural population possesses a narrow unpaired deltoidal module, which brings them closer to D. tenuis, but the density of modules is not high enough for being attributed to this species.

A recent attempt on the revision of the genus Dickinsonia, shows that the taxonomy of the genus is redundant. Based on the results of the study, they propose to reduce the number of species to two, the most clearly distinguishable. But this study mainly analyzed samples from Australia, and only 2 samples from the White Sea were used, which cannot reflect the entire range of intraspecific variability in D. menneri and D. tenuis.

Our study is the first large-scale attempt to revise the taxonomy of genus Dickinsonia using specimens from all three known localities. To evaluate intraspecific variability and aid in species delineation, we performed morphometric analyses on 259 specimens, utilizing extensive collections from the Melbourne Museum and the South Australian Museum (161 specimens), the White Sea coast (20 specimens), and the Ural Mountains (78 specimens).

Our findings reveal significant morphological diversity within Dickinsonia populations, challenging previous taxonomic classifications. Through principal component analysis (PCA) and clustering techniques, we identified distinct clusters corresponding to different geographic regions, with notable variations in size and module density. Importantly, our results support the division of the Australian collection into two clusters proposed by previous studies but also reveal two additional clusters encompassing Ural and White Sea samples.

This revised taxonomy provides a framework for more informed comparisons between Dickinsonia specimens from different localities, offering new insights into their ecology and evolutionary trajectories during the Ediacaran period. Furthermore, our study underscores the importance of considering intraspecific variation and geographic distribution in elucidating the

adaptations and developmental processes of Ediacaran organisms.

A tiny Cambrian euarthropod illuminates the early evolution of mandibulates

Han Zeng[1], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Yao Liu[2]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
(yaoliu@nigpas.ac.cn)

Abstract

The mandibulates are the most abundant and diverse euarthropods on the earth. Although the diverse stem- and crown-group mandibulate euarthropod fossils have been discovered from the Cambrian, the evolutionary gaps in the origin of mandibulates remain to be filled, and the phylogenetic position of the related groups of mandibulates need to be clarified. Cambrian Burgess Shale-type fossil Lagerstätten have contributed significant evidence for exploring these questions. Recently, we study a common few millimeters-large euarthropod that is a potential mandibulate taxon from the early Cambrian Chengjiang fauna, China, which lacks high-resolution morphology and has questionable evolutionary affinities. By using computed microtomography, scanning electron microscope and other imaging techniques, we have uncovered additional and crucial high-resolution morphology, encompassing the intricate structures and the precise position of the appendages, novel structural elements and the details of the soft tissue. Furthermore, we have conducted a comparative analysis of the key morphological characters with those of closely related groups within the mandibulates and chelicerates, while also providing an in-depth discussion on its Palaeoecology. Through the integration of morphological linkages and phylogenetic analysis, we have documented its precise phylogenetic placement and provided comprehensive insights into the intricate aspects concerning the origin and early evolution of mandibulates.

Complete radiodonts from the early Cambrian Chengjiang fauna: implications on radiodont evolution

Han ZENG[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (hzeng@nigpas.ac.cn)

Abstract

The Palaeozoic radiodonts are important for understanding the evolution and ecology of early euarthropods. Nonetheless, complete radiodont specimens are extremely rare and are only discovered from soft-bodied fossil deposits. Among these fossil records, the oldest Chengjiang Lagerstätte has yielded three radiodont species with complete specimens. Here we provide detailed redescription of a classical specimen from the Chengjiang fauna and assign it to a new taxon Innovatiocaris maotianshanensis gen. et sp. nov.. The head of I. maotianshanensis has a pair of stalked eyes, an ovate dorsal sclerite, a pair of frontal appendages composed of 11 distal articulated podomeres bearing spiky endites with only anterior auxiliary spines, and a putative triradial oral cone. The body possesses six anterior pairs of small differentiated neck flaps and ten posterior pairs of trunk flaps, with soft tissues including alimentary canal and musculature preserved. The tail includes a tail fan comprising three pairs of lateral blades and a pair of very long furcae. Another two possible species of Innovatiocaris, Innovatiocaris? sp. and I.? multispiniformis sp. nov., are also established based on the distinct features of frontal appendages uncovered from the Chengjiang fauna. The evolutionary implications of Innovatiocaris are discussed in the context of radiodont phylogeny. Phylogenetic analysis retrieves Innovatiocaris as either a basal member of Hurdiidae or early-branching species of the non-hurdiid clade. Innovatiocaris provides new insights into the radiodont phylogeny and illuminates the early diversification of Radiodonta.

Did ctenophores construct colonies in the Ediacaran?

Vladislav DESIATKIN[1]*, Trofimuk Institute of Petroleum Geology and Geophysics of Siberian Branch Russian Academy of Sciences (IPGG SB RAS) (desyatkinvd@ipgg.sbras.ru)
Dmitry Grazhdankin[2], Trofimuk Institute of Petroleum Geology and Geophysics of Siberian Branch Russian Academy of Sciences (IPGG SB RAS)

Abstract

Among all Ediacaran macroscopic organisms feather-like specimen stimulate minimal interest from the researchers. However, these organisms may provide us a lot of new information and make us reconsider our understanding of certain Metazoan groups.

Our study is based on exceptionally preserved fossils from Ediacaran Yorga Formation, Southeast White Sea area. In contrast to the feather-like fossils found in South Australia and Avalonia, which are preserved as high-relief casts on the surfaces of sandstone beds, the White Sea specimens are preserved as pyritized three-dimensional composite casts within sandstone beds. We have managed to observe not only well described morphostructures such as holdfast, axial structure, lateral antimers and rows of metamers but also some internal structures. Through observing certain specimens and CT-scanning we have discovered a set of membranes that apparently are continuation of lateral antimers in the axial structure. Internal membranes separate axial structure into high-integrated and distinct segments. We assume that an axial structure wasn't an organ that carried lateral antimers like an axial zooid of sea-pens. The metamers occur as rows that have alternated localization at the each segment. These data indicate a biradial symmetry and possible colonial organisation of feather-like fossils.

Recently, the possible colonial organisation of feather-like fossils has generally been regarded in the context of Cnidaria association hypothesis. However, the presented herein evidence contradicts this hypothesis. Despite the similarity between certain structures of Pennatulacea and the feather-like fossils we observe two different body plans. In this case, could we associate feather-like fossils with another group of Metazoa? Among all Metazoa types only Bilateria, Cnidaria and Ctenophora are able to construct complex multi-tissue bodies. This result in considering the less popular Ctenophora phylogenetic association hypothesis. Previously, the hypothesis couldn't operate with the informations about ctenophores that we have now, and therefore it wasn't able to provide answers to some critical questions. Since then, several morphological and molecular-genetic studies have yielded interesting results which allows us to consider the hypothesis. By studying the modern ctenophore genome and comparing it to the genomes of other Metazoa groups, we have identified several features that we consider as significant evidence for the hypothesis: an earlier separation of ctenophores from others; independent development of the neural and muscular system; phenotypic plasticity with common body-plan. If we assume that feather-like fossils are a stem or an extinct crown-group ctenophores, then the question arises regarding the colonial organization that we observe in feather-like fossils but not in modern ctenophores.

The basal position of ctenophores in the phylogenetic tree of animals, their high regenerative ability and phenotypic plasticity allows us to suppose the presence of the ability for colonial organisation and a sedentary lifestyle in stem ctenophores, which is typical in other Metazoa and lost in ctenophores during their evolution. The construction of feather-like fossils corresponds to the proposed construction of colonial sedentary ctenophore. The paleontological, morphological and molecular-genetic evidence presented above allow us to consider feather-like fossils as colonial ctenophores.

Putative soft-bodied structures in early Cambrian Orsten-type fossil lagerstätten of the Yangtze Platform

Yuqian CHEN[1]*, Shandong University of Science and Technology (rubbycyq@163.com)
Michael Steiner[2], Shandong University of Science and Technology
Ben Yang[3], Chinese Academy of Geological Sciences

Abstract

The Ediacaran–Cambrian transition is a fundamentally important period in the history of life on Earth, the global rearrangement of palaeo-plate tectonics, the palaeo-climate, the marine palaeo-environments and their diverse habitates and palaeo-biocenoses all underwent significant changes during this period. Therefore, the Ediacaran–Cambrian holds an important role in the origin and evolution of metazoan clades and marine palaeo-environmental changes.

Orsten-type preservation is an exceptional preservation that refers to an early, three-dimensionally stabilizing preservation of soft integument and soft-part structures by calcium phosphate (apatite). This type of preservation shows features that are usually not recognizable in fossils, and their detailed morphological characteristics provide convincing evidence of the general body plan, organ preservation, systematics, and ontogeny. In South China, Precambrian and Cambrian sediments have yielded multiple evidence of invertebrate embryos and larvae in Orsten-type preservation (including Doushantuo-type preservation sensu Butterfield). Some key Orsten-type lagerstätten with embryos have been reported from the early Cambrian of Shaanxi, Sichuan, Hubei, Yunnan, the upper to middle Cambrian of Hunan, and the Ediacaran of Guizhou. Here we discuss a new occurrence from the early Cambrian of the south-western margin of the Yangtze Platform. The assemblage contains eggs, embryos and hatchlings as well as small skeletal fossils (SSFs).

The Ediacaran-Cambrian strata of the Yangtze Platform of South China preserve rich sedimentary facies, continuous deposition and extensive exposure which makes them an important repository for unravelling the early co-evolution of life and environments. We provide an overview of the regional and stratigraphic distribution of the key Orsten-type taxa, extraordinarily preserved embryos, hatchlings, phosphatized organisms with putative soft-bodied structures, and some associated SSFs. In addition, we discuss a new interpretation of putative soft-bodied structure based on our newly found samples.

SSFs have been widely discovered in early Cambrian successions across the globe, and owing to their broad distribution and rapid evolution, SSFs have been applied for global correlation of early Cambrian strata. They are abundant in Early Cambrian carbonates of the Yangtze Platform and are found especially in shallow water environments. Based on the comparison of the SSF assemblages and other evidence of different regions in China, the similarities in the palaeoenvironmental

conditions for the Orsten-type preservation are considered. The new findings may have some relevance for the future recovery of potential Orsten-type fossil deposits on other palaeo-continents.

The structural diversity of mollusk shells in early Cambrian

Luoyang LI[1]*, Ocean University of China (liluoyang@ouc.edu.cn)

Abstract

The evolutionary success of mollusks can be related to the effective protection of their highly mineralized shells that were acquired during the period of the Cambrian explosion (~560–520 Ma) when most modern animal phyla first emerged alongside the acquisition of the ability of biomineralization. Mollusks can construct extremely intricate shells with crystals of calcium carbonate (CaCO3, mainly aragonite and calcite), >95wt%, embedded within a three-dimensional organic matrix that generally accounts for less than 5% of shell weight, and their multiscale hierarchical architectures endow their outstanding mechanical properties that are far superior to non-biogenic counterparts. Over the past decades, extensive studies and great interest in modern shells have allowed the biological, chemical, and material science fields to elucidate many principles of molluskan biomineralization. From a palaeontological viewpoint, mollusks originated and diversified very early in the Cambrian, flourished around the globe, and constituted major elements of Cambrian marine communities. Much attention has previously been paid to the taxonomy, phylogeny, biostratigraphic, and palaeogeographic implications of Cambrian mollusks, particularly based on millimeter-size ‘micromollusks’ that were retrieved from so-called Small Shelly Fossil (SSF) assemblage worldwide. Microstructurally, global phosphogenesis events across the Precambrian-Cambrian transition enabled the preservation of mollusk shells in fine detail, even at micrometer and sub-micrometer levels, however, biomineralization studies are still very challenging due to the long history and complex processes of diagenesis. Since the pioneering work of Bruce Runnegar, few authors have investigated the shell microstructures of Cambrian mollusks that were preserved on the surface of phosphatic steinkerns. So far, available but scattered fossil data has suggested that, possibly from an ancestral organic scaffold, different mollusk groups first constructed various laminar fibrous microstructures under weak control, followed by the evolution of more complex, more derived architectural organizations through time. A range of microstructures that are commonly found in modern shells was demonstrated to have also occurred in early Cambrian fossil shells, such as foliated aragonite, fibrous, prismatic, and crossed-lamellar forms, suggesting the rapid architectural diversity and increasing control over biomineralization of early Cambrian mollusks.

Cambrian Burgess Shale-type fossil Lagerstätten of North China

Pingli WANG[1]*, Shandong University of Science and Technology (wangpingli@sdust.edu.cn)
Michael STEINER[2], Shandong University of Science and Technology
Yuze WANG[3], Shandong University of Science and Technology

Abstract

The North China Plate is as a classical region for studying sedimentary strata and associated fauna of the Cambrian Period with a research history spanning over a hundred years. However, Burgess Shale-type fossil lagerstätten have only lately been discovered there and did not attract much attention until now. In recent years, some Burgess Shale-type fossils reported from North China have provided new data on the temporal and spatial distribution of important Cambrian taxa. Furthermore, their preservation as organic films offered valuable material for unique taphonomic studies. The previously documented Burgess Shale-type fossils include palaeoscolecids from the Early Cambrian of Anhui Province. Besides this, the majority of Burgess Shale-type fossils reported from North China comes from the Mantou Formation and the Panchegou Member of the Zhangxia Formation. Some of them are assigned into the so-called Weifang Biota and Linyi Lagerstätte. These preservations include bivalved arthropodsSeries 2, Shandong Province, eocrinoids (Series 2, Liaoning Province), the frontal appendage of anomalocaridsSeries 2, Hebei Province, the arthropod Sidneyia cf. inexpectans (Miaolingian, Shandong Province), articulated hexactinellids sponges (Miaolingian, Henan Province, hurdiadids (Miaolingian, Shandong Province) and trilobites with putative gut preservationMiaolingian, Shandong Province. The most recently reported Burgess Shale-type fossil Lagerstätte from North China is the Linyi Lagerstätte (Miaolingian, Shandong Province)which includes excellent preservation of arthropod limbs, eyes and gut-induced structures contributing to the general understanding of the preservational mechanisms of fossil lagerstätten. Moreover, the Linyi Lagerstätten indicate a close similarity in the taxic composition to Laurentian Lagerstätten. We extend the record of Burgess Shale-type fossils from North ChinaMiaolingian, Shandong Provinceby palaeoscolecids, slightly three-dimensionally preserved hexactinellids, new types of tubular remains, as well as trace-preserving hurdiids and arthropods Tuzoia. Especially the fossils preserved in organic-rich shales are helpful in identifying the remaining organic components and deducing on the fossil burial mechanisms, which shed light on exploring for more Cambrian exceptional preservation in North China.

Evolution in Polar Ecosystems: The Early Ordovician of Morocco and France

Gaëtan JM POTIN[1]*, University of Lausanne (gaetan.jm.potin@outlook.fr)
Farid Saleh[2], University of Lausanne
Lorenzo Lustri[3], University of Lausanne
Pierre Gueriau[4], University of Lausanne
Jonathan Pople[5], University of Lausanne
Allison C Daley[6], University of Lausanne

Abstract

Exceptional fossil preservation enhances our understanding of ancient ecosystems by providing a record of soft-bodied organisms lacking characterized structures. Sites containing such fossils offer valuable insights into past animal ecosystems, particularly during the Cambrian and the Ordovician, (~500 million years ago), when most modern animal phyla appeared and diversified. However, a significant challenge arises as most of these preservation sites are associated with paleotropical and temperate ecosystems, leaving a notable gap in our knowledge regarding past polar regions.

Addressing this knowledge gap is crucial for comprehending the evolution of animal life on Earth, especially since the Early Ordovician was characterized by elevated temperatures, warmer than those experienced today, with little to no ice at the poles. Earth's history has witnessed fluctuating environmental periods between Greenhouse and Icehouse conditions, characterized by the absence or presence of ice on the poles, respectively. This study explores two Early Ordovician fossil sites with soft-tissue preservation located in Morocco and France, both previously situated on the margin of the Gondwana continent within the polar circle.

The Fezouata Shale, the Tremadocian/Floian formation from Morocco, reveals an exceptionally diverse assemblage of marine animals including abundant arthropods, echinoderms, brachiopods, and graptolites. This biota provides, for example, unique insights into giant suspension-feeding radiodonts and the ontogeny of the oldest horseshoe crabs. The Cabrières Biota, from the Floian of France, has been recently discovered, and it exhibits a diverse assemblage dominated by arthropods and sponges. Being the closest biota to the paleo south pole, the Cabrières Biota likely served as an animal refuge amidst the high-water temperatures at lower latitudes. Due to their paleogeographical position and high biodiversity, the Fezouata and Cabrières biotas offer unique opportunities to explore animal adaptations under Greenhouse conditions in deep time.

Morphological comparison with Cambrian relatives reveals the evolution of tardigrades

Ji-Hoon Kihm[1]*, Korea Polar Research Institute (jhkihm@kopri.re.kr)
Xingliang Zhang[2], Shaanxi Key Laboratory of Early Life & Environment, Department of Geology, Northwest University, China
Jianni Liu[3], Shaanxi Key Laboratory of Early Life & Environment, Department of Geology, Northwest University, China
Tae-Yoon S Park[4], Division of Earth Sciences, Korea Polar Research Institute

Abstract

The phylum Tardigrada, commonly known as water bears, is renowned for their ability to enter cryptobiosis, the state of metabolic suppression. These microscopic invertebrates possess four paired limbs and are classified into two classes: Eutardigrada and Heterotardigrada. Tardigrades are believed to have evolved from lobopodians, ancient soft-bodied vermiform animals with lobopodous limbs that have been discovered mainly in Konservat-Lagerstatten. Unlike their closest relatives, onychophorans and euarthropods, the specific origin of tardigrade morphological features remains uncertain, and thorough comparison with lobopodians has been lacking.

We have conducted a detailed morphological comparison between tardigrades and Cambrian lobopodians. Our analysis includes a phylogenetic assessment encompassing a wide range of lobopodians and three panarthropod phyla. The result of the analysis suggests that ancestral tardigrades likely exhibited a morphology similar to Cambrian lobopodians and shared a most recent ancestry with the luolishaniids, a lobopodian group with two types of lobopodous limbs. Internally, ancestral tardigrades likely possessed a worm-like body shape devoid of segmental plates, but with cuticular structures surrounding the mouth opening. Additionally, their lobopodous legs terminated with claws, but lacked digits. These findings contradict the long-standing hypothesis of a stygarctid-like ancestor.

The highly compact and miniaturized body plan observed in tardigrades emerged after their lineage diverged from an ancient shared ancestor with the luolishaniids. This also warrants a future research topic for further comparison of tardigrade mouth structure with other ecdysozoans, such as palaeoscolecids.

Preliminary study on Cambrian shell fossils from the Xiweikou Section in Yuncheng, ShanxiChina

Zhao Wang[1]*, Northwest University (1306788040@qq.com)
Zhifei Zhang[2], Northwest University

Abstract

As a typical area of the traditional triadic Cambrian study, the North China Platform has carried out systematic trilobite stratigraphy since the last century. With the in-depth exploration of the Cambrian explosion, ecosystem evolution, and the scientific demand for intercontinental stratigraphic correlation with other plates in recent years, the Cambrian strata and shell fossils on the southern edge of the North China Platform have received renewed attention. Early research on Cambrian fossils from the North China Platform was mostly limited to the Xinji Formation, with abundant numbers and types of small shell fossils providing key materials for stratigraphic division and correlation, as well as paleogeographic reconstruction. The Cambrian stratigraphy of Yuncheng area is exposed completely, but its Cambrian lowest stratigraphic age is not clear. This paper preliminarily reports small shell fossils from the Cambrian Mantou Formation and the Zhangxia Formation in the Xiweikou section in Yuncheng, North China. The 7687 miniature skeletal fossils obtained through acid etching treatment include Brachiopoda, including 1 genus and 2 species of the Priestly family, and 3 genera and 4 species of the Lactiformes family; Mollusca, including 1 genus and 1 species of Heliocentera and 1 unidentified genus and species; 4 genera and 5 species of open cavity orthopedics; Uncertain species of the genus Pleuroglossa; In addition, it also includes fragments of echinoderms and trilobites, with the largest number of mollusk fossils, but mostly consisting of a core, making it difficult to identify them in detail. Based on the fossil biological assemblage of Cambrian the Mantou Formation, it is inferred that the Mantou Formation in the Xiweikou section belongs to the early Wuliuan Stage of Cambrian Miaolingian, this study provides an important reference for the stratigraphic division and correlation of the early and middle Cambrian in Ordos Basin.

Characterisation of Carbon isotope of the Cambrain Jialao Formation, Jianhe County, Guizhou Province, China

Zhen LI[1]*, Guizhou University (gs.zli21@gzu.edu.cn)
Xinglian Yang[2], Guizhou University

Abstract

The stratigraphy of Guizhou Province is relatively complete, in which the Cambrian strata are widely exposed, basically distributed throughout the whole province and more complete development. The Jialao Formation was deposited in the transitional region of Southeast Guizhou with sandy dolomite as the main lithology, where it overlies Kaili Formation and overlain by Loushanguan Formation. We selected the Balang section and Wuhe section as the study sections, which are deposited in the same county with the section of Miaolingian Series and Wuliuan Global Stratotype Section and Point (GSSP). A total of 98 samples were collected from the upper part of Kaili Formation, Jialao Formation and the lower part of Loushanguan Formation to determine carbon and oxygen isotopes. The results indicate that the δ13C profile of the two sections have the similar evolutionary trend, and comparing the study sections with other contemporaneous strata worldwide, it is found that although the absolute value of δ13C and the variation amplitude of δ13C are different, the evolution pattern of δ13C is comparable in a certain time scale background. And beyond that, DICE (the Drumian Carbon Isotope Excursion) was identified from the Jiaolao Formation in the Balang and the Wuhe sections, respectively. The identification of DICE in this study is considered reliable by combining DICE reported worldwide and biostratigraphic work done by predecessors in the contemporaneous formations. In conclusion, the correlation of δ13C profiles and identification of DICE not only indicate that the Jialao Formation has an important value and potential for stratigraphic correlation, but also provide a reference basis for the correlation of other strata with few fossils at the same time.

The lower Cambrian Sirius Passet lagerstätte in Peary Land, northernmost Greenland, is famed for its relatively well-preserved fauna, dominated by arthropods associated with common lobopods, trilobites as well as other organisms. The fossil density is high and especially the bivalved arthropod Isoxys volucris is extremely common. Nearly all sampled beds from the fossiliferous interval contain this fossil and blooms of juveniles are seen occasionally. The Greenlandic representative of Isoxys is equipped with cardinal spines that are longer than in most other species of this genus. Measurements of body and spine length in 84 specimens show that the ratio of cardinal spine length vs. carapace length decreases during ontogeny. This indicates that the spines most likely had a primary defensive function against predators rather than aiding swimming or bouncy, as have been suggested for Isoxys in the literature (Pates et al. 2021). However, the negative allometric growth appears inconsistent with a hydrodynamic function, as larger carapaces must be assumed to require equally longer spines, which is not observed. Instead, the negative allometry points to a defensive function where the long spines conceivably increased the overall size of smaller specimens to escape gape-limited predators. This interpretation as a defensive feature is further supported by the fact that Isoxys volucris is the most commonly occurring prey content within guts of several Sirius Passet taxa, e.g. Pambdelurion, documenting a high predation pressure on the species. The results thus corroborate the conclusions of another recent study on the coeval species I. minor from the Chinese Qingjiang Lagerstätte (Ma et al. 2023).

Comparison of mineralized skeleton and microstructure of early Cambrian tubular animals

Jingliang ZHAO[1]*, NorthWest University (zhaojingliang@stumail.nwu.edu.cn)
Zhifei Zhang[2], NorthWest University

Abstract

In the early Cambrian, the famous Cambrian explosion event occurred. During this period, a large number of metazoan animals with skeletons suddenly appeared. After death, the mineralized bones of these animals could be preserved as fossils, which became an important basis for the study of evolution in the early Cambrian . Tubular fossils are the most common of these mineralized skeletal fossil in this periods and tubular fossils are not standard taxa, but are distinguished by fossil morphology.Those kind of fossils are generally simple in shape, easy to identify but difficult to determine the relationship. The Yangtze area is a typical area for the study of Cambrian marine sedimentary rocks in China, which has the advantages of wide development of Cambrian strata, relatively complete stratigraphic sequence, obvious petrological characteristics and easy identification. The Nanzheng region of southern Shaanxi Province is located in the Yangzi Craton, and the fossils in this area are relatively comprehensive and complete. In addition, the Xiannüdong Formation in this area is rich in small shelly fossils, with abundant brachiopods, palaeocalpids, tommotiids and tubular fossils with abundant variety, which is the focus of this study.This paper describes the fossil assemblages of the Xiannüdong Formation in Dayingcun section, Fucheng Town, Nanzheng Area, Shaanxi Province. The fossil assemblage comprise brachiopods, palaeocalpids, tommotiids, order bradoriidas, sponge spicule and tubular fossils. We mainly focused on the morphology, microstructure and biomineralization of the tubular fossils. We identifie *Sphenothallus* Hall, 1847, *Torellella* Holm, 1893, *Hyolithellus* Billings, In 1871, *Mongolitubulus* Missarzhevsky, 1977, a sample of tubular fossils from four genera. Among these tubular fossils, we focus on the in-depth study of the shell morphology and microstructure of *Sphenothallus*. The morphological characteristics of 130 samples were measured and statistically analyzed. On this basis, morphological comparison with *Sphenothallus songlinensis*, *S. taijiangensis* was made. The longest length of the shell of this sample is 3.4mm, while the length of the shell of the above samples is more than 4mm, and the longest is up to 20.7mm. In addition, the maximum width of the base and aperture of this sample are 0.48mm and 0.94mm, respectively, while the base width and aperture width of the above other types are significantly larger than that of this sample, and the maximum width of the base is up to 1.32mm. Mouth width up to 5.0mm; Based on SEM images, it is considered that the sample has a lamellar fiber structure and a lamellar fiber structure, but the long axis direction of each layer of minerals is intersected at an acute angle. In addition, it is found that the shell has a layered superimposed transverse pattern, and the shell secretion pattern on the surface may be layer by layer. Lenticular thickening layers can be secreted on the narrow edges of both sides, and sometimes only one thickening layer is secreted. The thickening layer shows a tendency of middle

dense and loose edges, indicating that the secretion of thickening layer is carried out from the center of the lens to the periphery.

Shallow water fauna from deep-water deposits, in the Zhaolaoyu Formation, late Ordovician at Fuping area, southern Ordos Basin

Caibin ZHANG[1]*, Northwest University (961068755@qq.com)
Zhifei Zhang[2], Northwest University

Abstract

Deep water deposits have been the hotspot for oil and gas exploration, especially in gravitational systems. It is believed that the Zhaolaoyu Formation in Fuping area, Shaanxi Province, is dominated by deep-water carbonate deposits, deep-water gravity-flow deposition, radiolarian chert, and volcanic tuffs. The lack finding of fossils from the Zhaolaoyu Formation not only limits the deep exploration in relative deposits, but also makes it hard to reconstruct its depositional environment.

By systematic sampling on the carbonate and treating with acid-etching method, abundant skeletal fossils, including brachiopods, gastropods, tetrapod corals, echinoderms, bryozoan and some tubular fossils of undetermined classification, were obtained. The brachiopods are mainly consisted of acrotretids and orthids; the gastropods mainly include tower-shaped, lenticular-shaped and conical-shaped shells; and the echinoderms are mainly dominated by discrete ossicles with rounded and pentagonal outlines splitted away from the stem or carpus of crinoids that can be assigned to five genera and eight species, including Pentagonocyclicus sp.Yeltysheva & Schewtschenko,1960Pentagonocyclicus sp. GYeltysheva & Schewtschenko1960Pentagonocyclicus sp. CYeltysheva & Schewtschenko1960Lanxocolumnus sp.Donovan1989Pentagonocyclopa sp. AMoore1939Cyclocyclicus sp. AYeltysheva1955Cyclocyclicus sp. CYeltysheva1955Comptocrinus aff. comptusYeltysheva1955

It is obviously that the fossil assemblages retracted from the Zhaolaoyu Formation could be assigned to shallow water fossil assemblages, which doesn't couple with previous analysis of the depositional environment in the area. However, considering the lacking of carbonate microfacies analyses, it is hard to rule out the possibility that the fossils in the Zhaolaoyu Formation are originated by deep-water gravity flow transport deposits. Based on this preliminary reports, it can be concluded that the Zhaolaoyu Formation are with well preserved, high diversed and abundant skeletal fossils. Thus, with the contribution fauna assemblage, combined with carbonate microfacies analyses, the stratigraphic and depositional analyses for the Zhaolaoyu Formation will be determined, supporting oil and gas exploration in the Ordos Basin.

Evolutionary significance and biological affinities of Ediacaran to Cambrian tubular fossils

Yuze WANG[1]*, Shandong University of Science and Technology (wangyze_river@163.com)
Michael Steiner[2], Shandong University of Science and Technology
Pingli Wang[3], Shandong University of Science and Technology

Abstract

The Cambrian Bioradiation is mostly manifested in the worldwide appearance of so-called Small Skeletal Fossils (SSFs) and the dramatic increase in number, styles and complexity of trace fossils during the Fortunian Stage and continued during Cambrian stages 2 to 4 with the appearance of many new types of SSFs and the rapid diversification and dispersal of the Archaeocyatha and other Porifera. During the late stage of Cambrian bioradiation many crown group metazoans appeared in so-called ***Burgess Shale-type*** fossil lagerstätten of which the Weifang and Linyi biota are partly reviewed herein. There exists a general consensus on the idea that the earliest Cambrian diverse metazoan clades had Neoproterozoic ancestors. However, globally only few bodyfossils are known from the Ediacaran that are uncontroversially regarded as metazoan remains, such as the tubular cloudinids.

Many of the putative metazoan ancestors exhibit a tubular exoskeleton or housing structure, which led to the interpretation of an Ediacaran “wormworld” that also experienced a major extinction event prior to the explosive bioradiation of the early Cambrian SSF taxa. However, recent studies revealed that the tubiculous Ediacaran fauna (including cloudinids) persisted into the Cambrian. Our study documents the continuous occurrence of various tubiculous organisms into the Drumian Stage. The various morphologies and ornamentations, biomineral/ diagenetic preservation and ultrastructural characteristics of multiple tubiculous taxa are reviewed. We also discuss the potential affinities of the tubiculous organisms, assignable to the eukaryotic algae, cnidarians, annelids, and hemichordates.

Cloudinids are here considered to represent polychaete tubes due to ultrastructural characteristics, despite many recent studies assigned them with cnidarians. The nature of other putative ancestral metazoan remains of the Neoproterozoic with tubular construction, such as ***sinosabelliditids***, ***sabelliditids***, ***Sinocyclocyclicus*** etc. remains speculative and has been discussed controversially. Partially these fossils may represent eukaryotic algae.

By discussing the morphological characteristics, growth pattern and the chemical composition of tubular fossils it is intended to conclude on the environmental complexity. The degree of biomineralization, the type of sedimentary processes and the diagenetic alteration is thought to have had a major impact on the preservation of tubular fossils. Thus, it is concluded that the understanding of the taphonomy of tube-forming organisms is crucial for the biological interpretation of them.

Continental weathering during the Great late Ediacaran Glaciation revealed by Mg isotope

TIANZHENG HUANG[1]*, Peking University (tzhuang@pku.edu.cn)
Bing Shen[2], Peking University

Abstract

Conversion between icehouse climate and greenhouse climate in geological history is critical for understanding the evolution of surface Earth system and modern climate changes. Cryogenian - Ediacaran is the most ‘frozen’ period in geological history, containing Sturtian glaciation (717–660 million years ago
[Ma]), Marinoan glaciation(650-641 Ma) and late Ediacaran glaciation(560-580 Ma). The former two Cryogenian glaciations are ‘Snowball Earth’ events, in which global distributed glacial deposition occurred in paleo- equator. However, observations of the late Ediacaran are composed by multiple glaciation strata with poor chronological correlation . The late Ediacaran glaciation was thought to have multiple episodes, while a new hypothesis integrated glacial deposits to a global glaciation called the Great Ediacaran Glaciation (GEG) that approached to 30° latitude with paleomagnetism records. Limited by poor chronological and paleomagnetism records in Ediacaran, it is hard to further test the GEG hypothesis. Yet a global glaciation will cause decrease of weathering intensity due to low temperature and low atmospheric CO2, even if in non-glacial deposits. We tested the GEG hypothesis with Mg content-Mg isotope weathering proxy. Samples from Doushantuo Formation in South China block showed significant decrease of weathering intensity and extreme erosion signal during shuram excursion (SE) of carbon (C) isotope in 570-562 Ma. The decrease of weathering intensity and extreme erosion was caused by global cooling and low atmospheric CO2 in GEG, rather than South China block moving toward high latitude. Our study confirms the GEG hypothesis and reveals that the peak of GEG was highly correlated with strong negative C isotope excursion (SE), which is a new mechanism for onsets of Cryogenian - Ediacaran glaciations which are different from all Phanerozoic glaciations.

Morphogenesis simulations unravelling novel recognition biases in Paleozoic trilobite injuries

Xiaoyong YAO[1]*, Chang'an University (yaoxy@chd.edu.cn)
Xikun Song[2], Institute of Deep-Sea Science and Engineering, Chinese Academy of Sciences
Jian Han[3], Northwest University

Abstract

Trilobites exhibiting injuries are ideal paleontological achieves for Paleozoic predator-prey interactions. However, the recognition of trilobite scars mainly relies on various individual traits exhibiting ambiguity and lacks morphogenesis evidences. Here we establish a new discriminative system integrating exceptionally preserved trilobites displaying injuries from the Chengjiang Lagerstätte, and long-term comparative laboratory morphogenesis simulations utilizing both 'trilobite larvae' and late-stage juveniles of the extant horseshoe crab proxies. The experimental paleontological approach elucidates the crucial criteria for injuries on trilobite fossils: the old wounded exoskeleton remains unchanged before subsequent molting; after molting, the new repaired outside exoskeleton exhibits abnormalities with variable individual characteristics, with thickened margin or smoothed outline, or a small tip regenerated in a distoproximal order. This recognition system is fully applicable to 409 fossils of 141 trilobite species documenting abnormalities. It indicates that 95% of injured trilobites with clearly identifiable scars have experienced subsequent ecdysis and suggests that most recognizable unambiguous trilobite scars are limited to healed sublethal injuries fulfilled at least one subsequent ecdysis. This uncovers novel recognition biases leading to the underestimation of trilobite injury frequency, in addition to other biases already acknowledged in relation to fossil taphonomy and field collection. These biases address the significant incongruity between the intense Paleozoic predator-prey 'arms race' and the infrequent observation of injured trilobites throughout geohistory.

Isolated radiodont mouths: case study of two unique oral cones from the Fezouata Shale Formation (Early Ordovician, Morocco).

Gaëtan JM POTIN[1]*, University of Lausanne (gaetan.jm.potin@outlook.fr)
Pierre Gueriau[2], University of Lausanne
Farid Saleh[3], University of Lausanne
Allison C Daley[4], University of Lausanne

Abstract

Radiodonts are an emblematic group of the Cambrian Explosion, including apex predatory species such as the iconic Anomalocaris canadensis. During the Early Ordovician, abundant radiodont remains are found in the Fezouata Shale (Morocco). So far, three species have been described, to which we can add at least three other unpublished morphotypes. Those descriptions are based only on frontal appendages, the most commonly preserved bodypart of the animal. However, on rare occasions, other anatomical features can be preserved, such as the mouthpart. The radiodont mouthpart, also known as the oral cone, has a peculiar morphology characterized by a circular shape with overlapping plates of different sizes around a central opening. The rarity of oral cones in the fossil record and the fact that they are often found in isolation has made it difficult to associate oral cones with frontal appendages and bodies, complicating our understanding of radiodont taxonomy and feeding strategy.

In this work, we describe two almost complete but isolated radiodont oral cones from the Fezouata Biota. The first specimen consists of 28 plates in tetraradial arrangement and is one of the smallest oral cones ever found in the fossil record (3.1mm in diameter). The larger oral cone specimen has a unique morphology consisting of 24 plates, in tetraradial arrangement, and bearing prominent nodes on just two of the larger plates. The observed combinations of features are unique and neither oral cones can be confidently attributed to known radiodont taxa.

Based on morphological characters, multivariate statistics have been used to predict the most probable radiodont family and feeding strategy for these oral cones. These analyses show that two oral cone morphospaces can be distinguished for feeding strategies: the raptorial predators and the sediment sifters. However, there are no clear distinctions of oral cone morphospaces associated with different radiodont families. This is confirmed when the two oral cone morphospaces are mapped onto a radiodont phylogenetic tree, showing no clear distribution of oral cone morphotypes within the major radiodont clades.

This method shows that the feeding strategy of the newly discovered oral cones can be predicted, while their assignment to a specific family is unclear. This is likely the result of the lack of data concerning suspension-feeding radiodonts that are rare in the rock record but are abundant in the Fezouata Shale.

Modularity and fluctuating asymmetry in the early Cambrian trilobite Protoryctocephalus arcticus from the 'Tsinghsutung' Formation, South of China

Esteve JORGE[1]*, Universidad Complutense de Madrid (UCM), Spain (jorgeves@ucm.es)
Yang Xinglian[2], Guizhou University, Guiyang, China

Abstract

We conducted a study on the cranidium of the Cambrian trilobite Protoryctocephalus arcticus using geometric morphometrics techniques to delve into the intricacies of its modular structure and its implications for diversity within trilobites. Our primary objective was to unravel the underlying mechanisms driving the integration of various morphological features, particularly exploring the roles of developmental pathways and functional interactions in shaping the evolutionary trajectory of these ancient organisms.

Central to our investigation was the hypothesis that distinct modules of the cranidium, namely the anterior and posterior regions of the glabella (the central portion of the head shield) and corresponding sections of the fixigena compartments (the lateral portions), represent independent developmental units exhibiting differential variation. Through rigorous measurements, we assessed both inter-individual variation and random disparities within individual cranidia, specifically examining fluctuating asymmetry (FA).

Our analyses, which focused on elucidating the covariance patterns between the anterior and posterior segments of the glabella compartments via partial least squares methodology, revealed a notable degree of integration between these compartments. This integration was evident not only in terms of individual variation but also in the context of FA. Consequently, while it might appear that the anterior and posterior components of the glabella act autonomously, their covariance suggests a shared developmental trajectory largely responsible for the observed variation in this region.

In summary, our findings suggest that both inter-individual variation and developmental perturbations contribute to the shaping of cranidial morphology, with these influences being integrated across multiple compartments. Interestingly, while some variation can be attributed to localized processes within specific compartments, the overarching modular structure of the cranidium suggests a more complex interplay between development and function than previously assumed. This challenges the notion that functional associations exclusively dictate the modular organization of trilobite cranidia, highlighting the need for a nuanced understanding of the underlying processes shaping morphological diversity in these ancient arthropods.

In this manner, representatives of oryctocephalid trilobites, as well as others such as ptychopariids or redlichiids, particularly those from the Cambrian Series 2, Stage 4 of southern China, present a unique opportunity to investigate the modality in these Cambrian arthropods and assess how rapid the diversification of these groups was during the Cambrian Explosion.

Taxonomy and Morphology of Choia from the Qingjiang Biota

Laiyuan Wu[1]*, Northwest University(China) (202121907@stumail.nwu.edu.cn)
Hao YUN[2], Northwest University(China)
Xingliang ZHANG[3], Northwest University(China)
Qingshan WANG[4], Northwest University(China)

Abstract

Early diversity of sponges in Animal Tree determines their importance in interpreting the origin and early evolution of muticellular animals.The Choia is one of the representative demosponges that occurred during the Cambrian Explosion. Although fossils of Choia were discovered in a wide spectrum of Cambrian biotas, the body shape and growth pattern of this sponge group have not been scrutinized. Three species of Choia, including Choia qingjiangensis sp. nov., C. striatus sp. nov., and C. carteri Walcott, 1920 from the Cambrian Stage 3 Qingjiang Biota are described herein. Based on previous data, new taxonomic models for the preservation of Choia is provided to restore the body shape and original orientation of this animal. The results indicate that the Choia is flat obconic in shape and has a thin wall with two layers of spicules. There are three levels of height to width ratios: the first one refers to small, near-flat, and dwarf conical shapes that usually retain their outlines after burial; the second is a relatively high conical shape, which is usually prone to being flattened laterally during burial and left fan-shaped specimens; the third one is intermediate in shape between the former two, which is usually preserved as an oval outline with a broken central disc and rare coronal spicules.

New artiopodan euarthropods from the Chengjiang fauna (Cambrian, Stage 3) at Malong, Yunnan, China

Yuyan ZHU[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (yyzhu@nigpas.ac.cn)
Han ZENG[2], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Yao LIU[3], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Fangchen ZHAO[4], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences

Abstract

The artiopodans, consisting of trilobites and their relatives, were a group of euarthropods that were abundant during the Cambrian and then became extinct in the Permian. Since the first discovery of Naraoia from the lower Cambrian Chengjiang fauna (Cambrian Series 2, Stage 3) in 1984, new artiopodans are constantly being discovered. Here we describe three new artiopodan species from the Chengjiang fauna at Malong, Yunnan, China. Zhugeia acuticaudata gen. et sp. nov. is a new xandarellid with an elongated needle-like median tail spine. Tonglaiia bispinosa gen. et sp. nov. is a new type of trilobitomorph with a pair of parallel posteriormost tail spines. Sidneyia malongensis sp. nov. is the oldest species of Sidneyia with eight imbricated tergites and two abdominal segments. The evolutionary affinities of these new taxa are reconstructed and discussed in a phylogenetic context. Phylogenetic analyses resolve Z. acuticaudata among the xandarellids and T. bispinosa gen. et sp. nov. as a trilobitomorph with an uncertain placement. This is the first discovery of non-trilobite artiopodans other than Naraoia from the Chengjiang fauna at Malong area. These three new species provide new insights into the differential spatial distribution of the Chengjiang fauna across eastern Yunnan and enriches the diversity of non-trilobite artiopodans from the Cambrian.

Ecological and environmental implications of predatory groups in the Cambrian Guanshan Biota

Deguang JIAO[1]*, Yuxi Normal University (103256437@qq.com)

Abstract

The Guanshan Biota (Southern China, Cambrian Stage 4) is often considered a crucial link between the Chengjiang Biota of the Cambrian Stage 3 and the Kaili Biota of the Cambrian Stage 5, specifically burying multiple groups of soft fossilized organisms. The fossil treasure trove itself contains many unique and distinct fossil organisms. The diversity of the predatory group of its stem group of arthropods is rich, including *Anomalocaris canadensis*, the currently known endemic genus Paramalocaris, and Tamisiocaridae in southern China, which includes *Anomalocaris kunmingensis* and other new materials that need to be studied, as well as true arthropods with ecological indicative significance such as *Astutuscaris bispinifer* gen. et sp. nov and *Lihuacaris ferox* gen. et sp. nov. This predatory group combination differs from the Chengjiang Biota, Kaili Biota, and other reported fourth order Cambrian biota that have preserved shrimp fossils. And the above-mentioned fossil organisms were found in the same section and layerwhich type specimen are collected at Yuxi Normal University . The collective appearance of multiple top-level predatory groups in the same water environment reflects the diversity and subdivision of predatory niches, representing highly complex ecological community types. This conclusion indicates the importance of continuously discovering as many different profiles as possible in order to gain a more comprehensive understanding of the ecology and environment of early animals.

Mineralogical characteristics of pedogenic carbonates in Devonian paleosols and their environmental implications

jingru LUO[1]*, Chengdu University of Technology (luojingru@stu.cdut.edu.cn)
Meng Ning[2], Chengdu University of Technology
Tianzheng Huang[3], Peking University
Bing Shen[4], Peking University

Abstract

The mid-Paleozoic colonization of land by plants catalyzed a metamorphosis of the Earth's surface environments, accelerating the transformation of the atmosphere, promoting chemical weathering and the formation of soil, which represents the largest carbon pool in terrestrial ecosystems. Pedogenic carbonates serve as a significant component of the soil inorganic carbon (SIC) and play a crucial role in the terrestrial carbon cycle.

Pedogenic carbonates preserve essential climatic and environmental information throughout their formation process. Previous research studies of pedogenic carbonates were focused on the reconstruction of paleoenvironmental conditions by using their geochemical indicators. However, the basic mineralogical characteristics of pedogenic carbonates and their potential to reveal the pedogenic processes and environmental conditions have been ignored. Here, we investigate the mineralogical characteristics of pedogenic carbonates formed during the mid-Paleozoic colonization of land by plants to reveal their environmental implications.

Pedogenic carbonates from the Lower Devonian Guijiatun Formation (Lochkovian) and Xujiachong Formation (Pragian-early Emsian) in Qujing district, Yunnan province, China were recognized in paleosols with root traces and alternating soil horizons. Morphological, petrographic, and mineralogical analyses including SEM and XRD demonstrated that authigenic dolomites constitute an important part of the mineral composition of the Devonian pedogenic carbonates. These dolomites were precipitated as primary minerals during pedogenesis, indicating an arid-evaporative pedogenic environment. Considering the positive correlation between the contents of dolomite and illite, we propose that clay mineral may play a role in inducing the formation of pedogenic dolomite. Furthermore, the more positive δ18O values of pedogenic dolomite from the Guijiatun Formation (average= -7.98 ‰) coupled with the higher dolomite content indicating a transition from a strong arid-evaporative pedogenic environment during the Lochkovian stage to a semi-arid-evaporative pedogenic environment during the Pragian-early Emsian stage.

Devonian coevolution of forests and tetrapods

Gregory John RETALLACK[1]*, University of Oregon (gregr@uoregon.edu)

Abstract

Central New South Wales has a rich fossil record of Late Devonian (Famennian) fossil fish (8 species, mostly Bothriolepis and Remigolepis) and a single tetrapod (Metaxygnathus). Trace fossils, fossil plants, and paleosols of the Hervey Group provide new evidence for evolution of Devonian trees and tetrapods. Late Devonian paleosols of the Hervey Group in New South Wales formed in a semiarid climate with low shrubby desert vegetation, but at two levels including one with a tetrapod, there is evidence of subhumid woodland. That double spike to subhumid climate matches paleoclimatic spikes in Pennsylvania cued to global atmospheric spikes in carbon dioxide correlated with the Annulata event of marine black shales dated at 365 Ma. This evidence supports the woodland hypothesis of tetrapod origins rather than the idea that they evolved from fish escaping shrinking desert ponds, or evolved in tidal flats. The Canowindra fish bed of mass mortality in a desiccated billabong (oxbow lake) at a stratigraphic level of arid paleosols is a stunning example of what happened in drying desert ponds. New South Wales has no clear evidence of intertidal vertebrates, and trackways which inspired this hypothesis are now controversial. In otherwise aquatic Late Devonian tetrapods, limbs may have been adaptations to negotiating or hiding from predators in streams choked with woody debris, and their necks allowed feeding on land, or in water shallower than their bodies.

A preliminary study of three vascular plants from the Middle Devonian Haikou Formation of Qujing, Yunnan Province, China

Gaofeng ZHENG[1]*, Peking University (2201210120@pku.edu.cn)
Jinzhuang Xue[2], Peking University

Abstract

In recent years, plenty of studies of the early land plants in Devonian have been mainly focusing on the evolution of vascular plants in the Early Devonian and the early forests and early seed plants in the Late Devonian. However, the Middle Devonian was also an important epoch in the evolution of the early land plants, when many important plant species originated and evolved. Thus, more collecting from the Middle Devonian is needed to further reconstruct the evolutionary history of the early vascular plants throughout the Devonian period.

Based on our recent exploration of the Middle Devonian Haikou Formation in the Qujing region of Yunnan, China, we have unearthed and conducted preliminary examinations on three distinct plants. A lycopsid plant assignable to Tomiodendron sp. is characterized by its distinctive ligule pit that bifurcate at the apex, which displays a curvature reminiscent of the letter M, and simple dichotomous branching and inconspicuous ligule cushion. Its leaves are arranged in pseudo-whorls on slender branches, 8-10 per whorl. Additionally, it also preserves intact reproductive structures, sporangia are aggregated to form a strobilus about 18 cm long, sporangia are situated in leaf axils, and the sporophylls are different with the sterile leaves. The sporophylls often curve inward in the shape of a sickle, while the sterile leaves remain slender and straight.

A second plant is a euphyllophyte, which displays evident tertiary branching. The first-order branches protrude from the main axis oppositely, presenting a triforked structure, the second-order branches extend exclusively from the upper surface of the first-order branches at obtuse angles, and the third-order branches bifurcate from the second-order branches, forming an approximate "antler-like" structure. Within its reproductive structure, subelliptical sporangia are borne on the terminal twigs, with 2-3 sporangia forming a truss. Terminal twigs commonly bifurcate.

A third plant is also a euphyllophyte, which is characterized as a slender herbaceous plant with stem less than 1 mm in width. Preserved specimens appear fragmented, exhibiting a simple branching structure. The reproductive structure is well preserved, 3-5 elongated sporangia are borne on thin branches extending from the side of the main stem, forming a sporangial cluster reminiscent of a "finger-like" structure, and such structures often occur in pairs.

This study enriches the composition of the flora from the Haikou Formation, and expands the stratigraphic and paleogeographic distribution of Tomiodendron-type lycopsids.

Coupling relationship between radiation of early vascular plants and the long-term water cycle

Jinzhuang XUE[1]*, Peking University (pkuxue@pku.edu.cn)
Bingxin Li[2], Peking University
Jiashu Wang[3], Peking University

Abstract

The origin and diversification of early vascular plants (EVP) contributed to the Silurian-Devonian terrestrial revolution and induced profound changes in continental weathering, erosion and sediment transport systems, and biogeochemical cycles of carbon, nitrogen, phosphorus, and other elements. As a consequence of the diversification of EVP, there emerged distinctive soil-plant-atmosphere continuum (SPAC) systems in different plant groups, including among others the zosterophyllopsids, drepanophycaleans, pseudosporochnaleans, and archaeopteridaleans. Each of these groups has been extensively studied and can be described by different SPAC models. Key innovations that are closely associated with water transport processes, and that involve roots, vascular tissues, stomata, leaves, and body size and architecture, evolved in different groups, leading to more complex and presumably more efficient water cycling in the SPACs. The earliest vascular plants of the Silurian and Early Devonian periods typically show small aboveground stature with shallow roots, although some groups such as zosterophyllopsids and drepanophycaleans are characterized by extensive rhizomatous clonal growth, producing complex and shallow underground rhizome systems. Nevertheless, deeper underground water did not become available to plants until deep roots evolved during the Middle to Late Devonian. Within the evolving SPAC systems, soils from the Early Devonian onward showed increasing thickness and complexity of horizonation, increased maturity in composition, and diversification of soil classes. Forest canopies that first appeared in the Middle Devonian would have had a profound impact on water runoff, evaporation and transpiration. Therefore, the evolution of plants in both their underground and aboveground tissues, as well as their enhanced effects on water cycles and weathering domains, led to a dramatic expansion of the Earth's Critical Zone.

The radiation of EVP enhanced feedbacks among vegetation, geomorphology and water cycles. From the late Silurian onward, the tracheophyte-type land-ocean hydrologic continuum (LOHC) was established as an essential landscape on the Earth's surface, as exemplified by the Old Red Sandstone facies of the Laurussian paleocontinent and the non-marine siliciclastic sequence of Qujing, Yunnan of the South China Block. Such LOHCs are characterized by geomorphological stability of inland drainage basins and coastal areas, leading to establishment of vegetated, stable lowlands that provided accommodation space for increasing volumes of fine-grained particles derived from plant-induced intensified weathering. Such lowlands provided abundant opportunities for preservation of plant fossils and organic matter, contributing to an apparent increase in plant diversity from the late Silurian through Late Devonian; that is, the diversification

of EVP enhanced landscape stability, thus providing more opportunities for plants themselves to be preserved in the fossil record. The evolution of EVP was closely coupled with changes to carbon and water cycles by SPAC and LOHC systems and the underlying processes. Development of geomorphologically stable wetlands favored an increase in burial of terrestrial organic carbon as coals and other organic-rich sediments, as well as long-term pedogenesis on dryland floodplains, processes leading to an increase in organic and inorganic carbon sequestration, respectively.

The cycle of S element in pyrite from Carboniferous bauxite in South china

Yulei CHEN[1]*, Chengdu University of Technology (434846733@qq.com)
Chaochao Xing[2], State Key Laboratory of Geohazard Prevention and Geoenvironment Protection, Chengdu University of Technology
Bing SHEN[3], Key Laboratory of Orogenic Belts and Crustal Evolution of the Ministry of Education, and School of Earth and Space Science, Peking University
Xianguo LANG[4], State Key Laboratory of Oil and Gas Reservoir Geology and Exploitation, and Institute of Sedimentary Geology, Chengdu University of Technology

Abstract

The bauxite of Jiujialu formation of the Carboniferous was widely distributed in Guizhou, South China, and has obvious characteristics of high sulfur content. Based on sampling analysis of pyrite from different paleogeographic locations (coastal, karst depression, karst valley/funnel), we suggest these pyrites be initially classified into three categories according to the classification of bauxite. These profiles have different vertical characteristics of sulfur isotopes, lithology, and mineral composition. In the coastal sections, pyrites develop along the beddings and are preserved in carbonaceous shales in the form of nodules or laminae, the surfaces of which are partly dissolved, and the δ34S tends to be stable (-10~-25‰). In sections of karst depression area, pyrites are preserved in the form of nodules in the ferruginous claystones or distributed in the form of scattered bauxite cement, and the surfaces were also partially dissolved, with δ34S varing widely from -25 to 38‰. In the karst canyon/funnel sections, pyrites were scattered in claystones in silty crystal form or preserved funnel areas as huge nodules, and the δ34S varies widely too (-28~18‰). In addition, micro-region characteristics of these pyrites are also different. Due to intense weathering, leaching, frequent volcanism and transgression in the bauxite formation area, the sources of sulfur element of the pyrites might be very complicated. Therefore, to track the sulfur cycle of pyrites in Carboniferous bauxite in Guizhou, South China, it is necessary to conducting both macroscopic and microscopic analysis of pyrites.

[Keynote] In situ preservation enhances systematic study: a case in research of the Wuda Tuff Flora, Inner Mongolia

Jun WANG[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (jun.wang@nigpas.ac.cn)
Mingli Wan[2], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Weiming Zhou[3], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Dandan Li[4], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences

Abstract

A peat-forming forest was preserved in situ by a 298.34 ± 0.09 Ma volcanic ash bed in the Wuda Coalfield, Inner Mongolia, being called Wuda Tuff Flora. With respect to the geologic and taphonomic similarities to the world-famous Italian UNESCO World Heritage Site of the Roman city of Pompeii, this flora has been also called Chinese “vegetational Pompeii”, well known as a plant fossil lagerstätte, snapshooting a glimpse to the late Palaeozoic peat-forming forest.

Such a T0 deposit provides an unrivalled chance to reconstruct not only the taxonomic diversity but also the vegetation structure and density, small- to medium-scale distribution patterns, and synecological associations. Along with the progress of the open-cast mining of the Wuda Coalfield in the past two decades, numerous outcrops have been accessible from time to time, offering opportunities for fossil collecting and in total certain area over 10, 000 square meters quantitative investigation of forest ecology, which have yielded a larger collection of the material.

The completeness and the exquisiteness of plant remains certainly facilitate a thorough systematic study of many taxa of this peat-forming forest. In many cases, the size of the specimens even enables us to assess the natural variability and the reconstruction of whole-plant taxa, which is impossible in most other localities due to the often small number and the limited size of specimens. Nearly all the taxa of this peat-forming forest show both gross morphology and anatomy, and both vegetative and fertile parts, and thus likely to facilitate restoration as whole plants and natural species. Here we present the latest research progress on the systematic study of this flora. Ten species are described in a sense of whole plant species (organs including gross form, fertile, vegetative, stem anatomy, in situ spore), such as the lycopods Sigillaria cf. S. ichthyolepis (Presl) Corda; sphenophytes Sphenophyllum angustifolium (Germar) Geoppert, Sphenophyllum parvifolium Libertín et al.; the calamitacean sphenopsid Palaeostachya guanglongii Liu et al.; the eusporangiate fern Scolecopteris libera Li et al.; the noeggerathialean progymnosperms Tingia unita Wang, Tingia pentalobata Shen, Paratingia wuhaia Wang et al., and Paratingia wudensis Wang et al. Several taxa reaching a status of natural species (both fertile and vegetative organs known) include the zygopterid fern Nemejcopteris haiwangii Pšenička et al.; the sphenophytes Sphenophyllum cf. oblongifolium (Germar et Kaulfuss) Unger, Sphenophyllum cf. angustifolium (Germar) Geoppert; the eusporangiate ferns Scolecopteris minuta Wan et al., Scolecopteris zhoui Zhang et al., Eoangiopteris congestus Sun et al.; the leptosporangiate ferns Oligosporangiopteris zhongxiangii Frojdová et al., Chansitheca wudaensis Deng, Sun et Li emended He et al., Botryopteridium sinensis Zhou et al., Hansopteris uncinatus Zhou et al.

Besides those, some taxa only with abundantly vegetative information have been identified through their anatomic features, including the eusporangiate fern Pecopteris lativenosa Halle emend. Li et al.; the leptosporangiate fern Diodonopteris virgulata Zhou et al.; the pteridosperms Wudaeophyton wangii Pšenička et al., Yangopteris ascendens Zhou et al.

The Middle-Late Triassic Boundary Extinction: Palynological evidence

Yuewu SUN[1]*, Research Center of Palaeontology and Stratigraphy, Jilin University (sunyuewu@jlu.edu.cn)
Ying ZHANG[2], International Center for Geoscience Research and Education in Northeast Asia, Jilin University, China
Xiang LI[3], Huzhou Zhili City Construction Investment Operation Group Co., Ltd., China
Shuqin ZHANG[4], Research Center of Palaeontology and Stratigraphy, Jilin University, China

Abstract

The Middle-Late Triassic Boundary Extinction, i. e. Ladinian-Carnian Boundary Extinction is less attractive than the End-Permian Mass-extinction, Carnian Pluvial Event and End-Tiassic Mass-extinction, but it is genuine as the Ladinian crisis. However, due to lack of detailed investigation on Ladinian-Carnian transition, the vegetation extinction and renovation are thought to be resisted Ladinian crisis (Ruban, 2017). Recent palynological investigation engaged in the Middle Triassic and Upper Triassic transitional zone in the Ordos Basin, China (Li et al., 2023) reveal the End-Ladinian vegetation crisis. The palynoflora during the latest Ladinian was composed of 121 species of 47 genera, including 54 species of 17 genera from fern spores and 67 species of 30 genera from gymnosperm pollen; while the earliest Carnian palynoflora was only 35 species of 29 genera which include fern spores (9 species of 6 genera) and gymnosperm pollen (26 species of 23 genera). Ladinian-Carnian Boundary crisis is characterized by 70% fern species and over 30% gymnosperm species lost. The crisis covered every types of eco-plants from aquatic plants, under-story herbs, tree ferns, bushes, evergreen and deciduous arbor forests. Meanwhile, vegetation renovation and innovation ongoing quietly in mesophytic and xerophytic gymnosperms. As the emergence of Discisporites (Cheirolepidiaceae) and Perinopollenites (Cupressaceae), the earliest Carnian climate should be much drier than the latest Ladinian. Thus, we are preferable to attribute the End-Ladinian vegetation crisis to the arid climate. However, there are still some aquatic lycopods, river bank or lake shore sphenophytes, and some evergreen trees in the earliest Carnian vegetation. Meanwhile, the depositional environment indicate that the earliest Carnian deposits are deep lacustrine with anoxic eutrophic characters, and the sediments are organic rich shales and oil-shales. Therefore, the earliest Carnian climate was thought to be strong seasonal arid on one hand and high seasonal precipitation on the other hand, which is the typical monsoon climate. It is the enhanced arid season that caused a great loss of plant biodiversity in the end-Ladinian vegetation although there are some pluvial interruption exist.

New material of Radula heinrichsii (Radulaceae, Porellales) from mid-Cretaceous Myanmar amber

Xiangbo SONG[1]*, State Key Laboratory of Palaeobiology and Petroleum Stratigraphy, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing 210008, China (xbsong@nigpas.ac.cn)
Zixi Wang[2], State Key Laboratory of Palaeobiology and Petroleum Stratigraphy, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing 210008, China
Diying Huang[3], State Key Laboratory of Palaeobiology and Petroleum Stratigraphy, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing 210008, China

Abstract

Radula Dumortier, with ~260 living species, is one of the largest genera of the Porellales and the phylogenetically isolated genus of the leafy liverwort family Radulaceae. Radula heinrichsii Feldberg et al. is the second species of Radula reported from the mid-Cretaceous Kachin amber. Here, we review and illustrate Radula heinrichsii based on the new fossil specimen from Myanmar amber. Our new finding represents the first fossil species of Subgenus Amentuloradula Devos et al. present knew and adds new information on morphological diversity of this genus. The fossil specimen shares many diagnosis of Radula: gametophyte densely pinnately branched, with a few irregularly Radula-type branches, mostly entire-margined and complicatedly bilobed leaves with a large dorsal lobe and a smaller ventral Lejeunea-type lobule, rhizoids produced on leaf lobules, and absence of underleaves. In contrast to the previous fossil material, the new specimen exhibits one-three amentulose shoots by irregularly pinnatedly branching at the base of the leaves. Therefore, the fossil is assigned to subg. Amentuloradula. Extant subg. Amentuloradula usually occurs in tropical forest, where they grow as epiphytes on the bark of trees and shrubs, indicating that there was likely an extensive epiphyte flora in the mid-Cretaceous of Myanmar. The new fossil specimen enhances our comprehension on the morphological evolution and diversity of Cretaceous leafy liverworts.

Tracking Darwin's climbing plants in a 298 Ma swampy forest

ZHOU WEIMING[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (wmzhou@nigpas.ac.cn)
WANG JUN[2], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences

Abstract

The late Paleozoic era emerged as a pivotal period in the genesis and advancement of terrestrial forest ecosystems. From the emergence of the first forests in the Mid-Devonian period, these ecosystems exhibited a trajectory of gradual complexity through the evolution of plants and their interactions with the environment. During the Permo-Carboniferous period, the forests were characterized by a diverse array of climbers with adaptations akin to those seen in modern angiosperms. However, the documentation of these climbers across various ages and locations has posed challenges to our understanding of their ecological role in late Paleozoic forests. In this study, we undertook a comprehensive investigation of the climbers within the earliest Permian fossil Lagerstätte "Wuda Tuff Flora" (also known as the Chinese "vegetational Pompeii"). Our investigation revealed that the five climbing strategies outlined by Darwin—twining, tendril-climbing, hook-climbing, leaf-climbing, and clinging—are all represented within this forest community. The examined climbers exhibited modified appendages that showed convergence with those observed in contemporaneous pteridosperms and extant angiosperms. Remarkably, some vines or lianas employed multiple strategies to secure support or ascend. Moreover, the estimated species proportion of climbers stands at approximately 22.4% (11 out of 49), a figure comparable to that observed in modern tropical forests. Furthermore, individuals from various climbing species frequently shared a common tree support, with instances of one climber ascending upon another, indicating nuanced space allocation likely stemming from pervasive space competition. These groundbreaking discoveries provide valuable insights into the intricate forest dynamics of Permo-Carboniferous swampy forests.

Eusporangiate Fern from the Early Permian Peat-forming Forest in Wuda, Inner Mongolia, China

Dandan LI[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (ddli@nigpas.ac.cn)
Jun WANG[2], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences

Abstract

Eusporangiate fern is one of the most ancient of the living fern groups, appeared first in the Late Carboniferous and diversified through late Paleozoic until the present day. During the Permo-Carboniferous, most eusporangiate elements with erect stem belong to the Psaroniaceae, Marattiales, and are the main component of peat-forming forest canopy. Due to the incompleteness of plant fossils, most taxa of Paleozoic eusporangiates have been found only with single part of parent plant that makes a big trouble in reconstructing whole-plant and exploring evolution of eusporangiates.

An autochthonous peat-forming flora was found from early Permian in Wuda Coalfield, Inner Mongolia, which is buried by volcanic ash and named as “vegetational Pompeii”. There are seven groups in the vegetational Pompeii, namely lycopsids, sphenopsids, pteridophytes, progymnosperms, pteridosperms, Cycadales, and Cordaitales. Among all classes, eusporangiates (pteridophytes) has the highest diversity in the species number. According to the features of reproductive organs, there are at least six genera, nine species of eusporangiates in this flora, including four species of Scolecopteris, one species of Eoangiopteris, one species of Acitheca, one species of Asterotheca, and two new genera with two new species. Those species are supposed to have similar entire morphology, like several pinnate fronds locate in the top of an erectly unbranched stem. However, there is only one genus of permineralized or impressed stem of eusporangiates has been found in the vegetational Pompeii, Psaronius with 4 species (permineralized stem) and Caulopteris with 8 species (impressed stem); only two types of permineralized axis have been found. Evidences from the organically connected specimens from vegetational Pompeii show that one type of eusporangiate stems could bear two different types of fronds. Not only in the vegetational Pompeii, but the generic numbers of different organs of eusporangiates in the literature are not comparable. Of Paleozoic eusporangiates, there are about 30 genera of reproductive organ, three genera of compressed stems, three genera of permineralized stems, four genera of permineralized axis, and four different types of vegetative pinnae. The distinction in the number of different organs demonstrates that the evolutionary diversification of reproductive organs was much higher than shown in stem and leaf axes in eusporangiate plants. Evolutionary conservatism of stems and leaf axes compared to fertile organs indicates that the fossils had modular evolution with different modules (roots, stems, axes, vegetative and fertile pinnules, sporangia, etc.) evolving at different rates.

Biomarkers in fossil resins (ambers) – diversification and application

Jan PAŃCZAK[1], AGH University of Krakow
Paweł Kosakowski[2]*, AGH University of Krakow (kosak@agh.edu.pl)
Adam Zakrzewski[3], AGH University of Krakow

Abstract

Fossil resins ("ambers") are one of the tree exudate products, produced by gymnosperm and angiosperm taxa. Through conventional geochemical methods (e.g. chromatography), an insight into ambers' extracts, composed of hydrocarbons mostly from a terpene group, is possible. Various terpenes in ambers serve as biomarkers, the compounds that provide the genetic information on the amber origin. The terpenes in ambers are more volatile (mono- and sesquiterpenes), and less volatile (di- and triterpenes). Except for the terpenes, ambers can contain carboxylic acids in significant quantities, such as succinic acid which occurs in high concentrations in succinite, the Eocene-aged amber from Central Europe (e.g., "Baltic amber").

Volatile terpenes occur in minor amounts in comparison with a primary resin composition, due to their loss in the initial stages of resin transportation and deposition in sediments. In particular, monoterpenes in ambers play numerous roles in modern plants defense system; for instance, borneol, camphor, and fenchone indicate deterring and antimicrobial behavior in modern plants. These compounds occur in Baltic amber; although, in relatively low concentrations. Mono- and sesquiterpenes are observed in the extracts of ambers younger than the Cretaceous because in older ambers these compounds predominantly undergo advanced maturation and cross-linking processes. Their presence was observed in many fossilized dammar resins from South-East Asia, such as in Miocene-aged amber from Sumatra.

Di- or triterpenes occur as the most abundant compounds in all amber extracts; these compounds are mainly the biomarkers of several tree families among the gymnosperm and angiosperm clades. Thus, their occurrence has a chemotaxonomic significance. Usually, the occurrence of diterpenes indicates the gymnosperm origin of the analyzed material; although, ambers from the angiosperm Fabaceae family contain enantio-diterpenes (e.g., Dominican amber) which possess the chiral configuration of the occurring diterpenes. Except for the Fabaceae, the ambers of angiosperm origin are rich in triterpenes. The more advanced attribution of an amber sample to its botanical origin requires more detailed studies on comparison of modern and past plant products; however, some ambers contain biomarkers which pinpoint their origin to only one family. For example, glessite, a type of Bitterfeld amber, contains betulines, which might indicate the Betulaceae as the source family.

Ambers can contain compounds that may indicate their more advanced stages of maturity. Amberene (15,19,20-trisnorlabda-5,7,9(10)-triene), a diterpene from the labdane class, occurs in numerous Cretaceous-aged ambers, such as in Spanish amber from Álava. The compound might indicate more advanced stages of resin acids diagenesis processes. We have found this compound in other Cretaceous ambers - valchovite from the Czech Republic and in amber from Trepcza in

the Polish Carpathians. This, together with the general resemblances of the chemical composition, might suggest a similar botanical origin of the ambers.
Therefore, various biomarkers in ambers can be applied as a chemical tool in paleobotany to track the plants evolution and their state of maturation.

Abstract

The present study deals with the Early Permian floral diversity, palaeoenvironment, palaeoclimate and depositional setting using a multiproxy approach that include morphotaxonomy, palynology, and organic geochemistry of Karo OCM (Open Cast Mine), East Bokaro Coalfield, Damodar Gondwana Basin, India. The Gondwana sediments are widely regarded as fluvio-lacustrine deposits. The macroplant fossil assemblage exhibits the presence of Glossopteridales, comprising *Glossopteris*, *Gangamopteris*, and *Vertebraria*, as well as Coniferales, which includes *Noeggerathiopsis*. The palynological assemblage encompasses the dominance of the striate bisaccate pollen *Faunipollenites* sp. and the sub-dominance of the non-striate bisaccate pollen *Scheuringipollenites* sp. with Glossopterid affinities. The megafloral and palynofloral assemblage confirms the biostratigraphical age to be Upper Barakar palynoflora of Kungurian affinity. The studied morphological characteristics led us to envisage the presence of dense forest that prevailed during their deposition. Moreover, it also confirmed that a warm and humid climate prevailed during the deposition of Upper Barakar sediments. The organic geochemical characterization based on functional group and biomarker analyses reveals the diagenetic effects on organic matter. Aliphatic symmetric (2865–2855 cm-1) and asymmetric stretching (2930–2910 cm-1) peaks are identifiable in coal samples, whereas they are absent in carbonaceous shale. The A-factor vs. C-factor plot suggests that the kerogen type is Type III, which can generate mainly gaseous kerogen. The vitrinite reflectance studies (Rr av. 1.1%) show increased maturity of the

samples, which is support-ed by the *n*-alkane distribution pattern and the absence of hopane terpenoids. The Indian floral assemblages in contemporary of southern Gondwana continents reveal a stronger inclination/affinity with the flora of Africa than that of South America, thereby supporting the age to be of Artinskian-Kungurian.

Abstract

The combined analysis includes miofloral, megafloral, palynofacies, petrographical and fossil charcoal for the sediments of the Jagannath coalmine section in Talcher Coalfield from the Mahanadi Basin. Attempts are made to establish the age, reconstruction of palaeo-environment and evidence for the occurrence of palaeo-wildfires. Palynological investigation reveals one palynoassemblage namely *Scheuringipollenites barakarensis* palynoassemblage zone and assessed Early Permian (Artinskian) age for studied section. The palynoassemblage shows dominance genera of Glossopteridales and sub dominance of genera of trilete spores followed by Cordaitales and Coniferales. Megaflora comprise a low diversity assemblage dominated by Equisetales (*Schizoneura* and *Paracalamites*), with less common Glossopteridales (*Glossopteris*, *Gangamopteris*) and Filicales (*Dichotomopteris*) indicative of dense arborescent vegetation. Petrographic indices suggest that peat-forming vegetation accumulated mainly in telmatic settings under ombrotrophic-mesotrophic (intermittent fluctuating) hydrological conditions. Palynofacies suggest that the deposition of organic matter (by high energy fluvio-deltaic agents) took place in an oxic to occasionally dysoxic setting. The macroscopic charcoal fragments exhibit presence of homogenized cell walls and anatomical characters such as uniseriate simple, multiseriate alternate pitting on the tracheid walls and rays of varying heights suggested that the studied charcoal has gymnospermous wood affinity. The parautochthonous origin for these charcoal due to it's excellent preservation, their large size and unabraded edges in most of the specimens. Our multiproxy study is significant for understanding Permian peat-forming ecosystems and environments and provides a robust age assessment based on inter and intra-basinal correlations of coeval sequences across the Gondwana.

Vegetation and climate oscilations during MCO/MCT in Central and Eastern Paratethys

Marianna Kováčová[1]*, Comenius University Bratislava (marianna.kovacova@uniba.sk)
Nela Doláková[2], Masaryk University Brno

Abstract

Originally, we analyzed the Late Burdigalian to Serravalian pollen spectra from the Czech and Slovak regions of the Central Paratethys, as well as the Mura-Zala basin and Transylvanian basin. These were compared with spectra from Eastern Paratethys in Turkey. The climax of the Miocene Climatic Optimum (MCO) revealed oscillations in climatic factors, such as increasing seasonality in temperatures and precipitation. Subsequent cooling and observable precipitation fluctuations were documented as evidence for the Miocene Climate Transition (MCT) (Doláková, Kováčová, Utescher, 2021). The vegetation character in Central Paratethys underwent significant changes due to the Alpine uplift of the western Alps and Carpathians, initiating altitudinal zonality. Differences mainly in quantitative representation of zonal elements between northern localities (Czechia and Slovakia) and southern parts of this are (Slovenia, Romania) indicates increasing of latidudinal zonality. In Eastern Paratethys, palynospectra indicated an earlier trend of gradual cooling and a notable shift towards more arid and continental climate conditions. This trend may be linked to the presence of the vast moderate Eurasian continent (Vernyhorova et al., 2023).

Palynofloral Succession on the Cretaceous-Paleogene Transition in Northeast China

Jiahui YU[1], College of Earth Sciences, Jilin University, China
Yuewu SUN[2]*, Research Center of Palaeontology and Stratigraphy, Jilin University (sunyuewu@jlu.edu.cn)
Shuqin ZHANG[3], Research Center of Palaeontology and Stratigraphy, JilinUniversity, China
Eugenia BUGDAEVA[4], Federal Scientific Center of the East Asia Terrestrial Biodiversity, FEB, RAS, Russia

Abstract

The mass extinction at the Cretaceous-Paleogene (K-Pg) boundary significantly changed the earth's ecosystem, and profoundly influenced the global animal and plant evolution. It is attributed to climate change resulting from the Chicxulub impact in the Yucatan Peninsula in the Gulf of Mexico and the massive Deccan volcanic eruption. However, the K-Pg boundary clay has not been reported in China and northeastern Asia either. The terrestrial sediments in the Jiayin area of Heilongjiang Province, NE China, had been identified as the 95th locality of the K-Pg boundary, mainly based on the palynological data (Sun et al., 2011). In order to better understand the vegetation succession and climate change, detailed palynological investigation was engaged again on the K-Pg boundary transition from the XHY2008 borehole in Jiayin of Heilongjiang Province, China. A total of 153 species assigned to 72 genera were identified from 157 palynological samples in a 14.50 meters long borehole striding the K-Pg boundary. The Cretaceous-Paleogene vegetation as a whole was pteridophyte-angiosperm rich flora. Two palynological assemblages and one assemblage were recognized for the latest Cretaceous and earliest Paleogene, respectively. The latest Maastrichtian palynological assemblages were named as in ascending order: 1) Gabonisporis vigourouxii - Pinuspollenites microinsignis - Aquilapollenites stelckii Ass., and 2) Laevigatosporites spp. - Monocolpopollenites spp. - Ulmoideipites krempii Ass.; and the earliest Danian assemblage was named as Osmundacidites spp. - Pseudointegricorpus clarireticulatus - Wodehouseia spinata Ass. The two latest Maastrichtian assemblages were productive in palynomorphs and with high pollen concentration, while the earliest Danian samples were much lower in pollen concentration. The index pollen for the latest Maastrichtian and earliest Danian age determination were the occurrences of Wodehousia spinata and Triatriopollenites confuses, respectively. The vegetation succession on the K-Pg boundary was characterized by the rise of Osmundacidites fern spores and the diverse of gymnosperm pollen, while the angiosperm pollen were decreased obviously and most species of the Aquilapollenites were disappeared. On the contrast, the latest Maastrichtian vegetation succession was characterized by great rising of angiosperm pollen such as Monocolpopollenites, Alnipollenites and Ulmoideipites, and decreasing of fern spores such as Gabonisporis and Triporoletes. From the general view on vegetation succession, there were not any great event happened on the K-Pg boundary. It showed us another scenario which is totally different from the asteroid impacts in North America. This work was funded by National Science Foundation of China (41972012, 31270277).

Middle-Late Permian Palynofloras in lacustrine-pluvial fan depositional system in Junggar Basin, northern Xinjiang, China

Yuewu SUN[1]*, Research Center of Palaeontology and Stratigraphy, Jilin University (sunyuewu@jlu.edu.cn)
Xueqin WANG[2], Research Center of Palaeontology and Stratigraphy, Jilin University, China
Shuqin ZHANG[3], Research Center of Palaeontology and Stratigraphy, Jilin University, China

Abstract

The Permo-triassic terrestrial deposits in Junggar Basin of northern Xinjiang are well developed, and have been studied in detail, especially the P-Tr boundary transition since 1980's. However, little palynological investigation was done after 1990. In order to see the vegetation and climate changes during the Guadalupian and early Lopingian, 170 palynological samples were collected systematically from the uppermost of Lucaogou-, Hongyanchi-, Quanzijie- and the bottom of Wutonggou- formations in the south limb of West Dalongkou anticline, Jimsar, norther Xinjiang, China. Among them, 39 samples are productive, and 69 species of 40 genera were identified. Based on the vertical distribution of palynomorphs in the Dalongkou profile, two distinct palynofloras were recognized in ascending order: 1) Corditina subrotata – Striatoabietes lipidus – Protowelwitschiapolis exolescus palynoflora (SLE), is occurred in uppermost of Lucaogou-, and Hongyanchi- formations. The palynomorphs in this horizon are characterized by abundant gymnosperms pollen, such as Cordaitina, Protowelwitschiapolis, Striatoabiites, Vittatina, Protohaploxypinus and Cycadopites. Spores are rare, only Raistrickia and Laevigatosporites. 2) Kraeuselisporites spinulosus – Tuberculatosporites homotubercularis – Potonieisporites turpanensis palynoflora (SHT), is located in Upper Quanzijie-, and Lower Wutonggou-formaitons. It is characterized by abundant both fern spores and gymnosperms pollen. Fern spores are mainly Kraeuselisporites, Tuberculatosporites, Raistrickia, Apiculatisporis and Cyclogranisporites. Neoraistrickia, Schopferites and Polypodidites are also seen. Gymnosperms pollen are mainly Cordaitina, Potonieisporites, Klausipolenites, Falcisporites and Platysaccus. According to the geological age span of known pollen and spores taxa in the two palynofloras, the SLE and SHT are assigned to the early Guadalupian and early Lopingian, respectively. As the palynomorphs in the lower Quanzijie Formation are closely related to those in SLE, we consider that the G-L boundary might be between the Lower and Upper Quanzijie Formation in West Dalongkou profile, although there would exist hiatus between the Hongyanchi and Quanzijie formations. Meanwhile, the paleoclimate of the SHT would be more humid than the SLE, and the paleoclimate of the lower Quanzijie Formation might be even much drier than the Lucaogou and Hongyanchi formations. This drived two types of fan deposits: the alluvial and pluvial fans. This work is supported by the National Natural Science Foundation of China (31670215).

The Leaf Fossils of Tuff Units in Metro Manila and Rizal, Philippines

Andrea Pamintuan[1]*, National Institute of Geological Sciences (andreapamints@gmail.com)
Alyssa Peleo-Alampay[2], Nannoworks Laboratory, National Institute of Geological Sciences, University of the Philippines, Diliman
Pastor Malabrigo[3], Department of Forest Biological Sciences, College of Forestry and Natural Resources, University of the Philippines, Los Banos, Laguna, Philippines
Arthur Glenn Umali[4], Department of Forest Biological Sciences, College of Forestry and Natural Resources, University of the Philippines, Los Banos, Laguna, Philippines

Abstract

Plant fossils found in sedimentary rocks have been utilized extensively for geological, evolutionary, and paleoecological studies. Plant macrofossils are particularly useful in correlational and evolutionary studies, as they keep records of morphological features of plants. Despite the rich flora of the Philippines, studies on fossil leaves from the Philippines are rarely reported, making this study particularly significant in deepening our understanding of the past environments that once thrived in this area. Consequently, paleoflora studies provide valuable insights into the geological and ecological history of the Philippines.

In this study, fossil leaves collected from Pleistocene volcaniclastic units in Metro Manila and Rizal Province are examined and identified. Insights into the paleoenvironment of the area was interpreted based on fossil leaf species identified and previous literature. Fossil flora families identified from Laguna Formation samples indicate a tropical climate and moist environment that could possibly be a mixed dipterocarp or sub-montane forest. Similarly, samples from the Diliman Tuff indicated a tropical to subtropical climate and a moist environment. General lithology, data from previous work and the nature of the fossil leaves narrows the paleoenvironment of the Diliman Tuff to a riparian setting. This is the first detailed work on fossil leaves in the Philippines, shedding light on the region's past ecological and geological landscapes.

Ostracod Faunas from the Early Cretaceous Liupanshan Group (Pingliang, NW China): Implications for Biostratigraphy and Palaeoenvironment

Yaqiong WANG[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (yqwang@nigpas.ac.cn)
Byung-Do CHOI[2], Daegu National Science Museum
Deyan WU[3], Yunnan University

Abstract

The Liupanshan Basin is one of the small-scale Mesozoic-Cenozoic rift basins, which situated in the northern part of the North-South tectonic belt and bounded by the Ordos Block, the Alxa Block, the Hexi Corridor belt, and the Qinling-Qilian orogenic belt. Within this basin, the Lower Cretaceous Liupanshan Group comprises five formations: Sanqiao, Heshangpu, Liwaxia, Madongshan, and Naijiahe formations, arranged in ascending stratigraphic order. This study investigates a non-marine ostracod fauna recovered from the Liwaxia and Madongshan formations, encompassing eight species belonging to seven genera: *Bisulcocypridea gaodianensis*, *Cypridea cavernosa astuta*, *C. elegantula*, *Mongolocypris* sp. A, *Liupanshania typica*, *Lycopterocypris debilis*, *Ziziphocypris costata*, and *Limnocythere* sp. A. Among these ostracods, the genus *Bisulcocypridea* is found in Aptian to lower Paleocene deposits in the USA, Mongolia, and China, while the genus *Mongolocypris* is recorded in Aptian to Paleocene strata in China, Mongolia, and Korea. *Lycopterocypris debilis* is widely distributed in Hauterivian to Albian non-marine strata in East Asia, and *Ziziphocypris costata* occurs in Aptian to the lowermost Danian non-marine strata in East Asia. Based on this ostracod biostratigraphy, the age of the Liwaxia and Madongshan formations in the Pingliang area is probably Aptian to Albian.

In this ostracod fauna, the endemic-dominated extinct genus *Liupanshania* is perhaps most closely related to the living genus *Cyprois* of the family Notodromadidae. All living species from the family Notodromadidae possess swimming ability, and most feed on the neuston. Additionally, notodromadidae are known to inhabit mostly lentic habitats. Furthermore, based on our previous findings, the other ostracod genera from this fauna may indicate a fresh to slightly saline lacustrine to fluvial environment. Therefore, we interpret the Liwaxia and Madongshan formations in the Pingliang area of the Liupanshan Basin as having been deposited in a fresh to slightly saline lacustrine environment.

Acknowledgments. This study is supported by the National Natural Science Foundation of China (42372022).

Exceptional preservation of reproductive organs and giant sperm in the Cretaceous ostracods

He WANG[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (wanghe0701@163.com)

Abstract

The bivalved crustacean ostracods have the richest fossil record of any arthropod group and display complex reproductive strategies contributing to their evolutionary success. Sexual reproduction involving giant sperm, shared by three superfamilies of living ostracod crustaceans, is among the most fascinating behaviours. However, the origin and evolution of this reproductive mechanism has remained largely unexplored because fossil preservation of such features is extremely rare. Here, we report exceptionally preserved ostracods with soft parts (appendages and reproductive organs) in a single piece of mid-Cretaceous Kachin amber (approximately 100 Myr old). The ostracod assemblage is composed of 39 individuals. Thirty-one individuals belong to a new species and genus, Myanmarcypris hui gen. et sp. nov., exhibiting an ontogenetic sequence from juveniles to adults (male and female). Seven individuals are assigned to a new species and genus Electrocypria burmitei gen. et sp. nov. and one to Sanyuania sp. Our micro-CT reconstruction provides direct evidence of the male clasper, sperm pumps (Zenker organs), hemipenes, eggs and female seminal receptacles with giant sperm. Our results reveal that the reproduction behavioural repertoire, which is associated with considerable morphological adaptations, has remained unchanged over at least 100 million years—a paramount example of evolutionary stasis. These results also double the age of the oldest unequivocal fossil animal sperm. This discovery highlights the capacity of amber to document invertebrate soft parts that are rarely recorded by other depositional environments. We further describe taphonomic traits indicating that the studied ostracods were quickly surrounded by resin and instantly immobilized. The palaeoenvironment is considered to be a vegetated brackish (mesohaline-oligohaline) lagoon.

[Keynote] Phenotype Puzzle: Challenges in Paleontological Studies

Yanhong PAN[1]*, Nanjing University (panyanhong@nju.edu.cn)

Abstract

Evolutionary processes, driven by the interplay of natural selection and genetic variation, shape the characteristics of biological populations over time. In the field of paleontological research, the primary focus frequently shifts towards phenotypes, which poses a challenge in distinguishing individuals and species due to inherent deficiencies in fossil records. The phenotypic characteristics recorded in fossil specimens can be broadly classified into two types: those indicating a binary presence or absence, which may effectively represent species even at an individual level. Others exhibit continuous variation necessitating the definition of species based on population characteristics. The latter arises from the blurred distinction between phenotypic characteristics, especially when specimens are limited and gathered from multiple locations. Nonetheless, this practice raises inquiries, such as the determination of whether specimens from distinct locations belong to the same species. It is also important to decide whether incomplete specimens can be discarded without compromising the integrity of the study. Moreover, the inquiry of what constitutes a sufficient sample size becomes a crucial consideration. To address these obstacles, we try to employ mathematical statistics and computational models to compensate for the limited sample sizes, aiming to enhance comprehension of fossil populations and their evolutionary dynamics. In conclusion, the phenotype puzzle in paleontological research requires solutions to navigate the challenges posed by incomplete and limited fossil records.

A review of non-marine ostracod faunas from the Cretaceous Gyeongsang Basin, South Korea

Byung-Do CHOI[1]*, Daegu National Science Museum (dinobd87@gmail.com)
Yaqiong WANG[2], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Min HUH[3], Department of Geological and Environmental Sciences & Korea Dinosaur Research Center, Chonnam National University

Abstract

Non-marine ostracod records from the Cretaceous Gyeongsang Basin, South Korea are reviewed here. Although many faunas show a relatively low diversity and poor state of preservation, a total of 36 species belonging to 10 genera of superfamily Cypridoidea are recognized. Basis on major generic compositions, three ostracod assemblages are established in ascending order: 1) Barremian–early Albian *Cypridea-Mongolocypris-Scabriculocypris* assemblage (Nakdong, Hasandong, and Jinju formations); 2) late Albian–Cenomanian *Cypridea-Ziziphocypris-Lycopteorcypris* assemblage (Iljik, Banyawoel, and Chunsan formations); 3) Turonian–Santonian *Lycopteorcypris-Candona* assemblage (Geoncheonri Formation); 4) Campanian *Mongolocypris* assemblage (Anpo Tuff) in ascending order. The most diverse group of these assemblages is genus *Cypridea* (including 12 species) as many strata in East Asia. Except several species, the Barremian–early Albian faunas show a high endemicity, which may indicate that many ostracod taxa evolved in the isolated environments; e.g., *Mongolocypris kohi* from the Albian Jinju Formation is considered an ‘early form’ of the genus. After faunal turnover, the post-early Albian faunas show affinities to those of the Late Cretaceous in China and Mongolia, providing evidence of active faunal exchanges. In addition, a restricted stratigraphic distribution of genus *Ziziphocypris* (late Albian–Cenomanian) is useful for biostratigraphic correlation. A comprehensive interpretation about ostracod faunal significances herein provides new information on the evolution, biostratigraphy, and paleobiogeography of the Gyeongsang Basin, as well as the Cretaceous of East Asia.

Late Devonian benthic ostracods from South China and their response to the Frasnian–Famennian event

Junjun SONG[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (jjsong@nigpas.ac.cn)

Abstract

The Late Devonian Frasnian–Famennian mass extinction (i.e., F–F event) is traditionally known as one of the Phanerozoic "Big Five" faunal crises, and had a severe impact on marine realm, especially the shallow-water ecosystems. In this study, Late Devonian ostracods are described for the first time from the Frasnian–Famennian (F–F) transition of the Zengpiyan section, Guangxi, South China. Forty-five ostracod species belonging to 25 genera are identified and figured and one is new: Jenningsina guilinensis sp. nov. The Frasnian–Famennian boundary (F–FB) in the Zengpiyan section is coincident with the lithological boundary between the Guilin Formation and the Dongcun Formation, and could be marked by the disappearance of Rectobairdia proximischimensis (Lethiers & Casier, 1998) and Jenningsina guilinensis sp. nov. The ostracods belong to the Eifelian Mega-Assemblage, which implies a shallow-water palaeoenvironment. The ostracod fauna and sedimentary features of the Guilin and Dongcun formations at the Zengpiyan section suggest a transition from subtidal to low energy tidal flat on the Guilin Platform during the Frasnian-Famennian event. The extinction rate of benthic ostracod species is about 61% during the F–F event in the Zengpiyan section. Two stages of faunal changes have been recognized in the event and the second stage is more severe than the first one.

[Keynote] Time Machine Biology: ostracod examples

Moriaki YASUHARA[1]*, The University of Hong Kong (moriakiyasuhara@gmail.com)

Abstract

Direct observations of marine ecosystems are inherently limited in their temporal scope. Yet, ongoing global anthropogenic change urgently requires improved understanding of long-term baselines, greater insight into the relationship between climate and biodiversity, and knowledge of the long-term consequences of our actions. Sediment cores and small fossils included there, so called microfossils (including various taxonomic groups of photosynthetic plankton such as coccolithophores and diatoms, various mixo- to heterotrophic protists such as planktonic and benthic foraminiferaand planktonic radiolarians, and small metazoans such as benthic ostracods as well as parts of larger organisms, such as the scales and teeth of fish and shark denticles), can provide this understanding by linking data on the responses of marine biota to reconstructions of past environmental and climatic change. Given continuous sedimentation and robust age control, studies of sediment cores have the potential to constrain the state and dynamics of past climates and biodiversity on timescales of centuries to millions of years. Here, we will overview the development and recent advances in "ocean drilling paleobiology" or "Time Machine Biology"—a synthetic science with potential to illuminate the interplay and relative importance of ecological and evolutionary factors during times of global change. Climate appears to control marine ecosystems on various timescales. I will showcase several examples from recent studies from our group, especially focusing on microfossil ostracods, and give an outlook on ongoing and future anthropogenic changes.

Late Ordovician ostracods of Valcour Island, New York State, USA

Yichi ZHANG[1]*, School of Biological Sciences, The University of Hong Kong, Hong Kong SAR, PRC (yichi@connect.hku.hk)
Moriaki YASUHARA[2], School of Biological Sciences, The University of Hong Kong, Hong Kong SAR, PRC
Skye Yunshu TIAN[3], Institute of Geosciences, University of Bonn, Bonn, Germany
Melanie HOPKINS[4], Division of Paleontology (Invertebrates), American Museum of Natural History, New York, USA

Abstract

Ordovician ostracods of the New York State had been recorded preliminarily with systematic paleontology under an unrevised classification scheme. New materials are collected from the Late Ordovician Crown Point Formation of Valcour Island, northeastern New York State, for thorough studies on systematic revision, diversity analysis, paleoecological and paleogeographical implications. Fifty-one species of 39 genera are identified with 6 species being reexamined and revised accordingly. Within the fauna, Krausella variata, Cryptophyllus oboloides, Eohollina depressa and Eurychilina placida are the most common species. Both beyrichiocopids and podocopids are dominant in the Valcour fauna. Faunal comparison shows close relationships between Laurentia and Baltica, Avalonia and Ibero-Armorica during this time interval. Hill number is used for diversity analysis on each sample, and a general increase in diversity is recognized. Furthermore, new exceptionally well-preserved materials of palaeocopid Eurychilina placida are collected, with development of moult retention. The phenomenon of moult retention has been found in several genera of Paleozoic ostracod, which are assigned to the Suborder Eridostracina empirically. New materials with moult retention not only reveals a new survival strategy for ostracods during the period of unstable environment, but also shows that moult retention possibly could not be the characteristic feature to define a suborder, and the classification scheme should be revised accordingly.

Distribution and community structure of ostracods across the Isthmus of Panama

Kk Aye[1]*, University of Hong Kong (u3007074@connect.hku.hk)
Moriaki Yasuhara [2], University of Hong Kong
Aaron O'Dea[3], Smithsonian Tropical Research Institute

Abstract

The complete emergence of the Isthmus of Panama between 4.0 – 2.5 Ma has completely shaped the present–day environmental conditions of the Caribbean Sea and the Tropical Eastern Pacific Ocean (TEP). The Caribbean Sea is biologically unproductive and exhibits higher surface salinity and sea surface temperatures with freshwater input from local precipitation. It is in stark contrast to the TEP which encompasses low salinity and well-stratified waters with some of the most nutrient-compressed waters originating from major coastal upwelling areas of Panama. Such heterogeneous conditions will produce unique habitats that prompt considerable differences in marine ecosystems on either side of the Isthmus of Panama. This project will make use of Ostracoda as a model system to provide insight into the relationship between the community dynamics (assemblage composition, depth distribution, abundance, diversity analysis, etc.) of ostracods in various regions of the Caribbean Sea and the TEP, as well as gain further knowledge of indicator species within the tropical shallow marine ecosystems. Ostracods are the ideal taxonomic group to explore this question in detail due to their high sensitivity to environmental changes and exceptional preservation quality. We will use 110 surface dredge and grab samples from the Panama Palaeontology Project (PPP) covering 4 major regions of the southern Caribbean Sea and 2 major regions of the northern TEP. Methods involve washing, sieving, drying, and picking of the surface samples and individual ostracods will be identified to the species level where possible. Based on several investigations into the Platycopid signal and response of ostracods to oceanic oligotrophic conditions during the Oceanic Anoxic Event 2 excursion, I hypothesise that ostracod assemblages will differ distinctly in the Caribbean Sea and the TEP by way of a higher abundance and diversity of oligotrophy-bearing Platycopid species on the Caribbean side of the Isthmus of Panama. Results on trends in ostracod community dynamics will be presented at the conference.

Ecological Impact of the Suez Canal: Distribution and Diversity of Invasive Ostracods in the Mediterranean Sea

Lalita WEERACHAI[1]*, School of Biological Sciences, The University of Hong Kong (lalita347@gmail.com)
Moriaki Yasuhara[2], School of Biological Sciences,The University of Hong Kong

Abstract

The Lessepsian invasion is a consequence of the construction of the Suez Canal in 1869. This human activity led to the migration of marine species from the Red Sea in the Indo-Pacific region to the eastern Mediterranean Sea. Both biologists and paleontologists have been studying the non-indigenous species to understand the history of marine biodiversity in the region. The results showed that the eastern Mediterranean has experienced a significant collapse in native biodiversity over the past few millennia, which has been aggravated by recent human activities such as shipping and ballast water, and climate change. To achieve more comprehensive understanding of the ecological impact of this invasion, it is important to consider the spatial distribution of small organisms as well as the diversity and faunal compositions. This study aims to investigate the distribution and abundance of ostracod species from core and surface samples. Ostracods are small and well-calcified bivalved crustaceans that inhabit a wide range of aquatic environments. They have been widely used as a bioindicator, and they can also be used to reconstruct historical changes, as ostracod shells have excellent preservation potential in sedimentary archives. Additionally, ostracods are often abundant and diverse, making them useful for biodiversity assessments and monitoring. The study of ostracod invasive species will provide us with the spatial distribution of ostracods following the opening of the Suez Canal.

OSTRACOD ASSEMBLAGES OF THE MIDDLE MIOCENE TRANSGRESSIVE SEDIMENTS IN THE CARPATHIAN FOREDEEP (JAWORZNO, SW POLAND; THE CENTRAL PARATETHYS)

Zbigniew Jan ZIAREK[1]*, AGH University of Krakow; Faculty of Geology, Geophysics, and Environmental Protection; A. Mickiewicza 3 Av., 30-059 Krakow, Poland (zbysiuziarek@student.agh.edu.pl)
Monika PILARZ[2], AGH University of Krakow; Faculty of Geology, Geophysics, and Environmental Protection; A. Mickiewicza 3 Av., 30-059 Krakow, Poland

Abstract

During the Middle Miocene the Fore-Carpathian Basin in Poland represented the northernmost part of the Central Paratethys. The Langhian in the Central Paratethys was characterized by a major marine transgression into the Pannonian and Carpathian Foredeep basins. Investigated area encompasses the Middle Miocene sediments of the western part of the Carpathian Foredeep in Poland, where the northern boundary is erosional in nature and the southern boundary is tectonic and correspond to the Carpathian overthrust. Profiles containing a sequence of the transgressive sediments in the north of this part of basin are very rare.

We present new results on samples taken from Jaworzno 5902 borehole located in southern Poland. Investigated area covers the northernmost isolated patch of transgressive Langhian sediments and are represented by marls, light ash-grey/green clay marls (the Klodnica Fm.) and grey clays (the Skawina Fm.).

Obtained material mainly consists of foraminifera, ostracods and detritus of bivalve shells.

In the ostracod microfauna two assemblages can be distinguished. The first (the Klodnica Fm.) is the *Aurila-Cytheridea* assemblage and is dominated by species: *Aurila punctata*, *A. angulata*, *A. haueri*, *Cytheridea acuminata*, *Olimfalunia pliculata*, *Loxoconcha* sp., and *Cytherura* sp.. This assemblage indicates the depth zone of 0-25m according to Keen (1989). Sissingh (1976) associates the dominance of *Cytheridea* and the co-occurrence of *Aurila* and *Loxoconcha* with an environment related to the infralittoral zone, constituting the shallower part of the sublittoral zone, not exceeding 50m. Mentioned species indicate a brackish environment. The second assemblage (the Skawina Fm.) is dominated by *Henrychowella asperrima*, *Parakrithe rotundata*, and *Pterygocythereis jonesii* – typical ostracods related to deeper marine environments. The coexistence with the shallow-water *Costa* sp. suggests that the basin depth did not exceed 100m.

Ostracods from Jaworzno show dwarfism, which suggests difficult environmental conditions. The abundance of ostracods in the samples varies widely, and their carapaces in the lower part of the profile are thin, sometimes transparent, whereas in the upper part, they are slightly thicker, which suggests changes in the environment. These data indicate transition from a brackish shallow-water environment (Klodnica Fm.) to a fully-marine one (Skawina Fm.).

The ostracods of the Klodnica Fm. in Jaworzno borehole resembles the assemblages from the

profiles located west (Nowy Dwor) and south (Polomia) of Jaworzno. Similarly, all these ostracods represent deposits of the shallow-marine brackish zone at 0-25m. The difference is observed in case of the Beczyn profile located in the Carpathian thrust zone. In this case assmeblage is rich and diverse in well-preserved thick carapace ostracods. This part of basin depth could not have exceeded 100m (Schiller, 1977). The studied ostracod assemblages show full analogies in species composition to the same-age assemblages described from the Vienna Basin in Austria.

The results of the study of the presented ostracod assemblages are consistent with the conclusions drawn from the analyse of foraminifera. On the basis of foraminifera, it was possible to determine the age of studied deposits as Langhian which corresponds to the Badenian in the Central Paratethys, *Orbulina suturalis* – *Praeorbulina glomerosa* Zone (Cicha et al. 1975).

Abstract

Within the intensively-studied, well-documented latitudinal diversity gradient, the deep-sea biodiversity of the present-day Norwegian Sea stands out with its notably low diversity, constituting a steep latitudinal diversity gradient in the North Atlantic. The reason behind this has long been a topic of debate and speculation. Most prominently, it is explained by the deep-sea glacial disturbance hypothesis, which states that harsh environmental glacial conditions negatively impacted Norwegian Sea diversities, which have not yet fully recovered. Our aim is to empirically test this hypothesis, using ostracod (Ostracoda: Crustacea) fossil assemblages (Middle Pleistocene-Late Holocene, i.e., 620.7–1.4 ka) from three sediment cores (MD992277, PS1243(-1), M23352(-3)) from the deep Norwegian Sea (1819 m–2800 m). Specific research questions are: 1. Has deep-sea biodiversity been lower during glacials than during interglacials? 2. Was there any faunal shift at the Mid-Brunhes Event (MBE) when the mode of glacial-interglacial climatic change was altered?

We empirically test the deep-sea glacial disturbance hypothesis by investigating temporal patterns of species diversity and comparing them to global climate proxies. Additionally, we apply comparative analyses to determine a potential faunal shift at the Mid-Brunhes Event (MBE), a Pleistocene event describing a fundamental shift in orbital climate cyclicity. Our results indicate that the deep Norwegian Sea diversity was not lower during glacial periods compared to interglacial periods; that Holocene diversity was much lower than that of the last glacial period; and that Faunal composition changed substantially between pre- and post-MBE. Therefore, these results reject the glacial disturbance hypothesis, since the low glacial diversity is the important precondition here. The present-day-style deep Norwegian Sea ecosystem was established by the MBE, more specifically by MBE-induced changes in climate cyclicity, which has led to more dynamic post-MBE. In a broader context, this implies that the MBE has played an important role in the establishment of modern polar deep-sea ecosystem and biodiversity in general.

Cretaceou stratigraphy and ostracod funa in the Songliao Basin, NE China

Dangpeng XI[1]*, China University of Geosciences (Beijing) (xdp1121@163.com)
Benjamin Sames[2], University of Vienna
Zhongye Shi[3], China University of Geosciences (Beijing)
Qin Zuohuan[4], China University of Geosciences (Beijing)
Xiaoqiao Wan[5], China University of Geosciences (Beijing)

Abstract

The Songliao Basin is one of the largest non-marine oil and gas bearing basins that developed during the Cretaceous period, recording an almost complete Cretaceous non-marine stratigraphy and biota, providing an important reference succession for understanding the non-marine Cretaceous. The Lower Cretaceous strata (Hautervian–Albian) in the Songliao Basin are dominated by volcanic-sedimentary deposits, while the lower-middle Upper Cretaceous (Cenomanian mid-Campanian) strata are dominated by lacustrine deposits, and the upper Upper Cretaceous strata (late Campanian–Maastrichtian) are dominated by fluvial-lacustrine deposits. Based on the lithostratigraphy, biostratigraphy, geochronology, magnetostratigraphy, and cyclostratigraphy, a comprehensive stratigraphic framework of the Songliao Basin has been established in this study.

Fossils are very abundant in the Songliao Basin, especially ostracod; and three biotas, the Jehol Biota, the Songhuajiang Biota and the Mingshui Biota are recognized in the Songliao Basin. Widespread non-marine deposits in the basin contain abundant ostracod. These well-preserved fossil ostracods provide valuable information about Cretaceous climate changes and biotic responses in a greenhouse environment. The Cretaceous International Continental Scientific Drilling Project core SK1 and SK3 from the Songliao Basin offers a rare opportunity to study Late Cretaceous non-marine ostracods over a long, continuously documented, time interval. The SK1 contains the upper Quantou, Qingshankou, Yaojia, Nenjiang, Sifangtai, and Mingshui formations in ascending order. The SK3 contains the Denglouku and lower to middle Quantou formations in ascending order. A high-resolution non-marine ostracod biostratigraphy based on SK1 and SK3 has been established. Twenty ostracod assemblages have been recognized from the upper Quantou to Mingshui formations. This series of zones can be correlated regionally and supraregionally. The preliminary biostratigraphic correlation indicates that assemblages 1 to 19 span the Cenomanian to Maastrichtian, while Assemblage Zone 20 might span the latest Maastrichtian to earliest Danian.

No-marine Ostracod fauna from the Early Cretaceous Jinchuan Formation of the Ordos Basin: Taxonomy and Biostratigraphy

Huazheng ZHU[1], 1. Nanjing University; 2. Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Yaqiong WANG[2]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (yqwang@nigpas.ac.cn)
Yanhong PAN[3], Nanjing University

Abstract

The Ordos Basin, also known as the Shaan-Gan-Ning Basin, stands as a significant reservoir of energy resources (coal, gas, and oil) in China, covering an expansive area of approximately 250,000 km^2. This basin is surrounded by the Yinshan Mountains in the north, the Qingling Mountains in the south, the Helan and Liupan Mountains in the west, and the Lvliang Mountains in the east. Within the basin, the Lower Cretaceous Zhidan Group comprises of the Luohe, Huanhe-Huachi, Luohandong, Jingchuan, and Fengshan formations in ascending order. Notably, the Jingchuan Formation is characterized by greyish-green breccias, conglomerates, yellowish-green calcareous sandstones, and variegated mudstones interlaced with oolitic limestone and marls. This formation hosts abundant fossil invertebrates (ostracods, clam shrimp, bivalves), vertebrate (dinosaurs), and plants, which have long been of interest to paleontologists. Recently, a non-marine “Purbeck-Wealden type” ostracod fauna is recovered from the Jinchuan Formation in Pingliang area; this ostracod fauna consists of five species belonging to three genera: *Cypridea* sp., *C. koskulensis*, *Lycopterocypris*? *multifera*, *L. debilis*, *Alicenula* sp. Of these ostracods, the species *Cypridea koskulensis* is widely distributed in Barremian to Aptian strata in China and Russia. *Lycopterocypris*? *multifera* was discovered in the Hauterivian to Albian Zuunbayan Formation of Mongolia, and *Lycopterocypris debilis* is widely distributed in Hauterivian to Albian non-marine strata in East Asia. Based on the available ostracod biostratigraphy information above, the age of the Jingchuan Formation is Barremian to Aptian.
Acknowledgments. This study is supported by the National Natural Science Foundation of China (42372022).

Geochronology and biostratigraphy study on the Early Cretaceous basins in the Jilin region, northeastern China

Yu-Ting ZHONG[1]*, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences (zyt9797@gig.ac.cn)
Yaqiong Wang[2], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, 39 East Beijing Road, Nanjing 210008, China
Byung-Do Choi[3], Daegu National Science Museum, Dalseong Yuga-eup, Daegu 43023, Republic of Korea
Jianfang Hu[4], State Key Laboratory of Organic Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou 510640, China
Yanhong Pan[5], Nanjing University, Nanjing 210023, China

Abstract

The Cretaceous system is well developed in Jilin Province, consists of two types: the Songliao Plain type and the eastern/western mountainous region type. Recently, we have undertaken biostratigraphic, geochemical and geochronological studies on the sedimentary basins of eastern/western mountainous of Jilin. These investigations have yielded significant primary data that will contribute to further exploration of the evolution of terrestrial biota and its connection to the destruction of the North China Craton (NCC).

The Baishan Basin is located on the northern margin of the NCC. The early Cretaceous is divided into the Yingzuilazi, Linzitou, Shiren, and Xiaonangou formations. The Yingzuilazi Formation comprises of the conglomerate, sandstone, siltstone, mudstone with coal seams yielding abundant fossils. The ostracod fauna from this formation includes Cypridea tuberculatis, C. horni, C. bulumensis, C. aff. multispinosa, C. cf. unicostata, C. beipiaoensis, Rhinocypris jurassica, R. sp., Djungarica sp., Ziziphocypris linchengensis, Lycopterocypris infantilis, L. debilis, Timiriasevia principalis, Alicenula? dadianziensis, A.? Leguminella, indicating a Hauterivian to Barremian age. Meanwhile, zircon U-Pb dating from the upper part of the Yingzuilazi Formation yielded an age of 128.5±1.0 Ma. The overlying Linzitou Formation mainly consists of acidic volcanic rocks, dated at 127.4 ±1.1 Ma at the bottom. Consequently, ostracods show the similarities with the second stage of Jehol Biota in the Yixian Formation of western Liaoning, although its absolute ages aligns with the first stage of the Jehol Biota.

In the Yanji Basin, the late Early Cretaceous to early Late Cretaceous comprise the Tongfosi, Dalazi, and Longjing formations. The Tongfosi Formation includes of thick conglomerates at the base, with sandstone, siltstone, and sandy mudstone layers, and oil shale in the top. Ostracod fauna from this formation include Vlakomia jilinensis, V. ustinovskii, Scabriculocypris tonfosiensis, S. yanbianensis, Mongolianella kyranbeki, Lycopterocypris infantilis, Candona spp., indicating an Albian age. And the Dalazi Formation has lower conglomerates and upper layers of muddy sandstone, sandy mudstone, shale, oil shale, and tuff, yielding fossil ostracods: Cypridea concinaformis, Mongolocypris yanjiensis, Cyprois sp., Lycopterocypris sp., Yumenella toorojensis, which indicates an Albian-Cenomanian age. The topmost of Dalazi Formation is dated

at 105.14±0.37 Ma. The Longjing Formation mainly comprises conglomerates, and sandstones, containing abundant vertebrate fossils. Ostracod fossils from this formation include Mongolocypris cf. rostrata, M. yanjiensis, Candoniella cf. candida, Candona sp., indicating an Albian-Cenomanian age. Combine with the precise U-Pb age of 101.039±0.061 Ma from the bottom of the Longjing Formation, it suggested that the Longjing Formation of the Yanji Basin may include the terrestrial Lower-Upper Cretaceous boundary. Additionally, ostracod Vlakomia and our geochemistry data may indicate that a correlation between the Tongfosi Formation's oil shale and marine transgression event.

The Luozigou Basin, zircon U-Pb dating on the lower and middle parts of the Dalazi Formation yielded ages of 104.6±1.2 Ma and 103.3±1.0 Ma, respectively. This precise radiometric age for the Dalazi Biota from Luozigou Basin provides an important temporal constraint on the evolution of major plant and vertebrate groups.

Acknowledgments. This research was funded by the National Natural Science Foundation of China (Grant Nos. 42372022 and 41873018).

Holocene hydroclimate changes in the source area of the Yellow River inferred from ostracod assemblages and their isotopes in Lake Gyaring

Xiangzhong LI[1]*, Yunnan University (xzhli04@163.com)
Deyan Wu[2], Yunnan University

Abstract

The Yellow River, as the mother river of China, is vital for the wellbeing of millions. The source area of the Yellow River (SAYR) contributes over one-third to basin discharge and is crucial for water conservation in China. However, understanding hydroclimate changes in the SAYR remains challenging due to limited hydroclimatic records. Here, we analysed ostracod assemblages, and their oxygen isotope (δ18O) values in 14C-dated sediments from Lake Gyaring, one of largest lakes in the SAYR, to reconstruct regional hydroclimate changes during the Holocene.

Based on the dominance of ostracod species Eucypris mareotica and their high δ18O values, we infer that Lake Gyaring experienced a prolonged period of high salinity and a closed lake state, suggesting persistently dry conditions in the SAYR during the early to middle Holocene. After 5.3 ka, however, the presence of Leucocythere sp., Fabaeformiscandona rawsoni, and Ilyocypris bradyi with decreased δ18O values, along with the absence of Eucypris mareotica and Limnocythere inopinata, indicates a transition of Lake Gyaring to an open-freshwater lake, suggesting a wetter climate in the region.

These findings provide valuable insights into the hydroclimate variability of the SAYR during the Holocene, contributing to a better understanding of regional climate dynamics. Such knowledge is crucial for informed decision-making in water resource management policies for this important river basin.

PALEOZOOGEOGRAPY OF THE LOWER CREATACEOUS QUIRICÓ FORMATION, SÃO FRANCISCO BASIN, MINAS GERAIS STATE, BRAZIL: A STUDY BASED ON LIMNIC OSTRACODS

Amanda MOREIRA LEITE[1]*, University of Brasília, Brazil (amanda_mleite@hotmail.com)
Dermeval APARECIDO DO CARMO[2], University of Brasília, Brazil
Lívio Reily DE OLIVEIRA GONÇALVES[3], University of Brasília, Brazil
Dangpeng XI[4], China University of Geosciences, Beijing, China

Abstract

This paleozoogeographic study is based on 20 species of ostracods recovered in sections from the Quiricó Formation, São Francisco Basin, Minas Gerais State, Brazil. Five of the 20 species (*Penthesilenula pintoi* Leite et al., 2018; *Alicenula longiformis* Leite et al., 2018; *Timiriasevia sanfranciscanensis* Leite et al., 2018; *Cypridea* sp. 1; *Cypridea* sp. 2) were recovered only in the Quiricó Formation and are restricted, to date, to this basin. The 15 species recovered in other basins from Brazil, Argentina (South America), and Gabon, Congo and Angola (Africa) are: *Brasacypris ovum* Krömmelbein, 1965, Berriasian (Tucano Basin, Brazil); *Cypridea infima* Krömmelbein and Weber, 1971, Berriasian-Valanginian (Recôncavo Basin, Brazil); *Cypridea hystrix* Krömmelbein, 1962, Valanginian-Hauterivian (Recôncavo Basin, Brazil); *Cypridea jequiensis* Krömmelbein and Weber, 1971, Barremian (Sergipe-Alagoas Basin, Brazil), Barremian-Aptian (Campos Basin, Brazil); *Damonella ultima* (Krömmelbein and Weber, 1971), upper Barremian-lower Aptian (Recôncavo Basin, Brazil), upper Aptian (Jatobá and Araripe basins, Brazil), Barremian-Aptian (Golfo San Jorge Basin, Argentina); *Wolburgiopsis plastica* (Musacchio 1970) and *Wolburgiopsis chinamuertensis* (Musacchio 1970), Barremian (La Amarga Formation, Neuquén Province, Argentina); *Harbinia angulata* (Krömmelbein and Weber, 1971), upper Aptian (Sergipe-Alagoas, Araripe, Cedro and Jatobá basins, Brazil); *Harbinia symmetrica* (Krömmelbein and Weber, 1971), Aptian (Araripe and Grajaú basins, Brazil; Gabon, Congo and Cabinda basins, Africa); *Harbinia alta* Antonietto et al., 2012, upper Aptian-lower Albian (Araripe Basin, Brazil), upper Aptian (Grajaú and Jatobá basins, Brazil), middle-upper Aptian (Potiguar Basin, Brazil); *Harbinia salitrensis* (Krömmelbein and Weber, 1971), Aptian (Araripe and Grajaú basins, Brazil); *Harbinia crepata* Do Carmo et al., 2013, middle-upper Aptian (Potiguar Basin, Brazil), Aptian (Araripe Basin, Brazil); *Penthesilenula martinsi* (Silva 1978), Aptian (Araripe Basin, Brazil), middle-upper Aptian (Potiguar Basin, Brazil); *Neuquenocypris* (*Protoneuquenocypris*) *antiqua* Musacchio and Simeoni, 1991, Aptian (Golfo San Jorge Basin, Argentina), Albian (Austral Basin, Argentina); *Brasacypris fulfaroi* Dias-Brito et al., 2001, Turonian-Santonian (Paraná Basin, Brazil). From the stratigraphic distribution of ostracods in the studied sections, together with the lithology, two different paleoecological contexts were recognized: one basal, with greater fluvial influence; and an upper one, with drier conditions and high salinity. From Berriasian to Barremian?, the São Francisco Basin was located in an area of

high precipitation and large volume of water. This condition is corroborated by the basal paleoecological context, with indicators of fluvial contribution, probably the product of a large drainage related to the paleo São Francisco River. Ostracod species from the Quiricó Formation that occur in other basins during this interval suggest a link between the São Francisco Basin and other basins from Brazil and Argentina. During the lower Aptian, the São Francisco Basin was under desert regime, corroborated by the upper paleoecological context of the Quiricó Formation. However, during the Aptian there is the greatest diversity of ostracods, which also occur in several other basins. This scenario of diversity, combined with arid conditions, suggests that the São Francisco paleodrainage was well established, connecting several basins. This study allows a great expansion of the paleozoogeographic correlation between the São Francisco Basin and other basins from the marginal rift system in central Gondwana, during the Early Cretaceous.

Holocene ostracod assemblages and paleo-water depth from a raised beach sediment near Lake Suribachi-Ike, East Antarctica

Satoshi SASAKI[1]*, Gunma University (satoshi-ssk@gunma-u.ac.jp)
Toshiaki IRIZUKI[2], Shimane University
Koji SETO[3], Shimane University
Yusuke SUGANUMA[4], National Institute of Polar Research

Abstract

Accelerated melting of the Antarctic ice sheet (AIS) is one of the major contributors to global sea-level rise. To better constrain future climate and environmental consequences, it is important to understand the history and mechanism of AIS changes. Regional sea-level reconstructions are critical components of these efforts to resolve past changes in ice sheets (IPCC, 2019). In particular, regional sea-level reconstructions have previously been attempted across the Skarvsnes area of Lützow-Holm Bay, East Antarctica (e.g., Takano et al., 2012; Verleyen et al., 2017). However, the results were not consistent, making it difficult to provide firm constraints on the past AIS in this region. Therefore, this study examined for paleo-environment and paleo-water depth near Lake Suribachi-Ike, Skarvsnes, based on grain size, CNS (carbon, nitrogen, and sulfur) elemental, and microfossil (ostracod) analyses of an outcrop of the Holocene-raised beach which was excavated approximately 4 cm from the surface by the 46th Japanese Antarctic Research Expedition (JARE 46).

As a result, the 14C dating of an annelid tube collected from the same outcrop was also conducted using accelerator mass spectrometry, which was estimated at approximately 5,800 cal. year BP. A total of 16 ostracod species belonging to 10 genera were identified for the first time from all study samples near Lake Suribachi-Ike, Lützow–Holm Bay, East Antarctica. The phytal species was discovered to be the most dominant, implying a rich seagrass and/or seaweeds environment at approximately 5,800 cal. yr BP. The paleoenvironment was estimated using the autecological method and the modern analog technique (MAT) on ostracod assemblages. The result from the MAT suggested that the paleo-water depth of approximately 30 m at that time is the most probable estimation, implying the glacial-isostatic uplift of approximately 30–40 m (5.1–6.8 mm/year) until sample date. It is concordant with the previous studies on the 14C ages of the marine shells collected from raised beach sediments near the present study site.

The results include a paper (Sasaki et al., 2022) and we will discuss the repeatability of using these methods on other sites.

Reconstructing Global Diversification Pattern of Non-marine Cypridoidea from Fossil Occurrence Data

Wonseop LIM[1]*, Seoul National University (david9456@snu.ac.kr)
Byeon-Gak CHOI[2], Seoul National University

Abstract

Studying the fossil records of an organism can provide a direct window to the past to study their long–term macroevolutionary dynamics. Non–marine cypridoidean ostracods, one of the most successful colonizers of freshwater environments, have exceptionally well–preserved fossil records starting from the Mesozoic. Thus, they have significantly contributed to our understanding of past ecological and environmental dynamics of non–marine environments. However, despite their importance in paleoecology and paleoenvironmental studies, the macroevolutionary dynamics of non–marine Cypridoidea have rarely been studied. Here, we compiled fossil records of non–marine Cypridoidea from existing literature and analyzed their diversification dynamics using the open–source software PyRate within a Bayesian framework. PyRate models the temporal dynamics of speciation and extinction processes using birth–death model, and can model the fossil preservation process with modified versions of the Poisson process. Given the fossil occurrence data, PyRate searches through the model space and infers posterior probability distributions of parameters for the diversification dynamics of the clade of interest. The results of PyRate analysis show that non–marine Cypridoidea underwent explosive radiation during the Jurassic period after their origination, although with high uncertainty in the estimation of speciation and extinction rates, possibly due to sparse fossil occurrences during the Jurassic. After the Jurassic–Cretaceous transition, the speciation rate of non–marine Cypridoidea declined, until it began to rise slowly around 100 Ma to the present. The extinction rate of non–marine Cypridoidea was inferred to be almost constant throughout time. However, there was an abrupt rise of the extinction rate around the Cretaceous–Paleogene boundary, presumably linked to the K–Pg mass extinction event. We also investigated the correlations between the diversification dynamics of the non–marine Cypridoidea and its potential biotic and abiotic drivers, such as intra–clade competition, and various climatic and geological variables. Our study attempted to reconstruct the past diversification patterns of non–marine Cypridoidea on a global scale in a quantitative framework, revealing patterns that necessitate further research to fully understand their macroevolutionary dynamics.

A new record of Notodromadidae (Ostracoda) from southern Thailand: preliminary result

Anisong Chitnarin[1]*, Suranaree University of Technology, THAILAND (anisong@sut.ac.th)

Abstract

Non-marine ostracods of Family Notodromadidae Kaufmann, 1900 are rarely known in Thailand and Southeast Asia. The only living species that has been found from rice fields in northern and northeastern regions of Thailand is Notodromas sinensis Neale & Zhao, 1991 (Savatenalinton and Suttajit, 2016). Recently, new materials from stream outcrops in Krabi Province, southern Thailand are found, and they are preliminarily classified to the Notodromadidae. The investigating site is located on Quaternary colluvial sediments bounded by the Permian limestone (Ratburi Limestone) and the Jurassic marginal marine rocks (Lam Tab Formation) according to a geological map of Krabi Province (Department of Mineral Resources, 2013). The outcrops consist of intercalations of thin-bedded fine-grained sandstones, shales, and mudstones showing gentle dipping. The lithology of the outcrops resembles the sequences of the Lam Tab Formation, although the age of the rocks is still controversial. Surprisingly, delicate ostracod valves are found embedded in the greenish grey mudstone. Carapace morphology and ornamentation suggest characters of the Notodromadidae, possibly belonging to genera Notodromas Lilljeborg, 1853 or Cyprois Zenker, 1854. However, the identification at specific level is still ambiguous because the soft parts are not preserved. This finding is the first record of subfossil Notodromadid materials in Thailand, and it provides a clue that the sediments might have been deposited in fluvial environments during the Pleistocene or Holocene.

Ritsuo NOMURA[9], Shimane University

Abstract

Lake Nakaumi is the fifth largest lake in Japan. It is a polyhaline lake at the mouth of the Hii River bounded by a sand barrier and connected to the Sea of Japan through a narrow strait. Benthic ostracods in the lake have been sensitive to minor changes in climate, abrupt climatic or geologic events, and anthropogenic impacts since the 20th century.

Thus, this study aims to reconstruct decadal to centennial spatiotemporal changes in ostracod assemblages and paleoenvironments in relation to climatic and anthropogenic impacts since the Little Ice Age.

Five short sedimentary cores were collected from the central part of the lake using a piston or gravity core from a ship. The cores were cut into samples of 0.5- or 1-cm thickness to analyze ostracod assemblages as well as total organic carbon, total nitrogen, and total sulfur contents (i.e., CNS elemental analysis). Furthermore, 14C, 210Pb, and 137Cs dating were conducted in some of the cores.

Approximately 50 ostracod species were obtained from the five cores. The most dominant species is *Bicornucythere bisanensis*. This species is abundantly found in enclosed inner–middle brackish bays in eastern Asia and can survive in oxygen-poor and organic-rich bottoms. Subordinate species comprised enclosed inner bay species, such as *Callistocythere alata* and *Spinileberis quadriaculeata*. *Cytheromorpha acupunctata* was also abundant, mainly in the upper samples, and it is a typical sandy mud dweller in inner bay areas. *Trachyleberis scabrocuneata* lives in relatively oxygenated areas under the influence of tidal and open waters and is present only in specific horizons.

Enclosed inner bay ostracods with moderate species diversity were developed from the 14th to 16th centuries. From the 17th to 18th centuries, ostracod abundance and diversity were low, reflecting weak water circulation and low salinity. Specifically, the lake deteriorated drastically from the late-17th to the mid-18th centuries probably because of high precipitation and low sea levels during the Maunder Minimum. In the 19th century, inflow from the Sea of Japan became strong and peaked in the mid-19th century. Since the 20th century, many anthropogenic impacts

have influenced environments and ostracods. The construction of an artificial dike in 1922–1930 AD greatly influenced the lake environment, and total organic carbon and total nitrogen contents rapidly increased, suggesting the intensification of eutrophication. After the construction of a water-barrier gate and dikes and land reclamation, conducted in 1968–1981 AD, eutrophication accelerated in the central part of the lake. However, improvements in water conditions occurred only near the mouth of the lake owing to the change in the seawater inflow route.

PALEOZOIC OSTRACODS FROM MONGOLIA

Yarinpil ARIUNCHIMEG[1]*, Mongolian Stratigraphical Commission (ariunyarinpil@gmail.com)
Yarinpil Ariunchimeg[2], Mongolian Stratigraphical commission

Abstract

One of the crucial problems in the study of stratigraphy is the boundary between systems. During the investigation of the Ordovician/Silurian, Silurian/Devonian and Devonian/Carboniferous boundary sections in Mongolia together with conodonts some ostracoda were found.

Ostracods together with conodonts Icriodella baotaensis, Icriodella cf baotaensis Eoplacognathus jianyeensis, Eoplacognalhus protoramosus, Baltonoidus alobatus, and? Ambalodus triangularis were found at the Undershil area from the sediments mapped as Silurian Onootolgoi Formation. According to the conodonts the age of the formation is early-middle Late Ordovician (Wang et al., 2008). Ostracods from the bed 1 of the section 141 are Microcheilinella aff. rozdestvenskaja Neckaja, Ovornina aff. ancoralis Melnicova, Ovornina sp., Martinssonozona sp. and indicate the upper Ordovician, but from the bed 4 ostracods such as Spinobolbina bispina Abushik, Bolbiprimitia sp., Microcheilinella sp., Lomatobolbina sp., Sarytumia sp., Eurychilina sp. and Collibolbina sp. were identified and they are more common for the Silurian. Based on the study of ostracoda L.Gereltsetseg (2003) suggested to draw the boundary between systems in this section below the bed with Silurian ostracoda. Some part of section with Ordovician fossils suggested assain to the Ordovician Zeeriinhural Formation.

Ostracods were found during the study of Silurian/Devonian boundary from the Tsagaanbulag section in the Shine Jinst area of Southern Mongolia. Conodonts discovered in the upper part of the Tsagaanbulag Formation are Caudicriodus neowoschmidti Wang et al., Caudicriodus sp. A, Kimognathus sp., ‘Ozarkodina’ planilingua, Pandorinellina optima, and Ozarkodina excavata and indicate that the upper part of section is middle Lochkovian rather than Silurian, as previously proposed (Wang et al., 2005). Ostracods in this section are rare and low diversity, represented by Microcheilinella (?) sp., which are common in Silurian in many different localities in the world. Brachiopods and bryozoans from this section also were identified as Silurian.

Late Devonian ostracoda Amphissites irinae Egorov, 1953 were found in Baruunhuurai area (Thomas et al., 2020) of the south-western Mongolia during the field work of IGCP 596. Later in detail the section at Hushoot Shiveetiin gol in the Baruunhuurai area was investigated. A generally well-preserved and diverse ostracods fauna was collected from the Famennian Samnuur-Uul Formation. It is the first rich assemblage of ostracods described from Mongolia. The ostracoda fauna consists of 19 genera and 25 species and is similar to coeval faunas in western China but also contains new, endemic species. Two new taxa Beyrichiopsis hushootensis and Ampuloides beckeri were described. Ostracods findings are characterized by the Eifelian Mega-Assemblage (I-III) representing a nearshore palaeoenvironment (Nazik et al., 2021). Late Devonian ostracods also are known from the Indert Formation in the Shine Jinst section (Thomas et al., 2024).

PLIOCENE NON-MARINE OSTRACODS FROM THE SHARGA BASIN

Belgutei Belgutei BOLD[1]*, Institute of paleontology,MAS (belguteibold001@gmail.com)

Abstract

Abstract

The study of ostracods in Mongolia has started in the mid 1950s in the southeast of the country in conjunction with petroleum exploration. Ostracods have been regarded as one of the most important microfossils for biostratigraphic correlation and paleoenvironmental reconstruction of Paleozoic, Mesozoic as well as Cenozoic sediments. Nonmarine Cenozoic sediments are widely distributed on the territory of Mongolia in the Great Lakes Basin. These sediments include the fossils of ostracods, charophits, gastropods, mammals and contains the bird remains.

The sediments in the Sharga basin in the Gobi Altai province consists of silts and clays of lacustrine origin, bluish-green in color with small marl inclusions. Moreover, it appears as a bright layers of gray and dark gray on satellite image. In the study area, the sediments overlay the middle Oligocene red clay with minor unconformity and correspondingly overlined by Miocene pale yellow sand sediments.

The three samples were collected from the section of light gray, greenish-gray clay, clayey argillite, and clayey sandstone (46°06’34.8’’N; 95°05’20.6’’E) in Ikh Berkh Tolgoi area. Two well-preserved ostracods belonging to two genera and two species were identified. This is a first report of non-marine ostracods from the Khyargasnuur Formation. Based on the line drawing of adductor scars Cypridopsis vidua and Ilyocypris brady species were identified and age of this sediments is considered as lower-middle Pliocene (Undariya et al., 2021). The ostracod assemblage indicates a shallow continental freshwater paleoenvironment at that time.

NON MARINE OSTRACODA FROM THE CRETACEOUS OF THE TSOGT-OVOO BASIN IN MONGOLIA

Jalbaa UNDARIYA[1]*, School of Geology and Mining Mongolian University of Science and Technology (j_undar@must.edu.mn)
Belgutei Bold[2], Mongolian University of Science and Technology

Abstract

Abstract: The Mongolian Cretaceous is subdivided into eight formations. The Lower Cretaceous iscomposed of the Tsagaantsav (Berriasian-Valanginian),Shinekhudag (Hauterivian-Barremian) and Khukhteeg (Aptian-Albian) formations. The Upper Cretaceous consists of the Baruunbayan (Albian-Cenomanian) Bayanshiree (Cenomanian-Turonian), Bayanzag (= Djadokhta) (Coniacian-Santonian), Baruungoyot (Campanian) and Nemegt (Maastrichtian) formations.
Non marine Cretaceous sediments are widely distributed and contain variously abundant ostracods in Mongolia.
We investigated a total 16 samples from these 22 sections, 10 of which appeared devoid of any microfossils, the remaining ones yielded either ostracods, charophytes or gastropods.
The genus Cypridea, Rhinocypris, Cyprideidini from the Upper and Lower Cretaceous were found in micropaleontological examinations.
Seven fresh-water ostracode species belonging to tree genera described from Cretaceous continental deposits from Tsogt-Ovoo basin in Mongolia. Seven ostracodes species have been recorded in the from Shinekhudag to Bayanshiree formations, Tsogt-Ovoo basin: Cypridea unicostata Galeeva, 1956, Cypridea trita Lubimova, 1956, Cypridea copulenta Lubimova 1956, Cypridea shuvalovich Stankevich, 1974, Langtonia setila rectidorsata Sylvester-Bradley, 1949, Rhinocypris panosa Lubimova, 1974 and Gobicypris tugrigensis Khand, 1974

In the Tsagaantsav Formation Cypridea trita Lubimova, 1956 appear, followed by Cypridea unicostata Galeeva, 1956, Cypridea trita Lubimova 1956, Cypridea copulenta Lubimova, 1956 in the Shinekhudag Formation. In the Khukhteeg Formation ostracods are abundant, including Langtonia setila rectidorsata Sylvester-Bradley, 1949, in the Baruunbayan Formation of ostracods are recognized, mainly including Cypridea shuvalovich Stankevich, 1974. In the succeeding Bayanshiree and Bayanzag formations, the first appearances of Gobicypris tugrigensis Khand, 1974 and Rhinocypris panosa Lubimova, 1974 are recorded.
In the present paper, biostratigraphy of the Upper and Lower Cretaceous is discussed in terms of ostracod assemblages.

The study of AI deep learning Yolov5 algorithm analysis for distinguish Ostracoda in meiofauna microscope pictures

Hyunsu YOO[1]*, Fisheries Science Institute, NRF Reserach center, Chonnam University
(youe1999@hanmail.net)

Abstract

Recently, methods to distinguish objects and living things using artificial intelligence algorithm analysis have continued to be developed worldwide. In particular, object detection algorithms are useful in distinguishing objects or living things, so they are being applied to various fields such as video surveillance, autonomous driving, and augmented reality. Yolo (You Only Look Once), an object detection algorithm, was first announced in 2015 and is widely used due to its high accuracy and speed in detecting objects.

Ostracods are included in meiobenthos and zooplankton and are distributed in a wide range of freshwater and marine water (even deep sea and extreme environments). Usually, this taxon is not a dominant organism in meiofauna communities, but often abundance blooms the environmental condition matches hatching. The main characteristic of ostracods is a carapace to protect their appendages. Usually, special features of the carapace are used to identify the family level. However, non-experts often confuse them with Bivalvia and Branchiopods because carapace shapes are similar. And then the size of less than 400um is misidentified as foraminifera.

Usually, when analyzing living things using artificial intelligence algorithms, large creatures (parrots, mammals, etc.) or insects (flies) that the eye can easily distinguish are used. In this study, we research conducted to determine whether it is possible to distinguish organisms at the level of higher taxa from photos of meiofauna, which are difficult to discern and in particular to find out what the margin of error is when distinguishing between ostracods.

A preliminary study on dividing subfamilies of insect larvae showed an accuracy of about 98%, so it is expected that if the characteristics are clearly distinguished, it will be possible to differentiate between Ostracods and other taxa. If the amount of data increases in the future, it is expected that programs can be created that can be easily identified even by non-experts.

Paleocene-Eocene Larger Benthic Foraminifera from Meghalaya and Indo –Myanmar Orogenic belt of Eastern Tethys, India, collision of Indian –Asian plates and global paleobiogeography

VINOD CHANDRA TEWARI[1]*, Professor of Geology (Retd.), Sikkim University, Gangtok – 737102, Sikkim, India (Professorvct54@gmail.com)

Abstract

Abstract :

. The Late Paleocene – Middle Eocene Tethyan foraminiferal – algal carbonate biofacies are well developed after Late Cretaceous – Paleogene mass extinction event in the Meghalaya, east India.The Paleocene- Eocene LBF and algal assemblage are important contributors in depositional environment of the Tethyan limestoes. The limestones have yielded the diverse LBF species of Alveolina sp., , Assilina sp., Miscellanea miscella Discocyclina sp., D.jauhrii ,Ranikothalia sp., Rotalia sp., Lokhartia sp., Quinculoculina sp., Nummulites sp. as dominant assemblage.The orthophragminid foraminifera assemblage of the Lakadong and Umlatodoh Limestone indicate shallow marine carbonate ramp, and tidal flat depositional environment. The predominance of coralline algae, Sporolithon associated with LBF assemblage indicates that the Paleocene – Eocene limestones of Meghalaya have been deposited in shallow, high energy tidal and open shelf environments.A correlation of eastern and western Neotethys has been established on the basis of Standard Benthic Zone(SBZ3-SBZ8)of European,Adriatic and Himalayan-Tibetan LBF zones.During the early Paleogene, Meghalaya witnessed several sea-level changes ranging in age from the late Paleocene to middle Eocene. Paleocene – Eocene Thermal Event (PETM)is also recorded from the Lakadong Limestone, Mawmluh Quarry area confirmably overlying the foraminiferal limestone.Their deposition commenced with the emergence of the carbonate platform in which the LBF - algal carbonates were formed formed. The western Tethyan LBF assemblage from Mediterranean, Adriatic platform(Trieste - Slovenia area)and the Middle East region is comparable with South Asian Himalayan assemblage. Recent stable C and O isotope chemostratigraphy of Meghalayan and Manipur Ophiolite Belt (MOB) limestones is comparable with the Tibetan shallow marine limestone. The north-eastern region represent a complex tectonic set up due to the juxtaposition of Indian-Eurasian and Myanmar plates. The MOB is a part of Tethyan oceanic crust involved in collision of Indian and Myanmar micro plate during Late Cretaceous –Eocene as suggested by LBF. In Ladakh area , Western Himalaya, LBF assemblage have suggested that the regression of the Tethys sea from Indus- Tsangpo –Suture Zone (ITSZ)initiated in Ypresian time ,however in the Indo –Myanmar region, the regression took place from east to west. The Indo Myanmar ranges continue towards Andman-Sumatra subduction zone which also marks the junction between Indian and Eurasian Plates.The Subathu LBF yielding limestone is found in Shimla and Jammu areas in western Lesser Himalaya and Bhainskhati valley in Nepal Central Himalaya.Marine Eocene (Ypresian – Lutetian) LBF is known from Subathu type area near Shimla and in small limestone bands in adjoining parts of Indian Lesser Himalaya.

It represents marine transgression in the Lesser Himalaya of India and Nepal. The LBF distribution and paleobiogeography of the Eastern Tethys (Meghalaya, Subathu Lesser Himalaya, Ladakh) and its correlation with western Tethys is reconstructed in the light of India – Asia collision and emergence of the Himalaya.

Foraminiferal assemblage and palaeoenvironmental reconstruction of early Eocene Umlatodoh Limestone form south Shillong Shelf: Signature of ETM2?

T. Ngamlengin Haokip[1]*, Assam university, Silchar (tngamlengin.haokip@gmail.com)
Urbashi Sarkar[2], Assam University, Silchar

Abstract

Microfacies analysis of Early Eocene shallow-marine carbonate successions are sampled from the outcrop of Thangskai, Jaintia Hills, Meghalaya, India and the subsequent integration with sedimentology has been used to produce a detailed palaeoenvironmental reconstruction. From the forty-one meters high outcrop, nine microfacies types, viz., quartz abundant wackestone (MFT1), rotaliid grainstone (MFT2), sandy foraminiferal packstone (MFT3), Oolitic grainstone (MFT4), fossiliferous dolomitic grainstone (MFT5), *Ovulites* grainstone (MFT 6), alveolinid miliolid grainstone (MFT7), fossiliferous wackestone (MFT8), and glauconitic mudstone (MFT9), are identified. Larger benthic foraminiferal and coralline algal assemblages are the dominating constituents here and larger benthic foraminifera indicates the age as SBZ 6 to SBZ 9. Four facies belts have been inferred associated with specific facies, for example, the facies U-MFT1, U-MFT3, U-MFT8, and U-MFT9 are located in the sheltered lagoon (SL); U-MFT4 indicate the facies belt shoal setting (SS); U-MFT2, U-MFT6, and U-MFT7 indicate deposition in the high-energy back shoal (BS); and U-MFT5 is designated to be deposited in the fore shoal (FS) belt. Overall, two types of faunal associations are identified: perforate foraminifera (*Nummulites* sp. and *Discocyclina* sp.) and porcelaneous forams and green algae (*Rotaliid-Alveolinid-Miliolid-Ovulites*). The faunas are dominated by both r- and k-strategists in an oligotrophic nutrient regime during this time. Dominant foraminiferal species are *Alveolina* sp., *Glomalveolina* sp., *Quinqueloculina* sp., *Biloculina* sp., *Idalina* sp., *Periloculina* sp., *Lockhartia* sp., *Nummulites* sp., *Orbitoclypeus* sp., *Discocyclina* sp., *Bolivina* sp., and *Textularia* sp. Subordinate constituents of bivalve and ostracods are observed. The algal components include *Ovulites* sp., *Halimeda* sp., and Dasycladalean (*Salpingoporella* sp.) represent green algae, and *Distichoplax* sp. represent the non-geniculate coralline-red algae. Also, sutured type horizontal and parallel stylolite present in the MFT8 indicates the upper part is subjected to dissolution, and underwent tectonic stress during diagenesis. Thus, variable energy above the fair-weather wave base influences the depositional architecture of the Umlatodoh Limestone, which ranges from hypersaline lagoonal to normal marine within the inner shelf of shallow marine carbonate settings. Concurrently, the foraminiferal diversity and subsidiary abundance of rectilinear benthic foraminifera (biserial forams) and the small size of larger benthic foraminifera can be correlated with the transient climatic Eocene Thermal Maximum -2 (ETM -2) (SBZ 8; 54.1 Ma) event.

LARGER BENTHIC FORAMINIFERA (LBF) BIOSTRATIGRAPHY OF PALEOCENE – EOCENE SEDIMENTS IN PARTS OF ASSAM SHELF OF ASSAM AND ASSAM ARAKAN BASIN WITH REFERENCE TO DEPOSITIONAL ENVIRONMENT

KALPANA DEKA KALITA[1]*, DEPARTMENT OF APPLIED GEOLOGY, DIBRUGARH UNIVERSITY, ASSAM. INDIA (kdkalita@dibru.ac.in)
KALPANA DEKA KALITA[2], DIBRUGARH UNIVERSITY

Abstract

The Assam and Assam Arakan Basin is a category 1 petroliferous basin situated in the northeastern part of India covering an area of 11,6000 square kilometres producing oil and gas commercially for more than a century. Larger Benthic Foraminifera (LBF) biostratigraphy provides insights into the age and depositional environment as well as play a crucial role in the hydrocarbon exploration endeavours of this basin. Three major tectonic elements of this basin include Assam Shelf, Naga Schuppen belt and Assam-Arakan Fold belt. The Assam Shelf extends from northeast of Shillong Plateau, Garo Hills, Khasi and Jaintia Hills, Mikir Hills and include the Upper Assam Valley. Geologically the Upper Assam valley is regarded as the Upper Assam Shelf. This study provides LBF biostratigraphy of Paleocene -Eocene sediments of Sylhet Limestone Formation in southern parts of Shillong Plateau and parts of the Upper Assam Shelf. The five members namely Lakadong Limestone, Lakadong Sandstone, Umlatodoh Limestone, Nurpuh Sandstone and Prang Limstone of the Sylhet Limestone Formation are exposed in Meghalaya where as in the Upper Assam Shelf, the clastic sequence nonconformably overlying the granitic basement complex and is conformably overlain by limestones of the Sylhet Formation. Identified twenty-five numbers of LBF species dominated by Nummulitidae family from an oil well of Kathaloni area in Dibrugarh District of the Upper Assam Shelf indicates shallow marine to transitional environment where Palaeocene -Eocene subsurface sediments are reported at depth more than 2977metre. Twenty-six species of LBF associated with various species of coralline red algae and green algae reported from Lumshnong area of Jaintia Hill district, Meghalaya suggests inner ramp, mud-free shallow neritic shelf carbonate sedimentation of the Umlatodoh Limestone showing depositions in calm water, low-energy conditions in the lower part changing to moderately high-energy conditions in the middle followed by low-energy restricted environment represented by micrite towards the upper part in lower Eocene. Ten genera of LBF reported from of Nongthymai Mawsmai Area, Cherrapunji, twelve genera of LBF from Ri-Kaleng Limestone Mine, both belonging to Lakadong Limestone and fifteen species of LBF of Prang Limestone from Sohbar Nongjiri road section of east Khasi Hill district, Meghalaya are interpreted to be deposited in shallow marine environment. Evidenced from the larger benthic foraminifers reported from Paleocene-Eocene limestone sediments in parts of Meghalaya suggest shallow marine environment while in the Upper Assam Shelf the subsurface sediments of Paleocene-Eocene age suggesting marine to transitional environment of deposition.

The studied shelf sediments of Paleocene-Eocene age of Cherrapunji and Lumshnong area in southern part of Shillong Plateau is at approximately 1000m and 580m above Mean Sea Level (MSL) respectively. The LBF identified in the Kathaloni area of the Upper Assam Shelf indicate that the of Paleocene- Eocene sediments are reported at depth of more than 2977m. The LBF data of the studied areas suggest that these sediments were part of the same palaeo shelf sea during Palaeocene -Eocene age. Because of tectonic modification of the Assam and Assam Arakan Basin, the sediments are reported at different level.

[Keynote] Larger Benthic Foraminifera: Valuable Proxies in Biostratigraphic Evaluation of Paleogene Carbonate and Siliciclastic Sequences in Indian Petroliferous Basins

VINOD CHANDRA TEWARI[1]*, Professor of Geology (Retd.), Sikkim University, Gangtok – 737102, Sikkim, India (Professorvct54@gmail.com)
SUDHIR SHUKLA[2], EX.ONGC LTD. INDIA

Abstract

Larger benthic foraminifera in the Indian Paleogene are highly diversified and represented by important genera such as Nummulites, Assilina, Miscellanea, Lockhartia, Alveolina, Daviesina, Operculina, Operculinoides, Actinosiphon, Discocyclina, Lepidocyclina, Pellatispira, Heterostegina, Spiroclypeus, Cycloclypeus and Miogypsinoides. Several species amongst these genera have great index value in high impact biostratigraphy in order to serve as excellent age dating tools facilitating inter and intra-regional stratigraphic correlations. Indian Paleogene sequences are prolific with the warm, shallow water carbonates build up of rich and diverse larger benthic foraminifera, additionally compounded with reefal elements such as corals, algae, bryozoa, crustaceans and associated faunal elements. In the areas of turbidity and clastic sedimentary influx, siliciclastic sediments or carbonate muds have also shown a rich assemblage dominated by the imperforate larger benthic foraminifera related to the Coskinolina, Medocia, and Dictyoconoides groups. Local SBZ / LBF zonation were established and successfully correlated with international multimicrofossil (LBF) zonations, thus making them immensely useful in the bio-chronostratigraphic determinations of Indian Paleogene.

During earliest Paleocene, although true larger foraminifera are believed to be absent excepting for probably Laffeiteina which is reported from North-Eastern India from the stage Danian (Meghalayan) referred to planktic stages P1 & P2= SBZ 1. This is followed by the occurrence of Miscellania & lockhartia akbari, Disticoplex & Rotaliid-Miliolids on the Meghalayan shelf. Highest Paleocene and early Eocene in Indian sedimentary basins show relatively lesser diversification in the larger foraminifera, excepting for the appearance of Orbitolites and Sakesaria close to the Paleocene / Eocene boundary. Alveolina is an important constituent in the LBF assemblage here. Early Eocene shallow marine, transgresive sediments comprising mostly carbonates and some finer clastics have abundant, well diversified larger foraminifera where the diversity of Assilina is at maximum, however, it is during the Middle Eocene that the larger foraminifera diversity reaches its acme, further on slightly declining during the younger ages, so that the number of genera touches lowest level near to the Eocene / Oligocene boundary.

The diversification of Nummulites is rapid during middle Eocene where a number of new forms are added. Middle-late Eocene boundary almost coincides with the extinctions of Assilina, Lockhartia, Alveolina, Dictyoconoides, Coskinolina & others. Reticulate Nummulites & Lepidocyclina (Eulepidina) frequent on the western shelf characterizing the “nummulitics” of early Oligocene. Post early-Oligocene nummulitids are dominated by genera Operculina,

Operculinoides, Grzybowskia, Lepidocyclina (Nephrolepidina), Hetrostegina and Spiroclypeus, some of which continue up to Recent times. Another LBF acme along with diversity of genera / species is witnessed during late Oligocene, when new forms (Miogypsinids) are added, however, throughout the Paleogene larger foraminifera are dominated by Nummulites in almost all the Indian sedimentary basins.

Keeping in mind exceptional index value of the larger benthic foraminifera, the E&P companies, in recent years, promoted domain specific research and expertise needed to develop more real time biostratigraphic analysis and provide innovative solutions to the geological problems. An emphasis was also made on combining geosteering / biosteering applications utilizing larger benthic foraminifera with other multi-microfossil proxies to reduce operating costs and enhance production more particularly from inclined

Abstract
Triassic- Jurassic deposits are related to Khaneh Kat, Nyris and Surmeh Formations and they are in the Interior Fars from High Zagros belt of Iran. Triassic deposits (Kaneh Kat Formation) with 420/6 m thicknes and the include Sand stone, Dolomitic and limestone also Jurassic deposits (Nyris and Surmeh Formations) with 680m thicknes and the include Dolomitic limstone and Limestone in Kaftar stratigraphic section. In total, after studying 600 microscopic thin sections and identifying benthic foraminifera, 5 biozones for Triassic deposits and 5 biozones for Jurassic deposits were introduced. Some of these benthic foraminifera include: Nodosaria cf. shnnablensis, Aulotortus gacchei ,Arenovidalina chialingchiangensis, Involutina communis , Glomospirella friedli, Glomospira meandrospiroides, Lenticulina sp., 4- Agathammina austroalpina, Pragsoconulus cf. robustus , Pragsoconulus cf. robustus, Pfenderina trocoidea,Meyendorffina sp., Andersenolina elongata , Kurnubia palastinensis, Nautiloculina cf.cricularis, Andersenollina elongeta
Trocholina palastinensis, Pseudomarssonella plicata, Nautiloculina cf. cricularis.These Trassic biozones(Early to Late Triassic) are reported for the first time in the SW Iran. According to evidence of biostratigraphy and lithostratigraphy, the boundary between Kaneh Kat and Neyriz Formations is disconformity.In the base part of the Jurassic deposits can be seen with a layer containing bivalves of the Lithiotis , which contains benthic foraminifera with Bajocian-Callovian age.

Insights into raphiophorid trilobite glabella spine as a sensory organ for collective behaviour

Iván Gómez[1], Universidad de los Andes
Matheo López-Pachón[2], Universitat Rovira i Virgili
Esteve JORGE[3]*, Universidad Complutense de Madrid (UCM), Spain (jorgeves@ucm.es)

Abstract

Raphiophorid trilobites are small blind trilobites with a glabella expanding forwards and inflated anteriorly, usually with anteromedian spine, or with a tubercle in comparable forward position. Two of the common genus of this family are Ampyx and Lochodomas with a wide geographical distribution (Morocco, Czech Republic, France, Sweden or USA) and bearing a long anterior glabellar spine. In the case of Ampyx appear communally in the Lower Ordovician (upper Tremadocian-Floian, ca 480 Ma) Fezouata Shale of Morocco as linear clusters. Here we explore the hydrodynamic behaviour of Ampyx by means of fluid dynamic simulations (CFD) in two different scenarios: i) a single individual or ii) a linear cluster with two or three individuals. In addition, we assess the influence of the long anterior glabellar spine into the drag and lift coefficients and the results shed no influence in any case. Some specimens from the Lower Ordovician of Sweden show pits in the cuticle what is pointed out a sensorial organ rather that a hydrodynamic tool. Therefore, the combination of our CFD results and the fossil evidences support the idea that the long glabellar spine in raphiophorids as well as the long genal spines were mechanical sensors as was suggested by Vannier et al. (2019).

Enrolment in trilobites: insights for development and phylogeny

Esteve JORGE[1]*, Universidad Complutense de Madrid (UCM), Spain (jorgeves@ucm.es)
Alejandro Corrales-García[2], University of Saskatchewan
Jesús María[3], Facultad de Ciencias Exactas Físicas y Naturales, Universidad Nacional de Córdoba, Córdoba, Argentina
Francesc Pérez-Peris[4], Iowa University

Abstract

The study of enrolment in trilobites has bring the interests of palaeontologists during last century. This is because enrolment is an adaptive behaviour against predators and environment. Functional morphology shows us that enrolment and interlocking devices enhance throughout the evolution of this group and seems that different lineages tend to develop independently a sphaeroidal enrolment style. Trilobite also shown a great adaptation of morphology to achieve different enrolment styles through the growth. In some cases, the adaptation is as consequence of the morphological variation of some trilobites such as the Cambrian trilobite Solenopleuropsis or the Silurian trilobite Aulacopleura. Esteve & Hughes (2023) have shown how ontogenetic development controls the enrollment style throughout the development of the Silurian trilobite Aulacopleura koninckii, varying from spheroidal to spiral and finally external spiral. However, other trilobites such as the phacopid Ordovician trilobite Pterygometopus sclerops change the enrolment style without putative variation in the number or shape of its thoracic segments but changing the size. Within Phacopida, the genera Cybele, Pterygometopus, Pliomerops and Placoparia show a tendency towards inverted enrolment type where the pygidium is anchored on the dorsal anterior edge of the cephalon. P. sclerops could present a transitional form from spheroidal to inverted, with Placoparia being the taxon that most developed the inverted style. Finally, the fact that P. sclerops presented two types of enrollment styles throughout its development would be the earliest evidence of the importance of ontogenetic control in the development of different types of enrollment.

[Keynote]Distinct causes underlie double-peaked trilobite cephalon disparity, but this disparity is unrelated to exoskeleton moulting behaviour

Harriet Bethany B. DRAGE[1]*, University of Lausanne (harriet.drage@unil.ch)
Stephen Pates[2], University of Exeter

Abstract

Trilobites had strongly biomineralised exoskeletons with a diversity of morphological adaptations to different niches across the Palaeozoic. The group was extremely influential on the development of Palaeozoic ecosystems, having a global range and being found in vast abundance in varied marine environments. Correspondingly, there is a long history of research on their functional adaptations, diversity, and disparity, which we are increasingly able to develop using expanded datasets and technological advancements. We used a global dataset of c. 1000 trilobite cephalon outline curves (including 387 specimens resampled from Suárez and Esteve, 2021) to create an expansive morphospace exploring the full extent of trilobite cephalon outline morphometric disparity. We then used these data to analyse the differences in morphospace occupation across the Palaeozoic and between taxonomic orders. Elliptical Fourier transformation visualised as a Principal Components Analysis suggests significant differences in morphospace occupation and disparities for order and geological Period groups. Cephalic outline disparity increases from the Cambrian to Ordovician, apparently as a result of radiations to new niches. This is followed by morphospace occupation constriction to the Silurian, a second disparity peak in the Devonian caused by within-niche diversification, and a further constriction following the Devonian. The latter decline was likely the result of a high number of species going extinct, notably forms at the extremes of occupied morphospace. The post-Devonian survivors and trilobites that originated after the end-Devonian mass extinctions are constrained towards the centre of the morphospace. Kmeans clustering analyses support this constriction in natural grouping through the Palaeozoic. However, analyses interrogating the predictiveness of cephalon outline morphometry suggest that order and geological Period assignment cannot be robustly predicted for an unknown trilobite, except for Harpida and the Cambrian and Ordovician Periods. Analyses of morphological disparity can also be used to explore key trilobite behaviours, such as exoskeleton moulting. Like all euarthropods, trilobites moulted their exoskeletons repeatedly throughout their lives to grow and develop, but were uniquely variable in the behaviours involved, partly because of their cephalon morphological disparity. However, analyses using this dataset suggest cephalic shape had little overall impact on moulting behaviour, with the behavioural groups almost entirely nested in morphospace. Further, cephalon morphometry cannot be used to predict moulting behaviour from this dataset. Perhaps trilobites demonstrated high phenotypic plasticity in moulting that cannot be explained by individual variables or evolutionary drivers such as morphometry.

Computational fluid dynamics simulation indicates morphological selection of the Upper Ordovician graptolite dicranograptids by hydrodynamics

Shijia Gao[1], Central South University
Wenhui Wang[2]*, Central South University (whwang@csu.edu.cn)

Abstract

Graptolites is one of the iconic and dominant zooplanktons within the Paleozoic Evolutionary Fauna. It underwent rapid evolution during the Ordovician and Silurian, making it an important biostratigraphic correlation tool. In the evolutionary history of planktonic graptolite, there are at least four obvious rapid increasing phases of morphological complexity. The triggering mechanism of these morphological complexity is suggested in association with sea-level increasing and high-stand. However, the specific mechanism how sea-level changes has exerted influence on graptolite ecology is still unclear. In order to test the role of sea-level increase has played in the morphological complexity of graptolites, we assume that the morphological change is triggers by hydrodynamic properties due to sea-level rising. Then we choose the late Middle to Late Ordovician dicranograptids, as target taxa to test the hypothesis. We reconstructed three-dimensional models based on the type specie of Jiangxigraptus as well as Dicellograpus, representing an earlier and later evolutionary forms of dicranograptids, respectively. Hydrodynamic properties (outer-wall pressure fields and velocity fields) can be obtained by using computational fluid dynamics (CFD). The models of both Dicellograptus and Jiangxigraptus keep rotating in different velocity in the simulation field. During rotational movement, Dicellograptus exhibits greater stability due to its wider construction of the U-shaped proximal end, which results in an expanded water-facing area. Additionally, the delicate branches of Dicellograptus compromise its resistance to hydrodynamic shocks. The thecal apertures of Dicellograptus, however, exhibit a higher volecity in the fluid medium, thereby augmenting its diffusion capability in water. The V-shaped proximal end of Jiangxigraptus rendered its rotational stability in the current more precarious. Furthermore, under equivalent ambient flow conditions, Jiangxigraptus exhibited a lower velocity of thecal apertures, indicating a comparatively weaker diffusion capacity. The results of our study suggest that the evolutionary transition from Jiangxigraptus to Dicellograptus in dicranograptids was characterized by an increase in both stability and rotational speed under hydrodynamic complex conditions when sea-level fluctuated. Our study highlights the importance of hydrodynamic constraints in shaping the evolutionary trajectory of planktonic graptolites.

Abstract

Echinoids possess a hierarchical multiplated skeleton and have shown a number of skeletal adaptions during their evolution. These skeletal modifications not only allowed them to expand into new environments and to exploit different food resources, but also have profound implications for their fossilization potentials. Studies on the biomechanics of the echinoid skeletons have dealt with major changes among different clades, on skeletal modifications during modular growth, as well as detailed mechanical studies on a few taxa. Studies with respect to biomechanics and taphonomic implications have concentrated on irregular echinoids including sand dollars. This study deals with regular echinoid taxa from shallow water environments in both recent environments and corresponding fossil occurrences. The combination of weakly articulated skeletons together with high energy conditions is usually associated with poor preservation potentials. The present study considers biomechanical aspects of skeletal architectures in combination with biotic and abiotic taphonomic processes including predation, disarticulation, fragmentation, encrustation and bioerosion. The morphology of specific echinoid tests is studied in detail using CT scanning techniques together with SEM analysis to explore morphological features including plate boundaries which can show interconnecting skeletal features such as pegs and sockets. Experimental fragmentation shows specific breakage patterns along plate boundaries. Echinoid remains from both recent and fossil environments are also compared with respect to the distribution of skeletal elements and size distributions.

[Invited] Exploring patterns of adaptive evolution across the Cambrian trilobite radiation

James Dougal HOLMES[1]*, Uppsala University (jamesholmes83@gmail.com)

Abstract

Evolutionary radiations—rapid diversifications within individual biological groups—have occurred frequently in Earth's history. These are often attributed to 'adaptive radiation', where diversification is driven by ecological speciation into different niches. However, despite being potentially responsible for much of Earth's biodiversity, almost all evidence for adaptive radiation comes from studies of extant animals that have diversified in the recent past (e.g. Caribbean anoles lizards, African Rift Lake cichlid fish). In the fossil record, adaptive radiation is often invoked whenever a group shows rapid initial diversification (the 'early burst' model of adaptive radiation), but purported instances of this process in deep time remain largely untested. Doing so requires demonstrating if diversification patterns are related to ecology, which is problematic for most fossil groups due to a lack of data. Trilobites are a group of biomineralizing marine euarthropods that underwent an explosive radiation beginning in the early Cambrian Period (starting c. 521 Ma), rapidly increasing in taxonomic and morphological diversity ('disparity'), and occupying a range of marine environments across different palaeocontinents. Here, I explore patterns of morphological disparity-through-time and morphospace occupation in Cambrian trilobites, in relation to biogeography, environmental parameters, and a recently published family-level phylogeny, to reveal if adaptive radiation was important in driving the group's rapid early diversification.

The Middle Ordovician Bivalves from Dali, Yunnan Province, SW China and their palaeogeographic significance

Yong WANG[1]*, Nanjing Institute of Geology and Palaeontology, CAS (yongwang@nigpas.ac.cn)
Zong-jie FANG[2], Nanjing Institute of Geology and Palaeontology, CAS
David A. T. HARPER[3], Durham University
Yu-chen ZHANG[4], Nanjing Institute of Geology and Palaeontology, CAS
Xin WEI[5], Nanjing Institute of Geology and Palaeontology, CAS
Ren-bin ZHAN[6], Nanjing Institute of Geology and Palaeontology, CAS

Abstract

An abundant and diverse bivalve fauna has been discovered in Dali, western Yunnan Province, SW China. It is from the Lower-Middle Member of the Hsiangyang Formation (Darriwilian, Middle Ordovician), and contains 18 genera and 22 species: Fasciculodonta impressa, F. fengyiensis, F. curvatum, Taselasmodum decussatum, Glyptarca sinensis, G. symmetrica, G. sp., Rhomboconcha tresdentes, Daliella daliensis, Haidongoconcha radialis, Erhaiconcha xiangyangensis, Paracyclas initium, Eopterinea aequiconcha, Biseriodonta simplex, Yunnanoredonia laevis, Redonia deshayesi, Trigonglyptarca magna, Goniophorina contracta, Prealeda sp., Modiolopsis sp., Similodonta sp. and Phestia sp., all of which are from 35 collections at the Haidong section beside the eastern bank of the Erhai Lake. Palaeogeographically numerical analysis on the distribution of 11 Middle Ordovician bivalve faunas shows two distinct faunal groups: the HPL group (including Morocco, Czech Republic, Argentia, Spain, France, UK, Portugal), representing the bivalves that lived in higher palaeolatitudes, and the LPL group (including Australia and South China) of the lower palaeolatitudes. The Dali bivalve fauna shares similarity with both groups, indicating that the Indo-China Palaeoplate was located in middle-high palaeolatitudes between the palaeoplates represented by the HPL and LPL groups. So, it is reasonable to propose that the Indo-China Palaeoplate was probably an isolated radiation center for bivalves during the Middle Ordovician. Community analysis for the Dali bivalve fauna shows that three possible bivalve-dominated communities could be recognized, the Fasciculodonta-Yunnnanoredonia-Redonia (FYR) community, the Taselasmodum (T) community and the Daliella (D) community, and the Daliella community (representing semi-infaunal life habit) was stratigraphically between the others (dominated by free-living burrowers, such as Fasciculodonta, Yunnanoredonia, Taselasmodum and Glyptarca), indicating the regularly fluctuating environment in that particular area during the Middle Ordovician. The triggers of environments changing could be founded with some sedimentology work.

[Keynote] Methods for β−level paleobiogeography using dendrogram and cladogram

Dong-Chan LEE[1]*, Chungbuk National University (dclee@chungbuk.ac.kr)
Jikhan Jung[2], Korea Polar Research Institute
Yeongju Oh[3], Korea Polar Research Institute
Tae-Yoon Park[4], Korea Polar Research Institute

Abstract

β-level paleobiogeography describes relationship among areas occupied by a group of taxa during a geologic time interval or change of relationship through time intervals. Dendrogram based on cluster analysis of presence/absence of taxa and cladogram based on parsimony analysis of morphologic characters of taxa are commonly used. A dendrogram shows affinity among areas as hierarchical clustering based on similarity indices calculated from presence/absence of taxa in areas. A method called “area distance expression” using similarity indices of clusters is devised to trace temporal changes of area relationship. The closest and furthest possible distance between two components of a cluster are employed, which represent the similarity index of a cluster calculated from a presence/absence dataset for each time interval and a combined dataset for all the intervals, respectively. The closest possible distance is expressed as an angle along a circle representing the furthest possible distance. The two distances are sequentially added from a cluster with the highest similarity index and the resultant 2D expression of area distribution can be used to trace how the affinity among areas changed through time. A cladogram showing ancestor-descendant relationship of taxa is used to infer relationship among areas inhabited by the taxa by replacing terminal taxa with the area(s), in other words, constructing area cladogram. A method called “area transition count” uses cladogenetic area transtions between an ancestral node and two descendant nodes in area cladogram. Combination of four anagenetic area transitions, range contraction, range expansion, range switch, and no range change, results in 10 theoretically possible cladogenetic area transitions. The area transition types and areas involved in the transitions are counted for each set of three nodes. The compilation of the counts for transition types and areas for each time interval can be used to explain how the distributional area change expressed as the counts affected evolution of a group.

Abstract

In the Mt. Qomolangma region of southern Xizang (Tibet), continuous and well-exposed Ordovician strata yield abundant cephalopod fossils. This study focuses on the classic Ordovician Jiacun section within the region, with an emphasis on the cephalopod palaeontology and palaeogeography. From a collection of cephalopod specimens, a total of 30 species (including two new species: Wutinoceras multiseptum new species and Wennanoceras remotum new species) in 16 genera belonging to 10 families and 6 orders have been identified and systematically described, wherein newly documented specimens have been discussed for their biostratigraphic implications, broadly indicating the age of the lithostratigraphic unit with questionable geological age. We also collect Ordovician cephalopod occurrences of the northeastern peri-Gondwana region: on the one hand for Igraph R package-based network analysis and on the other hand for PAST software-based cephalopod fauna biodiversity research, new understanding and discoveries have been made regarding the cephalopod provinces on the northeastern peri-Gondwana region and the appearance of cephalopod fauna in southern Xizang. Overall, this study provides more Ordovician cephalopod occurrence data and improves the faunal composition of Middle–Late Ordovician cephalopod in the Mt. Qomolangma region of southern Xizang by utilizing new fossil materials and emerging data analysis methods, with biodiverse and palaeobiogeographic implications explained.

New insights into the Great Ordovician Biodiversification Event: Evidence from the Early Ordovician Liexi Fauna

Xiang Fang[1]*, Nanjing Institute of Geology and Palaeontology, CAS (xfang@nigpas.ac.cn)
Ying-yan MAO[2], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences

Abstract

The Ordovician Lagerstätten record substantial amounts of excellent preservation and soft-bodied fossils during the Great Ordovician Biodiversification Event (GOBE). However, few Lagerstätten are known from the Lower Ordovician, most of which are preserved in the restricted environment and high latitude areas. Here a new tropical Lagerstätte, Liexi fauna, has been recently discovered from a carbonate succession within the Lower Ordovician Madaoyu Formation in western Hunan, South China. It contains a variety of soft tissues, exceptional preservations, as well as rich shelly fossils, including paleoscolecidan worms, possible Ottoia fossil, trilobites, echinoderms, sponges, graptolites, polychaetes, bryozoans, conodonts, and other fossils. The Liexi fauna includes up to 11 phyla of marine animals, which suggests they occupied a wide range of niches. A biologically complex and complete marine ecosystem with diverse organisms and varied lifestyles is proposed here, including endobenthic (palaeoscolecidans, possible Ottoia, linguliform brachiopods and machaeridian polychaetes), sessile benthic (dendroid graptolites, echinoderms, sponges, rhynchonelliform brachiopods and bryozoans), mobile benthic (demersal trilobites), nektonic (conodonts) and planktic taxa (agnostids, planktic trilobites and graptoloids). The Liexi fauna is regarded herein to be one of the most well-preserved and most fossiliferous Ordovician Lagerstätte. The fauna includes taxa that not only belong to Cambrian relics, but also Ordovician origins, constituting a complex and complete marine ecosystem. This scenario would imply that the GOBE represents a long, gradual and continuous evolutionary process following the fade-out of the Cambrian explosion. The Liexi fauna represents one of the diverse open-marine communities, located in a specific tropical area in the peri-Gondwanan region, indicating a complex and complete ecosystem at the transition between the Cambrian and the Palaeozoic evolutionary faunas.

A distinctive type in the earliest Phanerozoic reef pattern: calcimicrobial-cement reefs from the Cambrian Series 2 Xiannüdong Formation, China

Daecheol KIM[1]*, Kangwon National University (dckim@kangwon.ac.kr)
Jino Park[2], Kangwon National University
Jongsun Hong[3], Kangwon National University

Abstract

Marked changes in the late Proterozoic ocean-atmosphere system triggered the development of skeletal frameworks and decreased abiogenic precipitates, resulting in the prevalence of lower Paleozoic microbial-skeletal reefs. While the microbial crust-cement reefs during that time stand out for their abundant early marine cement and sparse skeletal metazoans, it remains poorly understood how this distinct structure and composition from contemporaneous reefs have occurred. This study examined the developmental process of the Cambrian Series 2 *Girvanella* crust-cement reefs in the Xiannüdong Formation of Sichuan, China. *Girvanella* crust-cement and thrombolitic reefs together comprise a closely spaced, 2-m-thick microbial-dominated reef complex with the surrounding peloid-*Girvanella* crust packstone to grainstone and fine-grained siliciclastic thin beds. *Girvanella* crust-cement reefs are amalgamated bioconstructions of a centimeter- to decimeter-scale cabbage-like porous structure. This structure consists of vertically to horizontally aligned thin arcuate *Girvanella* crusts, attached to closely spaced to one another, with the pore spaces filled by abundant fibrous and blocky calcite cement and rare internal sediments. Thrombolitic reefs reaching heights up to 1.5 m are composed of largely mesoclot-forming calcimicrobes and microbial lumps and rare irregular archaeocyaths. Their interstitial spaces are equilateral pores a few centimeters in size, nearly completely filled with internal sediment. The surrounding deposits point that the reef complex had formed in moderate- to high-energy shallow subtidal with frequent siliciclastic influxes. The crust-cement reefs were constructed by a coalescence of *Girvanella* crusts with the aid of marine cementation. Much lower content of internal sediment, dense arrangement of the reef-building *Girvanella* crusts and presence of crust-rich surrounding deposits, indicate that the crust-cement reefs were possessed vulnerable, semi-closed frameworks. These architectural characteristics seem to have hindered the incorporation of skeletal components within the reefs, leading to the formation of microskeletal reefs as microbial-abiotic hybrids. Since they are comparable to other lower Paleozoic calcimicrobial crust-cement reefs in composition, texture, and structure, ample occurrences of abiotic carbonate and the absence of skeletons in the coeval reefs elsewhere were also likely caused by the internal controls. Lower Paleozoic calcimicrobial crust-cement reefs broadly resemble Precambrian microbial-abiotic hybrid reefs in terms of key carbonate components. The differences in texture and the associated developmental process, however, suggest that such a distinctive development of lower Paleozoic calcimicrobial crust-cement reefs may have been significantly influenced by the Cambrian Explosion, rather than being an anachronistic variant of the Precambrian.

The global distribution of Upper Ordovician acritarchs

Kui YAN[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (kuiyan@nigpas.ac.cn)

Bing Huang[3], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Jun Li[4], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences

Abstract

The Peri-Gondwana and Baltica acritarch provinces are easily recognized in the Early-Middle Ordovician, illustrating a clear provincialism of the global phytoplankton. However, acritarch assemblages have been reported to become increasingly similar with a general cosmopolitanism towards the Late Ordovician, although acritarch assemblages from Laurentia and Baltica are reported to be rather different from those from peri-Gondwana, based on more recent studies. In the last decades, new acritarch assemblages reported from South America, Baltica, Iran, and Siberia as well as the new material from South China and Tarim provide additional data that helps to understand in more detail the palaeobiogeographical evolution of the phytoplankton during the Late Ordovician.

We reviewed Late Ordovician acritarch assemblages and built datasets with binary presence/absence data. Quantity analysis including Cluster Analysis (CA), Nonmetric Multidimensional Scaling (NMDS) and Network Analysis (NA)were used to understand the implication of acritarch palaeogeography in the Late Ordovician.

A strong palaeobiogeographic differentiation occurred in the Katian and weakened in the Sandbian and Hirnantian. The palaeogeographic distribution of the phytoplankton roughly parallels palaeolatitudes in the Katian, possibly leading to a global temperature zonation.

The high diversity acritarch assemblage normally existed around 30° in the Southern Hemisphere, which is similar to the LDG model in the Late Ordovician published by Zacaï et al. (2021).

The total diversity of acritarchs was highest in the Katian, together with a strong palaeobiogeographic differentiation in the Late Ordovician. This higher acritarch diversity may be linked to stronger palaeobiogeographic variations.

The proportion of the endemic acritarch taxa is very high in different plates (regions) during the Late Ordovician. The proportion of the cosmopolitan acritarch taxa was higher in the Hirnantian than that in the Sandbian and Katian. Acritarch assemblages from different plates (regions) exhibited various diversity trends affected by the Late Ordovician Mass Extinction.

Abstract

Stromatoporoid sponges were reef builders for over 100 million years in the Palaeozoic Era. Since the emergence and proliferation of stromatoporoids as reef builders in the late Darriwilian (Middle Ordovician), stromatoporoids played a key role in the development of complex reef ecosystems, especially contributing to the Great Ordovician Biodiversification Event. However, the mechanisms by which stromatoporoids were integrated into reef communities remain poorly known. Our discovery of stromatoporoids from the upper Tremadocian to the lower Floian (Lower Ordovician) in South China represents the oldest known stromatoporoids and sheds light on the initial stage of middle Palaeozoic reef development. These stromatoporoids are essential for building the structure of the reef, similar to those of the late Middle Ordovician and later, by binding other components and together with other reef builders formed a complex reef community. In particular, these Early Ordovician stromatoporoid reefs, in association with Cambrian biotic relics and Ordovician fossils, replaced late Cambrian microbial-dominated reefs in South China significantly earlier than in other continents, where microbial-lithistid sponge reefs persisted over the same time period. These newly-described Early Ordovician stromatoporoid reefs in South China thus are evidence for diachronous onset of metazoan-dominated reef community development among regions, and to a greater extent in South China. Combined with the available data, this early reef transition from microbial to metazoan domination in South China is most likely due to multiple environmental changes, including a global decrease in seawater temperature, an increase in dissolved oxygen levels, and the palaeogeographic position of South China within the tropical to subtropical climate zone. In perspective, South China served as a focal

point for reef evolution during the Early Ordovician. The earliest stromatoporoids, as newly emerging skeletal reef builders, expanded globally during the late Darriwilian, when environmental conditions became more suitable for metazoan reef development.

The Ordovician-Silurian boundary deposits in northwestern Tarim, Xinjiang: the Xikeer bed (new unit) and its implications

Yuchen ZHANG[1]*, Nanjing Institute of Geology and Palaeontology (yuchenzhang@nigpas.ac.cn)
Peng TANG[2], Nanjing Institute of Geology and Palaeontology
Renbin ZHAN[3], Nanjing Institute of Geology and Palaeontology

Abstract

A stratigraphic succession across the Ordovician-Silurian boundary is discovered in the northwestern margin of the Tarim Basin, Xinjiang, NW China, and is named Xikeer Bed, which ranges from uppermost Hirnantian (Upper Ordovician) to lowermost Rhuddanian (Llandovery, Silurian). The holostratotype of the Xikeer Bed is located at the Xikeer Service-area North section, Xikeer Town, Jiashi County, while the parastratotype is located at the Dawangou section, northwest of the Yingan village, Kalpin County. In the holostratotype, the lower part of the Xikeer Bed is composed of gray-green argillaceous siltstone, and the upper part consists of gray calcarenite, which produces brachiopods, corals (tabulate and rugose), bryozoans, stromatoporoids, and some other fossils, with a total thickness of 1.5 m. In the parastratotype, the Xikeer Bed has a sequence of gray-green muddy siltstone and silty mudstone with bryozoans, gastropods, cryptospores, algae and land plant fragments, with a total thickness of 2.5 m. In the Kalpin-Jiashi area, the Xikeer Bed is underlain unconformably by the Terekawat Formation (upper Katian Stage, Upper Ordovician), suggesting the absence of the lower-middle Hirnantian rocks in the study area, and is overlain conformably by the Kalpintag Formation (Rhuddanian, Llandovery). The Xikeer Bed is widely and stably distributed in the Kalpintag Mountains and some other places in the Kalpin area, and will serve as an important lithostratigraphic marker for the division and correlation of the equivalent strata. A brachiopod assemblage collected from the bed is typically represented by Cathaysiorthis yushanensis and Leptaena rugosa, which belong to the Edgewood-Cathay (EC) Fauna, the first brachiopod assemblage inhabited shallow marine after the Late Ordovician Mass Extinction (LOME). Based chiefly on the yielded brachiopods, the Xikeer Bed is well correlated with the Wulipo Bed in Meitan County and the Shiqian Bed in Shiqian County, northern Guizhou Province, along with the Weiba Bed in Zhenxiong, northeastern Yunnan Province, South China. These equivalent beds are assumed to be the products of global rapid transgression and climate warming in the aftermath of the Hirnantian glaciation and mass extinction. Due to the cold climate and sea-level drop in the Hirnantian, the Kalpin area was exposed and denuded until latest Hirnantian when the glacial climate ended and the sea level rose rapidly, and as a result the area began to accumulate deposits again. As shown by a trans-regional correlation, the absence of the lower-middle Hirnantian stratigraphic records also occurred in some areas of the Yangtze Region, such as northern Guizhou Province, northeastern Yunnan Province, the border area of Zhejiang and Jiangxi provinces, etc. This shared absence sheds light on the depositional history and paleobiogeography of northwestern Tarim Basin during the Ordovician-Silurian transition.

Paleozoic oxygenation event - evidence from late Silurian tubular trace fossils in South China

Yuxuan WANG[1]*, China University of Geosciences (Wuhan) (2514548715@qq.com)
Xiaole Zhang[2], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Peng Tang[3], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Liao Yang[4], China University of Geosciences(Wuhan)
Zhong-Qiang Chen[5], China University of Geosciences(Wuhan)

Abstract

The Paleozoic Oxygenation Event (POE) is the third major oxygen increase in atmosphere and ocean following the great oxygenation event (GOE) in 2.2-2.5 billion years ago and Neoproterozoic Oxygenation event (NOE) around 800-700 million years ago. Previous studies showed that the POE had a significant impact on biotic radiation and witnessed the emergence of vascular plants and terrestrialization process (including vegetation on land) during the Silurian. Geochemical and modelling studies estimated that the atmospheric oxygen content could be close to or reach modern levels (O2 >15-17%) during approximately 420-400 Ma. Nevertheless, how marine animal reacted the elevated oxygen levels during the Silurian has long remained poorly understood. Here we document abundant tubular trace fossils from the upper Silurian Xiaoxi Formation in the Guizhou, Chongqing and Hunan regions, South China, emphasizing burrowing behavior variations of trace-making animals during the late Silurian oxygenation process. The newly obtained trace fossils combining with the previously reported materials show that significant increases in burrow diameter of tubular trace fossils from the upper Silurian Xiaoxi Formation when compared with those from early-middle Silurian, implying the result of elevated oxygen levels in marine settings. Field observation and measurement also reveal that the burrowing density and diameter of tubular trace fossils negatively correlate each other. Accordingly, an increase in burrow sizes, coupling with decrease in burrowing density of tubular trace fossils is evident from the early Silurian (Xiushan Formation) to late Silurian (Xiaoxi Formation), implying the controls of water depth and oxygen level on trace-making animal activities at that time, reinforcing the occurrence of oxygenation event.

Latest Ordovician graptolite fauna of the Wufeng Formation in South China

Qing CHEN[1]*, Nanjing Institute of Geology and Palaeontology, CAS (qchen@nigpas.ac.cn)
Xu Chen[2], Nanjing Institute of Geology and Palaeontology, CAS

Abstract

The Wufeng Formation (Wufeng Shale) was first delineated as a stratigraphic unit established by Sun Yunzhu in 1931 based on the field surveys and graptolite specimens collected by Xie Jiarong and Liu Jichen at Yuyangguan Town, Wufeng County, Hubei Province, South China. The age and stratigraphic division of the Wufeng Formation had long been an unresolved issue in the Chinese geological community until a conclusive paper titled "On the Wufeng Shale" was published by Mu Enzhi in 1954. In this publication, a reliable conclusion was reached that the Wufeng Formation belongs to the Upper Ordovician based on the presence of graptolites within it. Over the past two decades, the Wufeng black shale in the Upper Yangtze Region has emerged as a significant shale gas production horizon. In this scenario, the division and precise correlation of graptolite biozones play a crucial role in identifying and comparing shale gas sweet spots underground. Achieving this requires accurate graptolite classification and identification. Since the 1990s, a large number of graptolites from the Wufeng Formation have been collected for research on the GSSP of the Hirnantian Stage in South China. Recently, better-preserved graptolite specimens, including a few three-dimensional ones, have been obtained from the Guizhou Province. This presents a valuable opportunity for further study of latest Ordovician graptolite fauna. In this study, a total of 25 genera and 80 species of graptolites are described using over 1,000 selected graptolite specimens. The descriptions cover research history, morphological characteristics, distinctions from similar species, and other pertinent discussions. Additionally, the study clarifies the stratigraphic ranges, distribution patterns, and ecological characteristics of the latest Ordovician graptolites across more than 70 sections and collection sites in South China and worldwide. Distinctions are made among various graptolite ecological types, and their evolutionary processes during the end-Ordovician mass extinction are examined. The graptolite fauna can be classified into three types: the background extinction unit, the mass extinction unit, and the origination unit. The end-Ordovician mass extinction impacted both the mass extinction units and the background extinction units. The effect of the mass extinction was consistent across all graptolite species, irrespective of the size of their geographic ranges. Biogeographic dynamics and evolutionary processes of graptolite species further support the transition from diplograptids to neograptids.

[Keynote] Integrative Ordovician stratigraphy of China: a critical constraint on orogenies and palaeogeographical evolution of NE peri-Gondwana

Yuandong ZHANG[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (ydzhang@nigpas.ac.cn)
Xiang FANG[2], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Wenjie LI[3], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences

Abstract

Present-day China comprises several independent tectonic palaeoplates or terranes and parts of other blocks, which have been assembled over geological time. During the Ordovician, these blocks included South China, North China, Tarim, Qaidam, Junggar, Qiangtang-Qamdo, Lhasa, and partially Himalaya, Sibumasu and Indochina, as well as the Altay-Xing'an and Songpan-Garze fold belts, which were likely discrete but adjacent. The Ordovician strata of China reflect a largely consistent and continuous deposition during the period, but with some significant interruptions or major facies changes on some of the constituent blocks due to regional orogenies or global factors. Therefore, an integrative stratigraphical framework of the Ordovician, including lithostratigraphy, chronostratigraphy, biostratigraphy, chemostratigraphy, cyclostratigraphy and magnetostratigraphy, would provide a critical constraint for the timing and extent of these orogenies, as well as major palaeogeographical dispersions or conversions of the constituent blocks in northeastern peri-Gondwana region. In South China, the Ordovician System is characterized by a major facies change from an extensive marine platform-slope-basin pattern into a pattern of restricted foreland basin with some isolated carbonate platforms in the Late Ordovician, which has been widely attributed to the Kwangsian Orogeny initiated in Sandbian and lasted until early Silurian. The Ordovician System of North China is dominated by carbonates including extensive deposits of evaporites in the Darriwilian, and shows distinctive occurrences of two major hiatuses, i.e. the two episodes of the long-lasting Huaiyuan Epeirogeny, one in the Early-Middle Ordovician and the other in the Late Ordovician which lasted until Carboniferous. In Tarim, the Ordovician System displays apparent facies differentiation from the west (marginal shelf-slope facies) to central (shallow-water platform with developed reefs) and to the east (largely siliciclastic flysch facies), and is distinctive in the occurrences of an extensive hiatus in middle-late Katian and another one in the Hirnantian. The Ordovician System of Tibetan terranes represents the oldest non-metamorphosed marine deposits in the region, typified by the occurrence of an extensive hiatus between the Ordovician and the underlying Cambrian basement caused by the Kurgiakh Orogeny, showing a likely close affinity with Sibumasu, and North China. The overall lithostratigraphical sequences and faunal assemblages, especially the benthic and nektonic organisms on constituent blocks of China show a prominent similarity between South China and Tarim, and a close relationship between North China and Tibetan terranes in the Early to Middle Ordovician. A dynamic palaeogeographic analysis of the Chinese constituent terranes through the Ordovician shows a complex dispersion and convergence pattern, which is highlighted by the

rifting of North China from Gondwana and the approaching of South China towards Australia and the equatorial region.

New techniques for studying the morphology of chitinozoan plugs

Yan LIANG[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (liangyan@nigpas.ac.cn)
Olle Hints[2], Tallinn University of Technology
Jaak Nõlvak[3], Tallinn University of Technology
Peng Tang[4], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences

Abstract

All chitinozoan chambers were sealed by a plug at the aperture side. The plugs are named operculum or prosome, which are of decisive significance in both chitinozoan systematics and exploring their biological affinity. According to the current chitinozoan classification put forward in 1999, an operculum is a disk-like plug sealing the aperture at the test lacking a neck and a prosome is an internal plug situated within the neck. Morphologically, the prosome could be as simple as a disk-like feature similar to the operculum, or as complex as a tubular structure with several horizontal septa. Both the operculum and the prosome could have a membrane expansion flaring anti-apertural ward. Hitherto, the descriptions of the morphology of the plugs inside an opaque chitinozoan test are based on optical microscopy (OP) with high light density, near-infrared microscopy (NIR), or scanning electron microscopy (SEM) of broken tests. However, neither OP nor NIR could provide high-resolution imaging, and SEM could not present enough data. We applied NIR, Micro-CT, and focused ion beam scanning electron microscopy (FIB-SEM) to determine the plugs' morphology and ultrastructure. NIR is involved in the first step to detect specimens with plugs preserved intact. Micro-CT is then used to reveal the morphology of the inner plugs without destroying the specimens. FIB-SEM is applied to cut the selected specimens at critical places and obtain high-resolution images of the ultrastructure of the plugs. With new data accumulating by these techniques, novel findings are expected to better understand the plugs' functional morphology and the biological affinity of chitinozoans.

Abstract

The Wenlock to Pridoli conodont biozonation has been well established in many areas of the world but has been poorly studied in China. The Silurian succession in western Yunnan and Xizang (Tibet) is relatively continuous and complete, but conodont biostratigraphy in these regions has not been extensively researched. In this study, conodont samples were collected from the Laojianshan section in Baoshan of western Yunnan, the Yalai West II section in Nyalam of southern Xizang, and the 5,118 Highland section in Xainza of northern Xizang. Analysis of the Laojianshan section identified seven distinct conodont zonal units within the "Lichaiba" and Niushiping formations, including the Pterospathodus amorphognathoides amorphognathoides Zonal Group, the Pterospathodus pennatus procerus Superzone (likely only the Lower Pterospathodus pennatus procerus Zone), the Ozarkodina sagitta sagitta Zone, the Kockelella ortus absidata Zone, the Kockelella crassa Zone, the Polygnathoides siluricus Zone, and the “Ozarkodina” eosteinhornensis s.l. interval Zone. Similarly, the Yalai West II section revealed five recognized conodont zonal units within the Pulu Formation, encompassing the Ozarkodina sagitta sagitta Zone, the Kockelella crassa Zone, the Kockelella variabilis variabilis–Ancoradella ploeckensis Zonal Group, the Polygnathoides siluricus Zone, and the “Ozarkodina” eosteinhornensis s.l. interval Zone. In the 5,118 Highland section, three conodont zones were identified, including the Kockelella crassa, Kockelella variabilis variabilis, and Polygnathoides siluricus zones. Utilizing these conodont findings in conjunction with graptolites from underlying strata, the "Lichaiba Formation" was assigned to the upper Llandovery (upper Telychian)-upper Wenlock (upper Homerian), the Niushiping Formation to the Ludlow-Pridoli, the Pulu Formation to the upper Llandovery (upper Telychian)-Pridoli, and the Zhanongema Formation to Ludlow. Additionally, the late Telychian conodont fauna from the Laojianshan section suggests a distal, open-shelf depositional environment. The widespread distribution of Wenlock to Pridoli conodont species across the Baoshan, Nyalam, and Xainza regions indicates that the cosmopolitan characteristics of the conodont fauna during this period were likely influenced by the circulation of ocean currents.

Yuandong Zhang[9], Nanjing Institute of Geology and Palaeontology

Abstract

A well-preserved radiolarian assemblage is described from argillaceous limestone of the Wulalike Formation in the NW Ordos Basin, North China. A total of seven genera and nine species are described, including Inanigutta gansuensis, I. quadrispinosa, I. complanata, Inanibigutta pinglianensis, Oriundogutta bella, Triplococcus acanthicus, Haplentactinia juncta, Syntagentactinia pupila n. sp. and Kalimnasphaera maculosa. Three-dimensional X-ray micro-computed tomography (Micro-CT) is used to make a detailed examination of the new species. Micro-CT examination results suggest that the Syntagentactinia pupila n. sp. is exclusively constructed from five initial spicules and two spheres with a pylome surrounded by an extensive net. And detailed structural analysis reveals that inner sphere is ectopic to outer sphere. This taxon is thus far known only from the Middle Ordovician rocks of the northwestern Ordos Basin, North China. This new species in the radiolarian assemblage from the Wulalike Formation at Well E-98 drill core, northwestern Ordos basin potentially provides a diagnostic tool for stratigraphic correlation and insight into the development of Paleozoic radiolarian taxonomy. Besides, this is the first documentation of radiolarian fossils from the Wulalike Formation and will contribute to better understanding of the features of Ordovician radiolarian faunas and facilitate stratigraphic correlation and subdivision in the Ordos Basin.

The Ordovician radiolarians from Qilian Orogenic Belt

Hui LUO[1]*, Nanjing Institute of Geology and Palaeontology (huiluo@nigpas.ac.cn)
Xuejin Wu[2], Nanjing Institute of Geology and Palaeontology
Yuandong Zhang[3], Nanjing Institute of Geology and Palaeontology

Abstract

In China, the study of the evolution and extinction process of the Proto-Tethys Ocean has been one of the hot topics of geoscience research on the Tibetan Plateau, but it is still quite weak. There is still a great deal of controversy about when it opened, how it evolved, and how it disappeared. A number of Early Paleozoic suture zones have been found in the Qilian Orogenic Belt and its adjacent areas in China, in which a large number of ophiolites, mélange and radiolarites etc. related to the Proto-Tethys Ocean are exposed, which record the evolution history of the Proto-Tethys Ocean. So far, there is a lack of systematic research on radiolarians in these siliceous rocks. In recent years, we have done preliminary collection and systematic paleontological research on radiolarians in different suture zones in this area, and found that there are rich radiolarian fauna in the Ladong section and the Donggoukou section of the northern belt, including Middle to Late Ordovician Spumellarian and Entactinia; In the Shihuiyao section of the southern belt, some Late Ordovician Spumellarian are found. The discovery of these radiolarian fossils will provide important biostratigraphic constraints for determining the expansion and extinction time of Proto-Tethys, and help to reveal the complete evolution process of Proto-Tethys Ocean in the Qilian Orogenic Belt and its adjacent areas.

The last episode of coral-stromatoporoid biostromes and faunal changes across a Devonian-Carboniferous Boundary section of South China

Kun LIANG[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (kliang@nigpas.ac.cn)

Abstract

This study reports the final occurrence of coral-stromatoporoid biostromes and the faunal and facies change across the Devonian-Carboniferous Boundary (DCB) at Changtanzi Section, Longmenshan area of South China. The final biostrome occurred in the third member of the Changtanzi Formation, represents the uppermost Famennian in age, and is characterized by a reefal environment composed of abundant and high diversity stromatoporoids and tabulate corals, which were subsequently greatly affected with the appearance of end-Devonian carbon isotope excursion (EDICE). Stromatoporoids and tabulate corals struggled to survive through the Famennian and their association was eventually terminated in the Lower Hangenberg Crisis (LHC) by extinction of Famennian stromatoporoids. Biotic recovery is found to occur as early as in the upper UHC, represented by solitary rugose corals Hebukophyllum sp., Neozaphrentis sp. and Uralinia sp., as well as abundant brachiopods, gastropods and an unknown tube organism, in general belonging to post-disaster fauna of low species level diversity. This study shows distinctive faunal and lithofacies changes during the Hangenberg Crisis, and examines the strong link between faunal, facies and environmental changes. The result reveals that the EDICE and Hangenberg Crisis caused sudden and significant impacts on marine ecosystems, leading to the disappearance of coral-stromatoporoid metazoan reefs that emerged during the Great Ordovician Biodiversification Event (GOBE).

Early Darriwilian evolution of North China conodont bioprovince: insights from sedimentology and conodont biostratigraphy

Sehyun Cho[1]*, Department of Earth and Environmental Sciences, Korea University (whtpgus307@korea.ac.kr)
Byung-Su LEE[2], Department of Earth Science Education, Jeonbuk National University
Suk-Joo CHOH[3], Department of Earth and Environmental Sciences, Korea University

Abstract

Ordovician strata of North China Block contain middle Floian-lower Darriwilian platform wide hiatus. Conodont biostratigraphy above the hiatus described the emergence of many new types and multimolecular complex and evaluated the new stage of evolution of North China conodont and distinct differentiation of North China Province from other continents. This study attempts an integrative study of sedimentology and conodont biostratigraphy in the middle Ordovician Makgol Formation immediately above the hiatus at the eastern margin of the North China Block and aim to evaluate the separation of the bioprovince and the evolution of numerous endemic taxa from sedimentological perspective.

We investigated 205 m-thick composite intervals of the lower to upper members of the Makgol Formation at the five sections distributed in the Taebaek and Yeongwol areas. The formation is mainly composed of micritic limestone such as massive to bioturbated lime mudstone and wackestone, with subordinate peloid-bioclast packstone to grainstone, tidal laminite, stromatolite, and caliche and carbonate breccia, which is interpreted as a micrite dominated inner platform carbonate tidal flat deposits. The Makgol Formation is characterized by repetitive accumulation of subtidal and peritidal meter-scale cycles, and the vertical stacking of peritidal cycles dominated lower and upper part, while subtidal cycles constitute middle part, suggesting that the Makgol Formation record overall transgressive-regressive sequence with subsequent transgression to deeper subtidal deposits of the overlying Jigunsan Formation.

Conodont biostratigraphic data is related to facies and type of meter scale cycles. The lower and upper part dominated by peritidal cycles show very poor conodont recovery, which was defined as conodont barren intervals. The lower Darriwilian endemic conodonts in the North China including Tangshanodus tangshanensis, Triangulodus changshanensis and Rhipidognathus laiwuensis are abundantly yielded from the middle part, and Tangshanodus tangshanensis-Histiodella holodentata Biozone was established. These results indicate depositional environmental factors for conodont distribution and habitat.

Conodont barren interval and endemic conodont dominated biostratigraphy is not confined to the Taebaek area. Similar biostratigraphic characteristic is also recognized in northern and southern part of North China, where peritidal to shallow subtidal depositional facies including laminite, carbonate breccia and bioturbated limestone are described in corresponding interval. Therefore, it is suggested that shallow marine environment similar to the current study area also covered significant portion of the North China Platform, and that re-inundated shallow water conditions

may have provided niches for conodont evolution. The integrative study of biostratigraphy and sedimentology provide diverse perspective on the evolution of the bioprovince and we suggest that similar integrative study needs to be conducted in other regions of North China.

Mollusk-dominated skeletal contributions during the Great Ordovician Biodiversification Event (GOBE) in the Darriwilian Sino-Korean Block

Myung-Jun Seo[1]*, Department of Earth and Environmental sciences, Korea University (joshuaseo0123@gmail.com)
Sehyun CHO[2], Department of Earth and Environmental sciences, Korea University
Sukjoo CHOH[3], Department of Earth and Environmental sciences, Korea University

Abstract

The Great Ordovician Biodiversification Event (GOBE), known for its unprecedented increase in marine biodiversity and complexity, also includes significant changes such as variations in life modes, the extent and intensity of bioturbation, and the skeletal contribution to carbonate production. These changes have been documented across continents. However, due to the middle Floian–lower Darriwilian depositional hiatus, which is followed by the thick overlying peritidal strata, the Ordovician records of the Sino-Korean Block (SKB) have been less understood in terms of biodiversity.

The middle Darriwilian Duwibong Formation located in South Korea, the easternmost part of the SKB, primarily composed of subtidal limestone deposits yielding various allochems (e.g., cortoids, oncoids, ooids, peloids, and bioclasts). The Duwibong Formation correlates with the Majiagou Formation in North China, characterized by low-energy shallow-shelf carbonates with extensive tidal flat dolomites and lagoonal evaporites. We investigated the Duwibong Formation at three sections through microfacies analysis, conducted on every specimen sampled at approximately 20 cm intervals in each section, to visually estimate component proportions.

The diversity and abundance of skeletal components in the Duwibong Formation significantly increased compared to the basal member of the Makgol Formation, composed of early Floian subtidal limestone deposits which currently occur in the field as a massive dolostone interval. Notably, mollusks and echinoderms show major increase, accompanied by the emergence of bryozoans, brachiopods, and algae. This trend, the quantitative increase and/or the addition of new components, is comparable to that observed in other continents, yet is driven predominantly by mollusks and echinoderms relative to the coeval strata in other continents. This study, by highlighting the shift towards a skeletal-dominated carbonate platform in the SKB during the Middle Ordovician, contributes insights into the marine-environmental evolution during the GOBE.

Early Paleozoic reef evolution in the Taebaek and Yeongwol groups, Korea: Insights into the peri-Gondwanan reef development

Jeong-Hyun LEE[1]*, Chungnam National University (jeonghyunlee@cnu.ac.kr)
Suk-Joo CHOH[2], Korea University
Jongsun HONG[3], Kangwon National University
Juwan JEON[4], Korea University
Jino PARK[5], Kangwon National University
Jusun WOO[6], Seoul National University

Abstract

Various early Paleozoic (Cambrian Series 2 to Middle Ordovician) reefs are found in the Taebaek and Yeongwol groups of Korea. In the Taebaek Group, reefs occur in every carbonate-dominant lithostratigraphic unit, but their morphology and composition differ markedly. The earliest Phanerozoic reefs in Korea are found in the Myobong Formation (Cambrian Stage 3?), where small columnar stromatolites develop in an intertidal setting. The Daegi Formation (Drumian) contains Epiphyton-lithistid sponge reefs formed in a shallow subtidal environment. The Sesong Formation (Guzhangian) and Hwajeol Formation (Jiangshanian–Cambrian Stage 10) contain several small dendrolites that formed in relatively deep subtidal environments. During the Early Ordovician (middle Tremadocian–early Floian), microbialite-lithistid-Calathium patch reefs develop in the shallow to deeper subtidal environments of the Dumugol Formation. A relative sea-level fall in the Middle Ordovician (Floian–early Darriwilian) established peritidal environments with microbial mats and stromatolites in the Makgol Formation. The Middle Ordovician (middle Darriwilian) Duwibong Formation exhibits some of the earliest skeletal reefs built by the stromatoporoid Cystostroma and bryozoan Nicholsonella around shoals. In the Yeongwol Group, reefs have recently been increasingly reported. The Wagok Formation (Cambrian Stage 10) contains stromatolite biostromes possibly formed in a peritidal environment. Stromatolite-like columns and thrombolite-like mounds composed of microbial carbonates, keratose sponges and minor lithistids develop in the Lower Ordovician (Tremadocian) Mungok Formation. The Yeongheung Formation (Darriwilian) contains several labechiid stromatoporoid-dominant reefs and microbial mats. These reef distributions can be compared to the coeval successions in North China, where various reefs and their evolutionary patterns are recorded throughout the Cambrian-Ordovician strata. The Taebaek and Yeongwol reefs demonstrate the evolution of reef ecosystems represented by the interplay between microbial and skeletal reef-builders during the early Paleozoic. They provide a window to understand peri-Gondwanan reef development that warrants further detailed study and comparison with coeval reefs globally to better understand the spatio-temporal patterns and drivers of early Paleozoic reef evolution.

Recovery of the earliest Silurian paleo-ocean: coupling evidence from both benthos and redox conditions in South China

Wenhui Wang[1]*, Central South University (whwang@csu.edu.cn)
Yong Wang[2], Central South University

Abstract

The Early Paleozoic witnessed a major diversity reduction in the Hirnantian-age Late Ordovician Mass Extinction (LOME), followed by subsequent post-extinction recovery cross the Ordovician-Silurian boundary. Understanding the pattern of post-LOME recovery is complicated by heterogeneity of patterns in time, and for different fossil groups. Different groups show strongly differentiated facies dependance, and thus show very different recovery patterns. Benthic fossil groups, which are the most severely affected by oxidative stress, offer the best opportunities for understanding both biological and ecological recovery after the LOME. Among benthos, many sponge-dominated community in South China have been found in the past decade, thriving immediately after the LOME and into the early Silurian. How the sponge proliferation is linked to the evolution of oceanic redox conditions during the earliest Silurian is unclear. In this study, in order to further explore the lateral and temporal distributions of sponges, and ecological effects of benthic recovery during this critical interval, we report two new localities (the Nanba section and TD 2 well, both in Hunan Province, South China) that have yielded sponge fossils. In addition, a combination of geochemical analyses reveals the bottom water redox conditions in which these sponges lived. The sponge communities show a relatively deep-water affinity and are preserved by pyritic spicule replacements. Geochemical analysis (total organic carbon (TOC) and major and trace element composition) in both sections show similar trends, indicating a shift in redox state of the bottom-water from persistent anoxia or intermittent euxinia in the earliest Rhuddanian, becoming oxygenated in the early Aeronian. Based on the present study and published data, the distribution of early Silurian sponge assemblages in South China demonstrates a gradual expansion towards deeper regions when ocean redox conditions ameliorated. The pioneering colonization of sponges in low-oxygen environments after the LOME may have set the stage for the subsequent recovery of other benthic organisms. This study contributes to the understanding of the main links between the development of the sponge faunas and changes in the marine environment.

First report of Late Ordovician sponge spicules assemblage from the Yangtze Platform, South China

Lixia LI[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (lxli@nigpas.ac.cn)
Guanzhou Yan[2], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Xin Wei[3], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Fangyi Gong[4], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Rongchang Wu[5], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences

Abstract

Sponges have played an important role in marine benthic ecosystems since the Precambrian. Most of our knowledge about the fossil record of sponges has long been based on the well-preserved sponges with whole skeletons from the outstanding fossil Lagerstätten. However, these remarkable fossil Lagerstätten are just a drop in the ocean, and most of the evidence for early sponges is from isolated spicules.

Previous studies have shown that the Early Paleozoic sponge fauna is dominated by siliceous sponges and a large number of siliceous spicules constitute the main part of the sponge body. However, in most cases, isolated spicules may not taxonomic significant unless they could be well matched to body fossils preserved together. It is also needed to put more effort into reassessment about the taxa previously established based on isolated spicules, in order to remove too many synonyms and form-taxa. In addition, the evolution of sponge spicules is high conservative, the relatively simple Cambrian types are still quite abundant and geographically widespread in the modern deep-water ecosystems. Therefore, although recent studies suggest that the Early Paleozoic sponge spicules are far more diversified and complex than previous expected, isolated spicules cannot play a prominent role in biostratigraphic and paleogeography. In view of this, there have been few studies on the sponge spicule assemblages for a long time, and not enough attention has been paid to this quite important group.

A diverse and abundant isolated sponge spicule assemblage of Late Ordovician age is first reported from the western margin of the Yangtze Platform in South China. The spicule assemblage was recovered from the argillaceous limestone dominated by conodonts, including 14 types which can be grouped into two categories: hexactinellid spicule types and demosponge spicule types. The assemblage is mainly composed of hexactines and their derivatives, including not only some distinctive types such as Kometia cruciformis, but also a large number of diagnostic spicule types that are quite common in hexactinellids, e.g. echinate hexactines, swollen hexactines, curved hexactines, stauractines. Demosponge spicule types are represented by tetraxons, a variety of desmas unique to lithistids also occurs. The highly modified hexactines, i.e. Kometia cruciformis, is recovered for the first time from China. This assemblage is currently the only spicule assemblage from coeval strata worldwide except the Australian one. The presence of unique modified hexactines (Kometia) in both assemblages suggest that particular spicules probably have great potential in biostratigraphy and show important biostratigraphic significance.

Furthermore, they also indicate that spicule assemblage represented by the unique modified hexactines may migrate multiple times along the periphery of Gondwana due to the Ordovician ocean currents, and have important paleobiogeographic significance. This spicule assemblage provides a new perspective for investigating the phylogeny, biostratigraphy, and paleobiogeography of Paleozoic sponges, and promoting the understanding of the siliceous sponge macroevolution.

Carbon isotope stratigraphy of the Lower Ordovician Dumugol Formation: Implications for global correlation

Eunsoo LEE[1]*, Department of Geology, Kangwon National University (esu@kangwon.ac.kr)
Jongsun HONG[2], Department of Geology, Kangwon National University

Abstract

Stable Carbon isotope excursions have been widely used in chemostratigraphic studies for intervals where age-diagnostic proxies are ambiguous. While these excursions have been widely explored from the Ordovician successions over the past two decades, understanding those in the Lower Ordovician, including their potential for global correlation, remains unclear due to their small magnitudes. In this study, we report δ13C values from the two sections of the Lower Ordovician Dumugol Formation, and discuss their relevance for global correlation. The Dumugol Formation represents a middle to outer ramp succession composed mainly of shale to marlstone, lime mudstone-shale interbed, and lime mudstone, with intercalating grainy carbonate. The depositional age of this formation is identified as middle Tremadocian to early Floian in age based on conodont biozone. The δ13C trend has three distinct fluctuations recognized in Dumugol Formation: 1) a δ13C shift is observed at Chosonodina herfurthi-Rossodus manitouensis biozone, indicating an increase of ~1.26‰ above the baseline value (rising from -0.62 to 0.63‰), 2) at the base of the Scalpellodus tersus biozone, maximum δ13C values increase by ~1.68‰ from the baseline value (rising from -1.55 to 0.18‰), 3) a prominent δ13C decrease of 0.85‰ below the baseline value (falling from -1.27 to -2.12‰) in the uppermost of the Scalpellodus tersus to the base of the Serratognathus bilobatus conodont biozone. These δ13C data show similarities in trend and magnitude to observed δ13C trends in coeval successions elsewhere. The first shift, correlatable with those of Laurentia, Precordillera, and other regions of peri-Gondwana (South China), is identified as the Top Skullrockian positive Isotopic Carbon Excursion (TSICE). The other two shifts appear to correspond to the Late Stairsian positive Isotopic Carbon Excursion (LSICE) and Late Tremadocian Negative Isotopic Carbon Excursion (LTNICE), recognizable in the Precordillera, peri-Gondana, and Baltica. These three prominent δ13C excursions identified in this study suggest that not only TSICE, previously considered to have strong potential for global correlation, but also other excursions (i.e., LSICE and LTNICE), once deemed uncertain for global correlation, can be valuable for the inter-continental stratigraphic correlation.

Biogeographic shifts of marine invertebrates during the Ordovician-Silurian transition

shasha LIU[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (ssliu@nigapas.ac.cn)
Qijian LI[2], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Lin NA[3], Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences
Wolfgang KIESSLING[4], Department of Geography and Geosciences, University of Erlangen-Nuremberg

Abstract

The first of the five major Phanerozoic extinction events unfolded near the Ordovician/Silurian (O/S) boundary, leading to approximately an 85% decline in marine species, it's common knowledge that a sharp global temperature plunge triggered this extinction event. The Impact of the extinction varied across higher taxa, with complete loss in some groups, partial declines in many, and others navigating through the end-Ordovician extinctions relatively unscathed. However, the translation of these changes into first-order biogeographic patterns remains elusive. Using network analysis and a large compilation of fossil occurrences from Paleobiology Database, we delineate bioregions of marine invertebrates across the O/S boundary. Simultaneously, by integrating the spatial and temporal dynamics of diverse biological assemblages, including sampling-standardized global diversity, beta diversity, and alpha diversity, we scrutinize how faunal turnover and nestedness influence paleontological spatial patterns. Our findings indicate that the decline in beta diversity during the Hirnantian and the Rhuddanian stages was primarily driven by a significant drop in spatial turnover of marine invertebrates. Environmental stress during the main pulses of the extinction even led to an increase in nestedness, mirroring contemporary cases. These results unveil crucial environmental drivers, providing insights into the co-evolutionary mechanisms of life processes and the environment during mass extinctions.

Graptolite biostratigraphy of the Ordovician Wulalik Formation in western margin of North China

Huaqing WANG[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (hqwang@nigpas.ac.cn)
Yuandong ZHANG[2], University of Chinese Academy of Sciences; Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences

Abstract

The Ordovician Wulalik Formation is characterized by predominant black graptolitic shale, and is widely distributed in the western margin of the Ordos Basin in North China. The formation has been targeted for exploration of shale gas by several petroleum companies a few years ago. However, the exploration of the formation is still at a low degree, largely because of the scarcity of geological data and a lack of comprehensive stratigraphic research, especially the graptolite biostratigraphy of the black shale, which appears to diachronous widely. We conducted biostratigraphical studies of one outcrop section and two drill cores of the formation in the western Ordos Basin. At the Dashimen outcrop section B in Wuhai, where belongs to northern part of western Ordos Basin, and the Well Qitan-11 in Etuokeqi, Inner Mongolia, as well as at the Well Huitan-5 in Yanchi, Ningxia in the central part of western Ordos Basin, a total of 144 graptolite specimens were collected for systematic paleontological and biostratigraphical studies. Based on the biostratigraphic occurrences of graptolite species, four graptolite biozones were identified within the formation in ascending order, the Pterograptus elegans, Didymograptus murchisoni, Nemagraptus gracilis, and Climacograptus bicornis biozones.

A biostratigraphic correlation of the Wulalik Formation is conducted between the studied Dashimen section B outcrops and the drill cores of Well Huitan-5 and Well Qitan-11. In addition to those biozonal species, some other species such as Amphigraptus divergens Hall, Dicellograptus angulatus Elles and Wood, D. flexuosus Lapworth, Jiangxigraptus sextans (Hall), Paraglossograptus sp. and Pseudoclimacograptus scharenbergi (Lapworth), are proven of stratigraphical importance due to their relatively short stratigraphical ranges. Didymograptus jiangxiensis Ni play a pivotal role in identifying the base of the D. murchisoni Biozone in Dashimen section B, and Jiangxigraptus sextans (Hall) and Paraglossograptus sp. play a pivotal role in identifying the base of the N. gracilis Biozone in Well Qitan-11, while some other species may also contribute significantly to stratigraphic correlation, but a comprehensive application of several species or other associated species may be needed.

Fossil evidence reveals sexual dimorphism in Anchiornis huxleyi

Yibo Zhou[1]*, Nanjing University (yibozhou@smail.nju.edu.cn)
Min Wang[2], Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences
Xiaoli Wang[3], Linyi University
Xiaoting Zheng[4], Shandong Tianyu Museum of Nature
Zhonghe Zhou[5], Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences
Yanhong Pan[6], Nanjing University

Abstract

There is a lot of evidence that sexual selection affects the early evolution of birds. Despite the hypothesis that sexual selection has been hypothesized as a driving force behind the occurrence of numerous morphological features across theropod evolution, it has yet to be thoroughly tested due to limitations in sample size and difficulties in identifying the sex in fossils. The feathered dinosaur Anchiornis huxleyi, is represented by a multitude of well-preserved specimens from the Late Jurassic Yanliao biota, with both articulated skeletons and plumages. It is remarkable that some specimens have black spots or stripes in forewing feathers while others do not, thus offering a unique opportunity to explore sexual dimorphism in a non-avian dinosaur closely related to the origin of birds. Here, we present a morphometric study of A. huxleyi based on the largest sample size of this taxon collected up to date. Through careful morphometric analysis, we aim to identify sexually dimorphic traits within this species and understand their implications for mating strategies and social behavior. Our results indicate that the distinctive black spots or stripes observed in forewing feathers may be indicative of sexual dimorphism. Statistically robust inferences have been made about the sexual dimorphism in body size, relative limb length and tail-feather arrangement, providing the earlist known sexual dimorphism in paraves evolution. The findings that males have longer forewings, suggesting that sexual selection may have driven the evolution of wings in dinosaurs, with flight emerging as an unintended consequence of these sexual display structures. Moreover, these results not only enhance our knowledge of Anchiornis huxleyi's biology and ecology, but also offer a comparative framework for understanding the evolution of sexual dimorphism in early theropods.

Evolution and dispersal of vertebrates in the Tibetan Plateau and surrounding regions

Tao DENG[1]*, Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences (dengtao@ivpp.ac.cn)
Feixiang Wu[2], Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences
Shiqi Wang[3], Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences

Danhui Sun[5], Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences

Abstract

During the gradual formation of the Tibetan Plateau, the shaping of modern biodiversity in this region was greatly influenced by its uplift, while at the same time, many species originating from the plateau and even the intercontinental spread of ancestors of modern widespread groups were also controlled by this uplift. During the Mesozoic era, the area where the Tibetan Plateau is located today covered with vast oceans, and the Triassic marine sediments in the Himalayas produced vertebrate fossils such as ichthyosaurs and Helicoprion sharks. By the Jurassic and Cretaceous, some areas in southeastern Tibet gradually separated from the marine environment and formed freshwater lakes in the Qamdo Basin, similar to the Sichuan Basin at that time. Reptiles such as dinosaurs lived near the lakes. The collision between the Indian Plate and the Eurasian Plate in the early Cenozoic era gradually uplifted the Tibetan Plateau. At that time, there was a water system connecting the interior of the Tibetan region with the tropical regions of Southeast Asia, resulting in the flourishing of tropical and subtropical fish. With the significant increase in terrain elevation in this area, the environment has become dry and cool, resulting in the extinction of warm-adapting fish and their transformation into snow carps of the Tibetan Plateau. The rapid rise of the Tibetan Plateau has led to the strengthening of monsoon climate, and the climate in the inland regions of Central Asia continues to move towards drought. The Miocene fauna in western China was mainly composed of drought-tolerant grassland mammals, as well as drought-tolerant birds and reptiles coexisting. The Tibetan Plateau finally reached its modern height during the Pliocene, and its climate and environment had the characteristics of a cryosphere, becoming the initial evolutionary center of the Ice Age fauna. The global temperature dropped below today's level for the first time at 2.6 Ma, and animals that have adapted to the freezing environment quickly spread to the surrounding regions of the Tibetan Plateau and more distant areas, becoming the foundation of modern animal diversity. The Tibetan Plateau has undergone complex and large-scale environmental changes during its geological history. A series of tectonic movements and geomorphological evolution have triggered and formed the climate pattern of the Tibetan Plateau and its surrounding regions, which may promote the development of

biodiversity in the region and may also lead to the extinction of organisms.

Deciphering the Evolutionary Dynamic of Melanosomes in Mammalian hair

Xin LI[1]*, Nanjing University (602023230008@smail.nju.edu.cn)
Shun-dong Bi[2], Centre for Vertebrate Evolutionary Biology, Institute of Palaeontology, Yunnan University
Yanhong Pan[3], Nanjing University

Abstract

Besides primates, mammalian hair color is predominantly determined by two pigments, eumelanin and pheomelanin, typically converging in the melanosome. The melanosomes, robust micron-sized organelles housing pigments, are most commonly encountered in mammalian fossil soft tisues. Melanosomes are considered crucial for reconstructing the paleocolor of fossil species, offering valuable insights into the evolution of mammalian hair color. While prior research has extensively explored the correlation between melanosome morphology and pigment types in non-avian dinosaurs and birds, its validation in both extinct and extant mammals remains limited. Here, we collected hairs from 59 extant species spanning 11 mammalian orders. We measured the color, melanosome morphology, and performed regression analysis to unravel the relationship between melanosome shape, color characteristics, ecological environment, and phylogenetic relationships in mammals.

In contrast to birds, our observations revealed that melanosome length, diameter and ratio did not exhibit significant associations with colors in mammals. Surprisingly, only melanosomes size and its coefficient of variation demonstrated a noteworthy correlation with the redness of the hair. This unexpected finding led us to attribute the variance to the absence of premelanosome protein (PMEL) expression in brown melanosomes. Furthermore, our study uncovered a robust correlation between melanosome morphometrics and habitat types (e.g diurnal habits, grand living, and dietary patterns) in mammals. Diurnal species exhibit larger and wider melanosomes, while dietary patterns also play a role in melanosome structures. These findings have profound implications for interpreting fossilized specimens, offering valuable insights into the ecological characteristics of extinct mammalian taxa. Our analysis of the melanosome morphology and taxonomic relationships, combined with phylogenetic analysis, demonstrated a significant phylogenetic signal in melanosome morphology, with consistent shapes within the same order. Comparisons between extant and extinct species revealed a close resemblance between independently obtained fossil data and reconstructed ancestral forms. This departure from the avian pattern suggests that mammalian melanosome morphology is not solely related to colour expression.

To broaden the scope of our study, we analyzed the melanosome morphology of the hair melanosomes in the Jurassic basal mammaliaform Vilevolodon diplomylos. Its melanosome characteristics closely aligned with the results of ancestral state reconstructions, suggesting that Jurassic basal mammals had a more constrained melanosome morphospace compared to Cenozoic

taxa. While restoring colors from fossils remains a challenging task, our study underscores the importance of capturing even subtle hues for a comprehensive understanding of ancient organisms. The expanded correlation between melanosome morphometrics and diurnal habits, grand living, and dietary patterns allowed us to predict the ecological habitat, aligning with interpretations from the skeletal features of extinct mammalian taxa.

The first record of the genus Prosantorhinus (Perissodactyla: Rhinocerotidae) of East Asia

Danhui SUN[1]*, Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences (sundanhui@ivpp.ac.cn)
Tao DENG[2], Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences
Shiqi WANG[3], Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences

Abstract

Prosantorhinus is a genus of small extinct teleoceratine rhinoceroses with shortened limb bones, widely distributed in Europe. However, the Asian evolution of the teleoceratine Prosantorhinus has remained unclear because of a scarcity of fossil records of the genus. Here, we report the first record of Prosantorhinus in East Asia from the Middle Miocene of Tongxin, Ningxia. The new specimen is characterized by a concave dorsal skull profile and elevated nasals; short and stout nasal bones with drooping margins on both sides; the thickened, enlarged, and roughened nasal extremity supporting a small horn; the semi-molarized upper premolars with a lingual bridge between the protocone and hypocone; the metaloph constriction present on P2–4; the protocone equal to the hypocone on P2; the crista present on P3; and the cement on the cheek teeth developed. With all the morphological evidence considered, we establish a new species, Prosantorhinus yei sp. nov.. A phylogenetic analysis based on 282 morphological characters scored for 36 taxa reveals that Prosantorhinus yei sp. nov. is a relatively derived taxon in the genus. Combined with the geological age of the layer where the fossil is located, we speculate that P. yei sp. nov. lived in the Middle Miocene. We hypothesize that Prosantorhinus yei sp. nov. lived in relatively moist environments.

Molecular taphonomy of Oligocene marine mammal bones from Hokkaido, Japan

Raman UMAMAHESWARAN[1]*, Department of Earth and Planetary Sciences, Hokkaido University, Sapporo, Hokkaido, Japan (raman.u@sci.hokudai.ac.jp)
Takuto Ando[2], Graduate School of International Resource Sciences, Akita University, Akita, Akita, Japan
Tatsuya Shinmura[3], Ashoro Museum of Paleontology, Ashoro, Hokkaido, Japan
Ken Sawada[4], Department of Earth and Planetary Sciences, Hokkaido University, Sapporo, Hokkaido, Japan

Abstract

Molecular taphonomy is the study of decay of organisms across geologic time from the perspective of the chemical constituents of their tissues. In this study, three mammal bones from the late Oligocene (28-25 Ma) Morawan Formation of Hokkaido – two desmostylian (Ashoroa laticosta and Behemotops katsuiei) and one whale – were analyzed by microscopic observation, scanning electron microscopy – energy dispersive X-ray spectroscopy (SEM-EDS), and lipid biomarkers in order to elucidate the taphonomic changes undergone by the fossils at the molecular level.

Petrographic thin sections were made of the samples followed by transmitted and fluorescent light microscopy. The cancellous bone tissue was clearly differentiated from mineralized and in-filled bone cavities under transmitted light. Fluorescent microscopy under UV light displayed weak fluorescence of the bone trabecular matrix which indicates an organic composition similar to amorphous kerogen (or possibly proto-kerogen). Sulphurized concretions (possibly pyrite) were also observed. SEM-EDS was used to chemically map the samples showing calcium-dominated bone cavities. The whale bone and B. katsuiei thin sections notably displayed spherical and elongated structures that, from a preliminary observation, resemble diatoms, particularly those that have been previously reported from the Morawan Formation. For biomarker analysis, the bone samples were first demineralized with 4 molar HCl, crushed to fine power, solvent extracted, and finally separated by silica gel column chromatography into saturated, aromatic, ketone, and polar fractions. All four fractions were analyzed using gas chromatography-mass spectrometry (GC-MS). The sediments constituting the surrounding matrices were also analyzed for comparison.

A methylphenanthrene index of 0.2 for the desmostylians indicated that the fossils had experienced a low level of thermal maturity. Phenanthrene was not detected for the whale bone, indicating even less maturity than the desmostylians. Cholestane, its isomer coprostane, cholestanone, and cholesterol were detected in the whale bone, while its higher homologues were absent, indicating that they are endogenous and possibly derived from the original bone cholesterol. The low maturity of the whale bone resulting in reduced diagenetic alteration could be an explanation for this greater level of biomolecular preservation. While cholesterol derivatives

were present in the desmostylians, C28 and C29 steroids were also observed, thus microbial origin cannot be ruled out. The steroid distributions for the surrounding sediments were different than the bone fossils. Notably, HBI thiophenes, which is a diatom biomarker, were observed in the sediment matrices. Thus, the C29 steroidal input in the desmostylians could potentially have a diatomaceous source, and further bolsters the supposition that the discrete microstructures observed in the thin sections could potentially be diatom fossils trapped within the bone cavities.

Multidirectional "shuttle dispersal" model and human origins

Xijun NI[1]*, Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences (nixijun@ivpp.ac.cn)
Chris Stringer[2], Natural History Museum, London

Abstract

Traditionally, it is postulated that there has been no speciation event since the origin of Homo erectus, and that all later human fossils should be included in Homo sapiens. As a result, H. sapiens has become a broad and vaguely defined species name. For a very long time, people have to use "archaic H. sapiens" to refer to Homo neanderthalensis, Homo heidelbergensis, and many Chibanian human fossils, such as Jebel Irhoud, Narmada, Dali, Jinniushan, Xujiayao, and so on. In recent years, more and more researchers have realized that Homo is a genus with quite a large number of species. More recent discoveries, such as Homo floresiensis, Homo antecessor, Homo luzonensis, Homo naledi, and Homo longi, have provided strong evidence that several independent species coexisted with H. sapiens during the Middle Pleistocene. Although the evolutionary relationships between these different Homo species are critical to understanding the origin of H. sapiens, they remain controversial. We developed a phenomic character data matrix containing 632 discrete and metric characters scored for 55 Homo species/populations, and used parsimony analysis and Bayesian tip-dating inference to reconstruct the Homo phylogeny and estimate the divergence time of all Homo clades. Our results suggest that H. sapiens and H. neanderthalensis are monophyletic groups that arose around 770 ka and 737 ka, respectively. Asian H. longi-like Homo, such as Dali, Hualongdong, Jinniushan, and Xiahe form another monophyletic group that diverged from the H. sapiens clade around 949 ka. H. neanderthalensis has traditionally been regarded as the sister group of H. sapiens, but our results showed that the Asian H. longi clade is the sister group of H. sapiens. Based on our newly established Homo phylogenetic tree, we tested 18 biogeographic models and estimated the number and type of biogeographic events. Our simulation suggests that instead of a unidirectional "out of Africa" model, a multidirectional "shuttle dispersal" model is more likely to explain the complex phylogenetic relationships among African and Eurasian Homo species/populations. The common ancestor of H. longi clade and H. sapiens dispersed from Africa to Eurasia between 949 ka and 917 ka. The common ancestor of H. sapiens and H. neanderthalensis dispersed from Europe to Africa between 1007 ka and 978 ka. H. sapiens dispersed from Africa into Eurasia between 490 ka and 416 ka. Africa provided more potential dispersals to other continents, while Asia received more potential dispersals from other continents. From this perspective, we propose that Africa is the "source" of evolution and biogeographic dispersal, while Asia is the "sink" of Homo evolution and dispersal.

Stromatoporoids from Upper Ordovician rocks of southern Kazakhstan and their palaeobiogeographical implications

Juwan JEON[1]*, Department of Earth and Environmental Sciences, Korea University, Seoul, 02841, Republic of Korea; The Institute of Basic Science, Korea University, Seoul, 02841, Republic of Korea (juwanjeon@korea.ac.kr)

Abstract

Stromatoporoids achieved their wide geographic distribution during the Katian of the Late Ordovician since their first appearance in the Early Ordovician. Their Ordovician diversity peaked in the same time interval, that coincides with the remarkable diversification of reef-builders during the later phase of the Great Ordovician Biodiversification Event. The Kazakh terranes, known for their rich assemblage of Ordovician fossils, have recently emerged as a focus for evolutionary studies, particularly concerning the early evolution and distribution of specific brachiopod groups. Despite their long-recognised presence in southern Kazakhstan, stromatoporoids have been given only limited attention in previous studies of Ordovician fossils, which have predominantly focused on major groups such as brachiopods and trilobites. In this study, we examine stromatoporoids from Upper Ordovician of southern Kazakhstan collected by some geologists between the 1950s and 1970s. A diverse stromatoporoid assemblage previously unknown from Kazakh terranes contains some new species and a few taxa with open nomenclatures. The majority of these stromatoporoids, such as Pseudostylodictyon poshanenese, Labechiella regularis, Thamnobeatricea gouldi, Camptodictyon amzassensis and Ecclimadictyon nestori, share characteristics with the Middle to Late Ordovician stromatoporoids of North China and Australian terranes of peri-Gondwana, confirming the palaeobiogeographic connection between the Kazakh terranes and peri-Gondwana. Furthermore, this assemblage is characterised by the presence of typical Laurentian and Baltic components, such as Stromatocerium and actinostromatid taxa respectively, which were not previously known outside the two continents. Thus the palaeobiogeographic characteristics of these stromatoporoids from southern Kazakhstan demonstrate multiple links between the Kazakh terranes, Baltica, Laurentia and Peri-Gondwana. During the Late Ordovician, the Kazakh terranes most likely acted as a dispersal hub for stromatoporoids, connecting faunas from other continents and terranes.

Abstract

Hong Kong is a heavily urbanized city with a long history of occupation. During its development, Hong Kong saw intense degradation of its coastal waters. Discharges of pollutants and activities such as dredging and land reclamation severely impacted the city's landscape and the subtidal communities. Nonetheless, little is known about Hong Kong's baseline pre-anthropogenic impact faunal conditions. In this context, organisms that produce calcareous structures, such as mollusks, provide a glimpse into past conditions and allow us to understand changes in the subtidal fauna due to anthropogenic impacts. Using Accelerator Mass Spectrometry (AMS) radiocarbon dating of dead shells of selected molluscan morphospecies from surface sediments around Hong Kong, we investigated possible changes in the subtidal community of Hong Kong. We collected shells by trawling in three subtidal regions of Hong Kong with different levels of impact: 1) West Hong Kong waters dominated by the Pearl River Delta; 2) South Hong Kong waters more influenced by oceanic waters; and 3) East Hong Kong in the historically polluted Tolo Harbor. Environmental data showed high eutrophication in the Pearl River Delta in western Hong Kong and heavy metal contamination in Tolo Harbour in eastern Hong Kong waters. Our analyses showed contrasting shell fauna composition in the three areas. The shell age analyses revealed that populational decline and possible local extinctions may have happened in certain mollusk species, such as in the species Placamen lamellatum, which lacks modern shells in Northwest Hong Kong, and Pecten excavatus, which has only pre-early 1900s shells in Tolo Harbor. Some baseline conditions species, such as Paratapes undulatus, have a continuous presence in Hong Kong waters. This species shows a mix of old and modern shells in west, south, and east Hong Kong waters. However, Paratapes undulatus may be undergoing a populational decline in areas where old shells dominate, such as in the Pearl River delta and the Tolo Harbor. In contrast, opportunistic species,

such as Murex trapa, Nassarius siquijorensis, and Turritella bacillum, have abundant numbers in modern impacted waters. Our results bring insights into past baseline conditions of Hong Kong subtidal fauna. Our shell age analyses show evidence that the environmental pollution and modification of Hong Kong's coastal landscape led to changes in its molluscan subtidal communities and possibly to the whole subtidal fauna in the city.

[Keynote] New record of the conifer wood taxon Brachyoxylon from the Middle Jurassic in southwestern China, and a global survey of paleobiogeography of the Mesozoic Brachyoxylon occurrences

Yongdong WANG[1]*, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences (ydwang@nigpas.ac.cn)

Abstract

Fossil wood is one of the most important proxies for terrestrial vegetation composition and continental paleogeographical reconstruction in Earth's history. The conifer wood Brachyoxylon is commonly found in Mesozoic deposits in Europe, Africa, South America, and Antarctica with more than one hundred known occurrences to date. However, only few occurrences (~5%) are so far documented in China of East Asia. We described a fossil wood from the Middle Jurassic Upper Shaximiao Formation at Yongxin of Chongqing City in southeastern Sichuan Basin, China, obtaining typical Brachyoxylon anatomy with mixed radial tracheid pitting and araucarioid cross-field pitting. According to the characters of radial tracheid pitting, cross-field pitting, and ray height, the wood is recognized as Brachyoxylon trautii (Barale) Philippe 1995. To better understand the paleobiogeography of the Mesozoic Brachyoxylon, a global survey of its occurrences is performed, which shows that Brachyoxylon was globally expanding over time with the widest geographic distribution in the Cretaceous.

The observed pattern indicates that Brachyoxylon has increased its distribution range throughout the Mesozoic, with a dominance of known records in the Northern Hemisphere. However, as previously discussed in the context of other plant-related paleogeographic patterns, i.e. the known occurrences of fossil charcoal as evidence for paleo-wildfires during the Cretaceous, such a pattern, with less data from the Southern Hemisphere, could also indicate some sampling or other researcher related bias. An observation hinting on such large scale biases is the relatively large number of published Cretaceous records from Argentina, a country with a comparatively large and active paleoxylological community. Further analysis of additional and so far understudied occurrences of fossil wood from the Mesozoic of, especially the Southern Hemisphere and other so far understudied regions, would certainly increase our understanding of the paleogeographic patterns observed in Brachyoxylon, but also other genera of fossil wood and plants in general.

Four endemic taxa of chondrichthyans from the Late Ladinian (Middle Triassic) of Guizhou and Yunnan Provinces, South China

Siyan ZHAO[1]*, School of Earth and Space Sciences, Peking University (2301210132@pku.edu.cn)
Zuoyu Sun[2], School of Earth and Space Sciences, Peking University
Jiachun Li[3], School of Earth and Space Sciences, Peking University

Abstract

The Middle Triassic chondrichthyans have predominantly been reported in Europe, whereas those from South China have been much less extensively studied, with only 20 taxa been identified or established based solely on teeth or dermal denticles before. We herein present a taxonomic study of four chondrichthyans based on isolated tooth fossils from the Late Ladinian (Middle Triassic) of Guizhou and Yunnan Provinces, South China. Teeth of an undetermined taxon of euselachian sharks (Euselachii gen. et sp. indet.), an undetermined taxon of Synechodontiform sharks (Synechodontiformes gen. et sp. indet.), an undetermined taxon probably belonging to the Neoselachii (Neoselachii? gen. et sp. indet.) as well as an undetermined taxon of neoselachian sharks (Neoselachii gen. et sp. indet.) are described and illustrated. The first three taxa are previously undescribed, while a tooth of Neoselachii gen. et sp. indet. had already been reported from the Ladinian/Carnian of Guanling City, Guizhou Province before this research. The feeding mechanism of these sharks is deduced through detailed analysis of the morphological characteristics of their teeth. Chondrichthyans from the Ladinian-Carnian intervals of South China are dominated by non-neoselachian sharks and almost devoid of durophagous euselachians as previously proposed. Such a high diverse shark assemblage is related with the Ladinian-Carnian transgression of South China, with many species apparently endemic to the shallow Yangtze Carbonate Platform.

New Umenocoleidae (Dictyoptera) from the Jinju Formation, South Korea

SooBin LEE[1]*, Korean Fossil Research Center (dinos20000@naver.com)
GiSoo Nam[2], Gongju National University of Education
André Nel[3], Institut de Systématique, Évolution, Biodiversité (ISYEB) Muséum National d'Histoire Naturelle, CNRS, Sorbonne Université, EPHE, Université des Antilles
Jong kyun Park[4], College of Ecology and Environmental Science, Kyungpook National University

Abstract

The Umenocoleidae family, first described by Chen and Tan in 1973, consists of 18 genera and 31 species. The fossil record of this family comprises taxa from China, Russia, Myanmar, Brazil, Japan, Jordan, Kazakhstan, Lebanon, Mongolia, the Russian Federation, Spain, and Hungary. This family was initially classified in Coleoptera, but a recent study by Luo et al., (2022) determined that it belongs to the Dictyoptera rather than the Coleoptera.

Here, we present three new fossil records of Umenocoleidae from the Jinju Formation on the Korean Peninsula, and attribute them to a new genus and three new species.

Our research revealed a new pattern of forewing venation, which includes: 1) veins M, Cu, and PCu1 fused at wing base, 2) M+Cu+PCu1 is appressed to R, and 3) distally CuP+PCu1 is not strongly concave. These characters were previously not described for the Umenocoleidae.
