Most damaging earthquakes are caused by the reactivation of pre-existing faults. Large earthquakes, typically those with magnitudes of MW 6.5 or higher, can lead to surface rupture. Surface ruptures associated with large earthquakes pose a significant risk to structures, infrastructure, and lifelines (such as roads, bridges, and pipelines), crossing or locating near active faults. For this reason, understanding the location and behavior of active faults is critical for seismic hazard assessment and for land use planning and engineering design for earthquake damage mitigation. The damages from surface rupture can be reduced or minimized by enforcement of regulatory building codes based on the safe distances or buffer zones from the surface ruptures. Regarding the issue of setback distance from active faults, although some countries have successively formulated relevant laws and regulations, accurate quantification of near-field deformation along earthquake surface ruptures is difficult due to the inherent complexity of the local geological and structural conditions as well as different building types. Detailed surface rupture data from several previous earthquakes were analyzed using fracPaQ (MATLAB toolbox). The analysis of surface ruptures from recent earthquakes showed that 98.1~88.1% of the total length of the surface rupture were not included in the minimum regulatory distance of the 15 m safety distance (safe distance keeping zone 1) defined by most countries, and 71.1~31.6% was not covered by the 200 m of zone 3 proposed by Hong (2021). These results indicate that the proposed safety distances by previous researchers do not adequately accommodate the surface ruptures generated by recent earthquakes. Because these distances are based on the traces of mapped active faults, the loss of life and property can increase exponentially if active faults are not properly surveyed. Therefore, detailed active fault survey and setting correct safety distance are the best way to effectively reduce the risk to the public from surface rupture damages during earthquakes.

This research was supported by a grant(2022-MOIS62-001(RS-2022-ND640011)) of National Disaster Risk Analysis and Management Technology in Earthquake funded by Ministry of Interior and Safety(MOIS, Korea).

The advantages of using a combination of ground, air, and space technologies for mitigating large landslides in Uzbekistan.

Rustam Aminovich Niyazov[1], Institute Hydroengeo, University of geological sciences
Abdulla Khasanovich Baratov[2]*, Institute Hydroengeo, University of geological sciences (abdulla0486@gmail.com)
Vali Khalikulovich Khidirov[3], State survey for monitoring hazardous geological processes

Abstract

The purpose of using a combination of ground, air, and space technologies to monitor landslides is to study trends in their distribution and collect data for early warning systems.

Various geodetic methods have been widely used for 35-45 years in Uzbekistan to measure surface crack development during ground observations in local stationary areas, totaling 150-160 cycles.

The process of landslides can be studied by analyzing satellite images. The boundaries of the affected area can be identified and recorded, providing a clear understanding of the extent of the landslide. By analyzing satellite images from past years, we can also map the history of the formation and development of the landslide process, including any repeated secondary landslides that have occurred over time.

Aerial surveillance using drones has become widely used in the past three years. This technology allows us to determine the main geometric parameters of landslides, such as their shape, area, main scarp zone in plan and depth, and lateral boundaries. By analyzing this information, we can determine whether the landslide was a one-time or multiple displacement, especially for larger landslides with a graben-shaped detachment zone. Furthermore, this technology can help us predict the further areal development of landslides due to vertical or horizontal movements.

Show the location, direction, and orientation of tension, compression, shear cracks, and extrusion zones on liquefaction landslides with massive development of multidirectional cracks.

When it comes to mudflows, it is important to record the boundary of the height of the flow, as well as whether there is a mass of soil inside. This information helps to determine the type of flow, whether it is laminar or turbulent. Additionally, it is necessary to map the formation features, location, height, shape of landslide blockages, and the presence of a dam lake.

In areas with historical landslides, new cracks and gullies are well documented to determine future landslide activity.

Generating plausible multifault ruptures with empirical rupture simulation

Timothy Austin STAHL[1]*, University of Canterbury (timothy.stahl@canterbury.ac.nz)
Ethan Walsh[2], PDP Nelson
Andy Howell[3], University of Canterbury
Thomas Robinson[4], University of Canterbury

Abstract

Multi-fault earthquakes present a challenge in seismic source models. Physics-based rules and simulations are invaluable for defining the various configurations of fault patches that may rupture together in single events. Historical surface rupturing earthquakes can also provide empirical constraints on plausible multi-segment and multi-fault earthquakes. We developed a numerical simulation that uses relationships derived from maps of historical surface ruptures to characterize different rupture pathways initiating on a seed fault. This 2D simulation uses step distance, number of steps, angular change, and kinematic change variables to compute a combined passing 'likelihood' for all considered fault section connections and subsequent active ends of the propagating rupture. Ruptures end when all possible active ends fail to pass to the next section and the next iteration begins. We applied this approach to a few seed faults and compared the results to independent constraints on paleoseismic magnitude, segmentation, and global estimates of rupture complexity. Rupture set characteristics change dramatically based on seed fault location and indicate that kilometer-scale structural discontinuities serve as barriers to rupture. Our preferred model reproduces total trace complexity of historical earthquake catalogues. This approach may be useful for filtering or weighting on-fault maximum magnitudes in earthquake rupture forecasts. Alternatively, it could be used a straightforward tool for estimating maximum magnitude scenarios.

Geo-engineering characteristics and performance analysis of the landslide mitigation measures implemented in the Rohingya camps in Bangladesh

Farhad HOSSAIN[1]*, University of Dhaka (farhad.geo@du.ac.bd)
A S M Maksud Kamal[2], University of Dhaka
Md. Zillur Rahman[3], University of Dhaka
Bayes Ahmed[4], University College London

Abstract

Landslides occur every year in the Chittagong Hill Tracts of Bangladesh and cause life and property damage, especially during the monsoon. Due to the ethnic and social cleansing in Myanmar, nearly a million Rohingya populations have fled to Bangladesh since 2017. They took shelter in an undulated topography and fragile lithological region – the Kutupalong Rohingya Camps (KRC). They raze forests and cut slopes for their shelters and food. Which immediately resulted in numerous landslides and killed many peoples in the monsoon. The KRC area is stratigraphically composed of upper cohesive soil and lower non-cohesive sandstone. They belong to the Pliocene to Pleistocene age DupiTila, Girujan clay, and Tipam Formations. The exposed slopes were relatively high (>15 m) and steep ranging from 40° - 70° which have numerous polygonal tension cracks and fissures. The landslides are mostly of slide and slump type and have multiple heads like stair-step morphology and have retrogressive failure modes. The upper residual soils have a bulk density of 1.49 - 1.97 g/cm3, liquid limit of 25 - 48%, plasticity index of 5 - 16%, and undrained shear strength of 23 – 46 kPa and show strain-softening behavior under stress. Whereas the lower sandstone unit has a bulk density of 1.44 - 1.94 g/cm3, an internal friction angle of 34° - 40°, and cohesion of 0.5 - 13 kPa. The mineralogical composition determined by the X-ray diffraction shows low clay mineral content, which does not seem to affect slope failure. The low shear strength of materials and strain-softening of upper soil facilitates landslides in the KRC area. The presence of a high permeable layer underlying the residual soil and tension cracks allows preferential water infiltration during rainfall which may also contribute to the landslide occurrence. The state of equilibrium determines by LEM and FEM simulations using the field shear strength parameters shows that under natural conditions i.e., without any overburden loads, slopes are stable. But slopes get unstable or critically stable when extra overburden loads are applied. Before the Rohingya settlement, there was no relict of landslides in the KRC area which in addition to the above-mentioned factors demonstrate that the large-scale anthropogenic interventions by the Rohingyas are the major cause of landslide occurrence. Numerous landslide mitigation measures (both structural and non-structural/nature-based solutions) were implemented in the KRC area to reduce landslide risk. The safety factor analysis of the slopes with mitigation measures shows that they give protection only to a marginal level and in some cases structural mitigation measures failure cause fatalities. Among the different mitigation measures based on LEM and FEM simulations and field observations, it is evident that concrete retaining walls are more effective in reducing landslides and slope reforestation controls

soil erosion. It is also observed that the cohesion and friction angle of lower sandstone and the cohesion of upper soil layers are crucial factors to be considered during designing any landslide mitigation measures in the KRC area.

Probabilistic Fault Displacement Hazard Analysis of a strategic dam in the Sansepolcro graben (Northern Apennines, Italy): methodologic implications for distributed faulting

Abstract

Earthquake surface faulting can be the source of hazard for critical infrastructure located close to the trace of a capable fault (near-fault conditions). Zonation and avoidance strategies are common practices during the design of new infrastructure, but this option can be not feasible for existing facilities. This issue can be addressed by Probabilistic Fault Displacement Hazard Analysis (PFDHA), assessing the likelihood of exceeding a certain level of displacement at the site of the infrastructure. The resulting hazard curves can help to choose the most appropriate mitigation strategies.

Since the early 2000s, several authors proposed different methodologies for different kinematic contexts. Particularly, empirical regressions have been proposed to assess the probability of occurrence and the probability of exceedance of certain values of displacement (for both Principal and Distributed faulting) starting from databases of coseismic ruptures of past earthquakes. Since the probability of exceeding a certain value of displacement at the site of interest also depends on the probability of occurrence of a surface faulting earthquake on a certain fault, the fault parameters and earthquake rates are needed to perform PFDHA.

We present the PFDHA of the Montedoglio dam located in the Sansepolcro graben (Northern Apennines of Italy), located 1.5 km off the trace of the principal active normal fault of the area, in the hanging wall: the Anghiari normal fault. After having verified the absence of surface faulting hazard due to a principal fault beneath the dam, we focused on the assessment of the distributed faulting hazard due to the Anghiari fault. To account for the epistemic uncertainties related to the high segmentation of the Anghiari fault, we considered different rupture scenarios, with fault parameters obtained from a paleoseisologic study. We obtained several hazard curves for the Montedoglio dam site, integrating different rupture scenarios and several empirical regressions available in the literature. The analysis has shown that the distributed faulting hazard at the site of the dam is very low. However, methodological issues raised from the application of the existing PFDHA models, such as the general poor constrain of empirical regressions for distributed faulting, for both the probability of occurrence and the expected displacement.

Landslide Prediction in Nepal Himalaya with a National-Scale Rainfall-Triggered Nowcast System

Ananta Man Singh Pradhan[1]*, Water Resources Research and Development Centre, Government of Nepal (anantageo@hotmail.com)
Hyuck-Jin Park[2], Department of Energy Resources and Geosystems Engineering, Sejong University
Suchita Shrestha[3], Department of Mines and Geology, Ministry of Industries and Supplies, Government of Nepal

Abstract

Landslides are becoming increasingly common in Nepal, and their incidence is expected to grow as precipitation patterns become more severe and road-building increases. This poses a significant threat to the lives and livelihoods of people in the region. In this study, we developed an integrated approach combining two modeling methods to predict the likelihood of landslide occurrences and develop a near-real-time warning system.

The first method involved using a probabilistic explainable artificial intelligence (XAi) approach that combines– random forest (RF) and extreme gradient boosting (XGB) - to predict the likelihood of landslide occurrences. The models incorporate multiple causative factors (CFs) and utilize data on geo-environmental factors related to landslide occurrence.

The second method involved developing a near-real-time landslide warning system by integrating the results of the landslide susceptibility modeling with decision tree-based selection criteria. To support the modeling procedures in this research, independent variables obtained from terrain analysis were included. Additionally, a global Landslide Hazard Assessment model for Situational Awareness (LHASA) was utilized to indicate where and when landslides may be likely in the study area.

The results showed that the ensemble model was more accurate than any individual model in predicting landslide occurrences. The accuracy of the model was 87%. The ensemble landslide susceptibility maps were classified using the natural break algorithm in the GIS platform.

A total of 69.72% of the area was categorized as having a very low susceptibility, 16.01% as low susceptible, 6.84% as moderate, 4.07% as high and the remaining 3.36% was considered to have very high susceptibility. About 81.51% of landslide data were located in the very-high-susceptibility class, demonstrating the reliability of the map.

The findings of this study could be used to improve landslide risk management in Nepal and other mountainous regions. The landslide warning system could help to save lives and livelihoods by providing early warnings of potential landslides.

Analysis of Landslide Hazard and Geoenvironmental Condition in Rangamati and adjoining areas of Chittagong-Rangamati National Highway Road, the South-Eastern Hilly Districts of Bangladesh

Lubna Yesmin KHONDAKAR[1]*, Geological Survey of Bangladesh (lubnayk@gmail.com)
Michel Jaboyedoff[2], University of Lausanne
Ivanna Penna[3], Ramboll Norway
Zillur Rahman[4], University of Dhaka

Abstract

Landslide hazards along the Chittagong-Rangamati National Highway Road and adjoining areas of the Rangamati district pose the highest challenges to development in the southeastern part of Bangladesh. On 13 June 2017, the area encountered extensive and dangerous landslides which caused 120 people to die and a huge loss of economy. The road was disconnected for one week so immediately after landslides and full damage at Sapchhari point in Chittagong-Rangamati National Highway Road. Hence it is crucial to identify the areas prone to landslides for appropriate risk management strategies. This study aims to investigate landslide location, mechanism, and geoenvironmental condition with experimental analysis of slope soils to map landslide hazard, vulnerability, and elements at risk assessment. 40 landslide locations are selected for fieldwork-based landslide inventory, collection of soil samples, and secondary data analysis. Google Earth images and the Geological Map of Bangladesh, GPS, and clinometers are used in the field to identify the landslide's location, geology, and slope angle. The displaced slope materials are mainly sand, silt, and clay. The elevation of the study area ranges from 0 to 483 m. Landslide susceptibility mapping is carried out by overlying the landslide inventory with factor maps such as geology, topographic wetness index, NDVI, land cover, road, drainage pattern, and aspect and slope using the weights of evidence (WoE) technique. The landslide susceptibility map is categorized into very low (6-37), low (37-59), moderate (59-86), and high (86-141). The landslide risk map is categorized into very low (6-50), low (50-120), moderate (120-220), and high (220-503). The assessment of the vulnerability (road and houses, element at risk) and risk map revealed that the Chittagong-Rangamati National Highway Road and surrounding areas represent low vulnerability and high risk for landslide hazards. Field observations revealed that most slope failures occurred in the residual soil and weathered silty sandstone. A total of 7 soil samples are tested using direct shear equipment. The laboratory determined that the moisture content of soil samples varies from 2.21 to 14.19%, with an average of 6.45%, respectively. The percentage of sand, silt, and clay-grained particles are 12-32%, 60-70%, and 6-21% respectively. The cohesion and friction angle results from the direct shear test range from 4.5 to 24 kPa and 31-39 degrees, respectively. Friction angles are found higher for sandy soils, but clayey soils represent higher cohesion values. The analysis shows that in addition to geotechnical factors, extreme rainfall in a short period and human interference are the main causes of landslide hazards, therefore it can be mitigated by proper geologic investigations and effective enforcement of land

use management regulations.

InSAR techniques and multi-risk assessment approach for monitoring Cultural heritage

Federica Ferrigno[1], ISPRA Geological Survey of Italy
Paolo Iannelli[2], Ministry of Culture
Gabriele Leoni[3], ISPRA Geological Survey of Italy
Francesco Menniti[4], ISPRA Geological Survey of Italy
Daniele SPIZZICHINO[5]*, ISPRA Geological Survey of Italy (daniele.spizzichino@isprambiente.it)

Abstract

The present work shows the results obtained in the framework of the first "National Plan for Monitoring and conservation of Italian Cultural Heritage" (NPMCH), it's aimed at the monitoring, conservation, and proactive protection of cultural heritage, threaten by different hazards, both anthropogenic and natural, including climate-induced extreme events.

The main target of this work was to develop a multi-risk assessment approach for the areas of interest, starting from a screening of the existing data and considering the peculiarities of the elements at risk, in terms of value of vulnerability, exposure, state of conservation, then the identification of all the possible relationships between the different geo-hazards and their interaction with the archaeological structures, has been carried out. The following phase predicted the use of Earth Observation data, and in specific the application of multi-temporal InSAR techniques, to detect the potential interaction between ground displacements and archaeological structures and to define potential unstable areas over the time, calculating anomalies and accelerations. Additionally, field surveys and integrated monitoring systems have been also planned and implemented.

Starting from this purpose, eight case studies have been selected among the national CH, from the north to the south of the Italian regions: the Port of Classe (Emilia Romagna) the Archaeological area of the Phlegrean Fields and the Archaeological Park of Paestum and Velia (Campania); Volterra and Pienza historical centres (Tuscany); Orvieto and Civita di Bagnoregio (Lazio) and the Villa Romana del Casale, Piazza Armerina (Sicily).

Depending on the sensor characteristics (e.g. spatial resolution, band, repeat cycles) SAR images acquired from different constellations (Cosmo-SkyMed and Sentinel-1A and 1B) have been processed using a D-InSAR approaches to obtain the spatial and temporal evolution of deformation induced by subsidence and slope instability phenomena. Based on ground and site conditions the existing algorithms built for the Permanent Scatterer (PS) and the Small Baseline (SB) approaches, have been exploited. As a result, we obtained: i) maps of the measurement points identified in the images and their spatial coordinates; ii) the average displacement velocity of each measurement points along the sensors Line Of Sight (LOS) (mm/year); iii) time series for each measurement points over the analysed interval time.

Focusing roughly on the period between 2016 and 2022, data processing has been performed using the Interferometric synthetic aperture radar Scientific Computing Environment (ISCE), the Stanford Method of Persistent Scatterers (StaMPS) and SARscape software. In the interferometric

processing has been used the SRTM 1 arc-second DEM, acquired with X and C-band radar system (resolution of 30m). Where available, local GNSS network data has been used to calibrate real rate of subsidence and displacement anomalies.
The main results of this study have highlighted the importance of the InSAR analysis providing very useful information to detect and monitor ground displacements and geo-hazards, thus offering to archaeological site managers a powerful tool for the prevention of ground related damage of cultural heritage. The anomalies shown up must be detailed in both spatial and temporal resolution to be correctly interpreted, validated and calibrated directly in situ

Abstract

Normal faults are common features in high mountain environments, and are often interpreted as the result of different process associated to deglaciation (upper crust-bottom valley uplift, glacial isostatic rebound, ..), isostatic recovery after long term-large scale erosion and adjustment to deep crustal and mantle changes. The Coronas normal fault (more than 11 km) is a prominent feature displacing the southern side of the Maladeta granitic massif (Central Pyrenees). It shows an accumulated vertical displacement reaching 155 ± 1 m. It's location fits with the epicentral area of the 1373 Ribagorçana earthquake (M ~ 6.2), one of the largest seismic events of the Iberian Peninsula historical record. Recently, the area has undergone a series of earthquakes starting in August 2023 with a maximum event of M 4.1. The driving forces of this seismic activity are now under discussion. Previous works interpreted the fault movement as part of a gravitational collapse of the massif towards the north. After two sampling campaigns in a mountain pass (Brecha de Llosás, 2850 m), we obtained the first chronological constrains of its exhumation history in a 50 m high scarp profile and using two different techniques to determine the exposure ages: the Schmidt Hammer (SH) technique, with three ages obtained from regional calibrated curves and SH onsite measurements, and 10Be cosmogenic technique, collecting and analyzing six samples taken along the scarp to obtain ages measured from quartz. We discuss the exposure history of the fault scarp in relation with the regional glacial chronology and possible driving faulting mechanisms.

Landslide Hazards and Forecast under Changing Climatic Patterns

Devesh WALIA[1]*, North-Eastern Hill University (deveshwalia.17@gmail.com)

Abstract

The study area is in the northern part of Ribhoi District, Meghalaya. Most of the area exhibits a rugged topography with high mountains and intermittent linear valleys. The area of study is selected on the basis of landslide zone close to road (NH 40) and the digging for the road has already undertaken decreasing the load from the toe area, which may increase the landslide incidences along NH 40, and disrupting the communication and supplies to Mizoram, Tripura and Lower Assam along with Meghalaya.

The study area is seismically active and displays high seismic activity, tilting and settlement of the river channel demarcated by trellis to sub- trellis drainage patterns, with low drainage density, low frequency and high bifurcation ratio. The circulatory ratio and form factor depict diversified slope, low discharge of runoff, high permeability of the subsoil and structurally controlled drainage system. The asymmetry factor also proves that watershed is under tilting and hence vulnerable to geohazard.

The FoS, maximum velocity vectors and respective contours of shear strain rate have been calculated for the vulnerable slopes by FLAC/Slope software.

The study indicates that landslides in the region would occur when the daily rainfall crosses 150 mm and three days antecedent rainfall (R3ad) exceeding 84 mm. These thresholds can be used as a predictive tool, but due care needs to be taken when used as an early warning system.

Citizen science in response to the climate crisis : focus on old building retrofit for low-income people

Jong-Won Lee[1]*, Korea Institute of Civil Engineering and Building Technology
(jongwonlee@kict.re.kr)

Abstract

In Korea, the issue of energy-poor households has gained urgency and prominence in recent years due to climate change and social problem-solving R&D issues such as heat waves and cold waves. Energy-poor households are vulnerable groups that are more exposed to natural disasters and suffer increased damages due to energy inequality but have less political influence, and the government is taking comprehensive measures. However, despite various welfare programs and policies related to energy-poor households, the lack of accurate survey statistics and systematic management remains the biggest policy and technical difficulty. Therefore, this study aims to propose a data accumulation plan that can provide fundamental and mid- to long-term solutions in terms of improving the living environment of energy-poor households. To this end, we interviewed stakeholders in energy poverty policy and business, investigated the necessary technologies, and prioritized the construction of a digital database and map of paper surveys. This was done with the participation of local citizens. We designed a survey questionnaire on the living conditions of energy-poor households and developed a data collection tool to digitize and collect paper surveys. In addition, we developed a start-up map platform that shows information on energy-poor households intuitively by linking survey responses to map data. The most challenging aspect of collecting this data was access to vulnerable populations. In general, it is difficult to know the location of vulnerable households' addresses, and the information on occupants is not known due to privacy issues. Therefore, this study devised a citizen science model based on the concept of crowdsourced data that allows citizens to directly participate in data collection related to energy and housing welfare. The photos of old windows collected through citizens are the dataset for AI training. By learning the collected window photos and extracting the insulation performance attribute information of the windows, supports a preliminary simple diagnosis to know the condition of the windows of the building displayed on the map. The aging building data platform developed through this research is a new approach that realizes the aging degree of buildings (especially windows) as online-based visual data, which is highly efficient in terms of time, cost, and manpower. It can be used to help prioritize the retrofitting of old buildings in energy-vulnerable neighborhoods across the country. In conclusion, this study presents a meaningful model and framework for engaging citizens in science to address the climate crisis.

Abstract

The magnitude and frequency of landslide disasters in Korea have escalated due to extreme rainfall patterns associated with climate change trends. Since 2000, the area damaged by landslides has doubled, and the annual average cost of recovery has surged to approximately 80 billion won. The records of lives lost to landslide disasters remain at a catastrophic level of severity. Notably, in 2023, human casualties from landslides exceeded 50, surpassing the toll of the historic and symbolic Umyeon mountain landslides in 2011. Against this backdrop, research aimed at developing advanced technologies for the prediction and mitigation of landslides is of critical importance. This paper introduces an initiative to develop and pilot a landslide early warning system in the city of Busan, in collaboration with local government officials. Furthermore, it discusses the installation and operation of a landslide monitoring system across 12 natural hillslopes within 8 national parks. Our strategies for mitigating landslides through the optimal design of debris barriers, based on numerical simulations, will be briefly addressed. Concurrently, the need for education on understanding, preparing for, and responding to landslide disasters is growing among students, officials responsible for landslide management, and the general public. In response to this need, three research institutes and universities from Norway, Korea, and Japan have embarked on an international collaborative project, known by the acronym GEOMME, supported financially by the Research Council of Norway. This paper will also highlight our ongoing experiences as participants in educating students and early-career researchers, as well as in engaging with public officials under the GEOMME project.

[Keynote] Geological risk assessment in Mexico City: The Interactive Observatory of Land Subsidence and Fracturing, OIHFRA

Dora Celia CARREON-FREYRE[1]*, UNAM (freyre@geociencias.unam.mx)
Raul Ivan Gutierrez-Calderon[2], Municipality of Iztapalapa
Mariano Cerca[3], UNAM
Carlos Felipe Alcantara-Duran[4], Municipality of Iztapalapa
Raul Basulto-Luviano[5], Municipality of Iztapalapa

Abstract

Land subsidence is a long-term studied phenomenon in Mexico City; however, the geological conditions, effects, and risks for urban infrastructure and inhabitants have been neglected. Damages in the short, medium, and long term imply maintenance and important mitigation costs. Over-exploitation of the aquifer has caused a continuous piezometric water level decline reaching about 80 m and up to 13 m of land subsidence in the central part of Mexico City during the last five decades. Consequently, the increasing intensity of the deformation has caused numerous problems to urban infrastructure, and estimations of damage are in the order of several thousands of millions of dollars. This represents a challenge for land and groundwater management in Mexico. Nowadays, there are no systematic studies that address methodologies for the estimation of the physical vulnerability of the geological media to deformation in Mexico City, one of the most populated cities in the world. Land subsidence in this fluvial-lacustrine basin and differential compaction of sediments and, volcanic materials associated with groundwater depletion have caused earth fissures, ground fracturing, and reactivation of regional faults. During more than 15 years of a collaborative work with the municipality of Iztapalapa, one of the most affected areas by ground ruptures in Mexico City, we integrated a multicriteria analysis to identify factors related with the generation of fractures using methods of characterization of geological materials and monitoring changes in their mechanical properties in time and space. The susceptibility to fracturing was analyzed using a deterministic approach. Fractures mapped and physical variables were integrated in a database for a proper correlation of the parameters that condition the spatial distribution of fractures. With the results the design of adequate monitoring systems were proposed aiming to the optimization of mitigation measures in the damaged sites. In 2022, with the support of a special call of the Mexican Council of Research (CONAHCYT) for the “Establishment of a network of universal access to scientific, technological and humanistic knowledge through art” was launched the Interactive Observatory of Land Subsidence and Fracturing, OIHFRA (Observatorio Interactivo de hundimiento y Fracturamiento) (https://oihfra.org/). The OIHFRA was created for the analysis of information and dissemination of the research results to the local and national communities of Mexico. Artistic and cultural activities are also encouraged as an outreach tool for water management, geological risk awareness and, for the improvement of local construction techniques. The spaces are advocated to: knowledge expansion through info-graphics; an interactive area with scale models for workshops addressed for primary and secondary students; scientific monitoring of deformation for the

generation of new data, to continue the research work and, an artistic gallery for temporary exhibitions of urban artistic expression related to geohazards. With the OIHFRA we seek to create a culture of adaptation to land subsidence and sustainable management of water and land use, to improve the resilience of the inhabitants of Iztapalapa and other affected areas in Mexico City.

[Keynote] The UNESCO Land Subsidence International Initiative (LaSII)

Dora Celia CARREON-FREYRE[1]*, UNAM (freyre@geociencias.unam.mx)
Pietro Teatini[2], University of Padua
Shujun Ye[3], University of Nanjing
Devin Galloway[4], USGS

Abstract

Society is facing many challenges related to the sustainable use of land and water resources that have been increasing in the last decades. The effects of climate change in terms of sea-level rise and variation in the distribution and timing of precipitation, runoff and recharge, are compounded by the increasing concentration of population in megacities. The UNESCO working group on Land Subsidence (LS) was created during the International Hydrological Decade, 1965-1974 when LS was first recognized as a globally prevalent phenomenon. The First International Symposium on Land Subsidence was organized in Tokio in 1969; since then, ten more international symposia have been convened through cooperation of UNESCO with the International Association of Hydrological Sciences (IAHS), and several other agencies and organizations. In the VIII Phase Strategic Plan (2014-2021) of the UNESCO Intergovernmental Hydrological Programme (IHP) that addressed Water Security, LS was considered as a major threat. Because of the strong anthropogenic component of the prevalent subsidence processes and significant local and regional impacts, the proposal to transform the working group in a UNESCO Initiative has been accepted during the IHP Intergovernmental Council of 2018. The LaSII is one of the IHP flagship initiatives in the IHP-IX Strategic Plan “Science for a Water Secure World in a Changing Environment” (Phase 2022-2029). LaSII enhances the scientific understanding and technical knowledge required to identify and characterize hazards related to natural and anthropogenic land-level lowering, and facilitates the international exchange of information regarding the design, implementation, and evaluation of risk assessments and mitigation measures. The main goals are to publish guidelines for the identification, investigation, development, and management of LS-related phenomena; to support capacity building in member countries to gain and advocate better understanding and handling of hazards, vulnerabilities and benefits involving LS; to raise awareness of decision makers and the general public of the importance of groundwater as a store of freshwater in order to encourage improved protection and sustainable exploitation of groundwater and, to strengthen capacity building and educational capabilities in urban water management aimed at relevant target groups, including decision makers, planners, and practitioners, with a special emphasis on developing countries and, to propose methodologies for establishing an inventory of subsiding areas in the world. Nowadays, over 150 areas of subsidence are known, some with as much subsidence as 10 m in countries such as Mexico, China, Indonesia and the United States. Many more areas of subsidence are likely to develop in the next few decades because of accelerated exploitation of natural resources to meet the demands of increasing population and industrial development in many developed countries of the world.

LaSII activities focus primarily on four main aspects: (1) LS due to groundwater resources overexploitation, (2) LS in coastal areas, related with sea-level rise, (3) LS related with earth fissures, ground fractures and fault reactivation and, (4) LS related with water security in urban areas (https://www.landsubsidence-unesco.org/).

Experience and challenges of popularizing sciences related to earthquake disasters in S. Korea

Jin-Hyuck CHOI[1]*, Korea Institute of Geoscience and Mineral Resources (cjh9521@kigam.re.kr)

Abstract

Korea is tectonically a slow-deforming yet active region and large earthquakes have a very long recurrence period as evidenced by no report of surface faulting earthquakes in historical periods. Geologic records of pre-historical earthquake surface ruptures are only evidence of large earthquakes in the past. In modern society, therefore, large earthquakes have been perceived not as a scientific phenomenon but as a terrifying disaster that cannot be prepared for. In 2016, an earthquake with a magnitude of Mw 5.5 (the largest event among the instrumental seismicity) occurred near the Yangsan Fault, one of the active faults in S. Korea, and earthquakes became a vague fear among the general public. Meanwhile, the possibility of a large earthquake in Korea was highlighted by the 2016 earthquake, and efforts were made to increase public understanding of earthquakes. In this presentation, I introduce the activities to popularize large earthquakes conducted by the Active Tectonics Research Center in KIGAM (Korea Institute of Geoscience and Mineral Resources) over the past years. Popularization activities are mainly classified into broadcasting (news, science talk shows, YouTube), article writings (newspapers, science magazines, newsletters), lectures (public/citizen lectures, college/high school student lectures), and exhibition and public relation (videos, exhibitions). Each research fields of our multidisciplinary investigation was used as an item for popularization, and we focus on communicate the case studies rather than simply conveying knowledge about earthquakes. Before the excavation investigation trench was restored, video of the investigation site was obtained, and exhibits were secured using epoxy from the trench wall and displayed in the lobby of the main building of the KIGAM and the Geological Museum. Kiosks were used for the exhibits so that the public could easily access explanations about the exhibits. As a result of these activities, it is felt that the public's perception of large earthquakes is gradually changing, but interest in large earthquakes is still not high in Korean society. Korea has a clear trend of ‘low frequency yet high risk’ of large earthquakes due to its lack of experience with large earthquakes in modern society and its industrialized cities and high population density. Therefore, earthquake preparedness and awareness training through systematic earthquake popularization activities are necessary.

Presenting the Outcome of Earthquake Prediction Spatial Probability Mapping Utilizing Explainable Artificial Intelligence in the Nepal Himalayas

Suchita SHRESTHA[1]*, Department of Mines and Geology, Government of Nepal (suchitashrestha@gmail.com)
Tae-Seob Kang[2], Division of Earth Environmental System Science, Pukyong National University, Busan 48513, Republic of Korea
Ananta Man Singh Pradhan[3], Water Resources Research and Development Centre, Government of Nepal
Hyun Jae Yoo[4], dInstitute of Environmental Geoscience, Pukyong National University, Busan 48513, Republic of Korea

Abstract

Earthquakes present significant risks to urban areas due to their destructive potential. Recent research suggests that integrating specific variables, such as elevation, topographic position index, magnitude density, depth, fault densities, fault proximity, and tectonic zones, into artificial intelligence (AI) models can notably improve the accuracy of earthquake probability mapping. However, the opaque nature of AI models raises concerns about their interpretability. This study investigates the application of explainable AI models in earthquake probability mapping to address this issue. Utilizing Shapley additive explanation (SHAP), the study predicts earthquake probabilities using two distinct machine-learning techniques: random forest (RF) and extreme gradient boosting (XGB). This approach facilitates a hierarchical understanding of the model's predictions, elucidating the influence of each predictor on the final outcomes. A comparative analysis of RF and XGB algorithms is conducted to evaluate the significance and impact of driving factors. Subsequently, SHAP is employed to interpret the results of earthquake probability models. In the context of earthquake probability assessment for Nepal, seven factors are considered for SHAP analysis. The resulting models achieve overall accuracies of 79% for RF and 76% for XGB, demonstrating the effectiveness of SHAP in refining earthquake probability mapping for Nepal. This study contributes to the advancement of earthquake risk assessment by enhancing model interpretability and providing insights into the factors influencing earthquake probabilities. Moreover, it underscores the importance of transparent AI methodologies in improving decision-making processes related to natural hazard mitigation and urban planning.

SINKHOLES AND UNDERGROUND WATER FLOW AS A RESULT OF PROLONGED RAINFAL; THE CASE OF SAKATA, CHOWE, AND ZOMBA IN SOUTHERN MALAWI

Joseph Martin CHIRWA[1]*, Department of Mines (chirwajoseph5@gmail.com)
Steve Gondwe[2], Malawi University of Science and Technology (MUST)

Abstract

Malawi, located in Southern Africa, has experienced above-average rainfall multiple times, leading to geohazards such as sinkholes, ground noise, floods, and mudslides. Geologically, Malawi is situated within the seismically active East African Rift System (EARS). The heavy rainfall from tropical Cyclone Idai in 2019 *and Cyclone Freddy in* 2023 *caused significant flooding and other geohazards in southern Africa, including Malawi, resulting in extensive damage and loss of lives. The country has seen above-average rainfall in* 2015, 2019, *and* 2023, *triggering geohazards like underground water flow, especially after the rainy season. Reports of unusual ground noise have surfaced across Malawi, particularly between March and May, with sinkholes posing a significant geohazard and generating peculiar noises, leading to public discomfort and infrastructure damage. This study utilized existing literature, case studies of geohazards in the Zomba and Machinga areas, field visits and random interviews with community members in the affected areas. Understanding the geological context and identifying potential causes of underground noise are crucial in addressing sinkhole occurrences. In areas like Sakata, where clay soil impedes water flow, sinkholes form through pore spaces in ant-hills. In Zomba central, continuous rainfall resulted in erosion and the formation of a sinkhole with vigorous water flow and noise. The geological settings vary in different regions, with Zomba characterized by basement rocks of Charnokitic gneiss and granulite, while Chowe is underlain by Precambrian gneisses intruded by alkaline rocks. Investigations into underground water flow and associated sounds in Chowe indicated that the high-pressure water belt was a result of prolonged heavy rainfall caused by a low-pressure air belt over Mozambique for approximately four days. Unlike sinkholes reported in parts of South Africa, where they are associated with dolomitic rocks and karst weathering, preliminary investigations linked sinkholes not to carbonate rocks but to certain clayey soils.*

Recent landslides of liquefaction in Uzbekistan triggered by resonant frequency oscillations during deep strong Pamir-Hindu Kush earthquakes

Rustam Niyazov[1], Institute of hydrogeology and engineering geology
Bakhtier Nurtaev[2], Institute of geology and geophysics
Mansurjon Makhmudjanovich TASHPULATOV[3]*, Uzbekhydrogeology (mansur.uzbek@mail.ru)

Abstract

Between 2009 and 2023, a total of 93 cases of liquefaction landslides were recorded in Uzbekistan, with an annual frequency ranging from 1 to 22. The Pamir-Hindu Kush zone of deep earthquakes is a permanent seismic source. Here in the central part of the continent, within a fairly small area (about 60-70 km2), there is an extremely high level of seismicity at depths ranging from 70-300 km. The frequency of occurrence of deep strong low frequency Pamir-Hindu Kush earthquakes with M > 4 in the spring season is approximately 35-45 events. Years with increased snowfall and rain, particularly in February and March, are associated with the highest number of landslides caused by these earthquakes (ranging from 22 to 10 cases per year). Landslides can occur simultaneously in multiple locations hundreds of kilometers apart. In average and low-water years, the frequency of landslides ranges from 4-6 to 1-2 cases. At the same time, during strong earthquakes that occurred in dry summer and autumn, the liquefaction landslides were not recorded at all. So the moisture content of loess and sandy-clay rocks is the key factor in the formation of mass movements caused by seismic vibrations.

Using digital seismic station CMG-6TD we determined frequency fluctuations, the horizontal to vertical spectra ratio (HVSR), and the dynamic liquefaction coefficient (Kg). As a result, the dominant oscillation frequency at many landslide points was from 1.5 to 2.5 Hz, the ratio of horizontal to vertical spectra was from 5.2 to 6.8, and the dynamic liquefaction coefficient Kg was from 15 to 35.

Depending on the geological structure, depth, scale, and development mechanism, liquefaction landslides are divided into quicksand and thixotropic liquefaction landslides, where the shape of the sliding surface is different. Quicksand liquefaction landslides happen when seismic waves cause compression in the slope due to the resonance effect, leading to groundwater movement acceleration. As a result, tension occurs in the upper zone of the slope, forming a graben-like main scarp. A wider distribution characterized thixotropic liquefaction landslides. Loess-sandy formations on flat watershed surfaces are often distributed and repeated as secondary landslides. Strong fragmentation, a system of different orientations of tension, shear, compression, and extrusion cracks characterizes them. Horizontal movement of the landslide occurs over the entire area of the landslide at a uniform distance of up to 20-25 m, and vertical movement up to 2-3 m. The main scarp zone does not have a clear circus shape. The key feature of this type of landslide is to repeat and expand. These findings may contribute to a more comprehensive understanding of the earthquake-triggering landslide mechanism and are significant for long-term landslide risk assessment in seismically active areas.

Geohazards and Risk Reduction Framework in India

VINOD KUMAR SHARMA[1]*, Geological Survey of India (vksharma_gsi@yahoo.co.in)

Abstract

Geohazards present threats to life and livelihood throughout the world ranging from minor disruptions to catastrophes. These are censorious geological conditions that can cause significant harm to life, property, and infrastructure and inflict colossal loss on the economy. Geohazards may be the result of slow and continuous geological and geodynamic processes or sudden or quickly developing phenomena viz. avalanches, landslides, earthquakes, and earthquake-triggered phenomena such as tsunamis, glacial lake outburst floods, and liquefaction, etc.

The geological, physiographic, geographical, seismotectonic, and population density in India is conducive to multitudes of hazards of varying dimensions. India has the highest mountain chain on earth, the Himalayas, which are formed due to the collision of Indian and Eurasian plates which causes continuous stress building in rock resulting in landslides and earthquakes of varying proportions. The Himalayan collision zone, which has the potential for massive earthquakes, is particularly vulnerable to seismic hazards, the other regions are the Kutch, the Andaman and Nicobar Islands, and the northeastern region together covering over 59% of India's land mass to moderate to severe seismic hazard.

Landslides and avalanches are among the major hydro-geological hazards that affect large parts of India that cover the Himalayas, the Northeastern hill ranges, the Western Ghats, the Nilgiris, the Eastern Ghats, and the plateau region, covering about 15 % of the landmass. Glacial Lake Outburst Floods (GLOFs) events, recognized as climatological disasters in the Himalayan are increasing due to global warming phenomena causing rapid deglaciation.

The risk reduction strategies of geohazards involve understanding the causative factors, and repercussions of these hazards, and implementing mitigation and prevention strategies. Geohazards are often unpredictable and have potentially damaging consequences. Climate change due to the global warming scenario has also been found to have a link with some geo-hazards. A spatial and temporal analysis of the threat of geohazards is difficult to determine accurately because of variable factors responsible for their occurrences and areas exposed to their risk. However, by employing strategies such as the development of policy framework, guidelines, preparedness, and mitigation of the hazards in specific geological domains, their impacts can be substantially reduced. Improving environmental, structural, and community resilience at the local, regional, and national scale calls for a novel risk reduction strategy.

India, being a signatory to the Sendai Framework for Disaster Risk Reduction 2015-2030, has a comprehensive framework for geohazards risk reduction. The policy framework (Disaster

Management Act,2005) and national policy on disaster management (2009) focus on promoting a culture of disaster prevention, mitigation, and preparedness in continuous mode. Geohazard preparedness includes spatial mapping of hazard-prone zones on a progressively larger scale. The temporal prediction for critical hazards includes an Early Warning System (EWS), which incorporates continuous observation of potential hazards.

Identifying and mapping high-risk areas, quantifying the hazard and the risk, and implementing structural, non-structural, and nature-based solutions for risk mitigation measures, including early warning systems, community preparedness, public awareness campaigns, etc. may address the impact of geohazards.

Man-Induced Landslides in Uzbekistan: Overview and Case Studies

Gany BIMURZAEV[1]*, Uzbekhydrogeology, Ministry of Mining Industry and Geology of the Republic of Uzbekistan (gany82@mail.ru)
Bakhtier Nurtaev[2], Institute of geology and geophysics
Azam Kadirhodjaev[3], Ministry of Mining industry and Geology of Uzbekistan

Abstract

Landslides are considered one of the most dangerous geological processes. In Uzbekistan, they cover an area of 17-21 thousand km^2, which is approximately 22% of the mountainous regions. More than 2,000 landslide areas identified in Uzbekistan, where over 12,000 displacements have occurred in the past 60 years.

An analysis of landslide processes since 1990 has shown that approximately 7,900 cases occurred in Uzbekistan. The number of landslides varies depending on various factors, with the highest number of occurrences ranging from 103 (in 2022) to 630 (in 2005) per year. The most active landslide processes occur in the mountainous regions of Tashkent (3,640 or 45.6%), Kashkadarya (1,604 or 20%), and Surkhandarya (1,438 or 18%) regions of the country.

This study aims to identify the triggers of landslide formation and assess the impact of man-induced factors on mitigating the risks of landslides on human activities. The effect of human activities on landslides is varied and widespread, mainly observed in mining areas, construction and operation of reservoirs, and intensive use of linear structures such as roads and railways. As a result of extensive construction in the foothill zones, landslides have been activated in these areas.

In the mountainous and foothill regions of Uzbekistan, there are mountain reservoirs for energy and irrigation purposes with a capacity of 150 million m3 to 2 billion m3.

Based on the results of long-term observations of the Verkhne-Turksky landslide, a pattern in the mechanism of landslide development was revealed. This landslide has a volume of 20.0 million m3 and is located on the left bank of the Akhangaran reservoir. The dynamics of the landslide process show a certain cyclicity, which corresponds to the level regime of the reservoir. It is associated with the fragmentation of the landslide mass at a generation where, due to a decrease in volume, the displacement rate increases. This type of landslide movement reaches critical movement speeds of 18-24 mm/day. The recommended approach for studying similar landslides during the operation of hydraulic structures is to use the mechanism of long-term development influenced by a reservoir.

Linear structures are often built by cutting slopes and this is usually done along ancient landslide areas. This can lead to the exposure of groundwater movement (unloading) or flooding of areas. Research over the years has shown that the proportion of landslides caused by the construction and operation of linear structures has been increasing annually. Between 1990-2000, their share was 17% of the total volume of landslides, while in 2001-2010 it increased to 32.1%. In the period between 2011-2020, it rose even further to 44.4%. At present, manifestations account for 50% of the total volume.

The intensive use of highways facilitates the formation and activation of landslide processes. On the Tashkent-Osh highway, where the daily traffic flow is 35,000 vehicles (including heavy vehicles) and the railway runs parallel, the vibration effect coincides with frequency fluctuations, leading to thixotropic processes in moistened rocks. Additionally, landslides occur most commonly in areas where linear structures intersect with tectonic disturbances.

Characters of Landslides Development in Arid Areas, Assessment and Trends

Azam Kadirhodjaev[1], Ministry of Mining industry and Geology of Uzbekistan
Gany BIMURZAEV[2]*, Uzbekhydrogeology, Ministry of Mining Industry and Geology of the Republic of Uzbekistan (gany82@mail.ru)
Bahodirjon Tulyaganov[3], Institute of hydrogeology and engineering geology

Abstract

The study of landslides in the aspects of geological-engineering service in Uzbekistan take place one of the key subjects, since exogenous geological processes are widely developed and observed in the mountain and foothill areas in the country. Every year, on average, more than 200 landslides occur, that resulted significant damage to various economic and social impacts.

This work analyzes the character of landslide occurrence for the period 1990-2023, and also examines the main factors influencing the activation of landslide processes. It was noted that in Uzbekistan about 7,989 landslide processes have been occurred since 1990.

Based on the results of the analysis (1990-2023), it was shown that the degree of landslide activity is distributed as follows: Low degree of landslide activity 15% (5 years); Medium degree of landslide activity 58% (20 years); High degree of landslide activity 15% (5 years); Catastrophic degree of landslide activity 12% (4 years).

The activity of the year is primarily associated with abnormal changes in climatic conditions (rain fall, precipitation, temperature, etc.) and man-made impacts.

In contrast, analysis for the period 1990-2000 years showed that there is a large change in the amount of precipitation between years - annual precipitation varied from 371-419 to 831-859 mm during this period and the 2,809 landslides have been occurred.

The next decade (period 2001-2010) is characterized by stabilization of precipitation, but an increase in the number of days with heavy precipitation - annual precipitation varied from 445 to 736 mm and during this decade the occurrence of landslides increased to 3,148.

Since 2011-up to 2023, precipitation has been recorded from 627 up to 501 mm, respectively, the number of landslides during this period is 1,496 manifestations.

Based on the analysis and assessment of the results of long-term monitoring of landslide processes, the authors developed a classification for the quantitative assessment of landslide activity of the year.

A coefficient of the degree of landslide activity has been established, where it is noted that at low degree (at Kak ≤ 1.0), medium degree (Kak from 1.1 to 3.0) and high degree of activity of landslide processes (Kak from 3.1 to 5.0) The State Tracking Service operates in high alert mode (around the clock), when there is a deterioration in the hydrometeorological situation, the onset of sharp fluctuations in temperature, precipitation, and rising groundwater levels. During this period, the main tasks are to strengthen observations and multi-stage monitoring of the condition of landslide-dangerous areas.

In case of catastrophic activity of processes (over 5.0), the State Tracking Service operates in emergency mode (around the clock). During this period (the occurrence and elimination of emergencies due to landslides, resulting in the death of people, the destructing /disturbing of economic facilities and communications), the main tasks are to issue recommendations to prevent additional casualties, new destruction of residential buildings and engineering structures.

The Kumalu catchment area, Bulolo District, Morobe Province, Papua New Guinea: Some findings and conclusions about the floods and landslides since 1950s

Shekinah Pilamp[1]*, Mineral Resources Authority (spilamp@mra.gov.pg)
Joseph Onglo Espi[2], University of Papua New Guinea

Abstract

Kumalu, in Morobe Province of Papua New Guinea, has been a region of flooding-and-landslide for more than 70 years that has impacted government infrastructure and human lives. A comprehensive study was undertaken to understand the history of the flooding-and-landslide and their social impacts. Data was collected through geological field mapping, use of remote sensing data, and slope analysis using DEM.

Through interpretation of these datasets, it was observed that the initial flow direction of Kumalu River was towards the north from its present location closer to the boundary with the northern ridgeline. The flow direction started to change when the landslides and floods started in the 1950's. There was evidence that an older similar event likely occurred based on field observations of older Quaternary sediments that were consolidated, and chaotically deposited, with absence of gradational deposition comparable to the recent flood deposits.

Landsat images showed that the river course migrated from the north to the south within the floodplain from 2000 to 2005. This movement was influenced by overbank deposits. As the river flowed near the northern ridge, sediment build-up began to increase. Perennial floods-and-landslides within these years also deposited large volumes of overbank sediments that built a levee on the northern side of the riverbank which created a natural buffer that pushed the water back south. This may have repeated several times diverting the river channel until the new south river channel formed. This process was repeated between 2005 to 2008, but this time, the overbank flood sediments created a levee on the south riverbank which pushed back the channel to the center of the floodplain. From 2008 to the present, the river course has been widening and thinning with minor changes in the course of the river within the center of the floodplain.

In 2005, the Mumeng government station was destroyed by a major flooding-and-landslide event. Statistics of infrastructure destroyed indicated that two villages were completely wiped out, three villages were partially affected, fifty-six houses, both local and government buildings were washed away, two bridges, one aid post, one primary school, two coffee plantations were washed away, and four lives lost that were recorded of. This data does not account for houses built after 1978 and up to 2005. The more recent events of flooding and landslides occurred in 2010, 2012, 2016, and 2019 with more sediment added to the flood plains.

Structural mapping indicated active fault shears are grinding into the metasedimentary rocks creating regions of areas prone to mass wasting along the steep slopes of the river upstream. Satellite imagery confirms cracks and scarp in the headwaters of Kumalu. The dynamic brittle deformation within the metasedimentary rocks with pre-existing planes of weakness along

foliations coupled with steep slope angles of over 70°, steep gradient of the river, and rainfall average of 2529 mm in wet seasons of November to March are highly in favor of mass wasting. This study has concluded that there is a possibility of another major destructive event in the near future.

Geological Survey Ireland, managing geohazards in a safe country, landslides, groundwater flooding and coastal change.

Koen M VERBRUGGEN[1]*, GEOLOGICAL SURVEY IRELAND (koen.verbruggen@gsi.ie)
Ted McCormack[2], GEOLOGICAL SURVEY IRELAND
Charise McKeon[3], GEOLOGICAL SURVEY IRELAND
Xavier Monteys[4], GEOLOGICAL SURVEY IRELAND
Silvia Caloca-Casado[5], GEOLOGICAL SURVEY IRELAND
Sophie O'Connor[6], GEOLOGICAL SURVEY IRELAND

Abstract

Geological Survey Ireland is a division of the Irish government Department of Environment, Climate and Communications, and has typical origins as a geological survey founded to map the nation's natural resources, in the 19th century. In recent years it has changed focus from more traditional geological mapping activities and methods to carrying out major projects of national societal value, supporting and developing policy initiatives, many of which also support the management of geohazards. While there are no major geohazards such as earthquakes or volcanoes, Ireland's geohazards include landslides, flooding, and coastal erosion. Landslides in upland areas have caused considerable damage to property and loss of life in historical times and are mainly related to failures of peat-rich water logged soils in upland areas. After two particularly damaging landslides in 2003, Geological Survey Ireland set up a Landslides Programme which has completed a National Landslide Database and subsequently developed National Landslide Susceptibility Mapping. This is now a dataset that must be consulted in all planning of upland Windfarms under national regulations. Groundwater Flooding after particularly wet winters in 2015/16 resulted in extensive groundwater flooding of seasonal lakes, called turloughs, that are common in Irelands lowlands that are underlain by Missisipian age karstified limestones. In response to this Geological Survey Ireland set up a Groundwater Flood/Climate Programme to better understand the issue and provide baseline data for the Local and National Authorities responsible for flood relief and safety. A methodology was developed to map the turloughs using satellite radar data, from the EU Copernicus Programme, in collaboration with third level researchers. This data was then validated through the development of a groundwater monitoring network which provides real time water levels which are then available online to relevant authorities. The combination of flood extent mapping with water levels and rainfall data allowed stage models to be developed both measuring and predicting the behaviour of individual turloughs. More recent work is focussed on modelling future groundwater availability and levels related to climate change models of rainfall changes. Coastal change, in particular coastal erosion, is a particular problem on much of Ireland's coastline, particularly where soft and/or low lying coastlines combine with strong coastal storms. Geological Survey Ireland have developed a Coastal Change Programme to develop data on the issue and in particular, to map coastal change from remotely sensed data and combine this with modelled Coastal Vulnerability Index (CVI). The CVI methodology has been refined in-house in collaboration with third level researchers and

draws on a range of inputs to provide guidance on the susceptibility of different sections of the coastline to erosion in particular. In all cases in relation to these geohazards there was a lack of the fundamental geoscience data required to understand occurrence and behaviour, which hampered the ability of authorities to deal with the issues. Geological Survey Ireland has therefore developed programmes to gather relevant geoscience data and develop models to help understand these issues and ultimately inform decision making and support

Abstract

Heavy rainfall events due to typhoons during Taiwan's monsoon season frequently trigger large-scale landslides, causing significant loss of life and property damage. Following the devastating Typhoon Morakot in 2009, the Geological Survey and Mining Management Agency (GSMMA) identified over 2,500 potential large-scale landslides across the island. However, existing classification methods lacked practical application due to limitations in standardization.

To address this challenge, this study presented a novel two-level classification and grading system for large-scale landslides in Taiwan. It leveraged methods from both the Japan Landslide Society and the Geological Survey of Norway (NGU). The Level 1 Landslide Topographic Feature Grading Form (LTFGF) incorporated the Analytic Hierarchy Process Theory (AHP) from Japan, assigning quantitative scores based on a landslide's location, developmental stage, and activity level. The Level 2 Potential Large-Scale Landslide Hazard Assessment Form (PLHAF) built upon the Norwegian approach, further classifying landslides by their mechanism (gravitational slope deformation, rotational slide, planar slide, or thick colluvium) based on specific characteristics and on-site monitoring data.

This new system was successfully applied to approximately 650 potential landslide sites using the LTFGF form. The combined LTFGF and PLHAF system was expected to provide a more comprehensive and nuanced understanding of potential large-scale landslide hazards, ultimately aiding in improved risk assessment and mitigation strategies.

Assessing the influence of geological structures and lineaments on the landslides in KwaZulu-Natal Province, South Africa: A case study on the Sangwana Mountain landslide

MAWANDE NCUME[1]*, COUNCIL FOR GEOSCIENCE (deyimawa@gmail.com)

Abstract

Landslides are devastating natural hazards which can cause damage to infrastructure and may lead to human fatalities. Intense rainfall events that triggered landslide phenomena, occurred early–mid December 2019 and in April 2022, in the Ndwedwe and eThekwini municipal regions, KwaZulu-Natal Province, respectively. The December 2019 Sangwana Mountain landslide, which is the largest (~15414 m2) in the Ndwedwe municipal region, produced debris flow runout that extended ~215 m downslope and endangered dwellings and a primary school. This terrifying event alarmed the surrounding communities and the Provincial Disaster Management authorities. In addition to this, the April 2022 landslide events in the eThekwini municipal region, which led to ~448 fatalities and ~1.9 billion worth of damage to infrastructure, alarmed the entire country. The Council for Geoscience (CGS), South Africa, commenced investigative research on the predisposing factors and their influence on these landslide events. This ongoing, regional multidisciplinary research on landslides forms part of the CGS National Geohazards Mapping Programme. This study aimed at assessing the influence of geological structures and lineaments on landslide occurrences within the eThekwini municipal region and to conduct kinematic analysis on the Sangwana landslide.

The methodologies employed included the utilisation of available geological and structural data including fracture and bedding plane measurements, field observations, kinematic analysis using the Dips 8.0 software, visual interpretation and digitisation of lineaments based on remote sensing and medium-resolution aeromagnetic data. Lineament density and Euclidean distance maps were created using ArcGIS 10.4.1 software, and the landslide site localities were overlain on the created map for ease of interpretation.

The Natal-Metamorphic Province gneisses and granites and Natal Group sandstones characterise the study region. Geological fractures and discontinuities, representing zones of weakness in which the strength and stability of the rock masses have reduced, are identified as factors inducing rock slope failures and deep-seated landslides. These geological features are more susceptible to weathering and contribute to rock mass strength reduction due to preferred stress accumulation. The weakened rock mass and residual soils from increased degree of bedrock weathering are prone to landsliding. The Sangwana landslide and slope failure occurrences in the eThekwini municipal region appear to be influenced by geological fractures, bedding planes and lineaments. Field mapping suggests that the Sangwana landslide is most-likely structural-controlled. Kinematic analysis using the Dips software suggests that the Sangwana landslide classifies as a

block-flexure topple failure, which agrees with our field observations. The findings of this study suggest that geological fractures, lineaments and bedding planes play a major role in landslide initiation. Comparisons between landslide distribution (1554) and lineament density and distance maps, for the eThekwini municipal region, reveal that 95% of landslides occurred in high and moderate density areas and are in proximity to fractures and lineaments (0–200 m range). The kinematic analysis method for the Sangwana landslide can be applied to other structural-controlled landslides in the province, especially to better understand stress dynamics. These data may be utilised to identify landslide-prone areas, which will aid infrastructure development and disaster management planning at local and national levels.

Abstract

On the 2011 off the Pacific Coast of Tohoku Earthquake, liquefaction-fluidization damage with land subsidence was observed in patches on the northern part of the Tokyo bay reclaimed land. In some of the damaged areas, the land continues to subside even though more than 12 years have passed. In order to clarify the cause of these, we investigated the geological characteristics by continuous borings and dynamic corn penetration tests.

Almost of the Tokyo bay reclaimed land were filled by the sand pump system from the mid-1960s to the mid-1980sThe reclamation material was supplied by dredging alluvial and shallow-marine late Pleistocene strata on the sea bottom of adjacent the Tokyo bay. As a result of observation of continuous boring core samples, the reclaimed layers, where are human made strata, are composed of shell fragment layer, shelly sand layer, sand layer and mud layer. And most of the parts that were liquefied and fluidized by the earthquake were the sand layer. In addition, the following common hydrogeological structures were observed in areas where the land continues to subside.

1. The thickness of the reclaimed layer is over 8m.
2. Thick impermerble mud layers, where are well continuous laterally, are interbedded in the upper part of the reclaimed layer. And the lower part of the reclaimed layer is composed of extremely loose liquefaction-fluidization massive sand layers.

Due to these characteristics, during an earthquake, the sand layer in the lower half of this reclaimed layer liquefied and fluidized, but it was unable to break through the mud layer in the upper half of the reclaimed layer and erupt to the surface. The liquefied-fluidized sand layer did not rapidly dehydrates and compact and remains extremely loose. It is assumed that the water in the liquefied loose sand layer continues to sink over a long period of time because dehydration progresses slowly through the overlying impermeable mud layer. When using reclaimed land, it is important to consider these hydrogeological characteristics and perform ground improvement in advance.

How do overpressure-driven hydrofractures grow in sedimentary basins?

Qing WANG[1]*, China University of Geosciences (qingwang@cug.edu.cn)
Qiliang Sun[2], China University of Geosciences
Kehua You[3], University of Texas at Austin
Martino Foschi[4], University of Oxford

Abstract

Overpressure-driven hydrofracture zones are pipe-like structures and widespreadly develop in sedimentary basins worldwide. They have the ability to penetrate vertically for multiple kilometers, acting as pathways for fluid on the basin scale. When the hydrofracture zone penetrates the near-seafloor, it can infuse the upper strata (transition layer) with a substantial quantity of overpressured fluid, leading to seabed liquefaction potentially. Similarly, if the hydrofracture zone breaches the seabed, it has the potential to destabilize the sediment, triggering the shallow gas eruptions. All these geological processes could cause submarine landslides potentially. Despite extensive research on hydrofracture zones, the mechanisms of their formation and evolution are still poorly understood. In this study, the hydrofracture zones are explored by numerical models constrained by well log data and seismic data in the South China Sea. Drawing upon the stress condition and the fracture pattern within the study area, we've deduced the critical pore fluid pressure and developed the coupled fluid-geomechanical fracture model. Then the multiple linear regression is used to analyse the factors influencing hydrofracture zone growth. We find that the formation of hydrofracture zone is mainly controlled by rock density, bottom overpressure, Poisson's ratio, and radius of hydrofracture zone at its origin. Moreover, there is always a pressure transition layer between the hydrofracture zone and the overlying hydrostatic pressure zone. The thickness of this layer depends on strata permeability, strata thickness, and pressure within the hydrofracture zone. What's more, hydrofracture zones can continuously act as fluid pathways for a long time after their formation. Our study quantitatively explores the development and evolution of overpressure-driven hydrofracture zone for the first time. This research has broad implications for marine engineering and geohazard assessment.

Submarine geohazards and renewable energy

Kiichiro KAWAMURA[1]*, Yamaguchi University (kiichiro@yamaguchi-u.ac.jp)

Abstract

In recent years, coastal facilities such as offshore wind power generation and nuclear power generation have attracted attention as carbon-free energy and renewable energy. In addition, the safe installation and maintenance of various structures from the coast to the deep seabed, such as optical cables, pipelines, and power cables related to offshore wind power generation, is also attracting attention. These structures are under continuous threat from submarine geological hazards. Submarine geological disasters are diverse, including earthquakes, volcanoes, tsunamis, liquefaction, submarine landslides, large-scale movement of sediments such as dunes, scours, and shallow gas. Their location, scale, and frequency are important items in assessing their risks. However, despite these threats, their importance remains unknown and bothers us. Here, we will introduce information on submarine disasters around the world shared by the International Union of Geological Sciences (IUGS) Seabed Disasters Task Group (TGSG), which we established in February 2023, as well as our company's response to submarine disasters. We will also introduce our efforts. Japan's offshore wind power project discussed at the Science Council of Japan. We would like to discuss how to respond to submarine geological disasters caused by active faults, submarine landslides, and volcanoes, including in Japan, where renewable energy development is expected to accelerate rapidly in the future. I demonstrate the recent activities associated with submarine geohzard studies, and discuss the future activities.

Key Technologies and Equipment of Geological Environment Observation in Deep-Sea Development

Yonggang Jia[1]*, Ocean University of China (yonggang@ouc.edu.cn)
Cong HU[2], Ocean University of China
Hongxian SHAN[3], Ocean University of China

Abstract

The deep sea holds abundant resources, and research on the geological environment of deep-sea is of great significance for achieving the goal of carbon emission and assessment around the world. To address the challenges of in-situ observation of the geological environment of deep-sea development projects, a deep-sea in-situ testing device for soil mechanics properties has been developed, with a maximum working depth of 11,000 meters. This device has successfully obtained accurate soil mechanics characteristics in the Philippine Sea and the rare earth deposit area in the ocean, making China the first country with the capability of in-situ testing of soil mechanics properties at full ocean depth. Furthermore, the first set of internationally advanced long-term monitoring equipment for complex deep-sea engineering geological environments has been developed. This equipment has achieved continuous in-situ observation of marine engineering geological parameters at a depth of 1,500 meters in the gas hydrate production test area in South China Sea for 12 months, filling the gap in long-term real-time monitoring of deep-sea engineering geological environments. In addition, an in-situ monitoring device for the impact of plumes during deep-sea polymetallic nodule mining has been developed. Over a period of three years, in-situ observation work has been carried out in the Western Pacific polymetallic nodule and rare earth areas, achieving synchronous in-situ observation of plume concentration and re-deposition thickness during deep-sea mining. Based on the above-mentioned in-situ observation devices, first-hand data on the geological environment of deep-sea development projects have been obtained, providing essential support for the geological safety of deep-sea development and environmental engineering.

Spatial time series variation of contourite drifts on active margins: Examples from the Kuril Trench in the NW Pacific

Hisashi IKEDA[1]*, Yamaguchi University (Hisashi.0906@outlook.jp)
Kichiro KAWAMURA[2], Yamaguchi University

Abstract

Contourite drifts that shaped by the persistent influence of bottom currents, represent a key focus in marine geology (e.g., Stow et al., 2002). In particular, contourite drifts have been extensively studied in the North Atlantic and Antarctic Oceans, and the geometry and depositional processes associated with deep water formation are well known (e.g., Rebesco et al., 2014). However, our understanding of contourite drifts is less advanced on the active margin due to differences in features during their identification (Bailey et al., 2021). Consequently, exploring contourite drifts and depositional processes in active margins has emerged as a significant issue in marine geology.
This study focuses on the active margin of the Kuril Trench in the northwestern Pacific, where the northward flow of the Lower Circumpolar Deep Water (LCDW) from the Antarctic Ocean occurs (Ando et al., 2013). Despite previous seismic studies suggesting the influence of bottom currents on erosional features, the identification of contourite drifts in this region remains elusive (Nakamura et al., 2023). To address this gap, we employed four sets of Multichannel Seismic Reflection (MCS) data (KT093, KT150, A2, R1) from the JAMSTEC Seismic Survey Database, aiming to: 1) identify and map the spatiotemporal distribution of contourite drifts and 2) elucidate changes in ancient oceanic environments, revealing the impact of bottom currents on deep-sea sedimentation.
Our methodology involved mapping seismic units and their horizons based on changes in sedimentary structure. Four criteria—onlap, downlap, apparent truncation, and vertical seismic facies change—were used to define horizons. Integration with the DSDP Site 436 stratigraphic package (Langseth et al., 1977) allowed us to assign depositional ages to these horizons. Stratigraphic interpretation revealed five seismic units (U1-U5) with estimated depositional ages ranging from 113 to 0 Ma. Notably, U4 and U5 displayed distinct contourite drifts, including a mound drift, a patch drift, and a sheet drift with sediment waves, each associated with specific erosional discontinuities.
The evolution of the deep-sea environment, as interpreted from the sedimentary structure, suggests three distinct stages: 1) a period dominated by pelagic sedimentation (U1 to U3), 2) a period characterized by weak bottom currents (U4), and 3) a period dominated by LCDW influenced by active orogeny and trench development (U5). In addition, our conclusion emphasizes that the sedimentary structure of contourite drifts deposited during the LCDW-dominated period (U5) reflects water mass relationships and their global-scale evolution.

Depositional process of contourite on active margins: Examples from the Kuril Trench and the Japan Trench in the NW Pacific

Hisashi IKEDA[1]*, Yamaguchi University (Hisashi.0906@outlook.jp)
Kichiro KAWAMURA[2], Yamaguchi University

Abstract

Contourites represent sediments shaped by the continuous influence of bottom currents, and their characteristics vary across deep-sea environments (e.g., Rebesco et al., 2014). While considerable knowledge has been amassed about these deposits in passive margins, their understanding in active margins is less comprehensive (Bailey et al., 2021). This disparity arises from distinct identification features, including diminished sediment supply from continental slopes and sporadic deposition of volcaniclastic debris challenging to transport via bottom currents. Consequently, delineating contourite facies and depositional processes in active margins has become a crucial focus in marine geology.

The Japan Trench and Kuril Trench in the northwestern Pacific, forming part of an active margin, channel the northward flow of the Lower Circumpolar Deep Water (LCDW) from the Antarctic Ocean (Ando et al., 2013). Despite this dynamic setting, no contourites formed by bottom currents have been identified in this region. Thus, our study focuses on piston core samples from the outer slope-outer rise of the Kuril Trench and the Japan Trench in the northwestern Pacific Ocean, aiming to discern contourite facies and the current depositional processes.

Piston core samples (KH-18-5 PC01, PC04, KH-20-8 PC01) from the cruises KH-18-5 and KH-20-8, conducted by the "R/V Hakuho-Maru", were utilized in our investigation within the outer slope to outer rise areas of the Kuril Trench and the Japan Trench.

When bottom currents are active, particles undergo selective deposition due to upward shear stress from turbulence interacting with the seafloor (McCave, 1995). Consequently, contourites typically exhibit upward coarsening structures during increased flow velocity and upward fining structures during decreased flow velocity along the bottom current axis. The Sortable Silt range is particularly indicative of these grain size changes. Analyzing core samples using laser diffraction at 2 or 4 cm intervals, we interpreted the grain size changes as indicators of varying depositional processes in the deep-sea environment.

Our study involved the classification of nine sedimentary facies based on mode diameter (small, medium, large) and sand particle content (small, medium, large). Mode diameters within the sortable silt range displayed a consistent trend: decreasing skewness with increasing strain and increasing skewness with decreasing strain, aligning with previous observations in contour sedimentology (e.g., Brackenridge et al., 2018). This implies that mode diameter categories correspond to the sieving action of the bottom flow. In contrast, sand content exhibited a shift from unimodal to bimodal grain size distribution. Smear slides indicated that the sand fraction comprised mainly volcaniclastic debris, unaffected by bottom current transport. Therefore, the nine sedimentary facies categories reflect contourite facies (siliciclastic or volcaniclastic) and the

intensity of bottom currents influencing these facies. Additionally, sortable silt mean grain size exhibited significant changes corresponding to both upward coarse-grained and upward fine-grained structures.

Abstract

Understanding the tectonic complexities and deformation in the Manila Trench forearc region is crucial for seismic hazard assessment. This study integrates gravity data, seismic reflection, and sub-bottom profiles to delineate faults in the area. A Bouguer anomaly map of the region was generated by combining ground gravity data with the Earth Gravitational Model 2008. Power spectrum analysis was employed to distinguish residual and regional effects, enhancing the resolution of the anomalies. Through this analysis, a prominent belt of high gravity anomalies was identified, notably west of Zambales and extending towards the northwestern tip of Luzon. This belt has previously been reported to be the offshore extension of the Zambales Ophiolite Complex. The occurrence of a tectonic mélange in the northwestern tip of Luzon indicates the sheared character of this ophiolite belt. We hereby identify this zone as the West Luzon Shear Zone, a relict tectonic boundary attributed to the northward translation of Luzon since the Neogene. Furthermore, the calculation of the first vertical and tilt derivatives of the gravity anomalies revealed displacements in the gravity belt indicative of the presence of younger strike-slip faults. These features are identified to be offshore extensions of the Philippine Fault Zone. These findings were corroborated by seismic reflection profiles, which showed the subsurface configuration of the offshore splays of the Philippine Fault Zone. Additionally, recent normal faults were documented by analyzing sub-bottom profiles, providing further insights into the tectonic evolution of the Manila Trench forearc region. The integration of gravity data, seismic reflection, and sub-bottom profiles has enabled a characterization of deformation structures, highlighting the complex interplay of tectonic processes in the area. The multidisciplinary approach employed in this work demonstrates the efficacy of integrating various geophysical techniques to unravel the subsurface dynamics of tectonically active regions.

Tectonic structure and deformation along the Manila Trench subduction zone: Implications on submarine geohazards in the South China Sea eastern margin

Leo ARMADA[1]*, University of the Philippines Diliman (ltarmada@up.ed.uph)
Armando Bambao[2], University of the Philippines Diliman
Carla Dimalanta[3], University of the Philippines Diliman
Elisha Jane Maglalang[4], University of the Philippines Diliman

Rurik Austria[6], Philippine Geothermal Production Company
Nathaniel Parcutela[7], Energy Development Corporation
Shu-Kun Hsu[8], National Central University
Yi-Ching Yeh[9], National Central University
Graciano Yumul[10], University of the Philippines Los Baños

Abstract

The eastern margin of the South China Sea faces significant risks from submarine geohazards, such as earthquakes, mass movements, and tsunamis resulting from tectonic activity. This research examines the tectonic structure and current deformation along the Manila Trench. Previous studies on the western Luzon offshore region have highlighted the diverse nature of the subducting slab beneath Luzon, leading to distinct deformation patterns in the subduction zone. The present investigation delves into strain rates in the overriding plate and their correlation with the mechanical structure of the subducting slab. Spectral analyses of bathymetry and gravity data are employed to investigate the complex characteristics of the subducting slab, aiming to understand the role of bathymetric highs (i.e., subducting seamounts and extinct spreading ridges) in the segmentation of the mega-thrust and the overlying forearc crust. Additionally, 2D gravity modeling of trench-arc transects contributes to developing a mechanical model for the subducting slab, incorporating factors like elastic thickness and buoyancy effects relevant to seismic coupling at the subduction interface. Integrating strain rate calculations from earthquake and geodetic datasets, the study assesses the mechanical behavior of the slab concerning its seismogenic potential along the mega-thrust fault. Potential seismic gaps in the forearc region are identified as likely locations for triggering cascading submarine geohazards in the eastern South China Sea basin.

In-situ Observation and Machine Learning Prediction of Marine Shallow Gas Emission

Cong HU[1]*, Ocean University of China (hucong@ouc.edu.cn)
Ting ZHANG[2], Ocean University of China
Yanyun XING[3], Ocean University of China
Yonggang JIA[4], Ocean University of China

Abstract

Marine shallow gas emission not only influences the marine environment and ecosystems but also can induce marine geohazards. However, our knowledge about the mechanism of marine shallow gas emission is still limited. In this study, a comprehensive investigation into the mechanism of marine shallow gas emission was conducted near the coast of Zhoushan Island in the East China Sea. A lander was deployed to study the correlation between hydrodynamics and marine shallow gas emission. The lander was equipped with an upward-looking 2M ADCP, a 6M ADV, a wave and tide gauge, and a dissolved methane sensor. Initial analysis of the in-situ observation results showed that pressure changes caused by tides was highly correlated with marine shallow gas emission. Methane concentration varies greatly when tidal pressure is at its lowest. Sediment resuspension induced by wave and current interaction often accompanies significant changes in methane concentration. Two different machine learning methods, Long Short-Term Memory (LSTM) and Random Forest (RF), were used to predict the influence of different hydrodynamics on marine shallow gas emission. Compared with the LSTM method, the RF method demonstrated a higher accuracy in predicting methane concentration changes and showed a better model performance. Its coefficient of determination (R^2) was 0.887, and the root mean square error (RMSE) was 2.618 nmol/L. The feature importance assessment of RF also indicated that tidal pressure and sediment resuspension were the key factors affecting marine shallow gas emission, followed by wave and current velocity. This study provides new insights into the mechanism of marine shallow gas emission and contributes to a better understanding of the controlling factors of seafloor fluid systems.

In-Situ Observation on the Interaction of Deep-Sea Internal Solitary Waves with the Seabed

Yong Gang JIA[1]*, Ocean University of China (404806030@qq.com)

Abstract

The benthic boundary layer instability caused by internal solitary waves can result in sediment resuspension and transport, leading to reshaping of continental margin topography and significantly impacting the transport of sediment solutes and biogeochemical cycles. However, there is currently very little research that combines the sediment resuspension and transport caused by internal solitary waves with direct measurements of bottom pressure or pore pressure, and little is known about how the driven pore fluid circulation and seepage processes affect the bottom environment.

This study is focuses on the Dongsha Slope in the South China Sea, and conducts IWBBLE (Internal Wave - Benthic Boundary Layer Experiment). For the first time, long-term high-frequency in-situ pore pressure observations are carried out in the South China Sea. The aim is to reveal the characteristics of seabed response under the large-amplitude internal solitary waves, and to explore the physical mechanisms of seabed response affecting sediment suspension and transport based on scientific discoveries.

The combined results of this study and previous observations indicate that the seabed pressure disturbance in the deep-sea has been underestimated. Deep-sea internal solitary waves exhibit distinct and sharp pressure signal characteristics. The maximum seabed pressure disturbance caused by internal solitary wave at a depth of 740 m on the Dongsha Slope is approximately 1.5 kPa, which is one order of magnitude larger than typical results observed in shallow seas. Using parameter R, the estimated maximum pressure disturbance of the internal solitary wave with a maximum amplitude of 173 m on the Dongsha Slope is predicted to be between 3.94 and 5.91 kPa. Using the DJL equation, it is estimated to be 5.68 kPa, which is roughly equivalent to the estimate of 5.91 kPa obtained using parameter R=0.4.

Pore fluid seepage caused by internal solitary waves results in pore fluid circulation across the sediment-water interface. The results confirm the lag of pore pressure response under the internal solitary waves. The maximum pore pressure response is approximately 0.69 kPa, with pore pressure changes concentrated in the surface sediment. The high pore pressure response core is observed beneath the peak of seafloor pressure disturbance. The depth of pore pressure response during IWBBLE is approximately 0.5 m below the seafloor.

Throughout the observation period, sediment resuspension induced by internal solitary waves was more significant compared to that caused by contour currents and internal tides, suggesting that internal solitary waves control the development of the bottom nepheloid layer at a depth of 740 m on the Dongsha Slope in the northern South China Sea. Deep-sea cameras have captured for the first time the transport of sediment particles, including bedload, saltation, and suspension, under the influence of internal solitary waves, with particles rapidly transported downslope after entering

the water column along the direction of bottom current. The global instability and vortex shedding of internal solitary waves dominate the intense vertical sediment transport at the rear of the waves, with suspended sediment heights far exceeding those caused by tidal currents and internal tides.

Submarine geohazards and educational materials

Kiichiro KAWAMURA[1]*, Yamaguchi University (kiichiro@yamaguchi-u.ac.jp)

Abstract

In order to develop human resources for submarine geohazards, it is important to develop teaching materials using various approaches. Here, I would like to introduce teaching material development from a multifaceted perspective, and share and exchange information at this international conference.

1) Observation of outdoor survey (https://www.youtube.com/channel/UCAG1N7HZbWVBh9NT4vIBE4g)

For on-site observations, it would be best to observe sedimentation processes along the coast. This allows us to understand the sedimentation and erosion effects caused by water flow. It is also desirable to distribute these using YouTube and use them as repeated teaching materials for students.

2) Observation of indoor experiments

For the sedimentation and erosion effects caused by water flow, it is often appropriate to observe sand particles in a laboratory using a water tank or channel. Experimental approaches are important for simplifying complex processes and understanding mechanisms in nature. Without experimental equipment, it would be impossible to teach many students at the same time, so classes could be conducted by making the experimental equipment cheap and simple, or by streaming videos. However, video streaming does not allow detailed observations, so it is desirable to create experimental equipment suitable for the number of students taking the course.

3) Utilization of open data (https://www.kyoumu.jimu.yamaguchi-u.ac.jp/portal/Public/SyllabusV2/DetailMain.aspx?lct_year=2024&lct_cd=1043600031&je_cd=2)

In recent years, ocean floor topography data has become open data and is being uploaded by various organizations. In order to promote the utilization of these data, I am working with TGSG to create an online program for universities. Every year, I invite famous teachers from around the world to teach us how to utilize data.

4) Development of tools necessary for observation (https://ds0n.cc.yamaguchi-u.ac.jp/~kawaken/index.html)

When conducting observations in the field or in the laboratory, it is necessary to develop teaching materials related to various observations, descriptions, and measurements. Here, I would like to introduce three that I have recently developed. The first is a simple clinometer made of plastic. This is an inexpensive and durable clinometer. A clinometer is used to measure the strike and dip of bedding planes and to measure the orientation. Many smartphone apps have been developed in recent years, but we developed this based on the idea that teaching materials that can get dirty are needed when used outdoors. The second is the particle size table. Equipment is required to measure the size of sand particles on-site. In recent years, only expensive ones are on the market, so I have been making inexpensive ones myself. The third is a safety aid when creating rock

slices. You can understand this by creating rock flakes, but it's easy to injure your fingers. They cut their hands on glass and grinders. To prevent this, the aids used to press the glass into the grinder are made of plastic. This can also be produced inexpensively.
Thus, I would like to do capacity development for submarine geohazards by devising various teaching materials.

An optimal geological method to decipher active faults and related lineaments at Yamaguchi, SW Japan

Momoko TSUTSUMI[1]*, Yamaguchi University (c018dgw@yamaguchi-u.ac.jp)
Kiichiro Kawamura[2], Yamaguchi University

Abstract

In active marginal areas like Japan, disasters related to tsunamis, earthquakes, and volcanic eruptions occur frequently, and these disasters are often recorded in the topography. However, the topography is made up not only of the topographical features at the time of the disaster, but also of natural changes over time, such as weathering and erosion. Therefore, in order to decipher the topographical features that serve as records of disasters, topographical and geological analysis methods are required. In this paper, we use the 10 m grid digital elevation model provided by the Geospatial Information Authority of Japan, the map drawing software GMT, and the image analysis freeware ImageJ to explore the optimal method for quantifying changing topography. The study area was located in the Tokusa area of SW Japan. We extract the lineament structure by the optimal method.

In general geological features, the SW Japan Inner Belt is located in the northern part of the median tectonic line being a dextral strike-slip fault with a total length of over 1,000 km, and the southern part is called the SW Japan Outer Belt, which is mainly composed of accretionary prisms dating from the Cretaceous to the present, and E-W faults related to accretionary processes can be seen.

On the other hand, lineament structures originating from the NE-SW faults are often seen in the inner belt. Most of them are thought to be closely related to the formation of the Sea of Japan from ~19 Ma to ~14.5 Ma during the Miocene period. The Japanese archipelago as a land arc being an onshore volcanic arc on the edge of the Eurasian continent, separated from the continent as forming a V-shape open while the Sea of Japan expanded, and became an island arc. These faults being "old scars" formed by large-scale events in the past are probably closely related to the current lineament structure of the Japanese archipelago and the active faults as well. These lineament structures characterize the topography of the Japanese archipelago, and in particular regulate the distribution and extension of river systems. In this study area, major rivers flow along the NE-SW lineament structure. However, many lineament structures are associated with the expansion of the Sea of Japan, and are often overwritten by subsequent crustal deformation. Such overwriting occurs due to igneous activity of the Aonoyama volcanic group of several hundreds thousands of years ago. This igneous activity caused major deformation of the topography, resulting in numerous river captures and complex changes in flow paths.

We discussed the optimal geological method to decipher active faults and related lineament structures based on digital elevation models, ground surveys, and prior data. As a result, the weighting parameter of the lineament length is important. In the future, we plan to apply this type of analysis method to research on submarine geohazards using bathymetry data.

Microplastics: diffusion into ocean floors by tsunamis and typhoons and application for age determination

Kiichiro KAWAMURA[1]*, Yamaguchi University (kiichiro@yamaguchi-u.ac.jp)

Abstract

Marine plastic pollution is a serious social problem. The sight of many plastic bottles washed ashore on the coast is a symbol of our current situation. These plastic materials typically degrade and shatter into microplastics, which are dispersed into the ocean. Pollutants (such as PCBs) attached to these microplastics accumulate in marine life. Such marine plastic pollution has been investigated at shallow depths, but unknown at depths deeper than a few thousand meters.

According to the Vinyl Environmental Council, plastic products have rapidly increased from 100 million tons per year in the 1960s to 200 million tons per year in 1991. But more recently, since 2008, it has been 180 million tons per year. These products and their particles are similar to microplastics. It accumulates continuously without decay, but is unknown. Most of them may have settled to the deep sea floor, been retransported by bottom currents, and accumulated somewhere on the deep sea floor. I believe that such missing sinks will become a future research topic in earth science.

Additionally, microplastics can be used in geoscientific research as reference fossils in a sense. Radionuclides are one famous example of age determination using artifacts. For example, we use cesium-134 and cesium-137 to determine age. 134Cs, which has a half-life of about two years, is an indicator of nuclear tests and nuclear power plant accidents. It plays an important role in the Fukushima Daiichi nuclear power plant accident (e.g. Oguri et al., 2013; Sci. Rep.). Cesium-137 has a half-life of approximately 30 years, and the age of the accident can be detected from sediments over a relatively long period of time. The famous peak of cesium-137 is a deposit from nuclear tests in the 1960s and the Chernobyl disaster in 1987. Microplastics are similar artifacts, and it may be possible to estimate the age of sediments by using them in the same way as radionuclides.

I have studied mainly a relationship between marine microplastics and geohazards. Nakajima et al. (2021; Frontiers in Marine Science) disclosed the effects of typhoon and related flood disasters, and Tsuchida et al. (2023; Mar. Poll. Bull.) discussed the effects of deep-sea sedimentary processes including turbidity currents and bottom currents. Kawamura et al. (2019; GS LondonSP) has reported a relationship between microplastic distribution and tsunami events. In this paper, I introduce the relationship between marine microplatics and submarine geohazards, and the implication of microplastic studies on submarine geohazards.

Abstract

A database of information concerning submarine landslides, earthquakes, volcanic centres, tsunamis, fluid emissions and Quaternary tectonics has been gathered in the frame of the EMODnet Geology Project. EMODnet (European Marine Observation and Data Network) is a long-term marine data initiative funded by the European Union. It provides easy and free access through a Central Portal (https://emodnet.ec.europa.eu/en) to marine data, metadata and data products and services spanning seven broad disciplinary themes (lots): bathymetry, geology, physics, chemistry, biology, seabed habitats and human activities.

EMODnet Geology provides full areal coverage of all European regional seas delivering maps at multiple scales on sea-bed substrate, sediment accumulation and erosion rates, Quaternary and pre-Quaternary lithology and age, geomorphological features, coastal behaviour, geological events and probabilities, minerals and submerged landscapes.

The Geological Survey of Italy – ISPRA coordinates the “Geological events and probabilities” work package which consists of digital maps of landslides, earthquakes, volcanoes, tsunamis and fluid emissions. Quaternary tectonics has also been considered since most of the events are connected to the underlying geological and structural setting.

Data, deriving from national and international Projects held by Partners or by third parties, were collated, validated and standardized. Each type of geological event occurrence is represented by features organized according to their geometries (polygons, lines and points) and complemented by a comprehensive pattern of attributes.

Besides the collection of events occurrences, events probabilities were also considered, although not easy to assess. Based on data gathered by WP6 and on parameters obtained from EMODnet Bathymetry (such as depth, slope, curvature, etc.), it was possible to elaborate a “Landslides susceptibility map” by applying the MaxEnt model.

Data, metadata and complementary information are displayed on the EMODnet Central Portal subdivided into layers at 1:250.000 scale, which include data at lower resolutions, and layers at 1:100.000 scale, which include also data more detailed than 1:100.000.

They provide a reliable and complete interoperable database which can be downloaded and may represent a baseline to support further research or to elaborate additional thematic maps.

Possible development and implication of subsurface fault structures offshore northeast Taiwan

Chien-Wei HSU[1]*, Institute of Oceanography, National Taiwan University
(r11241313@ntu.edu.tw)
Jih-Hsin Chang[2], Institute of Oceanography, National Taiwan University

Abstract

The geological structures of the North and Northeast Coast Taiwan are considered significant due to nuclear power infrastructures. As far as we know, northern Taiwan had experienced late Cenozoic uplifted mountain building and is now in the state of mountain collapse. As the northern extension of the collapsed mountain, northern offshore Taiwan is now dominated by a series of normal fault structures and regional extension. Historical records suggest that the activities of the major normal fault likely played a significant role in triggering tsunamis in northern Taiwan. The detailed geometries and possible activities of these fault structures are thus important. To derive detailed fault structures and to propose extension of the faults, we take advantage of new and reprocessed offshore marine multi-channel seismic reflection surveys data northeast offshore Taiwan. In our seismic dataset, a series of normal faults separating fault blocks, and two seismic sequence boundaries representing top-of-fault blocks and top-of-filled sediments are recognized, collectively showing several half grabens. The depths of the seismic sequence boundaries are mapped and interpreted to represent the offset of the normal faults. The offsets of these normal faults seem to gradually decrease towards the onshore region, where the sense of the fault is mainly reverse. Toward the offshore, however, we found that the offsets of these faults appear to gradually decreases as well and seem to disappears. Besides, it seems that the variations in depths of both seismic sequence boundaries seem not consistent, probably indicating that the formation of these fault blocks and activities of these faults are not in sequence. Detailed fault development in this study combined with historical depositional records of tsunami event can help us better understand the possible mechanism of tsunami, providing useful implications for future geohazard assessments in northern Taiwan.

Abstract

Northern Taiwan Strait is located in a geological environment of the transition zone from a compressional regime to an extensional regime. In this area, there are complex fault and anticline structures, including normal fault structures formed during the syn-rift stage, and reverse faults formed during the orogenic stage. Some of the reverse faults were reactivated along the Pliocene normal faults due to the westward advancement of the Taiwan orogeny. The active faults may cause shallow strata displacement and potentially impact the construction of offshore wind turbines. This study utilized advanced seismic data processing techniques to reprocess previously collected seismic reflection profile data and to improve the accuracy of profile location effectively enhancing the quality of the seismic image. From seismic stratigraphic analysis, we have identified two unconformities, the foreland basal unconformity and the last glacial maximum unconformity (LGMU), to build age models of geological formations. There are many normal faults present in the northern Taiwan Strait, with most of them being buried at depths. Several fold structures are identified, some of the crests were truncated by the LGMU, and the post-LGMU strata there have been uplifted by the folding. One of the active fold structures with a NE-SW trending fold axis has been mapped extending southwestward from near shore to off shore for 10 kilometers, and its strike is similar to the Chingtsaohu anticline on land. One of the reverse faults is the Hsinchu offshore fault, its strike is east-west and is a high-angle south-dipping reverse fault. It may be a reactivated fault, with a length larger than 6 kilometers, and its strike and dip angle are similar to the onshore Hsinchu fault. In this study, we have identified the distribution of faults and folds in the area where the deformation front may have extended from onshore to offshore, and provide valuable information for geohazard risk assessment of wind turbine generator locations and submarine cable deployment.

Shallow Subsurface 3D Velocity Structure Identification in Turkey Antakya based on Microtremor Horizontal-to-Vertical Spectral Ratio

Jikai SUN[1]*, Disaster Prevention Research Institute Kyoto University (sunjikai01@outlook.com)
Ziqian Wang[2], Disaster Prevention Research Institute Kyoto University
Eri Ito[3], Disaster Prevention Research Institute Kyoto University
Hiroshi Kawase[4], Disaster Prevention Research Institute Kyoto University

Abstract

Heavy building damages were caused by the 2023 Turkey Kahramanmaras Mw7.8 earthquake. According to statistics (Rapor, 2023), 22.39% of the houses in Hatay province suffered heavy or collapsed earthquake damage. In Antakya city, the capital of Hatay province, six strong-motion stations set up by the Turkey Disaster and Emergency Management Authority (AFAD) have observed seismic strong ground motions with high PGAs. Although the distance between each station is only 2-4km, the waveforms observed at the northeast, northwest and southern stations are very different from each other. We initially consider that there is strong site effect affecting the observed seismic strong-ground motions in the urban area of Antakya. Our team conducted site microtremor (surface background noise) observations in the urban area of Antakya in October 2023. We set up a 600m*600m staggered grid in the direction parallel to and orthogonal to the East Anatolia Fault. Considering the observation efficiency and the ease of field work, we observed 90 points. We then analyzed the Microtremor Horizontal to Vertical Spectral Ratio (MHVR) at each point and obtained the fundamental frequency of the site in Antakya urban area. We found that in the northwest and southwest corner areas, the fundamental frequency of the sites are very high, reaching 10Hz, while in the northeastern area of the city, the fundamental frequencies are around 4Hz, and the fundamental frequencies of areas close to the Asi River are about 2Hz. These results illustrate that thickness of the sediment layer varies greatly in different areas of Antakaya urban area. We next need to convert the MHVR of each point into the pseudo Earthquake Horizontal to Vertical Spectral Ratio (pEHVR), and then identify detailed three-dimensional velocity structure of Vs ≦ 3km/s based on the diffused field theory for EHVR (Kawase et al., 2011). We will analyze and simulate the seismic strong-ground motions in Antakaya urban area when the Mw7.8 earthquake occurs.

Framework for prioritization strategies for slope reinforcements under heavy rainfall based on probabilistic connectivity of road networks

Zhengying He[1]*, Tongji University (zhyhe@tongji.edu.cn)
Yu Huang[2], Tongji University
Zhen Guo[3], Tongji University

Abstract

Rainfall-induced landslides are common global phenomena, leading to significant traffic disruptions and compromised road network connectivity. To mitigate these impacts, it is crucial to quantify road network connectivity, facilitating the development of effective slope reinforcement strategies. However, current research on prioritization strategies for slope reinforcements predominantly focuses on the reliability assessment of individual slopes without adequately addressing road network connectivity enhancement. This study presents a novel framework for prioritizing strategies for slope reinforcements under heavy rainfall based on probabilistic connectivity of road networks. Rainfall hazard intensities are assessed by Generalized Pareto Distribution (GPD). Vulnerable slope locations are identified by field investigation and spatially correlated states of these slopes are estimated by fragility assessment and spatial correlation of landslides. The probabilistic connectivity of road networks is estimated considering spatially correlated states of multiple slopes, leveraging both geographical information systems (GIS) and graph theory. With the proposed framework, improved road network performance can be achieved by optimal strategy in slope reinforcement prioritization. As an illustrative example, the proposed method is applied to the road network in Lishui City, China, susceptible to rainfall-triggered landslides. The probabilistic connectivity of road networks is substantially enhanced with the pile-reinforcement strategy for slopes. This study not only offers a new perspective on addressing the prioritization strategies for slope reinforcements but also contributes to the broader field of disaster-resilient infrastructure planning.

Energy evolution of subaqueous gravity flows composed of viscous liquids and particles

Chen PENG[1]*, Tongji University (chenpenghn@tongji.edu.cn)
Xingyue Li[2], Department of Geotechnical Engineering, College of Civil Engineering, Tongji University
Yu Huang[3], Department of Geotechnical Engineering, College of Civil Engineering, Tongji University

Abstract

Subaqueous gravity flow is a geological process in which sediments consisting of gravel, sand, mud and water move underwater. The column collapse in water has been extensively used to investigate subaqueous gravity flows in previous studies, where the column is composed of either particles or non-Newtonian fluids like slurry. However, the real composition of the gravity flow can be much complex, and the simplified consideration of subaqueous gravity flows as viscous flows or particle flows makes it difficult to fully understand the flow dynamics controlled by interactions between different flow compositions. In this work, the collapse of a particle-slurry mixture underwater was simulated using the coupled computational fluid dynamics (CFD) and discrete element method (DEM), where the particles were simulated as rigid particles with DEM and the slurry was simulated as a Herschel-Bulkley fluid with CFD. As a reference case, the collapse of particles in water was also simulated. The adopted approach can reasonably recover the flow of mixtures rich in clay and coarse particles. In particular, the influence of Herschel-Bulkley fluids with different properties on the run-out distance and the energy evolution is explored. The results show two trends in the distance travelled by the particles in the mixtures. When the clay content of the slurry is high, the final runout distance can be larger than the reference case. On the contrary, a smaller runout distance can be obtained if the clay content is low. The opposite trends depend on the competing effect of the viscous force and the buoyancy on the particles. From the perspective of energy evolution, more energy is dissipated by particle collision, friction, and fluid viscosity at the early stage of the column collapse, and less is dissipated at the later stage. The efficiency of the conversion of kinetic energy from vertical to horizontal direction is critical in controlling the final runout distance of the particles. The numerical results in this study help understand the behaviour of mixtures composed by Herschel-Bulkley fluids and particles flowing under water, and explain the possible mechanisms of the promoting or inhibiting effect of viscous fluids on particle motion.

DEM modeling of undrained cyclic triaxial behavior in submarine loose sediments under wave loading: the influence of fine contents

Yandong Bi[1]*, Tongji University (2110056@tongji.edu.cn)
Yu Huang[2], Tongji University
Shu Zhou[3], Tongji University
Chongqiang Zhu[4], Tongji University

Abstract

The accumulation of pore water pressure in submarine loose sediments subjected to cyclic wave loading gradually compromises the stability of submarine slopes and poses a threat to offshore engineering. In order to investigate the mechanism underlying pore water pressure accumulation under cyclic wave loading and the influence of clay fine contents on the macro- and micro-mechanical characteristics of undrained granular assemblies, this study conducted a series of undrained cyclic triaxial discrete-element method simulations, which constituted a parametric study involving five factors: fine contents, initial void ratio, initial mean effective stress, cyclic stress ratio, and frequency. The discrete element model is established based on rational soil mechanics parameters. And the research results show that there is a threshold fines content (FC) that makes the cyclic liquefaction resistance and cyclic loading times reach the minimum value. Through analysis of the micro-scale particle that participate in the force chains and the contact information, such as mechanical coordination number and contact-normal-based fabric anisotropy, the evolution of internal structure of the granular materials under cyclic wave loading was quantified. The present study shed lights on the underlying pore water pressure accumulation under cyclic wave loading mechanism that effects of the presence of clay fine particles on liquefaction under cyclic triaxial test condition.

Prediction of landslide hazard using LS-RAPID model. A case study in Tia Dinh area (Dien Bien province, Vietnam)

Ha Duc NGUYEN[1]*, Center for Information, Archives and Museum of Geology (Viet Nam Geological Department) (nh14vn@gmail.com)
Ninh Hoang Nguyen[2], Vietnam Institute of Geosciences and Mineral Resources
Duong Huy Nguyen[3], Vietnam Institute of Geosciences and Mineral Resources
Van Thi Hai Nguyen[4], Vietnam Institute of Geosciences and Mineral Resources

Abstract

Landslides are among the most dangerous geohazards in many countries worldwide, including Vietnam. The loss of lives and properties has been getting more severe since the population and economic activities are expanding into mountainous areas, which are most prone to landslides. This study focuses on the Tia Dinh commune in Dien Bien province, situated amidst the northwestern mountains of Vietnam. The central area of the commune has been identified as a high-risk zone for landslides, posing imminent threats to local residents and infrastructure, including the People's Committee office building, health station, schools, and more than 69 houses.

Physical models are often highly regarded for their ability to determine the risk and extent of landslide impacts with high accuracy. However, these models are often only suitable for small, homogeneous geological areas. In large areas with many potential landslide surfaces, the parameters vary greatly, making it difficult to select a representative sample for the entire area. Moreover, in Vietnam, where three-quarters of the territory consists of hilly or mountainous terrain, conducting soil sample testing for all landslide-prone areas is challenging due to financial and time constraints. In areas with an existing risk of landslides, simpler and more practical methods need to be tested and replicated if feasible to quickly predict potential hazard areas.

The LS-RAPID model is advanced and capable of simulating and predicting landslide-prone areas and their potential impact. By applying the LS-RAPID model, this study has produced two main results. Firstly, it predicts the potential hazard under the worst-case scenario, and secondly, it identifies the water level that could trigger landslides in three high-potential landslide areas that have shown many signs of instability. The identified groundwater trigger levels can be combined with real-time water level monitoring devices for early landslide warnings. Predicting the potential hazard of landslides is essential for land-use planning. Therefore, the results of this study make an important and long-term contribution to the efforts to prevent and mitigate damage caused by landslides in the region.

Moreover, the LS-RAPID model application method can be extended to numerous mountainous regions across Vietnam. While the results of this model application may not always achieve pinpoint accuracy, they offer invaluable preliminary predictions and ensure safety, particularly through worst-case scenario assessments, all at a low cost and with rapid deployment potential. This adaptability and cost-effectiveness render the LS-RAPID model a valuable tool in safeguarding vulnerable communities against the hazards of landslides.

[Keynote] Rheological behaviour of pressure-controlled steady slope flow with coexistence of multiple flow regimes

Chongqiang ZHU[1]*, Tongji University (cqzhu@tongji.edu.cn)
Yu Huang[2], Tongji University
Jin Sun[3], Tongji University

Abstract

Natural disasters, such as landslides, debris flows and pyroclastic flows, usually lead to large deformation and complex flow of the granular materials involved. Understanding such behaviour of granular materials is thus important for modelling and simulation of natural disaster events. Instead of deforming homogenously, granular beds could indeed develop regions of intense shear (Artoni et al. 2018), i.e. shear zones, bounded by quasi-static or plug flows in the geophysical flows. Though the study of granular rheology has made significant progress on homogenous steady flows in a single flow regime in the past decades, the understanding of inhomogeneous steady granular flow with coexistence of multiple flow regimes still poses many challenges.

In this work, we explored the rheological behaviour with coexistence of multiple regimes using a pressure-controlled slope flow configuration. Specifically, the inclined flow is bounded on top by a lid that moves parallel to the slope with a velocity U and adjusts its normal position as dictated by a prescribed pressure P, which models the overburden in natural flows. Interestingly, 5 different flowing structures are found with their boundaries clearly delineated by the distinct velocity and volume fraction profiles as the controlled velocity and pressure of the top lid vary. We further investigate the rheology of the flows with coexistence of multiple regimes. The inertial rheology of the materials in the shear zone can be well predicted by the previous models determined based on homogenous simple shear flow. But these models fail to capture the rheology of the creeping zone, where the pressure is independent of the shear rate, similarly to the quasi-statice simple shear flow, but with a much lower magnitude. The deviation of rheology of the creeping zone from simple shear flow is also confirmed by our previous simulations of vertical chute flow (Barker et al. 2022) and inclined slope flow with erodible bottom boundary (Zhu et al. 2023). Moreover, the rheology with coexistence of multiple regimes for the different configurations collapses well, which suggests the possibility of a new rheological model for the different complex flow conditions, and further research to understand its universal physical mechanisms is warranted.

Simulating Cyclic Injection-Induced Fatigue in Rocks

Chang Xia[1]*, Hong Kong Polytechnic University (23036821r@connect.polyu.hk)
Qi Zhao[2], Hong Kong Polytechnic University

Abstract

This study focuses on the development of a numerical model for Cyclic Hydraulic Fracturing (CHF), a technique currently employed in subsurface energy extraction due to its benefits in reducing induced seismicity. However, a numerical modelling framework that can accurately replicate the hydraulic fatigue damage caused by CHF is not available. To address this gap, we have created a fully integrated hydro-mechanical damage model using the Discrete Element Method (DEM) method, UDEC. This model introduces a unique time-dependent failure model designed to simulate the hydraulic fatigue response. In addition, we have utilized the Grain-Based Model (GBM) to simulate the formation of heterogeneous incipient cracks. These cracks allow fluid flow following their formation. We have conducted numerical calculations of the fatigue caused by hydraulic injection under various fluid pressure levels. These calculations have been cross-verified with laboratory results, showing a reasonable consistency in breakdown pressures. This validation provides a solid foundation for the accuracy and reliability of our model. Following the development and validation of our model, we carried out field-scale studies using a large-scale model with pre-existing joint sets. These studies allowed us to thoroughly examine the impact of CHF on fracture network propagation and permeability enhancement. Our research provides valuable insights into the effects of CHF, and the findings could potentially guide practical subsurface energy exploitation. The development of this numerical model represents a significant advancement in our ability to understand and predict the effects of CHF, thereby contributing to more efficient and sustainable energy extraction practices.

Numerical Insights into Microbially Induced Desaturation (MID) in Layered Silts and Sands

Patrick Kwon[1]*, Arizona State University (pskwon@asu.edu)
Leon van Paassen[2], Boskalis

Abstract

A numerical reactive transport model was developed to simulate Microbially Induced Desaturation (MID), an emerging bio-mediated ground improvement technique. MID utilizes nitrate-reducing microorganisms to desaturate soil, thereby mitigating earthquake-induced soil liquefaction. The primary goal for the MID is to prompt gas bubble production by microorganisms, resulting in the desaturation of the target soils and subsequently enhancing soil cyclic resistance. This approach is especially notable for its ability to mitigate liquefaction non-disruptively, facilitating mitigation adjacent to and beneath existing structures. Numerical modeling is a valuable option for advancing the understanding of MID treatment, evaluation of field trials, and design of practical applications. The MID numerical model integrates fluid flow dynamics with the MID reactive processes, offering a comprehensive predictive framework for substrate and product distribution and the resultant changes in the soil properties such as porosity, permeability, and degree of saturation due to MID treatment. The reactive transport model employs biochemical reaction equations coupled with Darcy's law. The numerical model is implemented in COMSOL Multiphysics® finite element software and validated with the empirical data from a bench-scale tank experiment. The validation process involved a comparison of the degree of saturation, electrical conductivity, and time-lapse images of the flow front from the tank test with corresponding outputs generated by numerical simulations. This model was tested with various initial biomass concentrations and reaction rates to provide an enhanced understanding of MID treatment. This research significantly contributes to the advancement of MID as a non-disruptive means of enhancing infrastructure resiliency and sustainability through liquefaction mitigation and establishes a foundation for further exploration and application of this innovative technique in the field of geotechnical engineering.

Karst geohazard and climate change: case of Lithuania

Jonas SATKUNAS[1]*, Nature Research Centre, Vilnius (jonas.satkunas@lgt.lt)
Vytautas Minkevičius[2], Nature Research Centre, Vilnius
Julius Taminskas[3], Nature Research Centre, Vilnius
Rita Linkevičienė[4], Nature Research Centre, Vilnius
Vidas Mikulėnas[5], Lithuanian Geological Survey
Simonas Danielius[6], Nature Research Centre

Abstract

Karstic phenomena in North Lithuania are related with dissolution of sulphatic (mainly gypsum) interlayers of Upper Devonian formations, that occur under the 1-10 metres thick Quaternary cover. The process results with rapid occurrence of sinkholes very often causing with hazardous consequences. In some places more than 200 sinkholes of different size are counted in one square kilometre. In total, in the karstic region there are counted over 11000 sinkholes. Some of them are 14 m deep and 20 m in diameter.

Monitoring of the karst process comprise: mapping and measuring of volumes of new karstic sinkholes (in cubic meters) and measuring of amount of dissolved of underground gypsum (in cubic meters from 1 square kilometre of karstic terrain during one year. The monitoring displays that during the period 1925-2023 average annual chemical (gypsum) denudation was 232 m^3 km^{-2} year-1. The rate of karst denudation is increasing due to climate change.

In the period 2018-2023 sinkholes of generalised volume of 2.82 m^3 occured in 1 km^2 annually. This volume makes only 1 percent of the volume of ammount of dissolved gypsum, estimated by denudation. Therefore, we assume the average annual karst denudation in amount 232 m^3 km^{-2} year-1 could cause land surface subsidence of 0,02 m during the past 100 years.

Keyword

From Hazard to Opportunity: Success Story of Biogenic Gas Exploration in North Sumatera Basin through Heating Rate Analysis in Offshore Area

Anggit KURNIA[1]*, Pertamina Hulu Rokan (anggit.kurnia@pertamina.com)
Dhanny Triamindo[2], Pertamina Hulu Rokan
Casdira Casdira[3], Pertamina Hulu Rokan

Abstract

The North Sumatra Basin, renowned for its substantial hydrocarbon reserves, has produced over 4178.35 MMBOE of oil and gas, with an estimated 2088.54 MMBOE of remaining resources (S&P Global Inc, 2024). It unveils a narrative beyond traditional thermogenic gas deposits and oils derived from river-delta/lake sources.

Recent exploration drilling has consistently encountered significant shallow gas accumulations at relatively shallow depths, traditionally considered hazards. Geochemical analysis reveals a surprising truth: these shallow reservoirs hold high-quality biogenic gas, exceeding 98% CH4 with low impurities.

The key to this hidden potential lies in the Keutapang Formation, a shallow unit with less than 1,000 meters, boasting a high sedimentation rate and warm thermal gradient. This condition fosters an anoxic environment, favoring bacterial abundance and subsequent biogenic gas generation. By capitalizing on these favorable conditions, we identified a promising biogenic gas window. This was achieved by multiplying the sedimentation rate and thermal gradient to estimate the heating rate (OC/Ma).

Organic richness is meticulously determined using calibrated Total Organic Carbon (TOC) data and the Passey method (1990), further refined by laboratory results. Subsequent analysis, employing the maximum methane yield plot, classifies biogenic gas potential into four categories: non-potential (< 70C/Ma), unlikely (70-90C/Ma), probable (90-120C/Ma), and highly probable areas (120-180C/Ma) – guiding future exploration.

Compared to Thermogenic gas, biogenic gas presents advantages, boasting lower impurities and exploration costs. This study unveils the significant potential for biogenic gas development in the Keutapang Formation in North Sumatra. Our findings offer valuable insights for further exploration, contributing to Indonesia's energy security and facilitating the transition to cleaner energy sources.

Improving landslide susceptibility assessment using probabilistic back analysis and Markov Chain Monte Carlo simulation

Hyuck-Jin PARK[1]*, Sejong University (hjpark@sejong.ac.kr)
In-Tak Hwang[2], Sejong University
Jung-Hyun Lee[3], Sejong University

Abstract

The physically-based method for analyzing landslide susceptibility is promising because it takes into account the type and process of landslides using a physical slope model. This method uses input parameters, such as slope angle and shear strength of slope materials, which include geometric attributes and geotechnical properties, respectively, to evaluate slope stability. However, applying a physically-based landslide susceptibility analysis over a regional area can be challenging due to limited data availability, which causes significant uncertainty. The primary sources of uncertainty are the shear strength parameters of soil, including cohesion and friction angle. To reduce this uncertainty, this study utilized probabilistic back analysis to acquire supplementary data on the cohesion and friction angle. The study applied the Markov Chain Monte Carlo (MCMC) simulation method to a region with a history of landslides, but with limited data on shear strength parameters. Additional information on cohesion and friction angle was collected from randomly selected locations of past landslides using MCMC simulations. The updated thematic maps were created by obtaining newly acquired data for cohesion and friction angle. We then evaluated landslide susceptibility using the updated thematic maps. The landslide susceptibility results obtained from the updated input parameters were compared with those acquired from previously available limited data. The analysis results using the updated input parameters demonstrated superior performance compared to those using limited field data.

Seismic Imaging of Fault Structures Offshore Northern Taiwan Mountain Belt

Ching-Yun HUANG[1]*, National Taiwan University (jessie7532tw@gmail.com)
Cheng-Chun Chung[2], National Taiwan University
Ho-Han Hsu[3], National Taiwan University
Tzu-Ting Chen[4], Woods Hole Oceanographic Institution
Song-Chuen Chen[5], Geological Survey and Mining Management Agency
Liwen Chen[6], National Academy of Marine Research

Abstract

The geological environment offshore the northern Taiwan belt has transitioned from a compressional state caused by collisional orogenic buildup to an extensional state related to the subduction of the Ryukyu Island Arc and the rifting of the Okinawa Trough. This transition has led to the formation of several fault systems. To further understand the geological structures and potential geo-risks in this region, this study applies advanced seismic imaging methods with high-resolution sub-bottom profiler and multibeam bathymetry data to analyze the fault structures from the coast to offshore areas. The results present at least five main NE-SW trending faults, including the Offshore Jinshan Fault, Yehliu Fault, Xiaoyehliu Fault, Badouzi Fault, and Bitou Cape Fault from the west to east. The Offshore Jinshan Fault and Yehliu Fault, each extending to 30 and 26 km, respectively, can be associated with seafloor lineaments and ruptures. Both of these faults rupture the seafloor and form half-graben basins between them. The Offshore Jinshan Fault exhibits characteristics of a normal fault and may correspond to a similar fault onshore known as the Sanchiao Fault. As a result, it could be a significant fault extending from North Taiwan to the East China Sea Shelf. The Xiaoyehliu Fault is a blind fault and extends approximately 13 km, but as it extends seaward, it gradually transforms into a series of minor faults. The Kanchiao reverse fault onshore may correspond to either the Yehliu Fault or the Xiaoyehliu Fault offshore, indicating a post-collision tectonic setting. The Badouzi Fault extends to about 28 km and shows seafloor ruptures within a nearshore range of 11 km. The Bitou Cape Fault only ruptures to the seafloor near the coast and transitions to a blind fault toward seaward, with a length of approximately 10 km. It also may correspond to the Keelung reverse fault onshore. This study reveals that at least three offshore faults rupture the seafloor and may be linked to the onshore faults. Based on our improved seismic imaging results, we propose a fault distribution map and provide essential evidence for further geo-risk assessment offshore northern Taiwan.

Appraisal of the present-day geodynamics in Andaman Islands through campaign mode GNSS survey

SNEHASIS BHATTACHARYA[1]*, Geological Survey of India (snehasis.bhattacharya@gsi.gov.in)
SOUMITRA BHARGAB DASGUPTA[2], Geological Survey of India
AKSHAYA KUMAR MISHRA[3], Geological Survey of India

Abstract

The Andaman-Nicobar-Sumatra region is one of the most tectonically vulnerable areas of the world, where three tectonic plates e.g. the Indian, Australian and Sunda plates interact with each other by forming a triple junction. Unique tectonic setup of the archipelago carries significant potential to generate mega-thrust earthquakes. After the Sumatra-Andaman mega-thrust earthquake (Mw 9.2) on 26th December 2004, post-seismic crustal deformation studies using campaign mode GNSS (Global Navigation Satellite System) survey were taken up which unequivocally confirmed the convergence being accommodated through thrusting. It also indicated that the post-seismic and inter-seismic periods suffered simultaneous subduction perpendicular extension and contraction leading to transtension and transpression deformational environments respectively. We conducted the campaign mode GNSS (Global Navigation Satellite System) survey with the aim to understand the ongoing crustal deformation of this region. Three (03) yearly sets of campaign mode GPS data have been acquired from thirteen (13) campaign sites located at Radhanagar, Aerial Bay, Kalpong, Kishorinagar and Mohanpur of North Andaman; Karmatang (2 stations), Bajato, Baratang and Kadamtala of Middle Andaman; Saitankhari, Collinpur and Chidiya Tapu of South Andaman during January to March of 2021, 2022 and 2023. We selected the sites so as to cover all the major structural elements as well as different lithounits like dismembered bodies of Cretaceous ophiolite slices and Tertiary sediments (Mithakhari Group, Andaman Flysch Group and Archipelago Group). The GPS data (observation files) was acquired at 30 sec intervals for a continuous period of 4-5 days per site per year. The mask angle of the choke-ring antenna was set at 10° to minimize multipath while maintaining good GDOP (Geometric Dilution of Precision). We processed the acquired campaign GPS data in GAMIT-GLOBK suite of software along with 38 nos. of international GNSS stations located in the neighbouring plates as reference stations and 4 nos. permanent GPS-GNSS stations of Geological Survey of India (GSI) located at Hutbay, Port Blair, Rangat and Diglipur of Andaman Islands. Velocity of campaign sites with respect to the ITRF14 reference frame varies from a minimum of 18.07 mm/yr (Saitankhari of south Andaman) to a maximum of 48.79 mm/yr (Kalpong of north Andaman) with an average azimuth of N33°E. With respect to India fixed frame of reference, velocity of campaign sites varies from 11.84 mm/yr (Kishorinagar of north Andaman) to 39.06 mm/yr (Saitankhari of sou th Andaman) with the magnitude gradually reducing towards north Andaman. The strain analysis solving the Lagrangian displacement equation suggests that the average orientation of the horizontal principal axis of compression is E-W ± 35° across the island with distinct local variation along segments that divide the island into the northern, middle and

southern parts. The area in between Little Andaman and South Andaman shows positive area dilation in contrary to the North Andaman where area contraction is predominant. This study indicates that the North Andaman is in relatively locked position with the subducting Indian plate compared to the rest of the island.

Smart Monitoring System for Flexible Barrier Using Accelerometer and Corrosion Sensors

JunHa BAEK[1]*, Geobrugg Korea (junha.baek@geobrugg.com)
Seung il Choi[2], Geobrugg Korea
Dennis Gross[3], Geobrugg AG

Abstract

Due to climate change, natural disasters are increasing globally. These manifest in various forms such as heavy rain, drought, heavy snow, and earthquakes, and particularly in mountainous regions, disasters occur in the form of landslides, falling rocks, debris flow, and avalanches. As part of the countermeasures against these, flexible barriers are being widely used around the world.

Due to the characteristics of mountainous terrain, flexible barriers are often installed in high-altitude terrain, steep slopes, and deep valleys. However, due to the difficulty of accessing these locations, these flexible barriers often lack sufficient maintenance. Furthermore, although special corrosion-resistant coatings are applied to the flexible barrier to slow down corrosion, long-term corrosion degrades the durability of the flexible barrier, making it difficult to ensure the impact protection function as initially designed. An appropriate solution is needed to solve these problems.

This measuring system was developed as an IoT device to solve maintenance problems due to difficult site access and durability degradation due to long-term corrosion. By tracking and recording the impact energy delivered to the flexible barrier using an accelerometer, managers can easily identify the cause of the impact and take appropriate barriers. In addition, by detecting the progress of corrosion in advance with the built-in corrosion sensor, more efficient maintenance is possible by planning prevention and repair work based on this. Also, thanks to 7 to 10 years' battery life, it reduces the number of unnecessary inspections by managers, thereby reducing the risk and helping with the effective management of flexible barriers.

Ultimately, this system can analyze the measured data for the flexible barriers installed in hard-to-reach areas, enabling predictive maintenance by establishing an appropriate maintenance plan based on this. In addition, by quickly establishing the scale and response to the occurred event through the data, it can prevent damage to life and property, and it is expected to have a significant cost-saving effect.

These IoT devices can measure and transmit data in real time through a dedicated platform. Currently, more than 400 devices are in operation worldwide, continuously collecting and analyzing data. This system greatly aids in disaster prevention by enabling stable maintenance of

flexible barriers, thereby ensuring a safer environment.

Stability Assessment of the Rock-Cut Slopes Based on a Multi-Method Approach

Rajesh Singh[1], DEPARTMENT OF GEOLOGY, UNIVERSITY OF LUCKNOW, LUCKNOW-226007, INDIA.
PRATEEK SHARMA[2]*, DEPARTMENT OF GEOLOGY, UNIVERSITY OF LUCKNOW, LUCKNOW- 226007, INDIA. (prateeksharmarishi@gmail.com)
Rahul Kumar Verma[3], DEPARTMENT OF GEOLOGY, UNIVERSITY OF LUCKNOW, LUCKNOW- 226007, INDIA.
Pranshu Mishra[4], DEPARTMENT OF GEOLOGY, UNIVERSITY OF LUCKNOW, LUCKNOW-226007, INDIA.

Abstract

With its varied physiographic and climatic conditions, India is frequently susceptible to the unexpected occurrence of landslides. The transportation routes in the Himalayan region feature designed slopes that exhibit many sets of discontinuities and are susceptible to structurally controlled failures. The stability of slopes is significantly impacted by several factors, including the existence of primary and tectonic structures, the kind of weathering, and the pace at which cohesiveness is lost as a result of strength deterioration. To assess the present stability condition of slopes, the extensively used geo-mechanical classifications for rock masses are slope mass rating (SMR) and Continuous Slope Mass Rating (CSMR). These simplified methods were adopted for slope stability analysis and support suggestions. The authors attempt to utilize these classification systems for slope stability analysis together with the Geological Strength index-slope (GSI-slope) and Q-slope to investigate the engineering geological conditions of the cut-slope sections along NH-03, Aut to Manali, Himachal Pradesh, India. After studying all slopes, the results from the preliminary kinematic investigation indicated that the wedge failure is dominating and majorly responsible for the rock fall problem in the area. Based on the groundwater rating, surface circumstances, and adjustment factors of the CSMR, the rock cut-slope sections are also characterized using the GSI-slope and indicated unstable to critically stable conditions. Further, along with failure rates of 50%, 30%, 15%, and 1%, the stability analyses used the Q-slope method to calculate the stable slope angle for each location under the present conditions. The results could benefit the ongoing development and enlargement of roads along sections of the Lesser Himalaya transit routes. A comparison of the studies' data indicates that the present investigation has improved accuracy by establishing a comparative relationship between applied categorization methods.

Abstract

Geodynamic and gas-dynamic processes that occur during technogenic impact on rock masses pose a threat to the environment and the population. During scientific research, the location of 27 coal waste dumps was investigated and the following patterns were discovered. Spontaneous combustion of coal dumps which are located in geodynamically active zones occurs to 4 times more often than outside these zones. This phenomenon is explained by the migration of gases from the mines to the dump through the geodynamic zone. The entry of gases into the dump is a trigger that starts the combustion process. The second pattern concerns the nature of the migration of mine gases during the reactivation of tectonic fault by subsidence processes. Based on the results of computer modeling, it was established that when the walls of the fault shift, an alternation of asperities occurs, which creates pressure that causes gas to move towards the surface. The process of gas migration develops in 2 main phases: it is activated by a pulsating increase in gas pressure in the void space (1st phase) and continues to develop after the cessation of the pulse and a decrease in pressure to the initial one (2nd phase). From a practical point of view, this means that even a single pulsating increase in pressure up to 250 Pa can provoke mass transfer of gases along the tectonic fault to the surface in a short time and create a hazard.

GEOMORPHOLOGICAL EVOLUTION AND ASSOCIATED RISK ON THE SLOPES OF CERRO SOLO AND TECHADO NEGRO, TORRE GLACIER VALLEY, SANTA CRUZ PROVINCE, ARGENTINA

Daniela Ines SCHMIDT[1]*, Instituto de Estudios Andinos "Don Pablo Groeber (UBA-CONICET), Buenos Aires, Argentina (danielainesschmidt@gmail.com)
Diego Alejandro Winocur[2], Instituto de Estudios Andinos "Don Pablo Groeber (UBA-CONICET), Buenos Aires, Argentina

Abstract

During the last decades, the Torre glacier experienced a gradual retreat of its front and a notable loss of mass, thickness and volume of ice, causing the relaxation of the slopes that contain it. Both the northern slope of Cerro Solo and southern slope of Cerro Techado Negro are destabilized and susceptible to mass removal movements. In this work, the temporal evolution of the last fifteen years, 2007-2022, on both slopes is characterized and analyzed in order to contribute to the knowledge of the rate of movement in relation to glacier retreat and its influence on the potential slope destabilization process. The analysis of the results showed that in the last three years, 2019-2022, the rate of displacement of the material involved in the slope of Cerro Solo almost doubled its rate of movement compared to a period of four times greater, between 2007-2019. For the slope of Cerro Techado negro, the measurements did noy show significant changes in the movement associated with the main escarpment, however, the presence of new scars and slipped material that covers the slope was identified. In addition to the above, the values obtained for the 2019-2022 period show a loss of glacial ice tha almost doubles the result obtained for the previous twelve-year period, between 2007-2019. This scenario constitutes a geological risk due to the possible occurrence of a sudden event that slides large volume of material into the Torre proglacial lake, causing a sudden rise in the flow of the Fitz Roy River, which could cause damage downstream, in the Los Glaciares National Park and the El Chaltén town.

Study on coastal flooding from Probable Maximum Storm Surge(PMSS) by the changes in Probable Maximum Typhoon Intensity at the nuclear power plant site

JAEWOONG RYU[1]*, Korea Hydro & Nuclear Power Co., LTD. (jwryu4545@khnp.co.kr)

Abstract

The intensity of typhoons is increasing globally due to global warming and flood damage continues to be an issue in the coastal regions around the Korean Peninsula. Although Korea Hydro & Nuclear Power Co., Ltd. evaluated the safety of nuclear power plant sites from Probable Maximum Storm Surge(PMSS) including Probable Maximum Tsunami(PMT) in 2015 after the Fukushima nuclear accident in Japan, there is no clear methodology for estimating Probable Maximum Typhoon Intensity considering future ocean and atmospheric environments due to climate change. Therefore, this study shows the results of a preliminary evaluation of Probable Maximum Typhoon Intensity according to a new methodology which can simulate sea surface cooling effects by typhoon-ocean interaction using an ocean-atmosphere coupled model considering the changes of sea surface temperature and vertical temperature profile. For the evaluation of coastal flooding from PMSS, the standard typhoon is selected by analyzing the historical typhoons and then the standard typhoon is strengthened to Probable Maximum Typhoon within design lifetime of nuclear power plant. In addition, we evaluated the storm surge and significant wave height by the changes in Probable Maximum Typhoon Intensity after 10 and 40 years using storm surge and wave model. There is no significant difference in the significant wave height on the shore after 10 years according to the methods. However, after 40 years, the significant wave height calculated by an ocean-atmosphere coupled model is reduced by up to 0.46m compared to the result from empirical approach. Currently, we are planning to develop technology to predict Probable Maximum Typhoon Intensity for further research at the nuclear power plant site.

SUSCEPTIBILITY TO LANDSLIDES IN AN AREA OF 48 KM2 IN THE SURROUNDINGS OF BIOTOPO MARIO DARY RIVERA NATURE RESERVE, PURULHÁ, BAJA VERAPAZ, GUATEMALA

Gabriel Estuardo MORALES RECINOS[1]*, Universidad de San Carlos de Guatemala (ggmorales90@gmail.com)

Abstract

This study contains an inventory and landslide susceptibility maps of 482 km area in the surroundings of Biotopo Mario Dary Rivera nature reserve at a scale of 1:25,000 as a helpful tool to identify areas potentially prone to future landslide occurrence.

To carried out this investigation, a first stage of collecting information such as existing geological reports and aerial photographs was done, therefore creating the basis for the 6 thematic maps of conditioning factors (slopes, slope orientations, geomorphology, land use, geology and structural) that the susceptibility methodology requires for Weighted Sum in GIS

Along with this, an inventory of landslides was elaborated through analysis of satellite photographs and reports from 1998 hurricane Mitch, obtaining 47 landslides that were analyzed together with the conditioning factors to build a susceptibility matrix that assigned new values to the maps of conditioning factors therefore make a sum of maps and obtain the final landslide map which located several areas of high susceptibility

Analyzing the resultant map catches the attention an area located to the north in the populated areas of Panimaquito, Cuchilla del Nogal, Cumbre del Carpintero and Rio Colorado due to the high threat that it may represent landslide recurrence and high landslide susceptibility factors, recommending subsequent vulnerability and risk studies.

Estimation of debris flow damage areas using influencing factors and empirical formula

Jaeho LEE[1]*, Kyungpook National University (fabnm2003@naver.com)
Youjin Jeong[2], Kyungpook National University
Junghae Choi[3], Kyungpook National University

Abstract

Most of the landslides in Korea are debris flows that are triggered by rainfalls, such as heavy rains and typhoons that occur in July and August annually. Furthermore, the frequency and magnitude of landslides have gradually increased due to recent climate change. Since debris flows are a mixture of soil and water moving rapidly along the valley. It is important to predict the runout and flow path of debris flows and take countermeasures accordingly. Numerical and analytical models to predict debris flows depend on uncertain input parameters like volume, velocity, and friction coefficient.

Additionally, these models have limited capability in predicting regional areas. Therefore, using a simple empirical formula, this study developed a method to calculate the damage areas caused by debris flow. Applying a random forest algorithm enabled identifying strong correlations between factors that trigger debris flow and damage areas caused. The results indicated that the orientation of the valley mouth, distance to the fan apex, distance to the channel, and the average slope between the debris flow source and the fan apex exhibited a high correlation with the increase in damage area. Rickenmann and Scheidl (2012) classified the morphology of debris flows and presented an empirical formula for calculating the runout distance of an ideal fan-shaped debris flow unobstructed by buildings. Using the empirical formula Rickenmann and Scheidl (2012) developed, we calculated the runout distance of debris flows. We determined the damage area by assigning weights to four factors identified through the random forest analysis. The direction of the valley mouth was given the highest weight of 1 if it was in the same direction as the debris flow, and the weight was gradually decreased in a fan shape, while the weight was linearly decreased as the fan apex and channel became more distant. Finally, the average slope was given less weight because it had less effect as the angle decreased. The four fan-shaped weights with each of these weights were combined to build a damage risk map, and to verify the model, we applied the model to three areas in Korea where actual debris flows occurred: Yeoju debris flow in 2011, Chungju debris flow in 2020, and Yeocheon debris flow in 2023. The actual and predicted debris flow damage areas showed an 81% match, and these results are expected to serve as a useful reference for future urban planning and policy decisions.

Abstract

The ocean crust's permeable basalt rock pore space has massive capacity for sequestering carbon dioxide which, after injection, will naturally react with the basalt minerals and turn into carbonate rock, the most durable form of carbon storage. For a realistic total capacity, only taking into account ocean crust that is young and reactive for CO2 mineralization, is covered with at least hundreds of metres of sediment to initially seal CO2, and is located in the deep ocean where any accidental CO2 leakage cannot reach the atmosphere, globally there is potential for sequestering over 100,000 giga-tons of CO2.

We will present the Solid Carbon project which is focussing on all aspects of utilizing the ocean crust for carbon dioxide removal, from (1) carbon capture directly from the air or upper ocean seawater using renewable energy generated in-situ on floating platforms, to (2) planning an demonstration project by predicting the fate of CO2 in the ocean crust and preparing for future monitoring, reporting and verification, to (3) the social, regulatory and investor acceptance aspects around this idea.

CO2 injection into basalt rock as already been proven on land in Iceland (Carbfix) and Washington State (Wallula) where dissolved CO2 was injected, however onshore storage capacity and other required resources (e.g., energy generation) are more limited than offshore where it is also possible to inject pure CO2, and therefore offshore projects can be upscaled more effectively.

Our focus is on the most favourable test site, the Cascadia Basin in the northeast Pacific that alone has about 750 Gt of CO2 storage capacity, and where Ocean Networks Canada is operating a cabled seafloor observatory offshore Vancouver Island to enable open access monitoring, and furthermore where decades of ocean drilling has provided unique knowledge of ocean crust fluid flow, all helping to enable a most informed future sequestration experiment which is what we are currently aiming for.

Impact of Climate Change and Rapid Urbanization: A need for Climate Resilience Plans- based on Flash Flood Analysis in Hyderabad Metropolitan area through a Geospatial approach

Anoop V M[1]*, Geological Survey of India (anoop.m@gsi.gov.in)
Annie Daliya Nelson[2], Geological Survey of India
Nisha Rani Rani[3], Geological Survey of India
Muduru LachhnaA Dora[4], Geological Survey of India

Abstract

The study is an attempt to analyze the impact of climate change resultant meteorological disasters say flash floods, a sudden downpour in a short time on an area. One of the fastest developing south cities of India, Hyderabad, a global hub of Information Technology Industry, witnessed such an incident in October 2020.It was one of the worst occurred disasters faced by the city in the past 7-8 decades. More than ten lakh families were affected by inundation and about one lakh severely affected. The existing sewage system cannot drain away the rainwater due to flash flood which creates havoc to normal city life, economic loss, damage to infrastructure and loss of life. Hyderabad City had undergone rapid urbanization in the last decade. Hyderabad is currently having population of 10.5 million with an average annual growth rate of 2.53%.

The present study for climate resilience plan analyzed the change in the Land use Land Cover (LULC) pattern of the city through the last five years; using Sentinel 2A data of high spatial resolution shows about 9.37% growth in the urban built-up. The land use pattern reveals rapid urbanization and its severity on natural drainage system. The constructions along the existing drainage system and lakes due to improper urban planning and human interventions to the natural ecosystem observed during this study.

Drainage and topographic analysis using Digital Elevation Model (SRTM), correlating with LULC layer; it is observed that lack of proper interlinking from major lakes, tanks and water bodies with the existing drainage system and confluence towards the major river Musi is missing due to the encroachment.

Nine major flash flood influencing factors which control the severity of flash flood have been selected and analyzed by assigning weightage with the help of multi integrated approach Analytical Hierarchy Process (AHP).The result shows that the most important flash flood influencing factors are distance to river/waterbody (15.47%), (TWI) Topographic Wetness Index (14.72%), LULC (12.2 %)and precipitation (11.78). Flood susceptibility map have been derived as high (2.42%), moderate (44.15%), low (49.82%) and very low (3.59%) of flash flood susceptible areas. The generated model is validated and 78 % of the flash flood inundated locations are falling under high susceptible area. The study focuses to devise flash flood resilience plans like Strategic Drainage Development Programs in those areas of the high susceptibility, and suggest to bring strict protocols in the infrastructure development along the proximities of lakes, drainage and water body. This study proposes for the implementation of green landscapes, permeable

pavements and measures which helps to channelize the surface runoff in highly susceptible areas and help build resilience. The strategy aims to enhance the use of natural infrastructure to prevent urban flooding similar to City of Vancouver’s Rain City Strategy. Such methodology enables decision-makers to confront climate change- related issues in similar conditions in other cities or townships countrywide where recent cloud burst incidents occurred to determine and prioritize risk adaptation areas during urban planning.

Integrated assessment of gully erosion susceptibility for risk informed urban planning: A case study of Rundu, Namibia

Giesberta Naipopya Shaanika[1]*, Geological Survey of Namibia (Giesberta.Shaanika@mme.gov.na)
Miguel Vallejo Orti[2], Namibia University of Science and Technology
Michelle Hailonga[3], Geological Survey of Namibia
Israel Hasheela[4], Geological Survey of Namibia
Helmi Ipinge[5], Geological Survey of Namibia
Kaleb Negussie[6], Namibia University of Science and Technology
Norwel Mwananawa[7], Geological Survey of Namibia

Abstract

Gully erosion poses a significant threat to the town of Rundu in the Kavango East Region of Namibia, impacting critical infrastructure such as roads, buildings, sewerage infrastructure, telecommunication infrastructure, while exacerbating land degradation. The Division of Engineering and Environmental Geology (DEEG) of the Geological Survey of Namibia (GSN), conducted a study aimed at identifying the causes of gully formation and developed a predictive model for susceptibility mapping to inform future planning and expansion efforts. The investigation, supported by the Namibia University of Science and Technology (NUST), utilized a combination of remote sensing techniques, on-site observation and mapping, and drone surveys.

The mapping exercise revealed that gullies predominantly occur on the northern side of the town, affecting areas underlain by thick Quaternary sediments of the Kalahari Group. Natural factors such as soil composition and steep slopes, compounded by man-made influences such as insufficient stormwater drainage and the removal of natural vegetation, were identified as contributors to gully formation. A predictive model leveraging Python and random forest (RF) algorithm was developed, utilizing both natural and man-made predisposing factors to delineate areas susceptible to future gully formation. The resulting gully erosion susceptibility map (GESM) highlighted the northern slope between the town and floodplains of the Okavango River to be particularly prone to gully formation, necessitating careful urban planning considerations.

Recommendations for preventative measures were proposed, including the incorporation of engineering control structures for stormwater management, maintenance of drainage infrastructure, and enforcement of proper waste management practices. Furthermore, the study suggests conducting an Urban Hydrology study, implementing nature-based solutions such as re-vegetation of slopes, and adopting traditional methods like stormwater harvesting to mitigate gully formation. By employing predictive modelling and investigation of these hazards, allows for proactive planning and risk-informed urban development, which safeguards infrastructure and the environment from the adverse impacts of geohazards. This proactive approach will help to build a more resilient and sustainable future for Rundu and other vulnerable urban centers faced with similar challenges.

Carbon Capture, Utilisation, and Storage opportunities in South Africa's highest carbon dioxide emissions hub: opportunities for the Just Transition

Taufeeq DHANSAY[1]*, Council for Geoscience (tdhansay@geoscience.org.za)

Abstract

South Africa is recorded as the largest emitter of anthropogenic CO2 on the African continent. The country emits approximately 500 million tonnes of CO2 per annum. Much of these emissions stem from South Africa's reliance on coal as an energy generation feedstock and critical contributor toward the country's socioeconomic development. The coal industry accounts for more than two-thirds of all energy generation and at least 100,000 direct jobs. South Africa has however committed to reducing CO2 emissions. It aims to reduce emissions by at least 40% within the next ten years. This is planned, in part, through the development of alternative energy sources. However, worsening energy crises over the last 5 years, and its dire effect on the country's socioeconomic development imperatives has called for more practical energy solutions. South Africa will therefore still look to coal while attempting to transition toward alternative source of energy. Carbon Capture, Utilisation and Storage (CCUS) is proposed as an intervention to enable this transition. That is, to immediately combat anthropogenic CO2 emissions while allowing the needed time to enable the necessary energy transition. Research and development of CCUS technologies in South Africa have not advanced to pilot scale, largely because of misconceptions that the country does not have suitable geological reservoirs near large point-source emission hubs. This paper presents the findings of a geological investigation to identify suitable CCUS sites proximal to large point-source emitters in the Govan Mbeki Municipality of the Mpumalanga Province. Geological investigations considered, among others, geological mapping, structural geology, borehole data, reflection seismics, mineralogy, petrography, and geochemistry. The results suggest that the central region of the Municipality has at least several gigatonnes of storage potential. This includes deep saline reservoirs and basaltic storage. Crucially, this storage potential lay proximal to several key point-source emitters, including coal mining, energy generation, and petrochemical processing. The proximity to these industries also provides realistic opportunities to develop a carbon utilisation market. This can include the development of alternative sustainable fuels and fertiliser materials. Finally, the availability of potentially significant reservoirs should be considered in the context of the carbon trading market. This may include revision of South Africa's carbon taxation and trading policies.

Soil CO2 change and rainfall effect in growing season in a karst grassland of Slovenia

Cheng ZHANG[1]*, Institute of Karst Geology, Chinese Academy of Geological Sciences/International Research Center on Karst Under the Auspices of UNESCO (zhangcheng@mail.cgs.gov.cn)
Qiong XIAO[2], Institute of Karst Geology, Chinese Academy of Geological Science/International Research Center on Karst Under the Auspices of UNESCO
Mitja PRELOVSEK[3], Karst Research Institute, Slovenian Academy of Sciences and Arts
Jinliang WANG[4], Institute of Karst Geology, Chinese Academy of Geological Science/International Research Center on Karst Under the Auspices of UNESCO

Abstract

Soil CO2 is a critical driving factor for karst processes and the core index for studying soil respiration and its relationship with atmospheric CO2 source-sink. The rapid dissolution kinetics of karst carbon cycle and its sensitivity to ecosystem suggest that karst carbon cycle is still playing an active role in the global carbon cycle. Taking the typical grassland soil ecosystem in Dinar karst, Slovenia as an example, high-resolution online monitoring of soil temperature, water content and soil CO2 concentration at different depths was carried out during the growing season from June to September in year 2021, the data were recorded in 10-minute time interval. Results showed that mean soil temperatures at depths of 20cm, 30cm and 50cm are 19.69˚C, 18.54˚C and 17.42˚C respectively, implying soil temperature decreases gradually with increase of soil depth. Mean soil water contents at depths of 20cm, 30cm and 50cm are 23.2%, 21.7% and 24.9 % respectively. Soil moisture mainly was controlled by precipitation, i. e. the greater the rainfall intensity, the larger the moisture rises. The ranges of soil CO2 concentrations at depths of 20cm, 30cm and 50cm are 1884-6705 ppm, 2088-5516ppm and 2771-3606ppm respectively, with mean value of 3578ppm, 3468ppm and 3174ppm respectively. During the no-rain days, soil moisture presents a tendency of stair-stepped down, with decrease in day time and basically remain unchanged at night, and controlled by soil moisture, the multi-day changes of soil CO2 showed a jagged falling constantly. Soil CO2 down movement is observed during different rainfall conditions, soil CO2 concentration drops rapidly at the early stage of storm events, suggesting that pulse effect cause by rainfall infiltration is the main controlling factor to push CO2 move down quickly and enter to the underlying karst aquifer furtherly, thus providing critical driving force for carbonate rock dissolution. The value difference of CO2 decrease range and the pre-rain CO2 content suggested that 12%-33% of soil CO2 transported to karst aquifer and were involved in carbonate rock dissolution during the rainfall events. The monitoring results suggest that karst process is a lateral extension of carbon cycle in terrestrial ecosystems in karst area and has soil CO2 sink effect. It means that karst process has the function of alleviating the release of soil CO2 to the atmosphere, i.e. source reduction effect. Accordingly, Vegetation-soil-carbonate dissolution should be considered as a whole for studying the carbon cycle and carbon sink effect in karst area. Systematic monitoring and research should be carried out from the perspective of karst critical

zone, so as to obtain a complete understanding of carbon cycle processes in karst area and reveal their carbon sink effects, thus further evaluating the role of karst carbon cycle in global carbon cycle and in coping with climate change as well.

Evaluation of energy saving effects in university campus rooftop greening through the use of high concentrations of carbon dioxide in lecture rooms

Jeongwoo PARK[1]*, Dong-A University (1822247@donga.ac.kr)
Minju KIM[2], Dong-A University
Chang-Uk HYUN[3], Dong-A University

Abstract

Efforts are underway worldwide to mitigate global warming by reducing greenhouse gas emissions and increasing absorption to achieve carbon neutrality, where net emissions reach zero. Green spaces serve as one of the carbon sinks, and securing green areas within cities is considered an effective approach to practicing carbon neutrality. However, securing green spaces within urban areas is challenging due to the dense urban structure, high real estate prices, and various regulations. As a result, rooftop greening, utilizing the upper parts of artificial structures, is being employed for urban greening due to its low cost and high space utilization. University campuses, like many urban structures, generate significant amounts of carbon dioxide due to their high energy consumption.

This study aimed to implement rooftop greening on the campus of Dong-A University in the urban area and utilize carbon dioxide generated in lecture rooms as fertilizer for rooftop greening. It was confirmed that high concentrations of carbon dioxide (700-1,000 ppm), which enhance vegetation growth, were generated inside the lecture rooms. An experiment was conducted to simulate the supply of carbon dioxide captured inside the lecture rooms to the vegetation of rooftop greening (*Dendranthema zawadskii*). A comparative experimental group was established consisting of vegetation without carbon dioxide supply. Through 3D modeling, it was observed that vegetation supplied with carbon dioxide exhibited a greater growth trend compared to the comparative group.

Additionally, the energy savings between rooftop gardens supplied with carbon dioxide and those without were compared based on the building volume in the study area. Temperature measurement experiments confirmed a 0.53°C insulation effect for vegetation supplied with carbon dioxide compared to vegetation without carbon dioxide supply inside the lecture rooms.

Furthermore, the potential reduction in carbon dioxide achievable through rooftop greening at Dong-A University's Seunghak Campus was calculated. High-resolution aerial images were used to select buildings suitable for rooftop greening on the campus, and the volume of these buildings was evaluated. The experimental vegetation, Dendranthema zawadskii, was reported to absorb 3.65 kg of carbon dioxide per square meter annually. Assuming 60% greening of the rooftop area of the Campus buildings, it was calculated that rooftop greening in the study area could result in a reduction of 85 tons of carbon dioxide per year.

Artisanal Biochar Production: A Sustainable Pathway for Climate Resilience in Rwanda

Magalie NTAHOKAJA[1]*, University of Rwanda (mntahokaja@yahoo.com)

Abstract

The Republic of Rwanda, grappling with the dual challenges of climate change and sustainable development, is exploring innovative avenues to bolster its resilience against climate adversities while promoting green growth. This study delves into the artisanal production and application of biochar as a multifaceted solution aimed at enhancing agricultural productivity, providing affordable energy alternatives to low-income households, and facilitating Rwanda's transition towards a circular economy. Biochar, produced through the pyrolysis of biomass such as agricultural residues, animal manure, and forest waste, emerges as a carbon-rich, porous material with considerable potential to ameliorate soil fertility, water retention, and carbon sequestration. Aligning with Rwanda's Vision 2050 and the revised Green Growth and Climate Resilience Strategy, the adoption of biochar not only addresses the impending ban on charcoal sale but also capitalizes on the valorization of waste, contributing to the country's sustainable environmental management and economic innovation through carbon credit sales. Furthermore, the study underscores the significance of biochar in mitigating climate-induced agricultural vulnerabilities by enhancing soil health, thereby ensuring food security and livelihood sustainability for the majority agrarian population. Through an empirical lens, this paper presents a comprehensive analysis of the socio-economic and environmental benefits of integrating biochar into Rwanda's green economy blueprint, offering insights into policy implications, practical challenges, and future prospects for scaling biochar initiatives across the region.

Abstract

Extreme weather events are among the expected negative effects from the undeniable increase in both atmospheric and sea surface temperature due to climate change. The Philippines is highly susceptible to these hydro-meteorological hazards and is reliant on coastal infrastructures for protection, and economic development. These structures made from concrete are highly sensitive to changes in both moisture and temperature, and any drastic change from the environment may result in its weakening, and irreparable damage. Thorough assessment of the current quality of coastal concrete structures is necessary to ensure building resilience, prevent economic loss, and potential casualties brought about by these hazards.

This study focuses on the application of petrography to the in-depth assessment of selected coastal concrete infrastructures across different regions in the Philippines. Petrography provides information on the overall concrete quality, including raw material composition, water-cement ratio, occurrence of cracks and air voids, and other concrete deterioration phases. Based on the conducted assessment, common deterioration across all structures includes carbonation of the cement paste, cracking, presence of delayed ettringite formation, and minor alkali-silica reaction. These observed durability issues may contribute to the progressive degradation of concrete over time. Factors contributing to concrete deterioration including raw material source, current site conditions, microclimate, and past extreme events were also investigated for further correlation with the obtained petrographic data. The results gathered from the study will serve as technical

recommendations to the national standards related to coastal concrete construction, particularly on the determination of the appropriate concrete cover thickness, and concrete design mix for coastal environments.

Abstract

Understanding the impacts of CO2 leakage on hydrochemical and carbon isotope compositions of shallow aquifers during the early stages of CO2 leakage from underground storage sites is essential for developing effective monitoring strategies and addressing public concerns about geologic CO2 sequestration. To address this, two controlled CO2 release experiments were conducted in a siliciclastic shallow aquifer at the Environmental Impact Evaluation Test (EIT) site in South Korea.In the initial experiment, CO2 was injected as CO2-infused water at a rate of 55 m3/day for 26 days, at approximately 22 m below ground level (bgl). In the second experiment, CO2 was injected as a gaseous phase at a rate of 3.5 L/min for approximately 7 days, around 30 m bgl via an inclined injection well. Both experiments were conducted in a ~40 m thick heterogeneous aquifer, with artificially increased pressure gradients to ~10 times the natural gradient to establish flow paths along a monitoring well network. The monitoring well network consisted of four multi-level monitoring wells aligned along the pressure gradient flow direction, supplemented by five full-screened monitoring wells and the two wells for maintaining pressure gradient. In both experiments, the presence and migration of CO2 plume were determined at each monitoring well through decrease in pH, increase in the partial pressure of CO2 (PCO2), and elevated electrical conductivity (EC). Additionally, the carbon isotope composition (δ13C) decreased upon the arrival of CO2 plumes, demonstrating distinctive isotopic signatures between injected CO2 and ambient groundwater. In the first experiment, where CO2 was injected as CO2-infused water, observations from the monitoring well network indicated the migration of the CO2 plume along a preferential pathway. This migration pattern was characterized by overwhelming of induced pressure gradient due to water table mounding at injection point, followed by some degree of sinking, likely due to the higher density of the CO2 plume. Conversely, in the second experiment, where CO2 was injected as a gaseous phase, hydrochemical and isotopic responses were primarily observed in the multi-level monitoring wells along the induced pressure gradient (SMW-1 to 4), rather than the supplementary monitoring wells. This suggests a distinct migration

behavior, with the CO2 plume following the groundwater flow direction instead of a preferential pathway. In summary, our experiments yield significant insights into the behavior of CO2 plumes and underscore the need of adaptive and context-specific monitoring strategies to accurately assess the impacts of CO2 leakage. Such strategies are crucial for ensuring the safety and efficacy of geologic CO2 sequestration projects, emphasizing the importance of continued research in this field.

Yijian Wang[6], Geological Survey of Jiangsu Province/Research Center for Resources Engineering towards Carbon Neutrality of Jiangsu
Xiao Jia[7], Nanjing University

Abstract

Enhanced rock weathering (ERW) involves dispersing pulverized alkaline rocks on farmland to accelerate weathering and increase reaction rate with atmospheric CO2, leading to store carbon as HCO3- or carbonate. Various carbon verification methods have been developed, however, there is currently no consensus on carbon verification for large-scale ERW applications.

In this study, we aim to explore carbon capture potential and related agricultural benefits after applying basalt powders to farmland at field scale under winter wheat-corn rotation in Xuyi County, China. Fresh basalt was grinded into two grain size fractions, coarser (<1000 μm) and finer (< 100 μm). Basalt powders with two application rates of 1 kg/m2 and 5 kg/m2, were dispersed into designated blocks (labeled as C1, C5, blk, F1, F5, respectively) of farmland in June 2022. Soil pore water samples were extracted in-situ after precipitation events, approximately every 1-2 months. Crop yield and soil samples were collected after each harvest for further analysis.

Loss of [Ca+Mg] in the soil was calculated based on the aluminum content of bulk soil. The results showed that [Ca+Mg] loss only occurred after the wheat harvest (from October 2022 to May 2023), with C1-F5 soil losing approximately 51.7, 124.5, 40.1, 49.6 and 82.8 mol/m2, respectively (considering a 0.3 m thick soil layer), which is much higher than expected. While soil exhibited varied levels of [Ca+Mg] during corn growth (from June 2022 to October 2022), which may be attributed to biological activity.

No significant soil carbonate was observed due to sufficient rainfall. The DIC content of soil pore water showed that during corn growth, C1-F5 blocks stored 0.60, 0.37, 0.66, 0.95, and 0.89 mol C/m2, respectively. During wheat growth, the values were 0.07, 0.08, 0.14, 0.14, and -0.13 mol C/m2, respectively. Although the observed amount was higher than expected, a decreasing trend coincided with decreased reaction rate as modeling works predicted. It should be noted that using cation concentration of leachate may overestimate the amount of carbon captured since Ca2+ and Mg2+ contribute to 70% of the cation charge, while HCO3- only accounts for about 30% of the anion charge in soil pore water.

Although DIC in leachate/pore water serve as a direct carbon sink, its instability and sampling

challenges may hinder its use as a reliable CO2 drawdown verification proxy. In situ determination techniques are required to overcome these limitations. While the annual carbon sink budget was not substantial, the results showed an improvement in soil acidification from pH 5.4 to 7, and an increase in crop yield compared to the blank treatment. This study contributes to the further understanding of ERW through experiments conducted at a practical scale.

Research on a CO2 Internet of Things online monitoring system for marine carbon storage

Jianhua MA[1]*, Sun Yat-sen university (05161935@cumt.edu.cn)
Yongzhang Zhou[2], Sun Yat-sen university
XinYue Wang[3], Fudan university

Abstract

Marine carbon storage plays a crucial role in mitigating global greenhouse gas emissions. However, many potential storage sites are located near densely populated regions, and the risk of CO2 leakage poses significant ecological threats. Therefore, it is imperative to establish rigorous monitoring systems and early warning technologies for marine carbon storage. Considering the dynamic nature of the marine environment and subsurface CO2, monitoring technology must be adaptable to these dynamic characteristics. However, current monitoring methods have limitations in terms of monitoring cycle, cost, and stability, rendering them inadequate for meeting the dynamic monitoring requirements of marine carbon storage. In this regard, online monitoring technology that exploits the Internet of Things (IoT) presents a viable solution for monitoring marine carbon storage. This technology employs sensor networks to take measurements and utilizes wired or wireless communication networks to transmit the data, thereby enabling continuous monitoring and real-time feedback. Although existing research on marine IoT monitoring primarily focuses on the environment and agriculture, insufficient attention has been paid to marine carbon storage. Consequently, this work proposed a design concept for an online monitoring system that leveraged the IoT for marine carbon storage. In terms of sensor deployment, we adopted a strategic approach by initially placing sensors in crucial areas using fixed deployment methods, followed by expanding the monitoring areas through random deployment. We encrypted key monitoring areas for monitoring purposes and optimized topology through mobile deployment. Concerning sensor selection, infrared CO2 sensors were deployed near injection wells to facilitate comprehensive monitoring. In contrast, laser CO2 sensors were positioned in key areas such as wellheads for auxiliary monitoring. In terms of network topology design, cluster head nodes were strategically placed near injection wells or potential leakage sites in areas of high risk. Nodes within the network topology were connected to main cluster nodes, and redundant channels were established to ensure continuous monitoring of data flow in critical areas during emergencies. In peripheral areas, star or tree topologies were employed for data summarization. Sensor nodes and surface buoys were equipped with GPS positioning functionality, while underwater sensors utilized small-capacity capacitors for energy storage, enabling them to operate after short charging periods. The collected data were transmitted to surface buoys using inductive coupling and subsequently packaged and sent to shore-based data management centres via either 4G or satellite communication. Compared to other monitoring methods, the IoT online monitoring system enables continuous monitoring, rapid early warning, and real-time feedback on changes in the environment, making it well-suited to meet the dynamic

monitoring requirements. Furthermore, the IoT online monitoring system can consistently update and enhance the data model by utilizing long-term monitoring data. More importantly, it can analyse the magnitude and route of CO2 leakage through algorithms, integrate geophysical monitoring data, evaluate the risk of leakage and classify storage areas. In summary, an intelligent online monitoring system for marine carbon storage utilizing the IoT was established in this work. This system offers valuable insights into monitoring leakage and managing early warning in carbon storage in marine environments.

Yongchae Cho[5], Seoul National University

Abstract

In 4D seismic exploration, temporal changes in subsurface properties are measured using baseline and monitor data recorded at different times, which is used for monitoring in many areas, such as petroleum production and carbon capture and storage (CCS). However, to accurately detect temporal changes of subsurface properties in 4D seismic survey, it is essential to suppress non-repeatable noises caused by differences in survey geometry, preprocessing factors (e.g. temporal and spatial amplitude gain), source wavelet characteristics, seawater temperature or salinity, and weather conditions. The cross-equalization (XEQ) techniques have been widely used to suppress non-repeatable noises. Recently, several attempts have been devoted to applying machine learning techniques for XEQ; and a convolutional neural network (CNN)-based XEQ technique for post-stack data has been proposed using a masked image-to-image translation scheme. However, in the case of post-stack data, information on subsurface properties is limited because of a series of data processing procedures. To obtain more information, pre-stack data need to be employed.

In this study, we propose an XEQ technique for pre-stack data based on CNN and a masked image-to-image translation scheme, which introduces a mask generated by the eikonal equation. In addition, to solve the problems of signal overlap and amplitude variation of signals that appear in pre-stack data, supplementary methods, such as frequency-wavenumber (f-k) loss function, coordinate conditioning, and logarithmic rescaling, are introduced.

The synthetic data experiments show that the proposed XEQ effectively suppresses non-repeatable noise while preserving 4D signals even for pre-stack data and causes less damage on amplitude information representing the degree of change. Furthermore, the supplementary methods enhance the matching quality and training stability. We conduct sensitivity analysis for factors that can adversely affect XEQ, such as seawater velocity, source wavelet, ambient noise, and inaccurate masks. The sensitivity analysis confirms that the proposed XEQ shows robustness for those factors and successfully suppresses non-repeatable noise.

Abstract

Carbon capture and storage (CCS), which captures carbon dioxide (CO_2) from large point sources and stores it in sub-seabed geological formations, is presently considered as one of the most promising technologies to reduce the anthropogenic CO_2 emissions. According to Korean government's 1st national carbon neutral/green growth basic plan, South Korea plans to sequestrate 4.8 million tons of CO_2 annually through CCS from 2030. To achieve this goal, reliable CCS monitoring is vital.

There are two types of CCS monitoring methods, which are deep-focused and shallow-focused methods. Deep-focused method employs geophysical methods, such as seismic, gravitational and electromagnetic explorations, to monitor the storage reservoir and overburden. On the other hand, shallow-focused method, which is also referred to as the marine-environmental monitoring method, targets the seabed and the water column above a storage reservoir and aims to detect emission of gas/dissolved phase CO_2 and formation fluids from the seabed. However, due to the natural variability of the ocean, it is still challenging to accurately detect CO_2 emission while mitigating the false positive problem.

In this study, we share our experience of manufacturing a prototype of shallow-focused monitoring system for CCS. Our stationary system is intended to detect CO_2 emission near the injection well, which can be the most probable source of sub-seabed CO_2 emission. To mitigate the false positive problem and enhance the detection accuracy, we combined a variety of sensors in our system. Chemical sensors (salinity, pH, DO, pCO_2, oxidation/reduction potential (ORP) and turbidity), passive acoustic sensor, and optical sensor with light sources are attached to the system and several artificial CO_2 release experiments have been carried out to evaluate performance of the monitoring system. From the experiments conducted at a large water tank and at a shallow water depth of around 20 m, our monitoring system showed sufficient performance to detect emission of CO_2 from the seabed. Acoustic recordings of the bubble noise presented distinct frequency spectrum which can be separated from the background noise and correlation between pCO_2 and DO showed distinct deviation with the artificial CO_2 emission.

Numerical modeling of subsurface fluid injection using the poroelastic finite element code

Chan-Hee JANG[1]*, Kangwon National University (jch@kangwon.ac.kr)
Byung-Dal So[2], Kangwon National University
Soojung An[3], Kangwon National University

Abstract

As climate change remains a critical global challenge, we have focused on carbon capture and storage (CCS) technology as one of the solutions to reduce atmospheric CO2 emissions. Injecting artificial fluids into geological formations alters pore pressure and the subsurface stress field, potentially activating faults. By changing the hydro-geophysical properties of the fault (e.g., porosity and permeability coefficient) due to fault activation, the fault role as a conduit for fluids, which risks causing stored CO2 to leak from the reservoir along the fault. Such events pose economic and human risks while potentially heightening social acceptability concerns, which could hinder project progress. Therefore, numerical modeling to various injection scenarios and geological structures is essential for safe fluid injection prior to CCS project implementation.

With this in mind, we have used poroelasticity theory to develop a numerical modeling code for underground fluid injection scenarios. Poroelasticity theory describes the dynamic relationships that govern the interaction between pore fluid flow and elastic deformation of solids in porous media. The theory is widely used in numerical modeling related to conventional underground fluid injection due to its ability to simultaneously calculate pore pressure diffusion and the stress state's evolution. We performed a comparative analysis with a commercial FEM software, COMSOL Multiphysics, to increase the reliability of the code. In the process, we calculated the behavioral properties of the fluid and the pore pressure change due to fluid injection, and we also explored the influence of geological structural properties on the fluid injection environment. The development of such a code for simulating fluid injection environments aims to deepen the understanding of fluid behavior while localizing the code.

Repeatability analysis of time-lapse OBC data for CCS in the offshore of Pohang, Korea

YONGHWAN JOO[1]*, KIGAM (jooyh@kigam.re.kr)
BYOUNG-YEOP KIM[2], KIGAM
YUNSEOK CHOI[3], KIGAM
DONGHOON LEE[4], KIGAM
DOWAN KIM[5], KIGAM
WOOHYUN SON[6], KIGAM

Abstract

We conducted Ocean Bottom Cable (OBC) surveys in the offshore of Pohang, South Korea, for CCS 4D seismic monitoring research. During the acquisition of 4D seismic data, differences can arise not only from anomalies caused by injected fluids but also from variations of source and receivers positions, tides, and wave heights. In this study, to analyze the repeatability of time-lapse OBC data without 4D seismic differences, we performed 3D OBC surveys twice with short time intervals. After acquiring two sets of 3D OBC data, we applied identical 3D multicomponent seismic data processing. Especially, Due to the absence of acoustic transponders, we utilized the First-break Picking method to determine the precise positions of Ocean Bottom Cables (OBC). Subsequently, through processes such as trace rotation and PZ summation, we obtained the final seismic volume. To ensure similarity, we performed scaling on the amplitudes of the two final processed seismic volumes, and enhanced their similarity by designing and applying a match filter to both datasets. We calculated the NRMS values of the processed datasets, revealing that although the surveys were conducted in the same area without receiver position change, NRMS values exceeding 15% were observed. It is inferred that the magnitude of time-lapse difference by injected fluids must exceed this threshold for effective 4D seismic monitoring.

[Keynote] Building on Bedrock: Geosciences' Role in Mitigation and Adaptation

Lisa GRAUMLICH[1]*, American Geophysical Union (president@agu.org)

Abstract

Addressing the climate crisis stands as one of the most pressing challenges of our time. For decades, the scientific community has provided the critical evidence that unequivocally links rising greenhouse gas emissions to a cascade of environmental impacts: from more frequent and severe heatwaves and storms to accelerating ice melt and rising sea levels.

While the challenges of climate change are daunting, science also illuminates pathways forward. Fostering a global dialogue across the geosciences, including geology, will continue to spark collaborations and inform mitigation and adaptation solutions that our planet urgently needs. Moreover, bridging the gap between science and policy implementation at all levels of decision-making requires sustained collaboration, enhanced communication channels, and a commitment to evidence-based decision-making.

This presentation will draw on personal experiences on spanning science to action and highlight the influential role of the geoscience community, including institutions like AGU, in transforming science from usable to used. Highlights will include how AGU's efforts in open science and data are increasing the accessibility and usability of information and publications, how global convenings bring together scientists and practitioners to tackle specific climate challenges, and how scientists partner directly with local communities to co-create new knowledge and build climate resilience—collectively demonstrating how geoscientists are translating scientific insights into practical climate solutions.

Unraveling the Complex Nexus of Geology, Water Quality, and Forage Impact on Enteric Methane Emissions: A Case Study from North Kivu, Democratic Republic of the Congo

Tomple Byamungu Mayange[1]*, Seoul National University and Center of Expertise and Geological Survey - Congo (tomplemayange@gmail.com)
Alain Bindu Lumoo[2], International NGO Safety Organization
Guy Shungu Lama[3], Center of Expertise and Geological Survey

Abstract

Methane (CH4), a potent greenhouse gas (GHG) with approximately 28 times the global warming potential of carbon dioxide (CO2) over a 100-year period, poses a significant challenge to both the environment and livestock. This study delves into the intricate relationships between geological, hydrological, and nutritional elements in North Kivu Province, Democratic Republic of the Congo (DRC), and their combined influence on CH4 emissions.

North Kivu Province is renowned for its abundant geological resources, particularly minerals like tin, tantalum, tungsten (the "3 T's"), gold, and more. These resources owe their existence to the region's distinct geological formations, notably in territories such as Walikale, Masisi, and Beni. However, the pursuit of these valuable minerals has led to extensive artisanal mining activities, which have caused substantial land alterations and degradation. Forests have been cleared, and soil quality has been compromised through excavation and digging. The consequences extend to water quality, as discharges of pollutants from mining operations have infiltrated nearby rivers and water sources (Lowa, Luka, Luviro, Semliki, and Rwindi River), resulting in contamination. In the region, a significant population of cattle, sheep, and goats, primarily originating from East African countries, exclusively engage in grazing on pasture activities and consume water from the region. Consequently, they are susceptible to contamination and, therefore, contribute significantly to CH4. The production of CH4 in the region is influenced by a myriad of factors, notably before and after mining activities. During mining exploitation, the presence of specific minerals, such as Copper, Cobalt, Sulfur, Molybdenum, Iron, and others, contributes to amplifying CH4 production in cow stomachs. This phenomenon arises due to the geological characteristics of the province, which significantly affect the quality of groundwater sources. Moreover, after mining exploitation, the quality of forage plays a crucial role in CH4. Lower-quality forage can extend digestion times and foster increased fermentation in the stomach, ultimately resulting in elevated CH4 production. The diet, in this context, acts as a significant influencer of post-mining CH4 emissions.

In conclusion, the relationship between geological factors and CH4 emissions, though indirect, is profoundly impactful. A comprehensive understanding of these dynamics paves the way for the development of targeted strategies to mitigate CH4, enhance livestock sustainability, and promote environmentally responsible agricultural practices in North Kivu and beyond.

Feasibility study for subsurface imaging using onshore VSP geophone and DAS data

Hanjoon PARK[1]*, Seoul National University (hanjoon67@naver.com)
Donggeon Kim[2], The Pennsylvania State University
Dong-Joo Min[3], Seoul National University
Myunghun Lee[4], Seoul National University

Abstract

Distributed acoustic sensing (DAS) is an attractive technology for 4D exploration because it has low maintenance cost and high sampling density. However, because the response functions of DAS are different from those of geophones, which are commonly used for exploration, it is necessary to analyze its features.

This study is a preliminary study for subsurface imaging combining onshore vertical seismic profile (VSP) geophone and DAS data. Three-component geophone modeling is performed and we implement DAS modeling by changing the response function in the geophone modeling. Then, modeled geophone and DAS data are compared with actual VSP geophone and DAS data acquired at Janghang-ri, Gyeongju. The VSP survey was conducted by the Korea Institute of Geoscience and Mineral Resources' (KIGAM) research project aimed at constructing a deep composite geophysical monitoring system evaluating the activity of earthquake faults in the southeastern region of the Korean Peninsula. The modeling results show that DAS data shows phase lag compared to the data recorded using geophones, because the response function of DAS is average strain while the response function of geophone is particle velocity. In addition, we perform inversion using three-component geophone data and analyze the results. Through this analysis, we propose an imaging strategy that builds the initial velocity structure using geophone data with a high signal-to-noise ratio and then images the reflection layer in a high-frequency band using DAS data with a high sampling density.

Numerical Modeling of Two-Way Coupled Simulation for Geological Carbon Storage

Hyun Chul YOON[1]*, Korea Institute of Geoscience and Mineral Resources
(hyun.yoon@kigam.re.kr)

Abstract

When CO2 is injected into the saline aquifer or depleted reservoir for geological carbon storage, physical processes are tightly coupled, affecting the CO2 flooding and its trapping mechanisms. For example, injection induces pore pressure build-up and dilation of pore space, which can uplift the ground surface or tensile/shear failure of the caprock that may result in the leakage of CO2. Thus, rigorous analyses of coupled flow and geomechanics are necessary to predict the long-term security of the geological carbon storage. In this study, we employ the fixed-stress sequential method solving coupled flow and geomechanics. Fixed-stress sequential method is based on an operator splitting scheme, solving the flow operator first via fixing the stress rate and the geomechanics using the intermediate solution, until the two operators are converged within a tolerance value. Through the fixed-stress sequential method, we can couple the two-way physics between the fluid and geomechanics rigorously with unconditional stability and convergence upon the theory of Biot's poroelasticity. From the numerical experiments, we find robust computations of the coupled processes, highlighting the poromechanical effects along with major trapping mechanisms, e.g., residual/capillary and structural trappings for the CO2 geological storage. Compared to one-way coupling from fluid flow to geomechanics, the proposed constitutive relation and algorithm for coupled processes can predict flooding and trapping of CO2 underground more accurately.

Reservoir simulation study for the injectivity and geomechanical stability in the Gunsan basin

Taehun LEE[1]*, KIGAM (thlee@kigam.re.kr)
Byoungyeop KIM[2], KIGAM

Abstract

In order to realize carbon neutral 2050, one of the key technologies is carbon capture and sequestration (CCS) with the use of renewable or low-carbon energy, and improving of fuel efficiency. CCS is a process that can reduce greenhouse gas emissions by capturing CO2 from large industrial sources and injecting it into deep geological formations. However, CCS requires careful monitoring to ensure that the CO2 does not leak back into the atmosphere or cause environmental damage. Republic of Korea government want to find out the optimal CCS site and Gunsan basin in the Yellow sea of the Korean Peninsula is the one of proposed sites. The Gunsan Basin is located in the the South Yellow Sea, approximately 200 km from the west coast of South Korea and is is a shallow continental shelf with an average water depth of 44 m. The Gunsan Basin is considered as a proper storage option due to its proximity to possible capture sites along the west coast. In this study, geological model was constructed using the for the reservoir simulation and geomechanical simulation. The CCS must occur safe and stable, which requires geomechanical modeling to analyze the effects of formation uplift or subsidence. Case studies were performed for the CO2 injectivity and geomechanical stability.

Building an initial velocity for 3D OBC seismic data processing in the Gunsan basin, offshore western Korea

Woohyun SON[1]*, KIGAM (whson@kigam.re.kr)
Byoung-Yeop KIM[2], KIGAM
Yonghwan JOO[3], KIGAM
Moohee KANG[4], KIGAM
Yunsuk CHOI[5], KIGAM

Abstract

Accurate velocity information is crucial for precisely imaging subsurface structures using real seismic data. The 3D OBC data acquired from the Gunsan basin poses challenges due to its limited number of receivers (72 channels), making it difficult to derive precise velocities. To overcome the challenge of obtaining accurate velocities in this survey area, we use seismic data obtained through a long offset (3 km, 240 channels) streamer. Initially, we enhanced the signal-to-noise ratio by applying various high-resolution time-domain data processing techniques (low-cut filter, time delay correction, swell noise attenuation, velocity analysis, SRME, SRWEMR, predictive deconvolution, de-ghost filter, linear noise attenuation, radon filter, and Kirchhoff migration) to the long offset data. Additionally, we applied depth-domain data processing techniques based on MVA (Migration Velocity Analysis) to obtain accurate P-wave velocity with stable convergence of velocity errors. It was confirmed that the stack section derived from accurate depth-domain velocity significantly improved strata connectivity compared to the time-domain result. Consequently, by successfully applying the proposed time and depth domain data processing techniques to long-offset (3 km) data, we derived improved depth-domain stack sections and P-wave velocities. The obtained high-resolution depth domain velocity can be effectively used as the initial velocity for 3D OBC seismic data processing.

Development of a surrogate model to improve the efficiency of groundwater level fluctuation pattern-based hydrologic properties evaluation

JIHO JEONG[1]*, Kyungpook National University (iamwlgh@naver.com)
JINA JEONG[2], Kyungpook National University

Abstract

In this study, a method of aquifer hydrologic property estimation incorporating the deep learning method was developed to improve the estimation efficiency of a process-based model based on groundwater level fluctuation (GLF) patterns. As a reference study, a data-driven method suggested by Jeong et al. (2020) was considered; the uncertainty of the GLF patterns resulting from different yearly patterns of precipitation, which were considered as noise in the previous study, was effectively discarded using the newly proposed method of applying the conditional variational autoencoder (CVAE). The CVAE was used to acquire the specific GLF patterns under certain identical precipitation patterns for all the monitoring stations. The data-driven hydrologic property estimation model was developed to predict two hydrologic parameters (ρ and k) of the process-based model using the generated GLF patterns from the CVAE network as the input variables. The actual GLF and precipitation data that were acquired from nationwide groundwater monitoring stations in South Korea were applied to validate the developed method. It was found that the estimated and target hydrologic properties were highly correlated (correlation coefficients [CC]: 0.9833 and 0.9589 for ρ and k, respectively), which significantly improved the results when compared to the previous study (CC: 0.7207 and 0.8663 for α/n and k, respectively). Consequently, the developed model can contribute to a more accurate hydrologic property estimation of aquifers. Additionally, it can facilitate efficient groundwater development planning since the manual fitting of the process-based model by an expert is not required.

Machine-learning-based microearthquake detection for the southern Korean Peninsula

Byeongwoo Kim[1]*, Yonsei University (kbw8280@yonsei.ac.kr)
Minhwan Kim[2], Kyung Hee University
Tae-Kyung Hong[3], Yonsei University

Abstract

In South Korea, there were considered to have infrequent moderate to large scale earthquakes. Recently, there was apparent increase in moderate-size earthquakes that include the 2016 ML 5.8 Gyeongju earthquake, the 2017 ML 5.4 Pohang earthquake, the 2021 ML 4.9 Jeju earthquake, and the 2023 ML 4.9 East Sea earthquake. The successive moderate-size earthquakes increased public concern on the possible seismic hazards in the Korean Peninsula. We analyze scattered microearthquakes that are difficult to be detected in conventional methods such as short-term to long-term average ratio analysis and matched filter analysis. Conventional methods suffer from ambient noise and station density. We employ a machine learning approach to identify microearthquakes. We collect seismic data since November 2022 from >420 stations deployed in South Korea. We utilize the trained PhaseNet machine learning model to detect P and S phases from seismic records and identify microearthquakes based on coherent phase arrivals across the stations. We observe approximately 600 microevents per month, some of which may be induced by human activities. About 30% of these earthquakes may be natural microearthquakes. We identify more than twice natural earthquakes compared to conventional methods. Microearthquakes are clustered in the central and southeastern regions of South Korea, particularly around Gyeongju and Pohang areas. This method is effective in detecting microearthquakes, contributing to better understanding of seismic activity in South Korea.

Keyword

Abstract

A 3D high-resolution subsurface characteristic (HSC) model that integrates porous media (PM) and fractured rock (FR) media, was constructed based on a field investigation. For the realistic model representation, lithologic, hydrogeologic, petrophysical, and fracture information were obtained from various hydrogeologic and geophysical investigation techniques. On the 3D HSC model, a full-physics numerical simulation was conducted to predict DNAPLs contamination. By varying the seven input variables affecting the DNAPLs contamination, 180 numerical simulations were conducted to obtain three output variables: total DNAPLs mass in PM (y1), residually trapped DNAPLs mass in PM (y2), and Total DNAPLs mass in FR (y3). The input combinations and output variables predicted by the full-physics model were then utilized as training and test datasets to generate a surrogate model. In this study, Polynomial chaos expansion (PCE) and random forest (RF) methodologies were employed to train the surrogate models. Subsequently, the performance of the developed PCE and RF surrogate models was evaluated using test data. In addition, to identify and quantify the importance of factors influencing the fate and transport of DNAPLs in porous media and fractured rock, Sobol's sensitivity analysis and feature importance (FI) evaluation based on the PCE and RF surrogate models were conducted, simultaneously. As a result, for y1 and y3, both Sobol's sensitivity indices and FI indicated the depth of the groundwater table was the most influential factor on DNAPLs total mass in PM, followed by permeability anisotropy in PM and the residual saturation of DNAPLs. For the residually trapped DNAPLs mass, the residual saturation of DNAPLs and the depth of the groundwater table were the most and second most influencing factors, respectively. The study provides a comprehensive 3D HSC model for an integrated understanding of PM and FR, employing advanced algorithms from machine learning and statistics to analyze the importance of influencing factors on the DNAPLs fate and transport in the subsurface. The influencing factors explored by Sobol's sensitivity analysis and FI evaluation were consistent, indicating that the results were not algorithm-dependent. This surrogate model-based research framework is expected to be applicable in various hydrogeological fields, offering a cost-effective method to elucidate the complex

dynamic of DNAPLs contamination within the subsurface environment.

Improvement of performance of in-situ virtual monitoring system of the occurrence probability for high concentrations of naturally occurring radioactive materials in groundwater through the solution of the data imbalance problem

Hyeongmok LEE[1]*, Kyungpook National University (brotherneck@naver.com)
Ji-na Jeong[2], Kyungpook National University

Abstract

Two data-driven models for virtual sensors were developed to estimate the probability of high-concentration occurrence of naturally occurring radioactive materials (NORMs; 238U and 222Rn) in groundwater based on the in-situ groundwater quality monitoring data and geological information of the aquifer. The random forest approach was applied to develop the proposed estimation models based on the actual in-situ groundwater quality data (pH, temperature, oxidation–reduction potential, electric conductivity, dissolved oxygen, and bicarbonate ion concentration), rock type, and f the aquifer depth as the input variables. The NORM concentration measured in the laboratory was used as the output variable. Additionally, this study proposes three data sampling techniques (i.e., under-sampling, synthetic minority over-sampling, and a complex sampling technique using the under- and over-sampling) to improve the model applicability and accuracy. The developed models were validated using the actual data acquired from 201 locations in South Korea. The developed models for 238U and 222Rn showed estimation accuracies of 85% and 80%, respectively, even though the models used only in-situ information without laboratory experiments; the models with over-sampling showed even better performance. All the results verified the usefulness of the developed models in providing immediate information on the in-situ presence of NORMs in groundwater, and the over-sampling technique was confirmed to be an effective and practical solution to the data imbalance problem in data-driven geological estimation models. Thus, the developed models are promising virtual sensors for managing groundwater quality in real time.

Abstract

Worldwide, rural areas are mostly experiencing the increase of nitrate (NO3-) concentrations in shallow groundwater, posing a significant threat to the use of groundwater for drinking and domestic purposes. Previous groundwater studies in areas with mixed pollution sources primarily relied on multivariate statistical analysis of hydrochemical data, leading to less reliable outcomes and often incurred high costs due to the need for direct data collection from multiple sites. Therefore, there is a need for cost-effective and reliable data interpretation and evaluation in future groundwater research. This study conducted an integrated approach of multivariate statistical analysis and machine learning-based data interpretation on major hydrochemical (cations/anions) and nitrate isotope data from a total of 706 groundwater samples collected along the groundwater flow path in the southwestern region of Jeju Volcanic Island of South Korea over four years (2019-2022). Initially, wells significantly affected by nitrates were identified using geostatistical analysis techniques such as Robust Principal Component Analysis (Robust PCA) and Kriging. Excluding 43 outliers, the study performed the regression and classification modeling using the Random Forest machine learning algorithm on 663 samples, achieving more sophisticated and efficient interpretation. Specifically, 80% of the data (i.e., 544 samples) were randomly selected as the training dataset, and the remaining 20% (i.e., 119 samples) served as the validation dataset. The target variable was set as PC1, with predictors including land use, altitude, distance to the coastline, soil type, effective soil depth, geology, water level, and the Topographic Wetness Index (TWI). The study found that the spatial distribution of PC1 from multivariate statistical analysis closely matched the spatial distribution pattern of PC1 derived solely from machine learning predictors. This suggests that the pattern of groundwater contamination in volcanic islands follows a certain predictable pattern, independent of the localized distribution of

nitrate pollution sources. Furthermore, the study produced a probability map designating areas with a contamination probability exceeding 0.5 as contamination risk zones through Random Forest classification modeling, and compared the results with the existing map on groundwater resource conservation in Jeju Island. The water quality data-based machine learning approach adopted in this study will be very useful for the sustainable management of groundwater in volcanic island rural areas with multiple pollution sources.

Evaluation of the Feasibility of Applying Machine Learning Techniques for Landslide Prediction

Hyeyeon JEON[1]*, Kangwon National University (j.hyeyeon@kangwon.ac.kr)
Jiwook Jang[2], Kangwon National University
Jin-Yong Lee[3], Kangwon National University

Abstract

Currently, there is a gradual increase in the frequency of heavy rainfall due to the impacts of climate change, and this increase in heavy rainfall raises the risk of landslides worldwide. The occurrence of landslides can lead to numerous casualties and property damage, so it is important to predict the scale of future landslides to mitigate landslide damage. The purpose of this study is to evaluate the feasibility of predicting landslide occurrences and identifying factors affecting landslides through data obtained from indoor and outdoor surveys and machine learning techniques. In Earth sciences, various methods such as KNN, Naive Bayes, Decision Tree, and Random Forest are applied to enable precise predictions. In particular, methods of identifying landslides using machine learning show outstanding robustness and potential in solving problems. On the other hand, convolutional neural network (CNN) algorithms have strengths in feature extraction and processing of multidimensional data. Additionally, when comparing three machine learning algorithms (support vector machine, Decision tree, Logistic regression) for assessing landslide vulnerability, Support Vector Machine (SVM) proved to be superior to traditional statistical methods, with SVM classification surpassing the analytic hierarchy process approach in all evaluation indicators. It is important to derive parameters that can be used for landslide sensitivity analysis by combining geographic spatial data of landslide occurrences with other environmental data. Moreover, to improve the accuracy of the landslide sensitivity model, it is necessary to integrate additional controls on slope stability. This study evaluated the potential for applying machine learning to large past landslide damage cases, and the location, distribution, and damage status of landslides, along with long-term rainfall and climate information, and the geological characteristics of the area (particle size, density, soil moisture, etc.). Through this research, we hope to estimate the risk of future landslides and contribute to the development of measures to prevent landslide damage. This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (No.2019R1A6A1A03033167).

Convolutional LSTM networks for predicting spatio-temporal variability of standardized groundwater level index in South Korea

Sanghoon LEE[1]*, Korea Atomic Energy Research Institute (lshlsh2311@kaeri.re.kr)
Kang-Kun Lee[2], Seoul National University
Ji-Hun Ryu[3], Korea Atomic Energy Research Institute

Abstract

Groundwater level is a well-known quantitative indicator of water or energy resources. It also dictates water pressure and redox conditions, which are important factors in deep geological repository for disposal of high-level radioactive waste or underground storage system of energy such as carbon dioxide. Since the groundwater levels have characteristics that depend on both time and space, it is more informative to analyze spatio-temporal change of the groundwater level. In this study, spatio-temporal prediction of standardized groundwater level index (SGI) that changes according to location and time was attempted by applying convolutional long short-term memory network (ConvLSTM) with standardized precipitation index (SPI) as an input variable. The ConvLSTMs that can predict SGI on a national scale in South Korea was developed, and future groundwater changes were compared and evaluated for multiple scenarios by performing predictions up to 2100 according to future climate changes. Prediction results showed different change pattern of SGI by space within South Korea. In particular, most of the inland areas were greatly affected by the short-term drought indices such as SPI2 and SPI3, while in the Jeju area, the long-term drought index of SPI12 was greatly affected. The difference of SGI patterns according to location was found to be due to surrounding environmental features such as land use and hydrogeological unit. As a result of applying the SSP (Shared Socioeconomic Pathways) scenarios after the completion of the model, the increase of high SGI and the decrease of low SGI were evident over time in SSP2-4.5 and SSP5-8.5, but the SSP1-2.6 scenario considering eco-friendly development showed a similar distribution of SGI to the present. This research suggests that more diverse input variables and observed data should be considered as improvements for the further works. It could lead to more reliable and higher resolution predictions, in order to analyze patterns of the groundwater level change in South Korea and contribute to precise long-term environmental change prediction and policy establishment for water and energy usage.

Oil spill analysis around Small Island Developing States through multimodal large model

Xiaohui YU[1]*, Zhejiang University (yuxiaohui0626@gmail.com)

Abstract

Oil spills not only seriously threaten to the ecological development of the ocean, but also have long-term impacts on human health and the sustainable development of small island developing states (SIDS). SIDS are extremely sensitive to oil spills due to their unique geographical location and economic structure. Therefore, it is crucial to accurately identify and predict the spread trajectory of oil spills. To address this challenge, this study proposes to use a model that integrates the multimodal large model, remote sensing data, ocean dynamics models, and oil spill diffusion models to predict the scale and propagation direction of oil spills, as well as the possible damage of coastlines of SIDS to ensure the marine ecological security and sustainable development of them. In addition, the model combines time series analysis and artificial intelligence algorithms to analyze data from historical oil spill events to improve the accuracy of predictions. This research aims to provide a set of decision support tools for SIDS when responding to oil spills to ensure its marine ecological security and sustainable socio-economic development. While assessing potential environmental impacts, this study highlights the need for rapid and efficient response strategies. This model also provides important reference value for achieving many of the goals in the Sustainable Development Goals (SDGs), as well as for international cooperation and regional oil spill emergency preparedness.

Prediction of groundwater levels of National Groundwater Monitoring Network in South Korea using LSTM (Long Short-Term Memory)

hyowon AN[1]*, University of Science and Technology (UST) (attorney0107@naver.com)
Kyoochul Ha[2], Institute of Geoscience and Mineral Resources (KIGAM)

Abstract

Monitoring of groundwater level fluctuations over time is important for the sustainable use and management of groundwater resources. The groundwater level data are used for the related researches in groundwater such as water balance analysis and groundwater modeling, and it is essential to evaluate and predict the trends and variations of groundwater levels. Traditionally, time series analysis such as the autoregressive(AR), moving average(MA), and the combined AR and MA model (ARIMA) have been used to predict groundwater levels. But recently, machine learning and deep learning models are widely used due to its high accuracy and ability to handle nonlinearity. In applying these machine learning and deep learning techniques, auxiliary use of weather and environmental variables will compensate for missing data much more efficiently than using only groundwater level data and increase the accuracy of time series prediction. Factors that affect changes in groundwater level include various meteorological data such as precipitation and temperature, and environmental variables such as river level, seawater level, and groundwater usage, etc.

The purpose of the research is to predict groundwater level data by deep learning techniques within a watershed. For the study, we utilized the National Groundwater Monitoring Network in South Korea and used the LSTM (Long Short-Term Memory) model to analyze long-term time series. The model was used with input data such as precipitation, temperature, electrical conduction, and groundwater level of different wells. Other groundwater level data with a similar pattern to the groundwater level of the target well were used as input data to train the model. The results of the study showed that wells with high correlation in the same basin can be usefully used to improve time series predictability. Additionally, these results showed that time series forecasting was much more efficient than using only meteorological data such as precipitation. It is expected that these time series prediction can be useful in watershed-scale groundwater resource assessment and management.

A deep learning-based proxy model for 3D channel reservoir characterization

Youjun LEE[1]*, Seoul National University (youlee@snu.ac.kr)
Dogyun KIM[2], Seoul National University
Woosueng JO[3], Seoul National University
Jonggeun CHOE[4], Seoul National University

Abstract

Reservoir characterization is crucial for the success of oil field development plans, especially in the case of channel reservoirs where high uncertainties remain due to limited geological information and heterogeneity. Traditional approaches for channel reservoir characterization are ensemble-based methods, which are well-established stochastic history matching techniques with an ensemble of model realizations. Despite of their effectiveness, they often pose computational challenges, as updating multiple model realizations increases costs significantly.

To address this challenge, many researchers have proposed deep learning-based proxy models to reduce simulation costs of reservoir models. To reliably characterize channel features, such as connectivity and pattern, it is necessary to consider spatial variables of reservoir models. Furthermore, if it is limited to a single reservoir model, it is unsuitable for stochastic history matching preferred for channel reservoir characterization. In response, this research presents a novel scheme for a deep learning-based proxy model tailored for stochastic history matching, incorporating spatial static data of reservoir models. Combining convolutional neural networks (CNN) and long short-term memory (LSTM) architectures, the proxy model predicts dynamic data, exploiting CNN's image feature extraction capability and LSTM's proficiency in time-series prediction.

In this study, we perform Ensemble Smoother with Multiple Data Assimilation (ES-MDA) utilizing the proxy model for production forecast of reservoir models. For validation of our proposed method, its performance is compared with ES-MDA using a commercial forward reservoir simulator. We perform this analysis on a 3D channel reservoir, and results demonstrate the proxy model's accuracy in predicting reservoir dynamics, with computational efficiency significantly outperforming the conventional method compared. Channel features and uncertainty quantification of the updated models further confirm the effectiveness of the proposed approach in providing reliable channel reservoir characterization while reducing computational costs.

Kai SHENG[6], China University of Petroleum(East China)
Hao GUO[7], China University of Petroleum(East China)

Abstract

Marine carbonate is a significant target for oil and gas exploration globally, granular carbonate is the best type of reservoir controlled by facies. However, compared to clastic rock, the physical properties of carbonate rock components are similar. Diagenesis, especially cementation, leads to the convergence of rock physical properties and similar logging response characteristics. Hence, identifying granular carbonate reservoirs has always been challenging when studying carbonate rocks. Additionally, as depth increases, the cost of all kinds of data rises, and quality worsens. Limited by sample data, classification schemes, identification methods, and other factors, accurately identifying and characterizing deep and ultra-deep carbonate oil and gas reservoirs is difficult, particularly in identifying granular carbonate reservoirs. In this study, we established a large database based on the comprehensive use of core, slices, and well-logging data, including 2232 data points in the training set, covering 433 slices and more than 700 meters of core observation. According to the petrophysical model, we divided six carbonate rock structures, including micrite, crystal, granular, residual, brecciated, and others. By using a variety of machine learning methods, we have realized the accurate logging identification of the lower Paleozoic granular carbonate reservoir in Jiyang Sub-Basin. The results indicate that ensemble methods, such as subspace KNN and bagging, have the highest accuracy in identifying granular carbonate, reaching up to 87.2%. The most sensitive conventional logging parameters for carbonate rock structures are AC, DEN, and CNL. The identification accuracy of SVM, KNN, and kernel is significantly affected by the structural similarity of carbonate rocks. However, ensemble methods and neural network methods can effectively differentiate similar carbonate rock structures. Additionally, compared with the application of methods, the quality of the database and the pre-processing of the logging data are crucial. This research provides a foundation for the scheme design and method selection to identify granular carbonate reservoirs. This research also serves as a foundation for studying the parameter characteristics of granular carbonate rocks, the distribution and evolution of organic reefs and intra-platform shoals, and the evaluation of fine reservoirs using logging techniques.

Intelligent logging identification of petrophysical facies

Xinhao ZHANG[1]*, China University Of PetroleumEast China (1312909815@qq.com)
Xianguo ZHANG[2], China University Of PetroleumEast China
Huafeng LIU[3], China University Of PetroleumEast China

Abstract

The mature oil fields in eastern China have experienced long-term water flooding development and have generally entered the stage of ultra-high water cut. The differences in reservoir petrology and physical properties have a significant impact on development. Fine understanding of reservoir petrophysical facies is an important geological basis for achieving economic, efficient and green development of reservoirs. In this study, the Paleogene delta facies reservoirs of typical oilfields in the Bohai Bay Basin in eastern China were selected to carry out the study of petrophysical facies classification and intelligent logging identification, so as to reveal the distribution law of petrophysical facies and guide the efficient development of reservoirs.

Using core, thin section and well logs, combining lithofacies and sedimentary microfacies, and using the hierarchical clustering method of porosity-permeability overlap, the reservoir is divided into six types of petrophysical facies (RPF1 to RPF6). Capillary pressure curve analysis confirms that these six types of petrophysical facies have different pore structure characteristics. On this basis, petrophysical facies logging identification was carried out. Since traditional identification methods are difficult to represent complex geological parameters, and most "point-to-point" machine learning methods lack the ability to extract vertical well logging data features, this study uses one-dimensional convolutional neural network (1D-CNN) to give full play to its ability in multivariate sequence data. With the advantage of feature extraction capabilities, the logging identification of reservoir petrophysical facies in non-coring wells is realized.

The results indicate that the RPF1 and the RPF2 are mainly developed in the distributary channel microfacies, and the lithology is medium-coarse sandstone with excellent reservoir quality. 1D-CNN can effectively identify the types of reservoir petrophysical facies. The average F1 score of the six reservoir petrophysical facies is 0.88, which is 0.04 to 0.07 higher than the traditional machine learning method, achieving high-precision identification of reservoir petrophysical facies.

Productivity Prediction of shale basins in the USA using machine learning and data integration

Sungil KIM[1]*, Korea Institute of Geoscience and Mineral Resources (skim@kigam.re.kr)
Kwang Hyun Kim[2], Korea Institute of Geoscience and Mineral Resources
Jungtek Lim[3], SmartMind

Abstract

This study validates the application of machine learning (random forest, RF) to predict the 36-month production of oil and gas from six shale basins in the USA: Delaware, Marcellus, Barnett, Eagle Ford, Haynesville, and Midland. The input and output parameters of the RF model were 12 production well-related parameters and 36-month production of oil and gas, respectively. The total number of well data is 32,932, which was divided into training (26,345) and testing (6,587) data, respectively. In this study, three points were noted from the training and testing results by RF. First, an RF model based on the six basins-integrated data presented a successful prediction performance, although machine learning application for each basin had been taken as a more usual way. The integrated data-based RF brought a coefficient of determination (R2) of 0.758 and 0.707 for oil and gas, whereas separately trained RF models showed R2 of 0.699 and 0.690 for oil and gas. Second, the RF model from the six basins-integrated data was used as a pre-machine learning model to train separate RF models for each basin. The pre-RF models became a base model to be fine-tuned for well data of each basin. Consequently, those fine-tuned RF models brought the best prediction performance, R2 of 0.763 and 0.711 for oil and gas. Third, the used input parameters to forecast the production were composed of attainable and simple data such as latitude, longitude, true vertical depth, and fracturing-related data. The proposed method is expected to be generally applied to newly developed wells or even new target basins owing to its versatility and applicability.

Fracture identification based on graph convolutional network in continental shale oil reservoirs

Guoqing LU[1]*, China University of Petroleum, Beijing (zsdhdlgq@126.com)
Lianbo Zeng[2], China University of Petroleum, Beijing
Guoping Liu[3], Peking University

Abstract

The identification of natural fractures in continental shale oil reservoirs currently faces the problems of weak conventional logging response characteristics and limited amount of labelled data available from cores or image logs. To address this issue, we propose the Weighted Graph Convolutional Network of Graph Pooling and Edge Generation (GPEG-WGCN) method, which is an improved Graph Convolutional Network (GCN). The novel method determines the size of the graph pooling window according to core fracture heights, integrates the relationship information between the fractures and lithology into the edge generation method, and adds the generated edge weight into the message passing process, thereby effectively improving the accuracy of fracture identification.

The identification process is divided into four steps: first, reconstruct the logging curve and establish vertex sets for each lithology and individual lithologic layer using conventional logging sampling points as vertices . Second, determine the sliding window size based on core fractures and utilize the graph pooling section to filter and merge node information within the sliding window, enhancing the tool's response characteristics to fractures . Third, based on the depth sequence of a single lithologic layer and the Euclidean distance of the same lithologic vertex sets, the connection between vertices is established and overlapping edges generated by the above methods are given higher weights . Fourth, the vertices in the constructed graph are classified through graph convolutional layers, which are integrated into the edge weight information.

This method is applied in identification of fractures in Fengcheng Formation of the Mahu Sag in the Junggar Basin, western China. A conventional logging dataset was labelled by direct core observations from two separate wells in the study area. Compared to the GCN (boundless) without using the edge generation method and EG-GCN with the edge generation method but without the weighted aggregation mechanism, this method had higher accuracy, as well as exhibiting better precision and recall for fracture samples. Collectively, this reflects the superiority of this method in fracture identification by conventional logging data, providing a successful workflow for continental shale characterization.

Cascade Effects of Global Supply Chains Induced by Regional Conflicts Increase Global Inequality

Rongtian Zhao[1]*, Institute of Geographic Sciences and Natural Resources Research (zhaorongtian19@mails.ucas.ac.cn)
Daoping Wang[2], King's College London
Yong Ge[3], Institute of Geographic Sciences and Natural Resources Research
Mo Zhang[4], Institute of Geographic Sciences and Natural Resources Research
Die Zhang[5], Jiangxi Normal University
D'Maris Coffman[6], London's Global University
Qiuming CHENG[7], School of Earth Science and Engineering, Sun Yat-Sen University

Abstract

Regional conflicts have recently emerged as frequent focal points for extreme events, resulting in severe disruptions to global supply chains. Hence, there is an urgent need for a quantitative evaluation and accurate description of the propagation of shocks in regional conflict across multiple sectors and countries. Here, we modeled global multisectoral production losses and the cascading pattern of a grain supply shock in the Russia–Ukraine regional armed conflict by utilizing a geographic input–output method, encompassing 141 aggregated regions and 65 sectors in each region, utilizing the input–output method. Firstly, the grain supply chains are not equal to the impact chains of the grain shortage. Two major chains decide the spread of the impact during the grain shortage crisis: one "grain-processed food/livestock - other sectors" direct impact chain and one "light manufacturing-heavy manufacturing-textile" chain. Secondly, the textile and food processing sectors would face the most direct and significant risks of production losses attributed to disruptions in grain supply, experiencing declines of 17.04%±0.72% and 16.85%±0.5% (the 95% confidence interval), respectively. These risks were projected to magnify to two and three times larger in 2025 and 2030, respectively, due to overlapping effects in the production of multiple sectors. Lastly, using scenario simulations of production recovery, we found that the prolonged conflict and excessive effort might decrease the efficiency of production recovery in underdeveloped regions to amplify the inequality of production resources. If the conflict persists beyond 2025, an efficient resumption of production would become unattainable in underdeveloped regions. Our approach presents a quantitative framework for early planning for unexpected supply chain shocks. The findings support the need to ensure production recovery in underdeveloped countries for sustainable development.

Abstract

Sustainable global supply chains spanning various industrial sectors play a crucial role in promoting long-term economic stability. However, disruptions in input-output chains resulting from induced negative shocks may lead to cascading effects, resulting in substantial losses within specific sectors of the national economy. The quantitative assessment of shock propagation across global supply chains is paramount in mitigating these cascading damages. Here, we developed an innovative approach that integrates input-output model with geographical Petri Net. Termed the input-output geographical cascading (IOGC) model, this framework enables the quantification of economic losses, detection of shock propagation across global supply chains, and identification of risks for countries and sectors over time when subjected to induced negative shocks. To illustrate the model performance, we conducted a case study utilizing the COVID-19 lockdown as a negative shock. Four idealized scenarios were simulated within real-world supply chain networks. The findings revealed that smaller economies exhibited greater vulnerability to economic impacts, potentially experiencing losses nearly 20% higher than the global average. Furthermore, the study unveiled distinct impacts on countries and sectors based on geographical propagation patterns. The IOGC model is also suitable for simulating and analyzing the superposition of multiple shocks, as well as classifying cascade propagation types based on geographical patterns. As a general approach, the proposed IOGC model holds potential for extension to a broad spectrum of negative emergencies or extreme events (e.g., natural disasters, socially catastrophic events) for global supply chains. The outcomes of these simulations and analyses provide crucial early warnings and policy recommendations for nations, facilitating timely interventions to mitigate disaster-induced losses and enabling the rational allocation of resources.

Abstract

As the petroleum industry enters the era of big data, many oil companies have gradually accumulated massive data resources through global exploration and development processes. The key to fully leveraging these big data lies in finding suitable data analysis and processing techniques to identify patterns within existing data and make predictions in both time and space. This, in turn, guides research and decision-making in the field of oil and gas. Machine learning algorithms constitute a category of algorithms that automatically analyze data to uncover patterns and utilize these patterns to predict unknown data. This category includes many mature algorithms. It is a challenge faced by big data analysts to select the most suitable algorithm in practical work. This study, based on a large commercial oil and gas database, evaluates approximately 30,000 oil and gas reservoirs in major oil and gas basins worldwide as the fundamental assessment units. Various machine learning algorithms, namely the Gradient Boosting Decision Tree (GBDT), Bayesian Ridge Regression, and Adaptive Boosting, are employed to predict the geological reserves abundance of oil and gas reservoirs. The paper compares the performance of these algorithms in predicting geological reserves abundance of oil and gas reservoirs, analyzes the advantages and disadvantages of different algorithms, and fine-tunes each algorithm during training to align with the characteristics of the dataset. Ultimately, the Gradient Boosting Decision Tree algorithm demonstrates satisfactory accuracy in predicting the geological reserves abundance, providing inspiration and guidance for the application of machine learning in global oil and gas resource assessment, new project evaluation, and favorable target selection.

Comprehensive Evaluation of Tobacco-planting Soil Fertility Based on Machine Learning: A Case Study of Hezhou City, Guangxi

JUNXI TU[1]*, Sun Yat-sen university (tujx@mail2.sysu.edu.cn)
Wenjie Shen[2], Sun Yat-sen university

Abstract

As an essential attribute of soil, soil fertility has a direct impact on crop yield and quality. The rapid and accurate determination of its distribution is highly significant for sustainable agricultural development. Therefore, constructing a scientific and reasonable regional soil fertility evaluation system is crucial for ensuring economic efficiency while achieving standardized, rapid, and automated evaluation of soil fertility. And the exploration of the relationship between various indicators and fertility as well as the characteristics of abundance and deficiency can guide local soil ecological protection and the optimization of crop cultivation and fertilization programmes. In this study, the main t tobacco-planting area of Hezhou city was taken as an example, and 20 indicators were selected from aspects such as soil nutrients (Sn), physical and chemical properties (Spc), and climatic environment (Sce) to construct a total data set (TDS). Based on the improved fuzzy comprehensive evaluation method, four typical machine learning (ML) models in the field of soil fertility were constructed and the Shapley theory was used to identify the key indicators for constructing the minimum data set (MDS) to iterate the models and screen the model with the best generalization ability and prediction accuracy. The model was further interpreted to innovatively reveal the impact of changes in single-factor content on predicted contribution and fertility, combined with single-factor spatial interpolation to diagnose barrier factors in low-SFI regions. The results showed that the overall fertility of tobacco-planting soil in Hezhou was good, and the soil fertility of the two counties was mainly distributed in grades II and III. The comprehensive fertility of tobacco-planting soil in Fengxiang, Huilong, and Shanhu Town of Zhongshan County, Lianshan, and Fuli Town of Fuchuan County were all above Grade III. The Stacking_1 model based on the MDS had the best overall performance, with an R2 of 0.787, and the error of the mapping result was very small. Total nitrogen (TN) contributed the most to soil fertility, followed by available zinc (Zn), pH, and available phosphorus (AP). The variation trends of factor content, model contribution degree, and soil fertility conform to the membership function images, which also proves that the prediction results are real and reliable. The trends of single-factor content on the predicted contribution and soil fertility were consistent with the membership function images to which they belonged, proving the model prediction results were real and reliable. In low-SFI regions, the soil pH is generally high, and the contents of organic matter (OM), total nitrogen (TN), and available potassium (AK) are low, which should be improved by taking the corresponding measures of zonal precision fertilization. The research results have strong expansibility, replication, and promotion potential, which can provide a reference for the sustainable development of precision agriculture in different regions.

Leveraging Machine Learning, Natural Language Processes and Knowledge Representations to Facilitate the Discovery of Insights and Analogues in Unstructured Geoscience Literature

Phoebe MCMELLON[1]*, GeoScienceWorld (mcmellon@geoscienceworld.org)
Alistair Reece[2], GeoScienceWorld
Paul Cleverley[3], Robert Gordon University
Sandra Merten[4], Lazuli Consulting

Abstract

GeoScienceWorld (GSW) is a non-profit founded in 2004 by geological societies to advance the dissemination of earth science information, supporting over 250,000 researchers worldwide. The platform includes 210,000+ articles, 39,000+ eBook chapters, and 4.6 million geoscience abstracts and records from GeoRef.

With each new and emerging technology, research data and output in both structured and unstructured formats exponentially increase, driving the need for more sophisticated technologies and tools to find the most relevant information and data when we need it. Full-text indexing and keyword-based retrieval have significantly improved the discovery of information. Extracting geoscience insights across the corpus proves even more challenging. The emergence of Large Language Models (LLM) and text data mining tools have immense potential to address some of these discovery challenges within the geosciences (1-3) however cost-effective and easy access to the tools, technologies, and content repositories and risks associated with security, privacy, and copyright permissions present additional challenges.

To address these issues and challenges, GSW developed a digital assistant, GeoSapien®. A statistical model was developed from GSW's corpus of 140,000+ articles published in over 50 scholarly publications from over 40 leading society publishers. This uses text embeddings (arrays of numbers that can be used to represent words based on their co-occurrence), Natural Language Processing, and Knowledge Representations to put the power of text data mining in the hands of individual researchers. The geoscience domain-specific lexicon and taxonomy of 150,000 terms created from a variety of open sources enables a wide range of visualization options, including clustering, heatmaps, associations in geological time and space, correlation plots, and analogue suggestions. This enables geoscience researchers to test hypotheses, investigate anomalies, stimulate ideation, and discover new knowledge and insights to surface latent patterns from within large volumes of text and links back to the text, allowing researchers to validate sources.

GeoSapien® is currently in beta and initial feedback from the geoscience community is encouraging and we hope to make GeoSapien® available to the international geoscience community later this year.

An ensemble model for predicting mineral prospectivity: a case study in the Malipo W-Sn mineral district, Yunnan Province, China

Chenyi ZHAO[1], China University of Geosciences, Beijing
Jie ZHAO[2]*, China University of Geosciences, Beijing (jiezhao2014@163.com)

Abstract

The utilization of machine learning and data-driven approaches for mineral prospectivity modeling has become increasingly crucial in supporting regional mineral exploration. However, deep learning-based mineral prospectivity modeling often encounter challenges due to limited labeled data and an imbalanced ratio of positive and negative samples. Insufficient training samples can also lead to inadequate extraction of mineral-related features, diminished accuracy in predicting mineralized areas, and even non-convergences (e.g., overfitting or underfitting) of models. In this study, we propose a novel hybrid ensemble model that integrates various learner methods, including Generative Adversarial Networks (GAN) and pre-training techniques, to effectively address these challenges. In comparison to conventional techniques such as rotation-based generation of new samples from original geological data, GAN-augmented data exhibits close resemblance to the original dataset in terms of both structure and attributes. The process of pre-training involves training a model on a large-scale dataset prior to the target task, which enables it to acquire general features. Pre-trained models serve as a valuable foundation for transfer learning by leveraging acquired knowledge and features from the pre-training phase instead of starting feature representation learning from scratch for a new task. Overall, our proposed ensemble model based on stacking entails training multiple diverse base learners whose outputs are utilized as inputs to train a meta-learner model, subsequently obtaining desired prediction results from these meta-learner models' outputs. The ensemble model runs following the subsequent steps: (1) initially, a set of 20 models was selected for training in the first layer based on their performance encompassing a diverse range of typical classification models such as Logistic Regression (LR), Stochastic Gradient Descent (SGD), Random Forest (RF), Extra Trees (ET), Decision Tree (DT), Multinomial Naive Bayes (MNB), Multi-layer Perceptron (MLP), Support Vector Machine (SVM), K-Nearest Neighbor (KNN), etc.; (2) subsequently, a 5-fold K-Fold cross-validation approach was employed to train these models and obtain meta-features; (3) these meta-features were then integrated with the dataset to form the training set for the second-layer meta-model (i.e., CNN, Bagging, and Boosting); (4) by leveraging the Grid Search Cross-Validation concept, optimal model weights were determined through equidistant sampling within the specified parameter space; and (5) ultimately, a weighted average of prediction results from multiple meta-learners was computed as the final outcome. Those intelligent prediction techniques were applied to analyze the geological, geochemical, and geophysical dataset with the aim of delineating potential areas for W-Sn mineralization in Malipo County, Yunnan Province, China. The ensemble model demonstrated superior performance in the study area and proved to be an efficient tool for mineral prospectivity modeling. Furthermore, the ensemble model exhibited high

flexibility and scalability by allowing adjustments to be made on base learners' types and quantities based on data characteristics, and demonstrated substantial potential for application in various research domains within the fields of geosciences.

Drivers of Phanerozoic Marine Biodiversity: Insights from Machine Learning

Guoxiong Chen[1]*, China University of Geosciences (gxchen@cug.edu.cn)
Qiuming Cheng[2], China University of Geosciences

Abstract

Phanerozoic biodiversity dynamics was controlled by both abiotic and biotic factors. However, a rigorous quantitative assessment of the relative roles of these factors in regulating long-term biodiversity dynamics has not been carried out because of the complex interplay between these forces. Here, we developed a machine learning (ML) model, from a data-driven perspective, for reconstructing the Phanerozoic history of marine biodiversity using various time series records of biological and abiotic forces (e.g., continental fragmentation, temperature, sea level, oxygen level and nutrient availability) and their time change rate. First, the ML model is designed to isolate long-term trends in the Phanerozoic biodiversity by separating the complex abiotic controls and interactions. The results show a monotonically increasing curve of biodiversity, with three rapid increases in early Ordovician, Cretaceous and Cenozoic, suggesting biodiversity-dependent dynamics which can be well fitted by logistic model. Second, changes in abiotic factors appear to have collectively modulated the non-directional fluctuations in Phanerozoic marine biodiversity. Among them, temperature, sea level, and oxygen level could have played relative important roles on origination or extinction rate. Notably, the ML-based multi-factor analysis suggest a transition from oxygen level-dependent biodiversification before Paleozoic to oxygen change-dependent model. More broadly, this study amplifies that data-driven machine learning methods could provide a potential path forward for deciphering the complex co-evolution of mass, environment and life.

Intelligent Identification of Target Properties of Downhole Rockfall Funnels in Pulang Copper Mine

JIANGUO CHEN[1]*, China University of Geosciences Wuhan (jgchen@cug.edu.cn)
Xinhan Lv[2], China University of Geosciences (Wuhan
Zhijun Chen[3], China University of Geosciences (Wuhan

Abstract

In the process of underground mineral extraction, it is often necessary to conduct daily inspections manually in the tunnels to ensure the normal progress of production work. However, this inspection method tends to suffer from drawbacks such as frequent inspections, long duration, and high safety risks. To address these issues, this study proposes an intelligent recognition system based on binocular depth cameras to achieve remote automated identification and proportion analysis of rockfall block size and debris, which are used to determine whether there is blockage in the rockfall funnel due to excessively large block size and whether the mining operation is approaching the surface. Challenges such as low light intensity, high levels of dust and water vapor, large differences in rock size, and unclear boundaries pose challenges to the accuracy of intelligent recognition and segmentation. To address these challenges, this study first conducted data augmentation on high-resolution images captured by the binocular camera system in the complex real-world scenarios underground, including geometric and pixel transformations, aiming to enhance the model's learning ability for fuzzy boundaries and objects with large size differences and irregular shapes. Secondly, a stereo vision algorithm was designed to obtain high-precision depth maps, capturing the true size and shape information of ore particles in three-dimensional space, thus overcoming the limitations of traditional two-dimensional image processing in particle size analysis. Based on the original DETR model, we utilized the Deformable DETR network, which has higher recognition capability for irregular shapes and small particle size objects, to conduct detection and size selection of rockfall block bodies. In order to perform more accurate segmentation and proportion analysis of block bodies and fine particles, the Attn Mask R-CNN model used in this study improves upon the original Mask R-CNN model by incorporating channel attention modules and spatial attention modules into the Backbone and FPN positions, according to which the model's segmentation accuracy for rock and mineral block bodies was enhanced. Finally, a gradient-weighted activation mapping method based on non-circular contour detection is proposed, integrating a Hough transform module into Grad-CAM to enhance the network's attention towards non-circular contour objects in the image, thereby achieving the localization and identification of non-rock and mineral block objects such as vegetation roots and iron objects underground, implying that the mining operation is nearing the surface.

Abstract

Decades of geochemical research have accumulated sufficient data to map nearly every corner of the Earth. However, despite this wealth, the quantitative understanding of the Earth system as a whole entity is far from being achieved. Furthermore, the great advancements in geochemical instrumentation have exponentially increased the community's capacity to produce data, resulting in vast amounts of geochemical data that is commonly inaccessible to the public either due to being unpublished or published behind paywalls. To unlock the full potential of such large amounts of data, novel tools are needed to connect the various and numerous datasets at a global scale and through geological times. In response to these pressing needs, the AuScope Geochemistry Network (AGN) and collaborator Lithodat have built the AusGeochem data platform.

Funded under the National Collaborative Research Infrastructure Strategy (NCRIS), AusGeochem is an open-access, cloud-based geospatial data platform designed for archival, dissemination, and interrogation of global Earth Science samples and their associated data, adhering to FAIR (Findable, Accessible, Interoperable, and Reusable) data principles. The platform not only integrates publicly available legacy data, but also enables the seamless upload of geochemical data directly from laboratories, granting users full authorship and control over their data management, including the ability to obtain DOIs for their datasets. This allows the capture of the data at the source and therefore promoting public dissemination. Doing so, it also enables the users to integrate their own datasets and analyse them together within a rich framework of ever-growing public data.

The platform supports bulk upload of various types of state-of-the-art analytical datasets through specialized, bespoke data models, including sample metadata, major and trace elements, fission

tracks, (U-Th)/He, U-Pb, Lu-Hf, and 40Ar/39Ar, with more models currently in development. Each data model serves as relational schemas, unlocking the potential for seamless integration of diverse data types and numerical geoscience techniques in the future. The platform also provides users with powerful on-the-fly data synthesis and visualization tools, including TAS diagrams, spidergrams, bivariate and ternary diagrams, U-Pb plots, and direct exports to IsoplotR. Combining samples with various map layers and contextual paleogeographic reconstructions provides users with a broader perspective to analyze their data in a 4D framework.

Despite being young, AusGeochem has already demonstrated its efficacy within the community. Collaboration with Museum Victoria has provided direct access to centuries-old national collections (> 140,000 geological specimens, 60% currently in the platform); the AusGeochem platform tools helped identify potential mineral deposits using the large CSIRO legacy dataset from magmatic Ni mineralisation associated with mafic-ultramafic rocks from Precambrian Western Australia; recent Nature Scientific Reports published in 2023 have showcased the platform's capabilities in revealing the tectono-thermal evolution of various regions through the innovative tools and dynamic interrogation techniques of the AusGeochem platform.

In conclusion, the AusGeochem platform holds immense potential for advancing numerical geoscience techniques, promoting data interoperability, and driving further research and discovery in the field of geochemistry.

Decoding Informative Factors for Large Earthquake Occurrence Recognition from the Earthquake Catalogs with Explainable Machine Learning

Jinsu JANG[1]*, Kangwon National University (jinsujang@kangwon.ac.kr)
Byung-Dal So[2], Department of Geophysics, Kangwon National University, Chuncheon, Gangwon-do 24341, Republic of Korea.
Sung-JoonChang Chang[3], Department of Geophysics, Kangwon National University, Chuncheon, Gangwon-do 24341, Republic of Korea.
Yuen David[4], Department of Applied Physics and Applied Mathematics, Columbia University, New York, NY 10027, USA

Abstract

The spatiotemporal distribution and magnitude of earthquakes, which are important for seismic behavior analysis and hazard assessment, have been documented over a long period of time. Consensus on crucial factors hidden in primary earthquake information such as epicentral distance between earthquakes, time to subsequent events, and magnitude in the earthquake catalog remains elusive. Machine learning (ML) has recently been proposed to gain new insights from huge seismic data. In this study, we explain the ML training and testing process for classifying Large Earthquake Occurring (LEO) or non-LEO cases from spatiotemporally clustered earthquakes to quantify the relative importance of primary earthquake information (e.g., time, longitude, latitude, depth, and magnitude). Our explainable ML models show an AUC > 0.75 when the number of earthquakes in the window is 50. As the classification performance increases, the maximum magnitude of the earthquakes in the window becomes more influential in the ML classification processes. The maximum magnitude is the key factor that increases the classification ability, especially when the five most important statistical features are jointly trained. The ML explanation implies that the seismic moment release, which determines the magnitude of the earthquakes, is an informative factor for the occurrence of large earthquakes with an ML perspective. Our explainable ML provides a new approach to derive implications of earthquake physics from the condensed seismic data.

Explainable machine learning to uncover hydrogen diffusion mechanism in clinopyroxene

Anzhou LI[1]*, School of Earth Sciences, Zhejiang University (anzhouli@zju.edu.cn)
Sensen Wu[2], School of Earth Sciences, Zhejiang University
Huan Chen[3], College of Oceanography, Hohai University
Zhenhong Du[4], School of Earth Sciences, Zhejiang University
Qunke Xia[5], School of Earth Sciences, Zhejiang University

Abstract

Estimating the water content of mantle-derived magma using clinopyroxene (cpx) phenocrysts serves as a valuable constraint on the water budget in deep Earth. Intricate magma processes and the high hydrogen diffusion rate necessitate careful evaluations of whether the water content in cpx preserves its original state. Machine learning (ML) has been utilized to develop a classifier for judging hydrogen diffusion in cpx. Nevertheless, the opaqueness and complexity of most ML models hinder a clear understanding of their classification principles. To elucidate the mechanistic basis of the ML model, the Shapley theory is integrated to determine the contributions of major elements of cpx as features in a linear additive manner. This study achieves superior classification performance using an extreme gradient boosting model and innovatively presents a quantitative evaluation of feature importance at the sample level for each observation. The results indicate that Na plays a predominant role in the diffusion process surpassing other major elements and its associated hydrogen can easily diffuse out of cpx. Our model also identifies various hydrogen association modes in different elemental compositions and puts constraints on the properties of incorporated hydrogen with non-lattice forming elements in cpx. The findings demonstrate that the application of explainable ML methods in mineralogy holds significant potential for advancing the comprehension of geological phenomena.

Time-limited lithogeochemistry of marine and terrestrial alternation on the Tibetan Plateau

Xinwei Liu[1]*, Sun Yat-sen University (liuxw69@mail2.sysu.edu.cn)
Qiuming Cheng[2], China University of Geosciences/Sun Yat-sen University

Abstract

Due to the complex formation process of the Tibetan Plateau, there is still considerable divergence in our understanding of its formation history. Traditionally, researchers have primarily studied the uplift of the Tibetan Plateau from the perspectives of paleo-elevation, paleo-fossils, and tectonics. However, since the introduction of the tectonic environment discrimination map by scholars in the 1970s, whole-rock geochemistry of basalt has emerged as a crucial tool for exploring the background of magma formation and geodynamic processes. Nevertheless, research on the uplift history of the Tibetan Plateau from the perspective of tectonic environment transformation remains limited. Therefore, this paper employs a machine learning approach to elucidate the temporal and spatial evolution of the plateau's uplift by analyzing the transition of basalt's tectonic environment.

In this study, we collected and analyzed over 6000 basalt data points from known marine and terrestrial environments, as well as nearly 800 basalt data points from unknown tectonic environments on the Tibetan Plateau, utilizing the Global Geochemical Database. To distinguish between global marine and terrestrial environments, we employed a combination of machine learning algorithms, including random forest, support vector machine, k-nearest neighbor, and convolutional neural network algorithms. The results of our model were highly successful, demonstrating excellent performance in both the training and test datasets, with an accuracy rate exceeding 90%. Building upon these findings, we applied the model to the data from the Tibetan Plateau. Our analysis revealed that since 500 Ma, the Tibetan Plateau region experienced terrestrial phases at 38-62.5 Ma and 83-224.7 Ma, while the remaining periods were characterized by marine phases. Furthermore, we conducted an in-depth examination of the spatial-temporal changes of the marine and terrestrial phases across the Tibetan Plateau, taking into account their age-dependent variations. Through this analysis, we were able to validate the uplift history of the Tibetan Plateau from the perspective of tectonic environment transformation. These findings provide important insights into the evolution and uplift of the Tibetan Plateau. By combining advanced machine learning techniques with geochemical data, we have achieved a deeper understanding of the complex geological processes that have shaped this remarkable region.

Through this study, we have gained a clearer understanding of the formation history of the Tibetan Plateau while providing compelling evidence and fresh perspectives regarding its uplift history. By leveraging machine learning methods, we have enhanced our ability to explore the intricacies surrounding the plateau's formation, contributing to ongoing research in this field.

Calculation of crustal thickness and characterization of its spatial distribution in the South American Andes magmatic arcs

Kunyi WANG[1]*, Sun Yat-sen University (wangky28@mail2.sysu.edu.cn)
Qiuming CHENG[2], China University of Geosciences/Sun Yat-sen University

Abstract

The formation and evolution of continental crust is one of the main tasks of geological research, and crustal thickness, as an important parameter of continental crust research, has received extensive attention from many researchers. In addition to measuring crustal thickness using geophysical methods, some researchers have found, through globally compiled geochemical data, that the contents or ratios of certain geochemical elements are closely related to crustal thickness, providing a non-geophysical way of calculating crustal thickness. The question that arises is whether the correlation between these geochemical proxies and crustal thickness validated at the global scale can help in estimating crustal thickness at regional or even smaller scales?

In this study, we collected 30847 global whole-rock geochemical data related to magmatic arcs through the GROROC database (http://georoc.mpch-mainz.gwdg.de/georoc/). Interference from other lithologies and compositions was excluded by previous researchers' data screening methods, resulting in 6,288 samples containing five major and six trace element signatures. Modeling of crustal thickness calculations using a random forest regression model for whole-rock geochemical data showed that the model achieved excellent results on both the training and test sets, with goodness-of-fit greater than 0.95 and no overfitting.

In order to validate the effectiveness of the Random Forest regression model for calculating crustal thickness on a regional scale, the Andean volcanic zones in South America was selected as the study area for testing, and 2,733 samples were collected from a global database (GEOROC) to assess how crustal thickness variations can be captured by the Random Forest model. At the same time, we compare the results of two commonly used geochemical proxies (i.e., Sr/Y, La/Yb(n)) for calculating crustal thickness. The results of the application in the Southern Andean Volcanic Zone (SVZ) show that the range of results from the Random Forest model is more concentrated and the curves tend to be smoother and closer to the results from the geophysical models. In contrast, the crustal thicknesses calculated at regional scales for La/Yb(n) and Sr/Y have a wider range and the curves tend to fluctuate.

In this study, a model for calculating crustal thickness based on geochemical data constructed using a machine learning approach can effectively solve the problem of accuracy for application at the regional scale, avoiding the problem of discrepant estimates when estimating crustal thickness with a single geochemical indicator used previously.

Xiaoguang Wang[8], State Key Laboratory of Oil and Gas Reservoir Geology and Exploitation, Chengdu University of Technolog

Abstract

The exploration and development model centered on surface geothermal manifestations can no longer meet the growing demand for geothermal energy. In order to promote the large-scale and commercialization of global geothermal exploitation, it is essential to conduct a comprehensive assessment of the viability, suitability and economy of geothermal exploitation in a certain region, utilizing multi-source data and information. In this study, a global geothermal database for 100 geothermal cities with geothermal industry/utilization was established by artificial and large language model (Geo-GPT) extraction. This database contains administrative information, geographical data, geothermal geological data and geothermal exploitation data etc.. By visualizing geothermal data on global maps with different properties, we were able to identify patterns in geothermal exploitation and extract key factors that drive the evolution of geothermal development suitability. On account of the key dominant factors, a prediction model for geothermal resource potential was developed using a combination of data analysis techniques and a hybrid approach that incorporates both physical and data-driven methods. This model allows for the evaluation of the suitability of geothermal exploitation in specific cities within regions with high geothermal resource potential. Additionally, an analysis of technical and economic sensitivity was conducted to inform effective decision-making for economic and scalable geothermal resources development. Overall, we have integrated database, cloud computing, and artificial intelligence technologies to construct a global geothermal database and an analysis platform. These resources provide robust support for promoting large-scale commercial development and utilization of geothermal energy. The proposed methods and models aim to enhance the utilization rate of geothermal resources, reduce development costs, mitigate risks, and provide new avenues for the sustainable development of geothermal energy globally.

Quantitative analysis of fluid inclusions characteristics based on data drive

Xia QINGLIN[1]*, China University of Geosciences (Wuhan) (qlxia@cug.edu.cn)
Liu Qifeng[2], China University of Geosciences (Wuhan)
Jing Guozheng[3], No.3 Exploration Institute of Geology Resources of Qinghai Province
Hua Qi[4], China University of Geosciences (Wuhan)
Gao Yan[5], China University of Geosciences (Wuhan)

Abstract

Fluid inclusion studies provide a wealth of information about ore-forming fluids, such as temperature, salinity, density, pressure, and composition, for an in-depth understanding of the metallogenic process and the genetic mechanism of ore deposits. However, in the past, fluid inclusion studies were mainly carried out on a few typical deposits, and the amount of data was relatively small, which was not conducive to reflecting the overall characteristics of ore-forming fluids in the whole metallogenic belt. Moreover, fluid inclusion data are multi-source, different structures, complex, and computationally difficult, and it is difficult to analyze it comprehensively and effectively by using traditional linear statistical methods. Therefore, authors adopt a data-driven approach, taking the quartz vein-type tungsten deposit in the Nanling metallogenic belt as a case study, and uses machine learning to further identify the deep information contained in fluid inclusion data from 11 large and medium-sized tungsten deposits. Studies have shown that: (a) Firstly, the data are normalized, and the Wasserstein Distance (WD) is calculated, and it is found that the WD distance of the ore-forming fluid is closer to that of the deposits in the same ore cluster, indicating that they have similar metallogenic environments. In addition, the WD distance of ore-forming fluids of the same type of deposit is also similar, indicating that their mineralization is similar. (b) The obtained data of fluid inclusion freezing point temperature, uniform temperature, density, salinity, gas-liquid ratio, perimeter, area, bubble area and other data were used to carry out K-means clustering. After the normalization of each parameter and then the dimensionality reduction by the t-SNE algorithm, it was found that there was obvious clustering after t-SNE and normalization treatment, and the addition of fluid inclusions morphological data was more conducive to distinguishing fluid inclusions with different properties. Three distinct clusters were obtained by unsupervised clustering: the cluster-A has a higher uniform temperature and lower salinity and density, the cluster-B has a lower uniform temperature and salinity and a higher density, and the cluster-C has a lower homogeneous temperature and higher salinity and density. (c) A dataset of 196 fluid inclusions in the wolframite-quartz stage, 219 fluid inclusions in the quartz-sulfide stage and 90 fluid inclusions in the carbonate-fluorite stage were selected to construct a dataset, and the influence of the unbalanced dataset was eliminated by the SMOTE oversampling method, and 2, 2 and 1 sample data were randomly selected from the inclusions of the three metallogenic stages each time to form a blind test set with freezing point temperature, uniform temperature, density, salinity, gas-liquid ratio, perimeter, area and bubble area as feature inputs. The random forest model was used to intelligently classify the fluid inclusions in each metallogenic stage, and good results were obtained, and the accuracy of the blind test set was

greater than 90%. In conclusion, data-driven methods applied to fluid inclusion studies can obtain more mineralization information than conventional methods.

Machine Learning and Magma Fertility Determination: Revealing Spatio-temporal Variation of the Favorability of Porphyry Copper Formation

Yuanzhi ZHOU[1]*, China University of Geosciences, Beijing (yuanzhi@email.cugb.edu.cn)
Zhenjie ZHANG[2], China University of Geosciences, Beijing
Jie YANG[3], China University of Geosciences, Beijing
Peng ZHANG[4], China University of Geosciences, Beijing
Qiuming CHENG[5], Sun Yat-Sen University

Abstract

The magmas associated with porphyry copper deposits (PCDs) often exhibit unique chemical properties, referred to as magma fertility, which can serve as an indicator for the potential for porphyry copper mineralization. However, previous research has predominantly focused on subduction-related PCDs, lacking an understanding of the ore-forming magmas and their formation mechanisms in the post-collision setting. Here, we compiled the whole-rock geochemical composition of ore-bearing and ore-barren igneous rocks from both subduction and collision orogenic belts. We utilized two machine learning (ML) models, Support Vector Machines (SVM) and Random Forest (RF), to classify the metallogenic fertility (fertile vs. unfertile) of magmas. Both models achieved higher classification accuracy (~85-89%) than the bivariate discrimination plots, demonstrating the feasibility and effectiveness of using ML methods to distinguish fertile from unfertile magmas. The feature importance analysis of the RF classifier identified that the most significant parameters of fertile magma are low MnO, low Ho, low Y, and high SiO2. These characteristics further highlight the potential common role of hornblende and garnet fractionation in the deep crust in the formation processes of both subduction- and collision-related PCDs. As a case study, we applied our trained ML models to predict the metallogenic fertility of Mesozoic and Cenozoic magmas in the eastern Gangdese belt in southern Tibet. The results suggest that the magmas in the post-collision stage, especially the Miocene magmas, are notably more fertile than those of the subduction stage. The spatial mapping results of the predicted metallogenic fertility of the Miocene magmas reveal that the most fertile magmas during this period are primarily distributed between 90-92° E, which coincides with the least evolved magmas based on the Hf-Nd isotope mapping. This implies that the upwelling of depleted mantle materials caused by slab tearing has a direct impact on magma fertility. Therefore, this area represents a key prospecting direction in the eastern Gangdese belt. Our ML models may help reveal spatio-temporal variation in the favorability of porphyry copper formation.

The formation and evolutionary process of the North China Craton during early Precambrian: Implications from big data analysis

Zhenjie ZHANG[1]*, China University of Geosciences, Beijing (zjzhang@cugb.edu.cn)

Abstract

The North China Craton (NCC) is a venerable landmass with a multifaceted tectonic history spanning approximately 3.8 Ga. The majority (around 90%) of the NCC's continental crust was generated during the Archean period, rendering it a significant field of investigation for comprehending the formation of Earth's early crust and its subsequent tectonic evolution. Nevertheless, controversies persist regarding the genesis and progression of the NCC, with plate tectonics and mantle plumes posited as potential mechanisms governing its crustal evolution. In this study, we have meticulously compiled and analyzed published rock and mineral geochemistry data to unravel the intricate processes underlying the formation and evolution of the NCC. Leveraging the power of big data and machine learning techniques, we have successfully discerned novel patterns, structures, and relationships within these scientific datasets that may have eluded traditional geological approaches. Our findings unequivocally indicate that the North China Craton underwent a protracted phase of intra-oceanic arc aggregation and arc-continent collision, primarily manifesting in the eastern blocks from approximately 3.5 Ga (or possibly even earlier) to 1.5 Ga. Subsequently, after 1.5 Ga, the NCC as a cohesive entity actively participated in the grand global cycle of supercontinent amalgamation and dispersal. These findings extensively contribute to our understanding of the long and complex geological journey undertaken by the North China Craton.

Application of remote sensing to identify Copper–Lead–Zinc deposits in the Heiqia Area of the West Kunlun Mountains, China

yuhai FAN[1]*, Geological Exploration Institute of Aerial Photogrammetry and Remote Sensing Bureau (170269854@qq.com)

Abstract

The harsh natural environment and inaccessibility of the West Kunlun Mountains are barriers for their investigation via field geology. Remote sensing technology has the advantage of being efficient on a macroscale and not being restricted by terrain or road conditions in sparsely vegetated areas with exposed bedrock. This work focuses on copper–lead–zinc deposits in the Heiqia Area in the West Kunlun Mountains as a case study to illustrate the application of IKONOS remote sensing images as major data sources to fabricate a standard image map, the extraction of information on ore-controlling factors and mineralization through the use of image enhancement methods, and the interpretation of remote sensing data to identify mineral resources. Alteration anomaly information was extracted from ASTER data, verified via field survey and sampling, and used to develop a remote sensing model for utilization in future prospecting efforts. The results of the survey showed that in IKONOS (band 3, 2, and 1 synthesis) images, the copper mineralization zone exhibits interlaced gray-white, blue-gray, and blue tones in a narrow strip-like pattern, while the lead–zinc mineralization zone shows gray-white, light gray-yellow, and yellowish-brown tones in a strip-like pattern. The main remotely sensed alteration anomalies are characteristic of hydroxyl. Six hydroxyl anomalies were delineated in the study area, of which five were found to be copper–lead–zinc deposits. The location of the ore bodies coincides well with the ASTER anomalies extracted. Two Cu – Pb – Zn mineralization belts are present in the study area. The ore-bearing rock series of belt No. Ⅰ is phyllite interbedded with metasandstone, and the ore comprises mainly copper deposits supplemented by lead–zinc deposits. Belt No. Ⅱ is in limestone and consists mainly of lead–zinc deposits supplemented by copper deposits. A remote sensing geological prospecting model for structurally altered Wenquangou Group copper – lead – zinc deposits with a genesis related to hot water basins is established. This provides a basis for future prospecting for similar minerals in the West Kunlun metallogenic belt.

Abstract

Using clinopyroxene (cpx) phenocrysts to estimate the H2O content of basaltic magmas presents a promising avenue for investigating the deep Earth water cycle. However, due to the diverse substitution mechanisms of hydrogen (H) in cpx and the intricate evolution of most magmas, traditional geochemical methods struggle to ascertain whether the measured H in cpx phenocrysts reflects a primary signature indicative of mantle water content.

Support Vector Machine (SVM), a robust and well-established machine learning technique, offers an effective approach for classifying samples into distinct groups based on high-dimensional datasets. By simultaneously considering the complex relationships between H and major elemental compositions in cpx, SVM can discern samples that have undergone H diffusion from those that have not. In this study, we applied machine learning to major element compositions and H2O content of cpx phenocrysts collected from various global locations, and developed a classifier (with an overall accuracy exceeding 90%) capable of distinguishing between pyroxenes affected by H diffusion and those unaffected. Nevertheless, the inherent complexity of machine learning models often obscures a clear understanding of their classification principles. Additionally, we achieved superior classification performance using an extreme gradient boosting model and introduced a novel quantitative evaluation of feature importance at the sample level for each observation. The findings identified various modes of hydrogen association in different elemental compositions, shedding light on the properties of incorporated hydrogen with non-lattice forming elements in cpx.

The trained model holds significant implications for understanding the primary water content of magma and the fluctuations in water content during magma evolution, thereby offering insights into the deep Earth water cycle mediated by basaltic magma. These findings also underscore the potential of employing explainable machine learning methods in mineralogy to advance our understanding of geological phenomena.

Development of clustering model for XRD experimental data from the Ulleung Basin, Korea

Ju Young PARK[1]*, Kongju National University (leahlove6786@gmail.com)
Hongkeun JIN[2], Kongju National University
Sun Young PARK[3], Petroleum Energy Research Center, Korea Institute of Geoscience and Mineral Resources
Byeong-Kook SON[4], Petroleum Energy Research Center, Korea Institute of Geoscience and Mineral Resources
Sungil KIM[5], Petroleum Energy Research Center, Korea Institute of Geoscience and Mineral Resources
Kyungbook LEE[6], Kongju National University

Abstract

X-ray diffraction (XRD) is widely used for reservoir characterization, estimating hydraulic fracturing efficiency and understanding depositional environments. However, mineral composition analysis from XRD depends on the analyst's subjectivity and is time-consuming due to manual matching process of intensity profile. Recently, researchers have developed machine learning models to analyze mineral compositions using XRD data as input data. In the previous researches, the error between mineral compositions analyzed by experts and estimated by machine learning is below 1%. However, the machine learning models showed unreliable performance for few samples, which have outlier mineral composition. It is difficult for the machine learning models to learn peak tendencies of few samples due to the different intensity patterns compared to common samples, which have similar mineral composition. For the few samples, it is reasonable to be analyzed by experts instead of machine learning. The purpose of this research is to classify the few samples among whole samples to be analyzed by expert using k-means clustering. Because the unsupervised model requires only XRD intensity profile, each sample can be categorized into 'expert group' and 'machine learning group' before mineral composition analysis in detail.

The XRD experimental data provided by the Korea Institute of Geoscience and Mineral Resources consisted of 3,100 intensity with an incidence angle ranging from 3.01 to 64.99 degrees with an interval of 0.02 degrees. Among the total 488 samples, 439 samples were used as train data and the remaining 49 samples were utilized as test data. Because k-means clustering provides different clustering results depending on the number of clusters, sensitivity analysis was implemented to select the optimal number of clusters. The number of clusters was selected between 3 to 7 and the optimal number of clusters was determined with the minimum number of false positives (FP) in the confusion matrix. FP means that although samples are classified as machine learning group, they actually have an outlier mineral composition. This is because a smaller FP can increase the precision of the clustering model. After sensitivity analysis for the number of clusters, the optimal number of clusters was selected to be 5 because FP was 0, which shows high precision. Although FP was 1 when the number of cluster is equal to 4, 6, and 7, false negatives (FN) of them is larger, 16, 31, and, 15, respectively, than the 5-cluster case, 3 FNs. FN means that although samples are

classified as expert group, they have an usual composition. This means that a lot of samples are assigned to the expert group, even though they can be analyzed by the machine learning. Therefore, high FN diminishes the efficiency of machine learning-based analysis workflow. The developed clustering model can be used to improve the efficiency of composition analysis, and the outlier samples can be analyzed reliably by expert. Also, these model can be coupled with the previously developed composition analysis model, to create a analyzing system for mineral composition.

A Method of Geological Mapping Based on Deep Learning

Fengdan LI[1]*, Natural Resources Survey of China Geological Survey(CGS)
(13810107437@139.com)
Chang Liu[2], Natural Resources Survey of China Geological Survey(CGS)
Shuang Liu[3], Natural Resources Survey of China Geological Survey(CGS)
Yuanyuan Liu[4], Natural Resources Survey of China Geological Survey(CGS)

Abstract

High-precision identification of mapping objects is an important requirement of geological mapping work. The DGSS team proposed a geological mapping method based on deep learning, which can assist the mapping groups to narrow the working scope of finding key geological bodies and improve the identification accuracy.

1.Main idea

Mapping units and lithologies are the most basic objects of geological maps. The core of the method is to apply deep learning technology and mapping knowledge bases from the geologists' methods, experiences and knowledge to discover the correlation of geological characteristics between multi-specialty(geological, geophysical, geochemical, remote sensing), multi-modal (vector , raster , spatial and unstructed data), multi-scale and mapping units and lithologies, and to predict spatial position and direction, distribution position, and adjacent relationship of them.

2.Progress in key technologies

(1)A series of algorithmic models are proposed to meet the prediction of different geological objects (tectonic, lithologic, and lithologic combinations) to provide modeling capability for pre-study, field survey, and thematic research.A series of model evaluation indicators are summarized from the application perspective.The accuracy of the models exceeds 95%, the recognition accuracy of mapping objects exceeds 90%, and the overall architecture of the geological prediction maps is basically consistent with the geological measured maps.

(2)A set of AI application process synchronized with mapping work are formed to efficiently support sample data collection, processing, organization and modeling.Some software tools have been developed,including organization of various samples,management of process tasks , expression of prediction results, etc.

3.Test analysis

Since 2019, the DGSS team and mapping groups have carried out experiments in more than ten 1:50000 mapping projects.The result is remarkable:

(1)AI has strong ability and level of prediction of geological map in blank area.It also can accurately reflect the geological frame and spatial distribution pattern of the survey area.

(2)It has the ability to expose geological bodies in shallow coverage areas.The predicted geological mapping units can be verified by field survey at new outcrops.

(3)The spatial expression of the prediction results is conducive to the discovery of new problems and information, and has a strong significance for deepening the understanding and analysis of geological problems in the field work.

Data-driven Automated Detection and Characterization of Dinosaur Footprints

Yeoncheol HA[1]*, Department of Astronomy, Space Science, and Geology, Chungnam National University (duscjf1002@o.cnu.ac.kr)
Seung-Sep Kim[2], Department of Geological Sciences, Chungnam National University

Abstract

Dinosaur tracks provide important paleontological information for understanding various aspects of dinosaur biology, including body size, stride length, and speed. However, manual identification and marking of fossilized footprints at track sites are prone to errors due to factors such as poor preservation and atypical shapes. Convolutional Neural Network (CNN)-based models such as VGG16 and Xception have been employed for data-driven classification of fossil images or footprint outlines. However, challenges persist in detecting footprints from multi-resolution images, such as those obtained from handheld and drone cameras. In this study, we introduce a novel approach utilizing the YOLOv8 deep learning algorithm to automatically detect and classify dinosaur footprints. YOLOv8 offers comprehensive capabilities, including detection, segmentation, pose estimation, tracking, and classification in images containing multiple features using bounding boxes. Leveraging transfer learning on pretrained models trained on the Common Objects in Context (COCO) dataset enhances model performance. Our research utilizes the Korea dinosaur footprint image dataset from AI-Hub, in conjunction with independently collected dinosaur footprint data. The training dataset comprises 112,958 images for training and 14,104 images for validation. Computation was performed on the GPU-based supercomputer Neuron, which was provided by the Korea Institute of Science and Technology Information (KISTI). Based on distinctive morphological features, training commenced with labels categorizing footprints into pseudo-footprints (terrain changes, not actual dinosaur tracks), Theropod (footprints typically characterized by three sharp toe mark and longer than wider), Ornithopod (footprints characterized by three toes with blunt claws, with length similar to width), and Sauropod (footprints characterized by five toes, typically oval or circular in shape). The trained YOLOv8 model will automatically detect and classify dinosaur track photographs, including diminutive tracks not included in the training dataset. By overcoming challenges associated with manual identification and classification processes, such as misidentifications and oversights, our deep learning approach offers a more efficient and accurate means of analyzing extensive dinosaur track datasets. Additionally, the adoption of deep learning algorithms in paleontology not only streamlines data analysis but also opens avenues for new discoveries and insights into dinosaur behavior, evolution, and paleoecology on a broader scientific scale.

Deep Learning 3D Mineral Segmentation with micro-CT and micro-XRF

Yiming WANG[1]*, China University of Geosciences(Beijing) (3001220110@email.cugb.edu.cn)
Jie YANG[2], China University of Geosciences, Beijing

Abstract

The three-dimensional (3D) textures and compositions of minerals play a crucial role in inferring the physiochemical conditions within magmatic systems. Accurate characterization of the 3D characteristics of individual mineral crystals within a sample is of utmost importance. The accelerated progress in X-ray micro-computed tomography (micro-CT) has significantly expanded its application in 3D analysis of many rock types. In addition, micro-X-ray fluorescence (micro-XRF) enables non-destructive analysis to acquire element distribution on the sample surface, serving as a basis for mineral identification. Therefore, the primary objective of this research is to synergistically employ micro-CT and micro-XRF data, along with deep learning algorithms, to accomplish the 3D segmentation of mineral constituents within granite samples. Initially, we design an image registration workflow for multimodal data using 2/3D data from micro-XRF and micro-CT, respectively, to accurately locate the sample cross-section within the 3D data. This facilitates the acquisition of pixel-level sample label information necessary for training the model. Subsequently, based on the U-net network architecture design model, we achieve effective segmentation of multiple minerals data, even when faced with imbalanced conditions. This segmentation approach is then extended to encompass the entire CT dataset, enabling the three-dimensional representation of multiple minerals. The developed workflow enables the segmentation of crystals, facilitating the extraction of 3D features of primary and minor minerals present within the sample. Furthermore, the workflow effectively addresses the challenge of distinguishing non-metallic minerals that exhibit similar densities in micro-CT. This capability opens up opportunities for applying the model to other instruments and techniques, allowing for broader applicability in the field of mineral analysis.

Multi-scale full waveform inversion based on a convolutional neural network

Hong LIU[1]*, Institute of Geology and Geophysics, Chinese Academy of Sciences
(liuhong@mail.iggcas.ac.cn)
Wenda LI[2], Institute of Geology and Geophysics, Chinese Academy of Sciences
Lifeng WANG[3], Hainan Branch of CNOOC (China) Limited
Wenlei BAI[4], Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

As a most advanced seismic inversion technique, full waveform inversion (FWI) aims to generate high-resolution models of subsurface media by iteratively fitting the observed waveform, which enables us to extract more information from seismic data and create highly detailed velocity models. Due to the influence of the shallow tomographic component (mainly direct and diving waves), the FWI mainly updates the velocity information in the shallow layers, but hardly in the deep layers. RWI (Hu, 1987; F. Wang et al., 2013; Yao et al., 2018, 2020), developed on this basis, can update the background velocity information of the deep subsurface media, but it is still difficult to update the complex structural features of the deeper layers. This is a bottleneck in waveform inversion, which is the difficulty of updating deep velocity features. The development of waveform inversion is also limited by the huge computational effort involved.

Targeting the problems of traditional waveform inversion, researchers in recent years have combined deep learning algorithms with traditional inversion to come up with a number of creative ideas. First, the most widely explored method is to extract the hidden relationship between seismic data and velocity model by an intelligence network, such as mapping observed data (Yang & Ma, 2019; W. Wang & Ma, 2020; B. Liu et al., 2021) or migration imaging (Zhang & Gao, 2021; Y. Wu et al., 2021, 2022) to accuracy velocity model. The second is the use of AI methods as an aid to inversion and is part of the inversion process. Although all of the above methods have produced good results, there are still some problems, such as the lack of generalisability of some of them. Bunks et al. (1995) first proposed a multi-scale inversion strategy from low to high frequencies. Multi-scale FWI, in the process of inversion from low to high frequencies, can weaken the uncertainty introduced by high-frequency components and reduce data redundancy. The multi-scale FWI process, which is more consistent with the laws of physics, first inverts the background velocity through low-frequency information and then gradually reconstructs the fine structure through high-frequency information. The neural network inversion process is similar to FWI in that it also solves the inverse problem with strong nonlinearity. The same multi-scale algorithm can also be combined with AI inversion to make the inversion process more in line with the laws of physics, thus enhancing the inversion effect.

In this abstract, we proposed a multi-scale convolutional neural network (CNN) FWI (Ms-CNNFWI) method, which incorporated a multi-scale strategy into the CNN-based FWI algorithm. CNN-based FWI combined the initial velocity model with the corresponding migration image to estimate the subsurface unknown velocity model iteratively. We test the proposed Ms-CNNFWI

on some different models and demonstrate its effectiveness in reconstructing the velocity model in different subsurface media. Compared to conventional FWI methods, our approach can better invert the velocity structure of the deep layers. Furthermore, compared to other AI inversion methods, our approach exhibits strong generalization performance.

Improvement of YOLO Model for Borehole Breakout Detection Using Data Augmentation

Juyeol YEOM[1]*, Kongju National University (jy0506kr@gmail.com)
Hayoung Kim[2], Kongju National University
Chandong Chang[3], Chungnam National University
Yeonguk Jo[4], Korea Institute of Geoscience and Mineral Resources
Jonggeun Choe[5], Seoul National University
Kyungbook Lee[6], Kongju National University

Abstract

Borehole breakout (BO), caused by stress concentrations in wellbore, provides information for orientation and magnitude of in-situ stress. The stress is crucial for evaluating the stability of subsurface utilization including carbon sequestration. In general, BO is identified by experts manually based on image logs that causes time-consuming and subjectivity issues. Recently, machine learning has been applied to various studies to improve the limitations of the manual stress estimation. However, previous studies encountered difficulties in enhancing BO detection performance in terms of reliability and detection speed. In this study, we develop a real-time automatic BO detection model for image logs using you only look once (YOLO) algorithm with domain-knowledge based data augmentation. The data used in this study were acquired from the two boreholes, A1 and A2, in Gyeongju, Republic Korea. Well A2 was used for training a YOLO model, which consists of 91 datasets including BO images and their corresponding labels i.e., bounding box coordinates, through expert analysis. Well A1 data was used as an unseen data, which were not used during training and testing the model, to evaluate the applicability of YOLO model to other well data. To alleviate the issue of insufficient training dataset, domain-knowledge based data augmentation was applied to 57 training datasets including parallel shift, flipping, and rotation. The number of training datasets increased from 57 to 1,197 after the proposed data augmentation. When the two YOLO models, with and without the data augmentation, are compared. The YOLO model with the data augmentation (Case 2) increased in average precision, 121.8% higher than one of the YOLO model without the data augmentation (Case 1). To verify the performance and reliability of the two YOLO models, the result of BO detection using wells A1 and A2 image logs were compared with the expert analysis. Case 2 model significantly reduced in both false positive and negative detections compared to Case 1 model. Notably, when the two models were applied to 3-meter images from well A1, where no BO exists, Case 1 misidentified 182 BO objects, while Case 2 did only one BO object. These results demonstrated that the proposed data augmentation can significantly improve the performance of YOLO for BO detection. Additionally, the proposed model automatically analyzed BO information including azimuth and opening degree less than 0.1 seconds per 3-meter image log image, offering a higher efficiency than one of manual expert analysis.

Mineral Identification and Mapping Algorithm Based on X-ray Fluorescence Spectroscopy and Self-supervised Strategy

Weiming JIANG[1]*, School of Earth Sciences and Resources, China University of Geosciences (Beijing), Beijing, 100083, China. (3001220109@email.cugb.edu.cn)
Jie YANG[2], Institute of Earth Sciences, China University of Geosciences (Beijing), Beijing, 100083, China.

Abstract

Mineral identification and mapping play a fundamental role in geoscience research. In elemental analysis techniques, the X-ray fluorescence (XRF) analysis exhibits the capability to conduct non-destructive elemental mapping on raw samples, presenting a cost-effective alternative, which enhanced the ease of mineral identification and mapping processes. However, XRF images encounter challenges like intricate feature extraction, resolution heterogeneity and noise, thereby impeding effective mineral identification and mapping processes. In recent years, the development of large models has brought about self-supervised masked image modeling, which have the potential to solve the above problems. In this study, a comprehensive model tailored for XRF spectrum employing a spectral self-supervision strategy was introduced to harness the informational properties of the 3-D XRF spectral cubes and mitigate the interference of other factors in the spectrum. The model adopted Vision Transformer structure as a baseline and integrated spatial-spectral self-attention operations to extract both spectral and spatial features from XRF images. Employing the masked image modeling, the model reconstructed the masked XRF image spectrum, thereby facilitating enhanced feature learning capabilities. After model pre-training, we transferred the model and fine-tuned parameters of the model to effectively grasp mineral recognition and mapping techniques. The results showed that the correlation coefficient of our model in spectral reconstruction was over 99%, which indicated that the model's composition and image mask reconstruction strategy comprehensively capture the intricate structural features of XRF images. With an accuracy exceeding 89.5% in mineral classification and segmentation, the model accurately delineates the interspersed mineral structures during mapping. The robustness experiments demonstrated that the model is resistant to spectral resolution heterogeneity and noise within the XRF image spectrum. In general, our model is successful in XRF-based mineral identification and mapping owing to its adeptness in learning spectral image characteristics and robustness, rendering it readily applicable to diverse spectral related downstream tasks within geoscience research domains, thus holding significant promise for further advancement and exploration.

GIS Tool Learning with Large Language Model

Zhizhen YU[1]*, School Of Earth Sciences, Zhejiang University (steven.yu@zju.edu.cn)
Zhenhong Du[2], School of Earth Sciences, Zhejiang University

Abstract

Recently, Large Language Models (LLM) have garnered attention due to their powerful emergent capabilities and wide potential for application. However, LLMs exhibit significant limitations when tasked with specific jobs that require high-precision outputs. This is especially evident in the field of Geographic Information Science(GIS), where tasks such as spatial analysis and cartography demand high levels of accuracy and reliability in data. Tool learning is currently a focal point, with the integration of LLMs and tools offering a solution to the accuracy and reliability issues faced by LLMs. Nevertheless, at this stage, due to a lack of GIS tools available for AI utilization among other reasons, most research in tool learning has focused on common tools such as web crawlers, code execution, and API calls, with very limited scientific exploration into GIS tools. This study aims to explore and develop methods for integrating LLMs with professional GIS tools to address the issues of accuracy and reliability when LLMs undertake high-precision tasks within the GIS domain. By achieving such an integration, LLMs will be empowered to proficiently summon GIS tools as needed, thereby significantly elevating the fidelity of outcomes in tasks encompassing spatial data processing, analysis, and the art and science of cartography.

Improvement and Evaluation of the RAG Application

Jiarui CAI[1]*, School of Earth Sciences, Zhejiang University (qingmu_0722@163.com)
Zhenhong DU[2], School of Earth Sciences, Zhejiang Univercity

Abstract

Recently, there has been a growing interest among researchers in the capabilities of large language models (LLMs) to provide potential solutions for vertical domain problems. One such technology that has gained significant attention is Retrieval-Augmented Generation (RAG). RAG combines domain knowledge with LLMs to enhance their understanding and generation abilities in specific domains, thereby enabling them to address corresponding problems effectively. However, the application of RAG also comes with its own set of challenges. One of the primary concerns is the random generation effects, which can lead to inconsistent and unpredictable results. Additionally, the scarcity of domain-specific corpora poses another obstacle, as it limits the availability of relevant training data for the models. Furthermore, the evaluation systems used to assess the performance of RAG applications often lack clarity and precision, making it difficult to accurately measure their effectiveness. To address these challenges and improve the performance of LLMs in RAG applications, additional methods can be employed. One approach is to incorporate knowledge graph techniques, which can provide structured and organized information to enhance the models' understanding of domain-specific concepts. Moreover, iterative datasets fine-tuning can be utilized to iteratively refine the models' performance by continuously training them on updated datasets. By integrating these methods, the overall performance and robustness of large language models can be significantly improved in RAG applications. This study attempts to achieve above improvements of RAG within the Geoscience field. Meanwhile, establishing reliable evaluation systems is crucial to ensure the effectiveness of these approaches. Such advancements in RAG technology and its successful application in various domains have significant implications for further enhancing its capabilities and expanding its utility.

Predicting Methane Concentration in Chromitites: An Application of Ensemble Learning Algorithms in Chro-mitites from Greece

Elena IFANDI[1]*, University Brunei Darussalam (elena.ifandi@ubd.edu.bn)
Daphne Teck Ching LAI[2], School of Digital Science, Universiti Brunei Darussalam
Haezan JANGARUN [3], Geosciences Programme, Faculty of Science, Universiti Brunei Darussalam

Stavros KALAITZIDIS [4], Department of Geology, University of Patras

Abstract

Carbon capture and catalytic conversion to methane emerges as a promising carbon-neutral energy production method. We have examined methane-rich chromitites, which recent studies indicate contain minerals acting as Sa-batier catalysts. However, the petrographic and mineralogical features of previously studied methane-bearing chromitites have not been systematically evaluated. This lack of evaluation hinders the identification of prime ex-ploration targets for chromitites as commercial bulk catalysts, as these features can predict methane concentration. We quantitatively determined the abundance and grain size of the main mineral phases via point counting and ap-plied statistical analyses, including contingency tables and Kendall's tau correlations, to consolidate petrographic and mineralogical data. Given the low performance of traditional regression and classification algorithms ($R2 < 1$ and accuracy <50%, respectively), we opted for automated model selection using the Tree-based Pipeline Optimisa-tion Tool (TPOT), which evaluated over 60 algorithms and pipelines. Its results pointed to two models: a pipeline of Multinomial Naive Bayes (MNB) and Extreme Gradient Boosting (XGB) classifiers and the ExtraTrees classifier. With additional manual optimisation, we opted for a stacking classifier that utilised the MNB and XGB algorithms as estimators, yielding an accuracy of 74% and 70% for the training and testing data sets, respectively. Our detailed investigation of the predictors, based on Shapley Additive Explanation (SHAP) values, revealed that the stacking classifier had a more stable performance with less influence from dispersed data values. Our findings suggest that the presence and size of olivine, spinel, and veins can serve as predictors to classify rocks into "low" and "high" methane groups, aimed at enhancing field exploration operations. The notably minor impact of spinel on the overall prediction of methane concentration suggests that it is improbable to be the primary Sabatier catalyst. This research underscores the effectiveness of automated machine-learning algorithms, specifically multiple ensemble learning classifiers, for optimal model selection in addressing intricate geological issues. Despite the inherent complexity of such data, leading to the underperformance of traditional regression algorithms, our approach demonstrates the heightened performance of these classifiers, illustrating a promising avenue for future geological data analysis.

Deep learning-based multiscale digital rock modeling integrating 2D and 3D rock images

Peng Chi[1]*, China University of Petroleum (East China) (pch_upc@163.com)
Jianmeng Sun[2], China University of Petroleum (East China)
Weichao Yan[3], Ocean University of China

Abstract

Digital rock technology has emerged as an effective approach for investigating the microstructure and physical properties of rocks in geological and geophysical research. Nevertheless, rocks possess multiscale features, and conventional imaging techniques with a single resolution fail to capture the complete structural information. Presently, deep learning-based super-resolution techniques are employed to enhance the resolution of low-resolution images, facilitating multiscale rock images fusion. However, current methods primarily concentrate on the multiscale features of pores while neglecting the reconstruction of other constituents like clay minerals. Consequently, these approaches exhibit subpar performance in the multi-component modeling of digital rocks. To fully express the multiscale information of heterogeneous rocks, we applied an Attention-Guided Generative Adversarial Network (AttentionGAN) to integrate micro-CT images and SEM images of rocks, generating large-scale high-precision rock images. A pivotal aspect of this methodology is its emphasis on not only the multiscale pore structure during training but also the distinctive features of various components, including clays and rock skeleton. By employing this approach, we can generate high-quality digital rocks that faithfully encompass the multiscale information. Through analyzing the reconstructed digital rocks, we explore the influence of clay micropores on rock permeability in sandstone. The results showed that larger pores act as the primary fluid flow channels in rocks and undergo a transformation into micropores upon being occupied by kaolinite. During this process, rock permeability experiences a significant decrease, with a more significant effect observed for higher proportions and more complex structure of micropores.

Forecast of Shale Lithofacies Types in the Dongying Fault-depressed Lacustrine Basin Based on Machine Learning

Zhengwei FANG[1]*, School of Geoscience and Technology, China University of Petroleum (East China) (332527810@qq.com)
Liqiang Zhang[2], School of Geoscience and Technology, China University of Petroleum (East China)

Abstract

Shale oil is currently an important type of energy replacement in the fault-depressed lacustrine basins of eastern China. Many nearby provenancesvariable water body and fault activities have resulted in complex and diverse types of shale lithofacies in theses basins. How to accurately forecast the shale lithofacies types is a key challenge in selecting target for shale oil horizontal wells.Considering the shale of Dongying fault-depressed lacustrine basin as the research object, a lithofacies type forecast was carried out based on machine learning. Two machine learning methods, support vector machines (SVM) and extreme gradient boosting (XGBoost) were used to forecast shale lithofacies types under six different conditions.To improve the forecast accuracy, we applied the following approaches: first, the shale lithofacies were finely classified according to mineralogical composition and microstructure and the vertical change of lithofacies types was obtained. Second, we applied paleoenvironmental parameter data with well logging to forecast shale lithofacies types for the first time.Third, two sample extraction modes, namely curve shape-to-points and point-to-point, were used in the machine-learning process. Compared with the forecast results, in the conditon of selecting the curved shape-to-point sample extraction mode and inputing both well logging and paleoenvironment parameter data, using the SVM method can achieve the highest average forecast accuracy. The learning sample quantity and data value overlap of different lithofacies types affected the forecast accuracy mainly.When adopting machine learning methods, increasing the learning sample quantity, selecting the curve shape-to-point sample extraction mode, and using both well logging and paleoenvironment parameter data are effective ways to improve the forecast accuracy of shale lithofacies types in a fault-depressed lacustrine basin. The method and results of this study provide guidance to accurately forecast the shale lithofacies types in an another fault-depressed lacustrine basin.

A method using convolutional interactive perception network for well logging data prediction.

Xin LUO[1]*, China University of Petroleum (East China) (b22010034@s.upc.edu.cn)
Jianmeng Sun[2], China University of Petroleum (East China)

Abstract

Geophysical well logging data is an important foundation for evaluating underground resources such as oil, gas, and water in subsurface rock formations. Well logging curve prediction is an important approach to replace re-logging and solve the problems of poor or missing effects in certain logging curves. Faced with the extremely low non-linear relationship in complex reservoirs, we propose a convolutional interactive perception network to adapt to more complex well logging curve prediction tasks. The network model focuses on the formation changes reflected by well logging data and introduces wavelet transform technology to extract the change details of well logging curves. Meanwhile, an interactive module is designed to enhance the perception ability of well logging subsequences. Different convolutional kernels are used to effectively capture different temporal patterns and prevent information loss. By introducing physically-driven wavelet transform technology, this model is easily understood and highly reliable for geophysicists. To validate the effectiveness of our method, we conduct experiments using real well logging data for acceleration correction (short-term sequence prediction task) and interval completion (long-term sequence prediction task). The experimental results show that our proposed method outperforms the current mainstream well logging curve prediction models in various sequence prediction indicators. The generated well logging curve data has the highest accuracy, providing a better choice for well logging curve prediction.

Characterizing subsurface structures from hard and soft data with multiple-condition fusion neural network

Zhesi Cui[1]*, China University of Geosciences (zhsc0604@163.com)
Qiyu Chen[2], China University of Geosciences
Gang Liu[3], China University of Geosciences

Abstract

Subsurface structures exhibit inherent spatial variability due to intricate and enduring hydrogeological and environmental influences. Limited subsurface observations for estimating subsurface structures lead to substantial uncertainty, potentially introducing significant bias in subsequent simulations of flow and solute transport. Hydrological modeling stands as an effective and economical approach for swiftly characterizing subsurface structures in a noninvasive manner. Both hard (boreholes, etc.) and soft data (seismic data, etc.) are the most commonly used data types to reveal subsurface structures. Consequently, the effective utilization of diverse data acquired from hydrogeological surveys to construct a realistic representation of subsurface structures emerges as a critical concern. Existing deep-learning-based methodologies predominantly focus on the transition from multiple observations to subsurface structures. However, implicit non-linear correlations among diverse data sources often remain underutilized, leading to potential bias and errors. In this study, we introduce a multiple-condition fusion network (MCF-Net) to characterize subsurface structures based on both hard and soft data. To harness the full potential of multiple-source subsurface observations, two distinct neural networks extract implicit features from hard and soft data. The integration of these features is achieved through multiple-condition fusion blocks, designed to capture representative characteristics. These blocks are also adept at reconstructing heterogeneous structures and facilitating hydrological parameterization. MCF-Net exhibits accuracy in estimating subsurface structures across various types of subsurface observations. Experimental results underscore the utility and superiority of MCF-Net in applications of hydrogeological modeling and inversion. To illustrate the reliability of MCF-Net in practical applications, a case study is presented.

A new sedimentary facies geo-modeling method based on CGAN deep-learning algorithm

Yiming YAN[1]*, China University of Petroleum (yiming@upc.edu.cn)
Liqiang Zhang[2], China University of Petroleum (East China)
Yanjun Lu[3], China University of Petroleum (East China)

Abstract

Obtaining reliable sedimentary facies is crucial for accurately predicting sandstone reservoirs in siliciclastic sedimentary systems. However, for deep oil and gas exploration, the quality of drilling and seismic data is often poor, making it challenging to establish high-precision sedimentary facies maps. Traditional statistical and multi-point geostatistical modeling methods primarily focus on calculating facies distribution probabilities, with high requirements for geological stationarity. With the gradual improvement of deep learning technology, Conditional Generative Adversarial Networks (CGANs) are being gradually introduced into sedimentary facies modeling and have achieved good results. This study explores a Generative Adversarial Network (GAN) with a deep generator and multi-scale discriminator, successfully applied to modeling river facies sand bodies. Using an unmanned aerial vehicle, a digital outcrop of 1 km^2 of the Qingshuihe Formation oil sand outcrop area in the northwestern of the Junggar Basin was obtained as the modeling database. The reliability of the new CGANs modeling method was validated, with results showing a concordance of hard data of up to 95.31%. In addition, we collect and construct a dataset using Google Earth, which contains abundant and realistic fluvial patterns to reflect adequate prior geological knowledge. Extensive experiments have been carried out on this dataset, the results show that the generated images can reflect the fluvial style using little hard data, and the matching rate of the hard data is 94.78%. This outperforms traditional statistical and multi-point geostatistical modeling techniques, providing a solid basis for deep oil and gas exploration. In the future, Conditional Generative Adversarial Networks (CGANs) may exhibit even more outstanding performance in the field of geological modeling due to their efficiency and high-precision modeling results.

Application of BPNN neural network algorithm driven by data and model in bitumen content prediction of Silurian Kepingage Formation reservoir in Tazhong area

Yanjun Lu[1]*, 1809068709@qq.com (1809068709@qq.com)
Yiming Yan[2], 13792483582
Liqiang Zhang[3], 13105439684

Abstract

Abstract: The Silurian Kepingtage Formation on the Tazhong Uplift is an important oil and gas enrichment layer in the Tarim Basin with great exploration potential, and the accurate prediction of bitumen content in reservoir is of great significance to the study of reservoir heterogeneity. Data-driven neural network algorithms usually use rock logging response characteristics and data to predict reservoir bitumen content. This method has the disadvantages of poor interpretability, unclear geological meaning and difficult application in less coring well area. In this study, a mapping relationship is established by reconstructing a high-precision gamma logging data set which can reflect lithologic changes and a deep-shallow resistivity difference data set that can reflect bitumen differences. This mapping relationship can combine bitumen content, logging data and geological significance and propose a model-data dual-driven neural network model. The prediction results show that: The model-data dual-driven neural network model has high prediction accuracy. The correlation coefficient between the measured bitumen content and the predicted bitumen is 0.9066, and the maximum, minimum and average content errors are 0.016%, 3.889% and 0.956%, respectively. The maximum error of the traditional data-driven model can reach 7.63%. The model-data dual-driven neural network model proposed in this paper is of great significance for explaining the neural network ' black box ' decision-making and prediction process.

Bowen Sun[3], Research Institute of Exploration & Development, PetroChina Changqing Oilfield
Ruiqiang Chi[4], Research Institute of Exploration & Development, PetroChina Changqing Oilfield
Yanmei Wang[5], Research Institute of Exploration & Development, PetroChina Changqing Oilfield

Abstract

The shale oil in Longdong area of Ordos basin is typically featured with complex mineral composition and developed with nano-scale fractures and pores, bringing heavy heterogeneity and anisotropy of reservoir properties. It is ultra-difficult to characterize the lithofacies and petrophysical parameters based on conventional geophysical well logging data due to the low vertical resolution. We developed a novel method to predict the lithofacies with the aid of the fusion of multi-scale logging data. Firstly, the lithofacies are determined by the mineralogical and geochemical measurement, as well as the core description. We then obtain the quantitative feature parameter from the borehole electrical imaging data and establish their relations with the lithofacies through core calibration. Secondly, the beehive deep neural network dual-cycle fusion algorithm (BC-DNN) is implemented to establish the accurate mapping between the high-resolution feature parameter curves and the conventional resistivity curves, to improve the vertical resolution of conventional resistivity data. Lastly, we use the self-organizing feature maps (SOM) clustering method with optimized constraints to intelligently divide and identify lithofacies from the logging response and high-resolution characteristic curves, which establishes the accurate relations between the clustering results and lithofacies description based on the core calibration logging, to realize fine logging identification of different lithofacies. Researches show that we use the optimal intelligent algorithm to solve the impact of low vertical resolution of conventional logging data on the fine identification of shale logging effectively, which lays a foundation for the study of lacustrine shale oil reservoir classification and sweet spot identification.

Research on Knowledge Sharing of WRF Meteorological Simulation Based on Knowledge Graph Structure

Chunxiao ZHANG[1]*, China University of Geosciences, Beijing (zcx@cugb.edu.cn)
Yazhou QI[2], China University of Geosciences, Beijing

Abstract

As a crucial method for simulating and understanding geographical environments, model-based geographic simulation is vital for extracting geographical knowledge and unveiling geographical laws. The meteorological process, an essential component of the geographic environment, significantly influences various aspects of geographic simulation, thereby impacting the comprehensive simulation and resolution of complex geographic problems. However, the complexity of meteorological models often demands a high level of expertise, involving intricate simulation knowledge and various components such as input data and simulation scheme settings. Consequently, efficiently managing and sharing meteorological simulation knowledge has become a key step in enhancing the scientific rigor and accuracy of simulations.

In this study, we utilize case-based reasoning and knowledge graph techniques to unify heterogeneous knowledge of meteorological simulation. Additionally, we propose a retrieval method that considers both semantic and graph structure similarity to improve the sharing capability of meteorological simulation knowledge.

Firstly, we extract meteorological simulation knowledge from Chinese meteorological simulation literature using the Bidirectional Long Short-Term Memory with Conditional Random Fields model (BiLSTM-CRF). This extracted knowledge is then used to construct a meteorological simulation knowledge base within a knowledge graph, with simulation cases serving as the carriers of knowledge. For instance, in this study, we have constructed and stored 795 cases as nodes and edges in the knowledge graph.

Secondly, we develop a similarity assessment model for meteorological simulation cases that factors in both semantic and graph structure aspects. Specifically, the model utilizes the BERT semantic model, trained on a meteorological simulation corpus, to mine the semantic features of meteorological simulation knowledge cases. Additionally, it extracts structural features of cases stored in the graph and assigns weights using the Analytic Hierarchy Process (AHP) to accurately measure the similarity of meteorological simulation knowledge cases.

Thirdly, we create a visual prototype system for sharing meteorological simulation knowledge. This system can directly recommend parameter schemes for meteorological simulations based on user requirements and provide reference knowledge for geographic system simulation personnel

involved in meteorological processes. To validate the stability of the retrieval system, we selected 300 input cases, and the retrieval results provided the top 5 similar cases for each input. In this scenario, the system achieved an accuracy rate of 91.3%, significantly improving the efficiency of meteorological simulation knowledge sharing and reuse.

Diagenetic facies characteristics and quantitative prediction via wireline logs based on machine learning

Liqiang ZHANG[1]*, China University of Petroleum (zhanglq@upc.edu.cn)
Yiming Yan[2], China University of Petroleum

Abstract

Tight sandstone has low porosity and permeability, a complex pore structure,and strong heterogeneity due to strong diagenetic modifications. Limited intervals of Lianggaoshan Formation in the Fuling area are cored due to high costs, thus, a model for predicting diagenetic facies based on logging curves was established based on few core, thin section, X-ray diffraction (XRD), scanning electron microscopy (SEM), cathodoluminescence, routine core analysis, and mercury injection capillary pressure tests. The results show that tight sandstone in the Lianggaoshan Formation has primary and secondary intergranular pores, secondary intragranular pores, and intergranular micropores in the clay minerals. The compaction experienced by sandstone is medium to strong, and the main diagenetic minerals are carbonates (calcite, dolomite, and ferric dolomite) and clay minerals (chlorite, illite, and mixed illite/ montmorillonite). Four types of diagenetic facies are recognized: carbonate cemented (CCF), tightly compacted (TCF), chlorite coating and clay mineral filling (CCCMFF), and dissolution facies (DF). Primary pores develop in the CCCMFF, and secondary pores develop in the DF; The porosities and permeabilities of CCCMFF and DF are better than that of CCF and TCF. The diagenetic facies were converted to logging data, and a diagenetic facies prediction model using four machine learning methods was established. The prediction results show that the random forest model has the highest prediction accuracy of 97.5%, followed by back propagation neural networks (BPNN), decision trees, and K-Nearest Neighbor (KNN). In addition, the random forest model had the smallest accuracy difference between the different diagenetic facies (2.86%). Compared with the other three machine learning models, the random forest model can balance unbalanced sample data and improve the prediction accuracy for the tight sandstone of the Lianggaoshan Formation in the Fuling area, which has a wide application range. It is worth noting that the BPNN may be more advantageous in diagenetic facies prediction when there are more sample data and diagenetic facies types.

Machine learning-based approach for intermediate volcanic rock tectonic setting determination.

FengRui JIN[1]*, China University of Petroleum (East China) (1677167835@qq.com)
ShiKuo Lu[2], China University of Petroleum (East China)

Abstract

Intermediate volcanic rocks have significant geodynamic and rock formation implications, and accurately identifying the tectonic setting of these rocks is crucial for understanding global tectonic-geodynamics. Due to the diversity of intermediate volcanic rocks in elemental characteristics, genesis environments, and geographic distributions, traditional low-dimensional geochemical methods have limitations in identifying their tectonic setting. With the exponential growth of geoscience data and the advancement of artificial intelligence, machine learning provides a novel approach to address this challenge. Therefore, this study combines machine learning with geological big data to construct a high-precision model for discriminating the tectonic settings of intermediate volcanic rocks and to provide visual representations. A total of 3113 samples' major and trace element geochemical data from intermediate volcanic rocks were collected globally, selecting 48 common whole-rock geochemical characteristics. Unsupervised learning methods such as principal component analysis and t-distributed stochastic neighbor embedding are employed for high-dimensional data reduction. Various machine learning techniques including random forest, support vector machine, artificial neural network, and K-nearest neighbor are utilized for training. As a result, a random forest-based discriminator for intermediate volcanic rocks' tectonic settings is developed with an accuracy of 89.72%. Additionally, a relatively effective identification diagram is proposed to establish a foundation for identifying five tectonic settings: back-arc basin, continental rift, convergent margin, intraplate craton, and volcanic arc. This work extends the application of machine learning in intermediate volcanic rock tectonic setting studies, offering new insights for investigating tectonic-geodynamic processes.

Assessment of the effectiveness of a convolutional autoencoder for digital image-based automated core logging

Jaesung PARK[1]*, Kyungpook National University (pouy8286@knu.ac.kr)
Swan SO[2], Kyungpook National University
Ji-Na JEONG[3], Kyungpook National University

Abstract

Widely applicable convolutional neural network (CNN)-based lithology classification models are limited to interpret soundness of a trained model and require high computational cost. This study proposes a convolutional autoencoder (CAE)-based classification model to improve the efficiency of rock-core-logging analysis based on digital rock-core images (CAE model I) and suggest a more understandable classification model by extracting the lithological feature information from the network structure of the model. Moreover, input digital-image data transformation using the Canny edge-detection algorithm was implemented (CAE model II). The applicability of the developed models is validated by comparing them with a CNN model and the model proposed by the previous study (RGBE model). While implementing the proposed model, digital images of 85-m-long cores were used, which were acquired from the Satyr 5 well in the Northern Carnarvon Basin, Western Australia. It was found that CAE models I and II showed classification accuracy comparable to the CNN model (CAE model I: 96.4%, CAE model II: 94.9%, CNN model: 97.5%, and RGBE model: 94.4%). The extracted features of the trained CAE models are effective in interpreting the trained network structure. In addition, in terms of computational efficiency and training time, the CAE-based models are significantly better than the CNN model (CAE model I: 7 min 21 s, CAE model II: 7 min 34 s, CNN model: 12 min 6 s, and RGBE model: 24 min 35 s). Overall, the results demonstrate the feasibility of the proposed CAE-based models for automated rock-core logging.

Method of Segmenting the Origin of Soil samples in South Korea Using Deep Learning-based Feature Extraction Technology

SUBI LEE[1]*, Kyungpook National University (tnql0502@naver.com)
JINA JEONG[2], Kyungpook National University

Abstract

Isotope data of environmental samples, such as soil, groundwater, or rock, contain information about specific regional environmental characteristics, making it possible to guess the samples' origin. For this reason, isotopic data is widely applied to various research areas, including origin tracking, source tracing of environmental pollution or climate change research, etc. In particular, the ratio of 87Sr, which is naturally abundant in strontium isotope data, varies depending on the type of rocks and geological eras. Therefore, the geographical and geological origin can be inferred by comparing the strontium isotope ratio in the samples with baseline databases of strontium isotope ratios of each region. As a preliminary study to develop a model that can infer the origin of the environmental samples from the isotope data, this study applied a hierarchical clustering method to cluster data based on the geological properties of each geographical and geological origin, including information on rock type, tectonic provinces, major geochemical elements of rocks, and strontium isotopes. Dimensionality reduction techniques, such as principal component analysis (PCA) and autoencoder (AE), a deep learning technique, were applied to identify the complexity of the relationship between the origin and various geological information. The following three cases were considered for clustering: 1) Original data dimensionality, 2) Dimensionality reduction using PCA, 3) Dimensionality reduction using AE. The clustering results for each case were compared using silhouette scores. The actual database (soil samples) acquired from South Korea nationwide was applied to validate the proposed method in this study. Based on the low-dimensional characteristics extracted from AE, which yielded the best results, a total of 7 label were identified through hierarchical clustering, resulting in the creation of a geological origin label map.

Integration of Dense Well Network Architecture Unit Geological Knowledge Base into Generative Adversarial Networks for Modeling Reservoir Architecture in Fan Delta

Chao Jiang[1]*, China University Of Petroleum (East china) (b21010055@s.upc.edu.cn)
chengyan lin[2], China University Of Petroleum (East china)

Abstract

Fan delta reservoir architecture modeling is one of the crucial outcomes of finely describing reservoirs and is essential for numerical simulations and enhancing remaining oil recovery. Multiple-point geostatistical simulation (MPS) is one of the methods used for modeling reservoir architecture in fan delta. MPS typically extracts statistical features from training images (TI) to simulate patterns. However, MPS usually only extracts some stationary features from TIs, struggles to extract non-stationary features effectively, and cannot integrate some known subsurface geological information (such as sand body development scale, sand body stacking patterns, etc.). Generative Adversarial Networks (GANs) are advanced generative deep learning methods with powerful data integration and geological feature extraction capabilities, which have achieved certain results in the field of reservoir geological modeling. Additionally, Conditional GANs (CGANs) address the issue of generative models not being constrained by hard data. Based on CGAN theory, the precision of reservoir architecture modeling in fan deltas can be greatly improved.

This study utilizes conditional generative adversarial networks to simulate fan deltas, improving the structure of CGANs. A conditional loss function is defined based on the inconsistency between input sand body scale, sand body stacking pattern, and the characteristics exhibited by the output facies model, forcing the generator to learn not only geological patterns but also the consistency between input sand body scale information, sand body stacking pattern, and the output facies. A CGAN integrated with a dense well network architecture unit geological knowledge base is proposed for stochastic simulation of reservoir architecture in fan delta. Currently, based on two sedimentary microfacies, distributary channels, and mouth bar, this method can effectively integrate the generation of corresponding conditionally constrained reservoir architecture models for fan deltas and exhibit good architectural structural characteristics. After training, the quality of the generated facies model and the adjustability of the generator are evaluated.

Identification method of low-order faults in ultra-deep carbonate rocks based on convolution neural network

Hao LI[1]*, China University of Petroleum (Beijing) (lihaolalalalala@outlook.com)
Lianbo Zeng[2], China University of Petroleum (Beijing)

Abstract

Strike-slip fault system plays an important role in controlling the development of ultra-deep carbonate dissolved fracture-cave reservoirs. Its structural style, genetic mechanism and distribution are of great significance for reservoir evaluation. This study focuses on Ordovician carbonate rocks with an average buried depth of more than 7000m in Shuntuogole uplift,Tarim Basin. The research based on conventional fault sensitive seismic attributes in the study area has described the main strike-slip faults quite clearly, but the identification of low-order faults between main faults is poor.The "beaded" reservoir is widely developed in the area between the main faults, which shows a series of ellipsoidal strong reflections in the seismic plane and sections. The fault response of coherent attributes is a circle around the beads, which does not have the structural characteristics of typical strike-slip faults, so it is difficult to analyze its genesis and distribution. In this study, through the observation of a large number of outcrops and cores, a geological model of faults passing through the middle of beads is established.Then more than 400 artificial labels of faults are established based on this geological model through forward seismic modeling. These label data are used to train the 3D convolution neural network fault recognition model based on U-net structure.The model is used to identify the faults in the seismic data. The effect of this method is remarkable.The faults are shown to pass through beads rather than surround it in plane and sections, and has a certain strike and extension length. After analysis, the low-order faults across the main faults can be divided into the R fractures, the T fractures and the P fractures derived from the main faults under the Riedel shear mode according to the strike, and those between the main faults are commonly conjugated faults under the pure shear mode. This study provides a better method for restoring the shape of low-order faults in ultra-deep carbonate reservoirs and provides a research basis for the next step of oil and gas exploration in Shuntuogole uplift.

Improvement of Deep Learning-based Inverse Model with Reconstruction of Dynamic Data

Hayoung KIM[1]*, Kongju National University (nicehy1023@gmail.com)
Sungil Kim[2], Petroleum Energy Research Center, Korea Institute of Geoscience and Mineral Resources, Daejeon, Republic of Korea
Jonggeun Choe[3], Department of Energy Resources Engineering, Seoul National University, Seoul, Republic of Korea
Kyungbook Lee[4], Department of Geoenvironmental Sciences, Kongju National University, Gongju-si, Chungnam, Republic of Korea

Abstract

Quantifying geological uncertainty is essential not only for petroleum resource development but also for the stable utilization of subsurface, such as for carbon sequestration. For these purposes, geological characterization is a prerequisite by using geostatistics with static data and inverse modeling with dynamic data. In case of the inverse modeling, it can modify geological properties, which are generated by geostatistics, but data assimilation has a limitation in deriving a reasonable geological model from a geological perspective because it relies on a mathematical approach.

In this study, we aim to develop a deep learning-based inverse model that simultaneously enhances the efficiency and reliability of conventional inverse methods such as ensemble-based method. In detail, the convolutional neural network (CNN) algorithm is designed to predict a geological model in the output layer from the given oil production rates in the input layer. For supervised learning, a total of 800 data pairs, which consist of 2-dimensional channelized model with 25x25 grids and its 720 oil production rates with 90 observation points at 20-day intervals for 8 production wells, were prepared using ECLIPSE100. Notably, the number of neurons in the output layer is set as 200 using feature extraction from 625 grids through a convolutional autoencoder. From the 800 data pairs, 640 and 160 data pairs were used for train and test data, respectively. When the trained CNN model was applied to the test data, it had a limitation in reliably maintaining the channel connectivity of geological models.

To address this limitation, we reconstructed the 720x1 matrix input data into an 8x90 matrix to segregate the production data by wells, utilizing oil production rates from each well at each time point as 1-dimensional convolution channels. It allowed the CNN-based inverse model to extract features of the overall production trends of each well during a training process. The proposed reconstruction of the input data increased the average structural similarity index measure (SSIM) between the true and generated models on the test data from 0.359 to 0.419. Then, the performance of the trained CNN model was compared with that of ensemble smoother (ES) for the reference model, which was set aside as unseen data. The SSIMs for the proposed method and ES were 0.566 (single geological model) and 0.138 (average of 800 geological models), respectively. Therefore, the CNN-based inverse model with the reconstruction of dynamic data can provide a more reliable geological model than ES's results and reduce the time cost of the inverse process by approximately 52% compared to ES's time cost.

Fault detection based on 3D seismic images using an integration of GCN and U-Net

Guoqing LU[1]*, China University of Petroleum, Beijing (zsdhdlgq@126.com)
Lianbo Zeng[2], China University of Petroleum, Beijing

Abstract

Semantic segmentation is a computer vision task applicable to fault detection research using 3D seismic images. The FaultSeg3D method employs a simplified U-Net network to predict fault probabilities. However, due to the convolutional kernels' limited receptive field, the features extracted only represent the faults' local appearance. Merely increasing the model's depth does not optimally broaden the receptive field to capture the macroscopic distribution of faults. Furthermore, in the fault network, which includes faults of varying scales and non-fixed extension directions, the use of square convolutional kernels and regular image grids may affect the detection results for the extension direction and continuity of small-scale faults.

To address the issues mentioned above, we propose a fault detection method named GNU-Net, which integrates U-Net with graph neural networks (GNN) as illustrated in Figure 1. This method comprises two modules: fault segmentation and fault continuity analysis. The fault segmentation module performs semantic segmentation of faults based on 3D seismic images, while the fault continuity analysis module captures the topology structure of the fault graph and analyzes their continuity. The innovations of this method include: (1) A novel method for constructing fault graphs through vertex extraction and edge generation using grid-based 3D fault labels. This method establishes three-dimensional coordinates for the 3D fault labels and grids them. Positions where faults intersect each grid are designated as vertices, and edges between these vertices are generated in the velocity field formed after fault dilation, together constituting the fault graph structure. (2) An enhancement to the FaultSeg3D method, we added a fault continuity analysis module based on Graph Convolutional Networks (GCN). This module extracts hidden features from the U-Net network during the upsampling process based on vertex coordinates, obtaining the feature matrix of the fault graph structure. It then performs information fusion between the fault graph structure and the feature matrix to analyze fault continuity. (3) The modules for fault segmentation and fault continuity analysis are jointly trained and optimized, with a redefined joint loss model that includes both segmentation loss and continuity loss. (4) We have proposed data augmentation for fault topology, which transforms the coordinates of the vertex feature vector in the topology graph through a self-defined rotation matrix.

This method has been applied to the dataset described in the FaultSeg3D paper, achieving an accuracy of 97.39% on the test data and a Dice Similarity Coefficient of 83.37%. Compared to the FaultSeg3D results, these figures represent improvements of 3.96% in accuracy and 15.07% in DSC, respectively. Additionally, this method opens up a new avenue for research and a novel

approach for the intelligent detection of 3D seismic faults.

Seismic attribute optimization and fracture prediction model establishment based on artificial intelligence-A case study of dense sandstone reservoirs in the Northern Ordos Basin

Ziyi YANG[1]*, China university of Petroleum(Beijing) (zoeyangy122@163.com)
Lianbo Zeng[2], China University of Petroleum(Beijing)

Abstract

The development of fractures in tight sandstone reservoirs can greatly affect the development of oil and gas reservoirs. In order to improve the efficiency of oil and gas exploration and development. This study will use artificial intelligence methods to optimize seismic attributes, accurately characterize fracture characteristics in the study area, and establish a model of inter-well fracture development strength. In this study, three-dimensional seismic, core, thin section and borehole imaging logging data were used to calibrate conventional logging through core and imaging logging, and labelled sample data for fracture identification model training were established. Based on the fracture indication parameter method, the relative logging response changes of fractures are extracted by fractal, and the absolute logging response characteristics of fractures are extracted by fracture comprehensive parameters. Based on a variety of machine learning methods, the fracture indication parameter method is improved, and the recognition accuracy is improved from small sample classification, multi-scale nonlinear feature extraction, and prediction model variance reduction, so as to integrate the integrated fracture recognition model and realize the intelligent identification of conventional logging fractures. On the one hand, the seismic attributes are optimized by the correlation coefficient heat map method, and the gradient boosting tree ensemble learning algorithm is used to fuse multiple seismic attributes to gradually improve the fracture prediction accuracy and predict the cross-well development strength of fault-related and unrelated fractures. On the other hand, the maximum and minimum principal stresses are generated by finite element numerical simulation, and the rock fracture index in the study area is established according to the stress and rock fracture criteria. Finally, the collaborative sequential Gaussian simulation is used to interpret the single well fracture as hard data, and the numerical simulation results of reservoir geomechanics and seismic prediction results are used as soft data. The weights of the two soft data are automatically determined by matching degree, and finally merged into a more reliable inter-well fracture development strength model. The results show that the fracture intelligent recognition model based on integrated fracture indication parameters, random forest and SVM is used to identify the fractures of 140 single wells in the study area, and the recognition accuracy is more than 85 %. Coherence, curvature, maximum likelihood and ant body seismic attributes are optimized by using the correlation coefficient heat map method. At the same time, combined with the rock fracture index, the model of fracture development intensity between wells is established. The vertical and horizontal distribution of fractures is obtained by the analysis model. The fracture development area in the study area is mostly striped, and the fracture development intensity near the fault is

mostly high.

Carbonate Lithofacies Logging Identification Based on Machine Learning: A Case Study of Longwangmiao Formation in Moxi Area, Sichuan Basin

Mingqiang LI[1]*, China University of Petroleum (Beijing) (1453321427@qq.com)
Dali Yue[2], 15264288905
Wei Li[3], 15265489406
Wurong Wang[4], 18264851267

Abstract

Carbonate reservoir contains abundant oil and gas resources, which is one of the most important reservoir types in the world. Carbonate lithofacies identification and single well prediction are the basis of oil and gas exploration and development. However, under the influence of different sedimentary environments and diagenesis, carbonate rocks have different mineral compositions and fabric forms, which make their petrographic and chemical properties complicated. Moreover, drilling core and imaging logging data are costly but with few data. These factors increase the difficulty of lithofacies identification and prediction, and restrict the expansion of exploration scale and efficient development. Therefore, this paper proposes to integrate multi-scale geological-geophysical information for machine learning to identify carbonate rock facies. Firstly, according to the lithofacies classification scheme, the lithofacies are divided by thin section data, and the fabric characteristics of different lithofacies are defined. Secondly, the core data is used to carry out rock electrical calibration for the imaging logging to complete the petrographic interpretation of a single well, and then the logging parameters corresponding to different rock facies are extracted to establish the logging parameter set of different petrographic training samples. Then, different machine learning algorithms (BPNN, RNN, LSTM) are used to distinguish the lithofacies of core Wells. Finally, parameters and algorithms are selected to identify single well lithofacies of uncored well. Taking Longwangmiao Formation in MX area of Sichuan Basin as an example, four lithofacies types, including granular carbonate, granular carbonate, granular mud carbonate and micrite carbonate, are identified by the above method. By applying the machine learning model in the coring well, the coincidence between the three machine learning algorithms and the coring discrimination is 70.3% (BPNN), 86.6% (RNN) and 91.7% (LSTM), respectively. The analysis of the reasons shows that the logging data has obvious temporal or spatial sequence characteristics, and the vertical distribution of rock facies also has such characteristics. RNN and LSTM, as powerful series models, are better than BPNN in predicting lithofacies. In addition, RNN is prone to gradient explosion and disappearance in the training stage. Considering that log data are usually sequence data with smooth changes on the same lithology, there is a natural intrinsic matching between log data and LSTM. This method integrates the advantages of conventional logging, electro-imaging logging and machine learning algorithm, and can realize petrographic logging identification with high efficiency and high precision, effectively supporting the fine study of sedimentary microfacies of Longwangmiao Formation in MX area, and promoting the exploration and development of this area.

Wu Zhenzhen[7], RIPED of CNPC

Abstract

Since 1993, China's oil companies have been participating in global oil and gas exploration and development. Over the past 30 years, massive documents and data on global petroliferous basins have been accumulated through the purchase of international commercial oil and gas databases, independent acquisition of operational area data, and scientific research. Based on these massive data of global petroliferous basins, we developed a "Knowledge Base for Global Petroliferous Basins", which includes reports from 1 global-level, 8 regional-level, and 425 basin-level conventional and unconventional petroliferous basins, about 10 GB totally. This knowledge base includes knowledge and data of geological characteristics, oil and gas enrichment patterns, and oil and gas resource potential, etc. In order to fully and deeply mining the knowledge base and facilitate user application, an "Intelligent Question Answering System for Global Petroliferous Basins" was developed. The key involved technologies include document analysis and information extraction technology, graph database and graph search technology, question answering based on knowledge graph technology (specifically including entity word mapping, relationship semantic matching, query to obtain candidate answers, answer sorting, retrieval of candidate documents, deep semantic matching, etc.). The intelligent question answering system solves the different needs of users and provides researchers with an intuitive and fast knowledge mining platform, which has broad application prospects. Moreover, the establishment of the global knowledge graph of petroliferous basins can empower large language model (LLM) for global oil and gas industry in the future, including detecting the illusion of LLM, knowledge editing, and knowledge injection into black box of the large language model.

Artificial Intelligence and Machine Learning for the Automated Classification of the Seabed

Umberto DI LAUDO[1]*, National Institute of Oceanography and Applied Geophysics – OGS, Trieste, Italy (udilaudo@ogs.it)
Luca Manzoni[2], University of Trieste, Italy
Silvia Ceramicola[3], National Institute of Oceanography and Applied Geophysics – OGS, Trieste, Italy

Abstract

The interpretation of seabed features is a very time-consuming and costly exercise for geologists. Artificial intelligence (AI) and Machine Learning (ML) techniques can help scientists to automate this process, making it faster. The goal of the project is to build a model that automatically classifies the seabed, recognizing the various morphological elements present (i.e., submarine canyons, escarpments, mass movements etc.) as a support tool for geologists. For this purpose, the model needs a large amount of morphological data in the shallow coastal areas, that are provided by the Italian MaGIC project (Marine Geohazards along the Italian Coasts). The aim is to build a ML model receiving as input a 2D field in which for each coordinate the depth of the seabed, the slope angle, and the profile curvature are provided. As output another 2D field is provided in which each coordinate is labelled with the morphological features that are present. This representation allows the use of techniques of computer vision field and, in particular, of image segmentation. To build such a model we employ as training data the seabed data that have been interpreted in the framework of the Magic project by geologists in order to create the map of the seafloor's elements (target map). Hence human interpretations are used as ground truth to train the model so that it can automatically generate target maps from new input data. Our model consists in a convolutional neural network, specifically a U-Net, that performs a segmentation of the input data. As stated before it takes the 2D field with the three input channels as an input and directly returns the target map, i.e. the geological interpretation and classification of the seafloor's elements. Classifying the seabed using artificial intelligence (AI) involves utilizing machine learning algorithms to analyze underwater data and identify different types of seabed features. The overall aim of using artificial intelligence to classify the seabed is to automate and enhance the process of understanding and mapping underwater environments. The success of the AI model depends on the quality and diversity of the training data. Additionally, collaboration with domain experts, such as marine geologists, can provide valuable insights for accurate seabed classification.

Pyeong-Koo Lee[6], Korea institute of Geoscience and mineral resources
Seong-Cheon Shin[7], Korea institute of Geoscience and mineral resources

Abstract

Demand is surging for lithium, classified as critical minerals essential for the advancement to clean energy technology. In other words, securing lithium and enhancing lithium exploration technologies are emerging as vital issues. In the context of this study, the objective is to develop a predictive model for pegmatitic lithium anomalies in stream sediments as a part of the advancement in lithium exploration technologies. To this end, 1) geochemical data of stream sediment samples (n=23,094) collected throughout the inland of South Korea and geological information (e.g., lithology, fault, dike, pegmatite, etc.) were utilized, and 2) machine learning approaches (e.g., Naïve Bayes, J48, Random Forest, and Stacking) were applied to establish the prediction models. The anomalous values of lithium in the collected stream sediments were calculated by applying geochemical threshold values (e.g., Mean+2Standard Deviation, Median+2Median Absolute Deviation, the 90th, 95th, and 98th percentiles, Tukey inner upper fence, the break in the Cumulative probability distribution diagram). The results of this study showed that the geochemical data of stream sediments contain the geological information on pegmatite, and in the comparative analysis of predictive models developed utilizing the Naïve Bayes, J48, Random Forest, and Stacking techniques for the identification of lithium anomalies, the stacking approach demonstrated superior accuracy. This study confirms the potential of stacking model as an effective method for tracing pegmatite-derived lithium anomalies based on stream sediment geochemical data.

Physics-Guided Unsupervised Deep Learning Approach for the Inversion of Receiver Functions

BIJAYANANDA DALAI[1]*, CSIR-National Geophysical Research Institute, Uppal Road, Hyderabad-500007, India (bijayanandadalai@gmail.com)
PRAKASH KUMAR[2], CSIR-National Geophysical Research Institute, Uppal Road, Hyderabad-500007, India
MRINAL K. SEN[3], The University of Texas at Austin, Austin, TX-78758-4445, USA

Abstract

The converted wave technique, known as Receiver Function (RF), is commonly utilized to investigate the complexities of the Earth's crust and mantle. When analyzing receiver functions, deterministic physical methods such as inversions are often used to improve the accuracy of imaging the subsurface geological structures. However, the process can be complicated by the presence of anisotropic and dipping geological formations, which can sometimes limit the effectiveness of inversions. To address these challenges, we present a Physics-Guided unsupervised deep learning approach for inverting the Receiver function data. This method employs unsupervised deep learning enhanced with implicit neural representations to enable the estimation of key Earth model parameters such as thickness (H), S-wave velocity (Vs), anisotropy, trend, plunge, strike and dip without requiring any labeled data.The estimated parameters are then applied in a forward modeling process to generate the receiver functions, with the model being iteratively refined based on the differences between these simulated and the observed receiver functions. Application of this approach to both synthetic and real field data from the Indian shield has demonstrated its effectiveness in inversion task for anisotropic and dipping geological settings. By focusing on the analysis of subsurface structures, we believe this method holds significant promise in expanding the capabilities of subsurface exploration.

Research on data integration system development for excavation construction equipment fleet management

Skhan Park[1]*, LOTTE E&C (parkskhan@lotte.net)
Bong Chan Kim[2], LOTTE E&C

Abstract

A variety of large-scale data is being generated by geology, construction equipment, and process at excavation construction sites, but data connection technology for efficient use is lacking.
Future construction sites are expected to develop so that manufacturers establish equipment operation plans in connection with construction information (BIM) and provide fleet management services through the convergence of manufacturing and IT services, such as automated operation and failure prediction and maintenance. Telematics technology for domestic smart construction equipment is expanding from the existing one-way telematics system for each construction equipment manufacturer to a two-way connected system. However, due to the narrow domestic market situation and weak base domestic construction sites, domestic smart construction equipment telematics technology is only in the introduction stage.
Currently, products with machine guidance and control applications and remote control services are being provided, focusing on excavators. However, most of the detection sensors for smart construction equipment used are imported, and domestic investment in detection sensors to develop integrated control and management software for general construction equipment is still insufficient. This study seeks to develop an IoT device that can collect data from not only smart equipment but also existing non-automated excavation equipment, regardless of manufacturer, to generate basic data necessary for construction site operations.
A data integration system with a management system that can utilize basic data collected from equipment is needed. This study aims to promote the establishment of a smart construction ecosystem by developing an open platform such as providing API so that data can be easily utilized in various places, such as developing IoT devices that can collect data regardless of the manufacturer.

AI in solving geological problems using the example of uranium deposits in Kazakhstan

Abish SHARAPATOV[1]*, Department of Geophysics and Seismology, Satbayev University (a.sharapatov@satbayev.university)
Alisher Saduov[2], PhD student of Department of Geophysics and Seismology, Satbayev University
Nazerke Assirbek[3], Department of Geophysics and Seismology, Satbayev University
Nurlan Samanbetov[4], Geophysicist LTD "Geoken", Almaty, Kazakhstan

Abstract

Aim:
This research is primarily related to the synthesis of machine learning and geostatistical research methods to optimize the scope of work in predicting lithology and delineating uranium deposits of the formation-infiltration hydrogenic type.

Methods:
The study is based on the hypothesis of combining geostatistics and artificial intelligence can make a significant contribution to geological predictive mapping of ore bodies, thereby optimizing uranium resource exploration and mining processes.
The methodological framework of the study in pre-processing mode to overcome data integrity issues mainly results in the lack of results in the studied geological attributes. A higher reclassification of the lithology data was carried out, increasing the wide variety of lithology classes in seven manageable categories. This reorganization was critical to improving navigation through the dataset in the next step of machine learning. The RandomForestClassifier algorithm was used to build predictive models using a set of geophysical measurements obtained from well logging data. Additionally, cubic spline interpolation techniques were integrated to measure the spatial distribution of lithological classes, resulting in continuous stratigraphic visualization.

Results:
RandomForestClassifier has demonstrated impressive accuracy, especially in distinguishing between non-uranium and uranium-bearing forms, which are critical in dozens of uranium explorations. The models have demonstrated exceptional accuracy and completeness, especially for pay zones, reaching 99% accuracy. The F1 scores further highlight the balanced predictive performance, reinforcing the usefulness of the models for reliably producing statistically significant lithologies.
Conclusion:
The results of the study combine the effectiveness of machine learning with the failure of geological approaches, the essence of significant optimization of the scope of work performed in geological mapping and mineral resource accounting. The models have confirmed the ability to predict high-threshold lithologic classes and productive horizons, signifying Western advances in resources and exploration planning; in similar well logging data in similar geological conditions.

The effectiveness of using AI in geosciences depends on the quality and completeness of the input data; with the complexity of geological processes, it requires the involvement of expert assessments.

A new approach of mineral targeting in a concealed shear zone complex by Knowledge-Driven multi-thematic Mineral Prospectivity Mapping

PRASHANTH KUMAR K[1]*, GEOLOGICAL SURVEY OF INDIA
(prashanthkumar.k@gsi.gov.in)
CHHAYA MINZ[2], GEOLOGICAL SURVEY OF INDIA
PANKAJ JAISWAL[3], GEOLOGICAL SURVEY OF INDIA
PAWAN BARAIUD[4], GEOLOGICAL SURVEY OF INDIA
ADITI DAS[5], GEOLOGICAL SURVEY OF INDIA

Abstract

Over the last two decades, several successful case studies of mineral prospectivity mapping were carried out worldwide using multi-thematic data integration techniques. The present study envisages an assessment of the mineralization potential of North Singhbhum Mobile Belt (NSMB) using a GIS-based multi-thematic data integration method to generate mineral prospectivity maps with respect to base metal mineralization. NSMB is a 200km long, Proterozoic fold belt of eastern India juxtaposed between the Singhbhum Craton (SC) in the south and Chhotanagpur Granite Gneiss Complex (CGGC) in the north. The curvilinear Singhbhum Shear Zone (SSZ), marks the boundary between SC and NSMB and is developed along the southern fringe of the NSMB. NSMB in general, and SSZ in particular is a known host for multi-mineral deposits of structurally controlled and hydrothermal origin. The central and western parts of the SSZ is less explored as the exposures are limited and the terrain is largely soil-covered as compared to the eastern part. A systematic approach to target the possible extension of mineralisation by integrating geological data set from the Geological Survey of India's 1:50,000 scale map series (lithology, stratigraphy, structure), geochemical data from National Geochemical Mapping (NGCM) Program and gravity and magnetic data from National Geophysical Mapping (NGPM) Program has been attempted in this work. Spatial evidence thematic maps and variables are ranked for base metal mineralisation based on theoretical knowledge and information gathered from earlier exploration works. The ranked thematic variables were empirically evaluated for their spatial association with the known mineral occurrences. These ranked predictor maps were converted into rating maps using the Analytic Hierarchy Process (AHP) and a mineral prospectivity map was obtained for base metal mineralisation using the weighted multi-class index overlay method. The output shows an accuracy of 66% with a False Positive Rate (FPR) of 33% and sensitivity of 66%. The mineral prospectivity map of base metal reveals a regional and contiguous zone of high prospectivity along SSZ. The obtained mineral prospect zones were validated in the field through surface indicators as well as through chemical analysis of different sample media. The sub-surface continuity of anomalous values obtained from the surface sampling was further tested by selective drilling which intersected significant sulphide-rich zones. One borehole intersected a 1.5m zone of Cu with an average grade of 0.48% and another borehole intersected a 3.5m zone of Mo with an average grade of 0.1% associated with anomalous Cu, Au, U, and REE. From the synthesis of all data and field observations, it is evident that the regional scale multi-thematic data integration can

effectively be used for identifying the most prospective sub-domains which, in turn, can be targeted for advanced stages of exploration.

Intelligent Identification Technology for Sandstone Thin Sections

Yili REN[1]*, Research Institute of Petroleum Exploration and Development, China National Petroleum Corporation (renyili@petrochina.com.cn)
Xi LIU[2], Research Institute of Petroleum Exploration and Development, China National Petroleum Corporation
Xin LI[3], Research Institute of Petroleum Exploration and Development, China National Petroleum Corporation
Yanxu HU[4], Research Institute of Petroleum Exploration and Development, PetroChina Huabei Oilfield Company

Abstract

Thin sections identification can represent the mineral composition, rock structure, and pore structure of the reservoir, and is an important means of studying reservoir evolution and reservoir quality. Traditional identification methods rely on visual observation, which faces challenges such as low efficiency, insufficiently precise and quantitative results, and a scarcity of experts. This method cannot provide detailed representation of the reservoir, necessitating the development of intelligent identification techniques. The images of thin sections differ from ordinary natural images in many unique ways, such as multi-channel images, blurred features, and small yet clustered objects. Therefore, universal algorithms cannot be directly applied. Moreover, intelligent identification techniques differ from ordinary natural scenes, and intelligent identification methods need to be tackled urgently.

Taking clastic rock reservoirs as an example in this article, new deep learning algorithms developes for the specific characteristics of thin section image data and the unique requirements of intelligent identification scenarios, focusing on aspects such as backbone network design, feature extraction, and loss function. Research conducts on intelligent mineral composition recognition for multi-channel images, pore structure analysis based on deep learning, and rock structure evaluation using computer vision. Consequently, the following achievements and innovations have been made.

First, proposed a set of full stitching, seven-channel, position-free image acquisition method, as well as rock particle segmentation, mineral composition, and pore type labeling scheme, forming a set of intelligent thin-section identification data annotation methods that facilitate modeling and annotation simultaneously.

Second, an instance segmentation network Swin-based HTC for multi-channel images is proposed to recognize mineral composition, enabling the extraction of features such as extinction, interference color, and cleavage. The instance segmentation effect (mAP) of 12 mineral particles, including quartz, feldspar, calcite, miscellaneous base-mud, dolomite, and authigenic clay minerals, reaches 0.80.

Third, a semantic segmentation network PoreSeger based on semi-supervised training to construct a pore intelligent recognition model and a throat identification method based on key point identification is proposed. The semantic segmentation effects of pores reach an IoU of 0.76 and

F1-Score of 0.85, as well as the throat identification model has an mAP effect of 0.91. On this basis, a set of pore structure quantitative characterization parameter system is proposed to achieve the quantitative characterization of clastic reservoir pores.
Fourth, based on the Mask2Former framework, a multi-channel image-oriented rock particle segmentation network CoreSegr is proposed to achieve the extraction of rock particle edges and the identification of categorical attributes (rigid particles, plastic particles, non-land-derived debris, and filling materials). Based on this, quantitative characterization parameters and calculation methods such as compaction index and roundness index are proposed to achieve the characterization of rock structure.
Through the research in this article, the entire process of thin sections identification has been intelligentized and automated. Moreover, multiple result charts which can achieve diversified visual identification results display and provide more detailed and specific visual data for energy storage analysis can be drawn based on this methods. Compared with manual identification, the thin section intelligent identification system is more objective, and the identification results are more detailed.

A study on the analysis and prediction model of lime dosage for artificial intelligence-based mine drainage treatment

SEONG-SOOK PARK[1]*, Hanyang University (pss2907@hanyang.ac.kr)
GA-HYEON LEE[2], Hanyang University
SOON JEE SEOL[3], Hanyang University
DUK-MIN KIM[4], Sangji University
SUN-JOON KIM[5], Hanyang University
MI-SUN PARK[6], Korea Mine Rehabilitation and Mineral Resources Corporation (KOMIR)

Abstract

Mine drainage containing suspended solids (SS) and potentially toxic elements has contaminated abandoned mine areas in South Korea, as well as surrounding rivers and agricultural land. Mine drainage has been treated nationwide since 1992 by active or passive treatment methods. As typical coal mine drainages in South Korea, Fe, Mn, and Al as well as SS are the main contaminants. At the treatment facilities, metals are precipitated by pH adjustment using slaked lime. The dosage of lime showed a pattern that varied with the flow rate, pH, and influent metal ion concentrations.

However, the relationship between these inputs and lime dosage has not been studied beyond the empirical equation. Thus, in order to effectively manage mine drainage as a long-term plan, we predicted the lime dosage for two mine drainage treatment facilities (ST and HT) in South Korea using a machine learning (ML) technique that is currently attracting attention as a data-driven artificial intelligence (Al) approach.

Since most of the data was handwritten and some of it was not chemically valid, we removed the bad data (161 (ST), 565 (HT)) from the original data of ST (2,145) and HT (2,160) mine drainage treatment facilities accumulated over six years. The input data of ML model were selected as pH, flow rate, and metal ion concentrations (Fe, Mn, and Al) of the influent, which highly correlated with the lime dosage (label). The convolutional neural network (CNN) model was designed and trained to predict the lime dosage. Although the data was measured once a day for six years, it was insufficient to train a CNN model. Additionally, the data revealed a significant imbalance in the lime dosage. Fancy PCA data augmentation technique was used to compensate for the limited amount of data and maintain the characteristics of the original data. ST and HT data were divided into 3 groups based on the lime dosage, and the augmented ratio of each group was set to 20:30:40 to address the data imbalance based on lime dosage. The trained CNN model produced a lower MAE (mean absolute error) and a higher R2 than the empirical equation for the test dataset which was not used during training process.

The use of ML techniques to predict lime dosage is expected to increase the cost-effectiveness of mine drainage treatment facilities and provide basic design data for new facilities.

The intelligent identification and regional capacity estimation of submarine polymetallic nodules based on Segment Anything Model

Jingpeng LIU[1]*, Qingdao Institute of Marine Geology (ljingpeng@mail.cgs.gov.cn)
Baoguang Li[2], Qingdao Institute of Marine Geology
Guohui Su[3], Qingdao Institute of Marine Geology

Abstract

Abstract: Polymetallic nodules are a kind of autochthonous polymetallic mineral resource distributed on the oceans seabed. They are currently one of the most important deep-sea mineral resources and strategic resources, and further exploration and development of which holds of great strategic significance. Obtaining the distribution density of nodules in the submarine mining areas and estimating the regional production capacity and economic value is an indispensable part of the exploitation and utilization process of polymetallic nodules. Traditional measurement methods primarily rely on rough manual calculations, which has the problems of time-consuming, labor-intensive, and inefficient. In order to solve these problems, some research efforts have attempted to introduce deep learning models for the purpose of automated estimation and analysis of polymetallic nodules, but a substantial amount of real, reliable, and pre-labeled samples are required for training and validation of models. Segment Anything Models (SAM) is a large-scale image segmentation model that leverages prompt-based learning to be able to segment any object in any image without additional training, featuring generalization, efficiency, and inferability. To this end, this paper proposes an intelligent identification method for seabed polymetallic nodules based on the SAM model. To address the issue of lacking datasets annotated with polymetallic nodule labels, this paper combines the SAM model to construct a semantic segmentation model framework suitable for nodule targets, achieving accurate segmentation of nodule regions and seafloor substrate regions. Considering the problems of speckle noise and nodule tightness or adhesion in the segmentation results, this paper utilizes morphological image processing methods such as image denoising, opening and closing operations, and contour recognition to accurately obtain the rectangular contour range of the nodules, which lays a solid foundation for the calculation of the index parameters related to nodules. Based on the target segmentation and recognition of polymetallic nodules, further functionalities such as morphological recognition, size calculation, and parameter calculation are implemented to achieve the estimation of regional polymetallic nodule production capacity. The experimental results show that the semantic segmentation model framework based on SAM is able to moderately identify the nodule distribution without the need of labelled datasets for model training and validation, and the recognition accuracy and recall of the model in the image are 94.87% and 95.78%, respectively. Compared with existing methods or models, the main advantage of this approach is that it can automatically and intelligently identify polymetallic nodule targets with a single click, and to achieve the estimation of regional nodule production capacity without the need for other auxiliary information or data. This approach has the advantages of time-saving, manpower-free and

accuracy. It can provide support for further development and utilization.

Borehole Thermal Resistance Estimation and Optimization for In-Situ Borehole Heat Exchangers

Byoung Ohan SHIM[1]*, KIGAM (boshim@kigam.re.kr)

Abstract

The borehole thermal resistance (BTR) of a borehole heat exchanger (BHE) plays a crucial role in the efficiency of ground-source heat pump (GSHP) systems. Researchers have extensively studied methods to enhance BTR, focusing on factors such as backfill material, pipe material, and tubing configurations. Lower BTR values lead to improved system performance and allow for shorter borehole heat exchangers. Two critical elements affecting BTR are the thermal conductivity of the backfill material and the pipe configuration. To investigate these factors, in-situ thermal response tests were conducted at seven BHE sites. The demand for thermally enhanced grout (TEG) products has increased as a means to reduce BTR commercially. In this study, we estimated the BTR for each of the seven BHEs using three calculation methods: Paul, Multipole, and Koenig. Additionally, we compared simulation plots, considering shank spacing and the thermal conductivity of the backfill material, with the interpretation results from the thermal response tests (TRT). Our simulations incorporated various grout materials with thermal conductivities ranging from 0.5 to 2.5 W/mK. However, the actual thermal conductivities of the grout backfilled in the borehole fields fell between 0.76 and 1.73 W/mK. The calculated BTR values were then applied to the GSHP design for an existing building, determining the required total BHE length. Notably, our results revealed significant differences in BTR estimation models, particularly in cases of low grout thermal conductivity. This case study provides valuable insights for BHE installations, especially when adapting TEG and aiming for cost-effective designs. By optimizing BTR, we can enhance GSHP performance while minimizing drilling requirements and overall capital costs.

Abstract

The European-Mexican geothermal GEMex project aimed at developing non-conventional geothermal resources in the easternmost region of the Trans-Mexican Volcanic Belt. Two sites under development by the Comisión Federal de Electricidad (CFE, Mexican National Power Company) were investigated to assess possible superhot resources and to assist in developing an Enhanced Geothermal System, respectively in Los Humeros and Acoculco (Mexico).

In Los Humeros, geothermal energy is exploited since the 80's by CFE where dozens of wells have been drilled. The goal is to better understand the geothermal field under exploitation and to aim expected super-hot fluids to be exploited. The geothermal target is mainly located in the basament, pre-calderic rocks.

Acoculco is far less known. Only two exploratory boreholes have been drilled, showing high temperature but a lack of fluid. Here, the expectation is to develop the field using EGS techniques. According to existing studies, the geothermal target is probably located in the basement composed of calcareous, granitic, and metamorphic rocks.

On both sites, European and Mexican partners constructed 3D geomodels to describe and interpret the geothermal systems. The geomodels evolved from preliminary knowledge to the extensive integration of geological, geophysical and geochemistry data further acquired. European-Mexican teams developed the characteristics of the modelling in a "Knowledge and Data Sharing - Modelling - Validation" cycle. The construction of the geomodels was performed in a collaborative and interdisciplinary way to enable a consensual interpretation and representation among the several experts of the geoscientific disciplines involved in the process.

The outcome consists in four and five geomodels, dedicated to Los Humeros and Acoculco sites, respectively. These were developed at various scales depending on the needs of the investigations. The 3D geomodels were used by partners during the course of the project as input for computations and simulations based on the geometry of the geological structures. In addition, the geomodels are shared in open access media* for further use and evolution beyond the project.

The collaborative and interdisciplinary work to produce the geomodels benefited from many European and Mexican scientists. Authors want to acknowledge the contribution of all the experts of the H2020 GEMex project who participated to some degree in the discussion and revision of the several stages of the Los Humeros and Acoculco geomodels.

The authors wish to thank the technical experts from CFE for their assistance and support. This work presents results of the GEMex Project, funded by the European Union's Horizon 2020

research and innovation programme under grant agreement No. 727550, and by the Mexican Energy Sustainability Fund CONACYT- SENER, Project 2015-04-268074. More information is available on the GEMex Website: http://www.gemex-h2020.eu.

CEEGS - Novel CO2-based electrothermal energy and geological storage system

Marko KOMAC[1]*, INTRAW (m.komac@telemach.net)
Ricardo Chacartegui[2], University of Seville, Spain
Anita Stein[3], European Federation of Geologists
Marko Komac[4], European Federation of Geologists

Abstract

CEEGS is a 3-year long Horizon Europe funded project, that is developing a cross-sectoral technology for the energy transition, combining a renewable energy storage system based on the transcritical CO2 cycle, CO2 storage in geological formations and geothermal heat extraction. The technology is a highly efficient, cost-effective, and scalable (small- to large-scale) concept for large-capacity renewable energy storage. Extended capacity is obtained due to the underground system. It can be integrated into the grid, heating and cooling districts and industries. It also has the capacity for partial CO2 sequestration. The main objective of the project is hence to provide scientific proof of the techno-economic feasibility of the technology, raising the current low Technology Readiness Level (TRL) from 2 to 4 by addressing gaps in the interface between surface trans-critical cycle and the subsurface CO2 storage.

Based on theoretical principles models, simulations, and processes in which advanced numerical simulations integrate reservoir behaviour, wellbore design and surface plant design are being developed. Results from these help in experimental verifications of using digital functional and laboratory models. Most crucial components will be validated with results from the CO2 pilot-scale projects. To be successfully implemented, every new technology needs to be evaluated and benchmarked from social, economic and sustainability aspects. For this purpose, tools to evaluate impacts and concept deployment with a) renewables, b) hard-to-decarbonise industries, c) district heating and cooling, and d) in grid balance, are essential to the project too. Consequentially, CEEGS consortium included among the project's tasks social acceptance studies, Life Cycle Assessment (LCA) and Techno-Economic Analysis (TEA).

Consortium expects to achieve several key elements of the impact – facilitate decarbonisation of heating/cooling and electricity sectors, provide large storage solutions for excess electricity generated, propose storage solutions that are interoperable with the existing grids and develops technologies for renewable energy production.

In addition to the abovementioned CEEGS technology integration at TRL4, expected results are defining geological availably and geological system design to guide future exploration and feasibility studies; designing new system components and engineering solutions to make the concept technological and economically viable, and solving open issues on TCO2/underground storage design; validation of technical assumptions and complete risk analysis, including social acceptance that fosters decision-making in a stage-gate process, drafting a complete business model to simulate further investments towards TRL 5-7 and beyond.

Important outcomes of the CEEGS encompass full set of technical benchmark data for component and system level, their interoperability compliance with the grid and renewable energy sources, newly derived knowledge on interface and load change-effects on equipment and the CEEGS technology, scale-up and commercialisation needs of CEEGS components in partnership with companies, potentially to Demonstration Plant level by engineering solution provider, its full commercialisation and clear understanding of the process economics and feasibility including CAPEX and OPEX of the CEEGS system for different plant scales and geographical regions.

The Impact of Fluid-Rock Interaction on Environment in Geothermal Sites of Kuril-Kamchatka Island Arc

Julia Vladimirovna FROLOVA[1]*, Lomonosov Moscow State University (ju_frolova@mail.ru)

Abstract

Geothermal exploration and development of geothermal sites requires the investigation of their engineering geological setting and an assessment of the hydrothermal activity impact on the environment. Alteration of rocks due to the interaction with thermal fluids changes their physical-mechanical properties and promotes a broad range of geological phenomena that is indicated by many researchers on various geothermal sites all over the world. These processes have a great impact on the environment and influence on exploitation of the geothermal field. There are known cases when they caused economic damage, disrupting the production and reinjection wells, damaging geothermal stations, and even leading to human casualties.

In this work, we consider the influence of hydrothermal alteration on physical-mechanical properties of rocks and describe the geological phenomena associated with hydrothermal activity on the most well-known hydrothermal systems of the Kuril-Kamchatka island arc such as Mutnovsky, Pauzhetsky, Koshelevsky, Kambalny, Bolshe-Banny, Geysers Valley, Semiachinsky, North-Paramushirsky, and volcano Baransky. The Kamchatka Peninsula and the Kuril Islands are located at the ocean-continent transition zone of the northwestern segment of the Pacific “Ring of Fire”, which is one of the most dynamic structure on the Earth. Its tectonic position above the subduction zone provides the increased convective heat flow. The geological, hydrogeological and geothermal conditions of the region are favorable for the formation of hydrothermal systems. The studied hydrothermal systems are hosted in the volcanic formations of Neogene-Quaternary age, which generally characterized by sufficiently high strength and deformation properties. The circulating thermal fluids cause large-scale alteration in composition, porosity, and properties, both by weakening or strengthening the rocks depending on conditions. Hydrothermal alteration captures the parent rocks and changes their properties down to the depth of hundreds meters and deeper. The most intense alteration takes place on the surface near thermal water discharges, where the rocks undergo argillization, finally turning into clay-rich soils that leads to significant decrease in mechanical properties by 2-3 order of magnitude. Hydrothermal alteration of rocks and changes in their properties promotes a broad range of geological phenomena including slopes instability with landslides initialization, hydrothermal explosions, migration and change a regime of thermal manifestations, surface deformation and subsidence, reduction of well production, formation of silica deposits from waste thermal water etc. These processes influence on the exploitation of geothermal field, and in some cases could be hazardous for the economic or tourist development of geothermal site.

On Policies and Mechanisms for Collaborative Promotion of Electricity Market and Carbon Market under the Dual Carbon Goals

Jia LIU[1]*, Development Research Center of China Geological Survey (ljia@mail.cgs.gov.cn)
Wei Gao[2], State Grid Talent Exchange Service Center

Abstract

Abstract: The holding of the 28th Conference of the Parties to the United Nations Framework Convention on Climate Change (COP28) and the implementation of the European Union Carbon Border Adjustment Mechanism (CBAM) will have a profound impact on the low-carbon development of some export enterprises in China's industries. Faced with the pressure of approaching carbon peak time, China has accelerated the construction of a future electricity spot market, restarted the National Certified Voluntary Emission Reduction (CCER) market, and expanded the national carbon market, aiming to reduce greenhouse gas emissions through market mechanisms and achieve the dual carbon goals. However, the electricity and carbon markets have not yet been connected, and the two systems still need to be effectively coordinated and connected in areas such as accounting and verification, data exchange and unified certification among different environmental rights. In terms of carbon emission data accounting and regulation, the country has successively issued technical guidelines to standardize and guide the emission control enterprises that have been included in carbon market in their carbon measurement methods and verification technologies. At present, enterprises mainly use the emission factor method to measure the direct and indirect carbon emissions of greenhouse gases based on the guidelines and policy standards issued by the Intergovernmental Panel on Climate Change (IPCC) of the United Nations. This method provides a basic framework for carbon measurement in the electricity and carbon markets, but there are still shortcomings in data accuracy, completeness, and timeliness. More scientific, precise, and systematic measurement is needed to ensure market fairness and transparency. In this regard, the study aims to sort out the coupling relationship between the electricity market and carbon market, in particular the mechanism of effective transmission of carbon costs to electricity costs, and the deduction method of green electricity in enterprise carbon emission accounting by drawing on the experience of European countries and the U.S. Besides, the establishment of carbon monitoring standards that are compatible with international standards and an internationally recognized green power certification system is tentatively explored. In terms of data reliability, it is recommended to apply advanced technologies such as AI, IoT and big data, combined with multiple information sources for real-time monitoring, to improve the accuracy of emission data.

Geothermal Water Chemistry and Water Rock Interaction in the Olkaria Geothermal Reservoir, Naivasha Kenya.

Edwin Wafula WANYONYI[1]*, Kyushu University (wedwin.wafula@gmail.com)
Kotaro Yonezu[2], Kyushu University

Abstract

The United Nations' sustainable development goal number 7 focuses on the provision of affordable and clean energy; where from the year 2022 report, the amount of renewable energy consumption increased from 2010 to 2019, yet still only 17.7% of the final energy consumption could be attributed to renewable energy (UNSTATS, 2022). One of these critical resources is geothermal energy. The Olkaria geothermal area has a high potential for geothermal generation with a current installed capacity of 985 Mwe and is the 6th largest producer of geothermal energy in the world. The study of the origin, evolution, and nature of these geothermal fluids is important to geoscientists since it determines the type and quality of utilization that can be applied to a particular geothermal prospect. The isotopic signature showed a strong influence of local precipitation on the geothermal fluid whereby the geothermal system was mainly recharged through fractures and faults and later modified through high-temperature water-rock interaction with the local rock of volcanic origin. Even though the system was majorly composed of fluid of meteoric origin, the solution chemistry showed that Na, Cl, and SiO2 were the most significant elements in the solution, which is not typical of normal meteoric waters, ostensibly showing the high level of water-rock interaction and fluid modification that the Olkaria geothermal water had undergone from the fluid of origin. Based on the variation of the major cation/proton activity ratios for Na+, Al(OH)-4, Ca2+, and K+ as well as the activity of H2CO3 in the geothermal water samples evaluated in this study, at the reservoir temperatures considered, all the wells had attained nearly the same relative abundance of these major cations Na and K. This is usually the case for waters that have attained equilibrium with minerals in solution, especially in the Olkaria case where the Na/K ratios were controlled by equilibrium with albite and K-feldspar. The analysis of the saturation state with respect to the silica minerals quartz and chalcedony for the Olkaria geothermal water showed that quartz controls the concentration of silica in reservoir fluid given that the wells had high temperatures above 250°C. The high temperatures were related to the proximity of the heat centers to magma sources that have been shown from resistivity studies to be between 6-8 km at depth in Olkaria. Boehmite precipitation acted as the major tank for aqueous aluminum concentration, with aluminum hydroxide being the main aluminum species in the solution. In general, most of these reactions are supported by fluid migration through the structurally controlled Olkaria geothermal reservoir.

Transgeo Project - How to reuse abandoned oil and gas exploration wells, opportunities and constraints in Hungary

Ferenc FEDOR[1]*, Department of Geology and Meteorology, University of Pécs (fedor.ferenc@geochem-ltd.eu)
János Kovács[2], Department of Geology and Meteorology, University of Pécs
György Márton[3], CROST Regional Development Nonprofit Ltd.

Hannes Hofmann[6], Helmholtz Centre Potsdam GFZ - German Research Centre for Geosciences

Abstract

Abandoned oil and gas wells are a problem all over the world. However, given the right market, geological and technological conditions, these wells can be used for underground gas storage or geothermal heat and/or power generation. In the TRANSGEO project, led by the Helmholtz-Centre Potsdam German Research Centre for Geosciences, partners from Germany, Hungary, Croatia, Slovenia, and Austria are investigating the potential of five different geothermal technologies (BHE – Borehole Heat Exchanger, BTES – Borehole Thermal Energy Storage, HE – Hydrothermal Energy, ATES – Aquafer Thermal Energy Storage, EGS – Enhanced Geothermal System) to provide energy and/or heat for agriculture, industry, and municipalities. The project will carry out a socioeconomic analysis of the problem, review existing projects, and select pilot project sites based on the best practices and criteria catalog-based IT tool. The criteria catalog will be used as a basis for the decision tree, and platform-independent software will be developed to support the selection. A review of the conditions for implementation will be carried out, and on this basis, a transnational strategy will be developed.
Hungary has a long history of geothermal energy use, which mainly focus on hydrothermal heat recovery. Because of the past oil and gas exploration activity nearly 2000 deep wells already being remediated or abandoned, and almost 8000 currently in hydrocarbon production in Hungary. As a result of previous oil and gas exploration activities, nearly 2,000 deep wells have already been remediated or abandoned, and nearly 8,000 hydrocarbon wells are in production in Hungary. Reuse of these wells in hydrothermal projects could result in significant cost reductions as they do not need to be abandoned and new wells do not need to be drilled for geothermal purposes. The presentation aims to showcase the Hungarian experience in addition to the general project overview.

Hydrochemical features of geothermal waters in the Namaqua-Natal Province, South Africa

Musarrat SAFI[1]*, Council for Geoscience (musarratsafi@gmail.com)
David Ngobeni[2], Council for Geoscience
Senzangakhona Ndumo[3], Council for Geoscience

Abstract

Geothermal energy is under-explored in South Africa, however the Council for Geoscience has initiated exploring the potential of geothermal energy in South Africa. This study investigated the geology, geophysics, hydrochemical (major ions) and stable water isotopes of Shu Shu in the Namaqua-Natal Province, South Africa. This study aimed to locate the reservoir and its conduits, focusing on the geothermal flow (such as recharge zones, upwelling zones, and outflow plumes) and identify the nature of the resource fluids.

The geology of the area was mapped, which gave a better understanding of the structural controls. The geothermal waters were tested for their physical properties (temperature, pH, total electrical conductivity and salinity (sal)) and sampled for ions (HCO3, Cl, SO4, Na, Ca, Mg, K, and Fe, SiO2) and stable isotopes. The ions were analysed using an induced coupled plasma-optical emission spectrometer. Oxygen-18, deuterium, and tritium were analysed using an isotope ratio mass spectrometer and laser water isotope analyser. Magnetotelluric and gravity surveys were conducted at Shu Shu to investigate the circulation depths of the geothermal waters.

The results indicated that the geothermal waters ascended to the surface via fractures and a thrust fault (trending N-S) separating the various thrust sheets in the area. The constant water flow is mainly related to a fracture network connected to a recharge source indicative of no interference at the source (either from abstraction or severe drought).

Furthermore, Shu Shu geothermal water surfaces on the banks of the Tugela River at 50.5 °C, 1452 µs/cm (electrical conductivity), classified as Na-Cl-type water. This signature may represent either deep saline fluids or central upflow zones of the liquid-dominated hydrothermal system.

By integrating the geology of Shu Shu, the hydrochemistry of the geothermal water samples, and geophysics surveys, the conceptual model revealed that the geothermal source is located at a depth of 1500- 2200 m and heated to ~106-159 °C. From this investigation, the data suggests that this area in Namaqua-Natal Province has the potential to harness geothermal energy.

Fracture-matrix interactions of deep geological systems in the context of energy geosciences and carbon management

Qinhong Hu[1]*, China University of Petroleum (East China) (huqinhong@upc.edu.cn)

Abstract

The cost-effective development of shale petroleum and enhanced geothermal systems (EGS) involves hydraulic fracturing of deep (several thousands of meters below the surface) shale (for oil and gas) and granite (for geothermal energy) formations to create stimulated fracture networks for a sufficient flow of petroleum molecules and hot water to the producing wellbores for an economic development of petroleum and heat. These are different from other fields of energy geosciences involved in the energy transition, such as carbon capture, utilization, and storage (CCUS) for minimizing carbon emissions, underground hydrogen storage for an emerging hydrogen energy economy, as well as deep geological repository of high-level nuclear wastes for further increasing the share of nuclear energy. These arenas commonly involve shallow (hundreds of meters) geological formations of sandstones, carbonates, salt rocks, and basalt with coupled reservoir-caprock systems for a large-volume storativity and injectivity in reservoirs/excavated structures as well as efficient sealing capabilities for caprocks to prevent inadvertent leakage or loss of stored supercritical CO2, H2, or high-level nuclear wastes; in addition, the presence of natural fractures is considered to be a negative factor for the desired storage/capping systems. Fractures, either naturally present or hydraulically stimulated, play an important role in regulating the production of petroleum and hot water in tight matrix of shale and granite, and fracture-matrix interaction with intertwined coupled thermal-hydraulic-mechanical-chemical (THMC) fields and processes dictates how mass (petroleum) and heat transfer/extraction can be sustained for shale petroleum system and EGS viable in the pathways to carbon neutrality.

Microscopic characteristics of porous matrix – pore shape, pore-size distribution, pore connectivity – influence macroscopic behavior of fluid flow and chemical transport, and can therefore affect the performance of deep geological systems with natural and hydraulically-stimulated fractures in their desired usage of either extracting or storing various forms of energy-related fluids. This work discusses various, and complementary, approaches to investigating pore structure (geometry and topology), and the resulting anomalous imbibition and diffusion for typical geological formations associated with energy geosciences. These experimental approaches include imbibition, tracer diffusion, porosimetry (mercury intrusion porosimetry, vapor absorption and capillary condensation, and nuclear magnetic resonance with cyroporometry), and imaging (Wood's metal impregnation, focused ion beam/SEM). Results show that the nm-sized pores, combined with low pore connectivity, lead to extremely low diffusion in tight matrix as measured using liquid diffusion and laser ablation-ICP-MS. Chemical diffusion in sparsely-connected pore spaces is not well described by classical Fickian behavior; anomalous behavior is suggested by percolation theory, and confirmed by results of imbibition tests from a sample/fracture face and imaging approaches. Our evolving complementary approaches, with each component method

having its unique advantages for a holistic understanding of how microscopic pore structure affects macroscopic fluid flow and chemical transport, provides a rich toolbox for tackling the fracture-matrix interactions involving several orders of difference in porosity and permeability.

Optimal Selection and Development Plan Design for Buried Hill-Type Hot Dry Rock Targets in the Jiyang Depression

Shaozheng Wang[1]*, China University of Petroleum (East China) (wangshaozheng1105@163.com)
Yaoqi Zhou[2], China University of Petroleum (East China)

Abstract

The development and utilization of geothermal resources in China have primarily focused on shallow hydrothermal resources. The exploration and development technologies for deep geothermal resources are still in their infancy. Exploiting deep geothermal resources can enhance the proportion of renewable energy in the overall energy structure, improve the stability and diversity of the energy supply, enhance national energy security, and provide robust support for achieving the "carbon peak" and "carbon neutrality" goals. The buried hill zone in the Jiyang Depression of the Bohai Bay Basin possesses significant exploration potential for geothermal reserves. However, the hill-type hot dry rocks are deeply buried and have complex geological origins, and systematic studies on deep hot dry rocks in the Jiyang Depression are currently lacking. This paper utilizes 1:200,000 gravity data, 1:50,000 aeromagnetic data, drilling, and seismic exploration data, employing the Parker-Oldenburg inversion iteration algorithm, gravity-seismic joint stripping method, gravity and magnetic forward and inverse method, and magnetotelluric sounding method to interpret deep faults and buried hill uplifts that control the geothermal structures, establishing a conceptual model for the genesis of geothermal resources. Based on six indicators: Curie depth, Moho depth, geothermal gradient, reservoir lithology, cap rock thickness, and the scale of buried hills, five hot dry rock targets were optimally selected. For typical buried hill uplift targets within the depression, geological models of Ordovician hot dry rock reservoirs were constructed using Petrel and 3DGeoModeller software, and simulations were conducted with COMSOL software for different production and injection well distances, reinjection temperatures, production and injection volumes, and exploitation periods. The study reveals that the Jiyang Depression possesses a unique geothermal genesis characteristic of "crust-mantle endogenic heat, structure-controlled heat, buried hill heat storage, and cap rock insulation," forming a composite geothermal system in the basin with "conductive-type hot dry-hydrothermal coexistence, convective-type hydrothermal replenishment" as the main features. A checkerboard well pattern, a reinjection temperature of 20°C, a well spacing of 600m, and a production and injection intensity of 1500m3/d, constitute the optimal exploitation plan for a proposed 50-year extraction period. This has significant implications for efficiently developing buried hill-type hot dry rock geothermal resources.

Feasibility analysis of thermal solar energy storage in heterogeneous deep aquifer

Yating W[1]*, 15735513435 (15735513435@163.com)
Xiaoguang W[2], 19102863595

Abstract

This study investigates the feasibility of utilizing ATES (aquifer thermal energy storage) for seasonal solar heat storage through geostatistical modeling and hydro-thermo coupling simulations.Storing solar energy underground as heat is a promising method for energy storage and conversion, with great potential to address the temporal and spatial mismatch between energy demand and supply. Thermal energy storage in deep aquifers can convert intermittent solar energy into stable high-temperature geothermal energy. In this study, a new solar energy storage and conversion system is proposed where solar energy is first converted into heat using parabolic troughs and then stored in deep aquifers through high-temperature hot water circulation. Geostatistical modeling and hydro-thermo coupling simulations are adopted to investigate the feasibility and efficiency of solar energy storage in deep aquifers.

The study area selected is the Xiongan region in northern China. The thermal source is a parabolic trough solar energy collection system, and the reservoir is situated within sandstone at a depth of 2000 meters underground. Utilizing current local meteorological data, the solar thermal collection system is modeled, providing precise hourly data input for the underground aquifer thermal energy storage system. This study is primarily dedicated to analyzing the thermal-hydraulic response of the aquifer storage system under various operational parameters. Specifically, the research analyzed how factors such as injection rate, well spacing, and reinjection temperature influence temperature distribution, temporal and spatial evolution, and storage efficiency. Simulation results indicate the critical importance of selecting appropriate system parameters to maximize heat recovery rates.These findings contribute to a deeper understanding of the mechanisms behind solar energy storage in deep aquifers and offer valuable insights for field applications.

Huachuan Wang[10], University of Strathclyde
Shangtong Yang[11], University of Strathclyde

Abstract

We examine the use of abandoned mine shafts for interseasonal storage of curtailed wind energy in the form of heat. Surface engineered thermal stores are currently limited by size and the need for insulation, and the thermal storage opportunity within flooded mine shafts is substantial. As an example of the scale of the opportunity, in 2020, UK wind curtailment payments were £282M: enough to power 1.25 million homes: equivalent to £4 per MWh. If heat generated using curtailed wind can be safely stored in mines, then utilising 1% of UK mine entries could potentially provide heat for 10% of UK homes during a ‘worse case weather week’ (cold, still winter days, when heat demand is highest). This requires heating the shaft water to 55 degrees centigrade so that it can be used directly in heat pumps.

Here we examine the implications of raising the water temperature to 55 degrees and cycling the temperature within the shaft for: mineshaft stability, geochemical evolution of the water within the shaft, heat and water flow in the rock mass around the shaft. We also explore the wider energy system demands. Finally, we outline the experimental heat injection planned for 2024 at an abandoned mineshaft site in Scotland.

New understanding of Mesozoic-cenozoic tectonic features and geothermal potential evaluation in Weibei Basin

Xiaoxin SHI[1]*, CHINA UNIVERSITY OF PETROLEUM (b21010008@s.upc.edu.cn)
Yaoqi ZHOU[2], CHINA UNIVERSITY OF PETROLEUM

Abstract

This article analyzes the tectonic pattern of the Mesozoic-Cenozoic and evolution process in the Weibei Basin by reprocessing and interpreting seismic data, identifies the main stratigraphic interfaces and fault systems in the deep part of the Weibei Basin. Combined with the tectonic evolution history of the Tan-Lu Fault Zone, it is believed that the Mesozoic-Cenozoic in the Weibei Basin have different structural patterns. The tectonic pattern of the Mesozoic in the Weibei Basin is controlled by the northward extension of the activity of the Yi-Shu fault zone, which in the middle section of the Tan-Lu fault zone, and has the characteristic of "graben-horst interphase". The tectonic pattern of the Cenozoic is controlled by strike slip-extension, forming a dustpan shaped basin characterized by overlapped on the sourth, while the north, east, and west are faults. Weibei Basin is located in the eastern part of the North China Platform, with a high temperature background. Based on the geothermal data of the Weibei Basin and the research results on the restoration of ancient geothermal fields, it is proposed that Weibei Basin has a good condition for the formation of geothermal resources.The thermal source of Weibei basin mainly comes from the mantle, and the deep and large fault on the boundaries becomes the main channel for the thermal flux. The thick sediment layer of the Cenozoic Basin provides good preservation conditions for the formation of deep geothermal resources.The formation and distribution of geothermal resources in the Weibei Basin are closely related to the evolution of the geothermal field and the Tan-Lu Fault Zone, which is controlled by the activity of the Tan-Lu Fault Zone in the Mesozoic-Cenozoic and the Mesozoic tectonic pattern. The Zaohu fault nose zone in the eastern part of the Weibei Basin is located above the high part of the Mesozoic structure, close to the boundary fault, and is a favorable area for the formation of geothermal resources. The top limestone karst reservoir of the Ordovician is a favorable target for the exploration of hydrothermal geothermal resources,and its deep part has the possibility of forming HDR geothermal resources, and the amount of geothermal resources is estimated.

Characterizing geothermal heat pump system in relation to thermal property of different rocks by laboratory and field tests

Youngjin KIM[1]*, Daesung heatenersys Co.,Ltd (mkiss79@naver.com)
Hyoungchan Kim[2], Korea institute of Geoscience and Mineral Resources
Seyeong Hamm[3], Pusan National University

Abstract

For cooling and heating of homes and buildings, geothermal heat pump (GHP) system replaces fossil fuels and contributes to the reduction of CO_2 emission. In order to install GHP system, we should reflect and predict accurate rock characteristics. In this study, thermal conductivity measurements of several rock types in Korea by divided-bar method thermal response test (TRT) were conducted and the two methods were compared in terms of the measurement characteristics. In order to improve the efficiency of the existing GHP system, the measurement results of the divided-bar method were applied to the Ground Loop Design (GLD) program and the GLHEPro ver. 4.1.7 program. The relationship between thermal properties (thermal conductivity, thermal diffusivity, specific heat, and density) of the rocks was analyzed for designing geothermal heating and cooling system design. Thermal diffusivity values were estimated as 0.096 ~0.135 m2/day, the thermal conductivity values 2.5 to 3.5 W/mK, and the heat exchange length 6.4 to 7.8 km. The higher the thermal conductivity, the lower the thermal diffusivity. In the range of 0.096 to 0.135 m2/day of the thermal diffusivity, thermal conductivity values were between 2.5 and 3.5 W/mK and heat exchange lengths were between 6.4 and 7.8km. The higher the thermal conductivity, the lower the thermal diffusivity. In addition, the higher the thermal conductivity and the lower the thermal diffusivity, the shorter the heat exchange length. On the other hand, with the density of 0.80 mg/cm3 and thermal diffusivity of 0.096 ~ 0.135 m2/day, when the specific heat changes from 0.80 to 0.86 J/gK, the heat exchange length increases from 7.4 to 7.8 km. Therefore, as the thermal conductivity, density, and specific heat increase, the thermal diffusivity decreases; and the thermal diffusivity decreases, the heat exchange length decreases. Hence, reducing thermal diffusivity is an important factor for shortening heat exchange length.

Toward Sustainable Development of Offshore Wind Power at Active Margins - Importance of Submarine Geohazard Risk Assessment-

Yasukuni Okubo[1]*, Geothermal Energy Research & Development Co., LTD. (yasu-okubo@jcom.home.ne.jp)
Yasukuni Okubo[2], Science Council of Japan

Abstract

Offshore wind power is attracting a lot of attention in Japan. The objective of Japan is to establish projects of 10 GW by 2030 and 30 GW - 45 GW by 2040. However, there are risks in development unique to Japan. The risks derive from the bathymetry in an island arc active margin, which greatly differs from the one in continental inactive margin such as Europe. Around Japan, most of the promising offshore areas shallower than 200 m lie within 50 km off the coastline. In case of 50 m or shallower water depth, the areas lie within 10 km off the coastline. Further, Japan is in severe meteorological and oceanographic conditions and prone to earthquakes. In this geographical context, in addition to storm surges and high waves, impacts of the external forces of earthquakes, tsunamis, and typhoons in the limited shallow seafloor areas near the coast are big. Therefore, there is a high possibility that geohazards will occur in the seafloor. These "submarine geohazard risks" include liquefaction caused by earthquakes, high waves and submarine landslides. It is known that liquefaction is also closely related to scouring. Here, we point out three issues, (1) Submarine geohazard risks-aware development, (2) Developing systematic guidelines for submarine geohazard risks, (3) Need for utilization of existing offshore geoscience data, human resource development, and industry-government-university collaboration. Since there is a possibility that submarine geohazards may occur, we need to recognize such submarine geohazard risks toward sustainable development. In order to ensure full-scale development and stable operation in the future, it is urgent to develop systematic guidelines regarding submarine geohazard risks through collaboration of industry-government-university including experts. Promoting use of the existing data and improving the data sets by industry-government-university collaboration leads to efficient survey and additional investigation planning and activating technological development and human resource development. To this end, it is desirable to promote open access of submarine data and to establish a platform for open discussion. Accordingly, Japan can improve her status by enhancing international human resource development.

[Keynote] Submarine Geohazards Resistant Design Concept for Anchors and Cables of Floating Offshore Wind

Shinji Sassa[1]*, National Institute of Maritime, Port and Aviation Technology (sassa@p.mpat.go.jp)

Abstract

The offshore renewable energy systems are subjected to diverse forms of submarine geohazard risks, such as seabed liquefaction induced by earthquakes and ocean waves and associated large-scale sediment flows and submarine landslides. Amid global climate change, the ocean wave conditions are becoming more severe along more than half of the world's coasts. This fact makes floating offshore wind facilities that are installed in relatively deep waters compared with the bottom-fixed offshore wind facilities more susceptible to liquefaction under both earthquakes and severe ocean waves. Based on the state-of-the-art understanding of the seabed liquefaction-induced impact on coastal and offshore infrastructures, this paper presents a novel submarine geohazards-resistant design concept for anchors and cables of floating offshore wind. Seabed liquefaction governs the fate of floating or sinking of a structure resting in the seabed. Namely, under conditions where the overall density of a structure is lower than the mass density of a liquefied seabed ground, the structure floats up, whereas under conditions where the overall density of a structure is higher than the mass density of a liquefied seabed ground, the structure sinks into the liquefied seabed. In the case of the latter, the structure may settle into the seabed ground in association with the liquefaction and scour. A range of the field and experimental evidence show that pipeline floatation is closely linked with the seabed liquefaction. Our recent centrifuge test results demonstrate that the sinking and flotation of a pipeline and a cable is controlled by the relationship between the overall density of a structure and the mass density of a liquefied soil. The corresponding structure-liquefied soil density ratio equal to unity serves as an index value below which floating takes place and above which sinking ensues. Another recent finding from our field observation and experiments show that seabed liquefaction governs the fate of floatation, sinking and burial of a living organism in the seabed. Under conditions where the body density of a living organism is lower than the mass density of a liquefied ground, the benthic organism floats up, whereas under conditions where the body density of a living organism is higher than the mass density of a liquefied ground, the benthic organism sinks deep into the liquefied seabed. Accordingly, the living organism body density-liquefied soil density relationship determines the floatation with the associated transport and burial of the living organism during liquefaction. These results give rise to a novel design concept of the mitigation measures for such submarine geohazard risks-resistant anchors and cables that takes account of the relationship between the anchor/cable body density and the mass density of a liquefied soil. Importantly, the stability of a floating offshore wind can be kept continuously during the seabed liquefaction by preventing floatation, burial and settlement of the anchors and cables while keeping essentially the same depth in the ground. This also ensures a higher horizontally-moving resistance force for the anchors and cables owing to the higher mass density of the liquefied seabed ground than the

ambient fluid against submarine landslides.

Numerical simulation of the flow impact due to submarine landslide exerting on offshore wind turbines with a monopile type foundation

Kazuki MURATA[1]*, Port and Airport Research Institute, Japan (murata-ka@p.mpat.go.jp)
Shinji SASSA[2], Port and Airport Research Institute, Japan
Yasuhiro AIDA[3], Department of Oceanic Architecture and Engineering, College of Science and Technology, Nihon University
Tomoki IKOMA[4], Department of Oceanic Architecture and Engineering, College of Science and Technology, Nihon University

Abstract

Submarine landslide flow or liquefaction phenomena around coastal zones due to earthquakes and ocean waves can cause damage and failure of oceanic structures, breaking of the mooring chain of floating facilities, a collision between vessels, and scour of surrounding seabed. However, the corresponding detailed processes need to be sufficiently examined and evaluated. An understanding based on model experiments of the full spectrum of physical behaviour and dynamics could be very costly. Here, we take a numerical simulation approach to reproduce such phenomena.

The authors focus on the MPS particle method, which is one of the particle simulation methods developed by Koshizuka et al. (1999), and evaluate the applicability of its two-phase flow model to submarine landslide phenomena through the reproduction calculations of past model experiments. Then, we study the basic characteristics of impact pressure acting on offshore wind turbines with a monopile type foundation caused by submarine landslides that manifest in coastal areas. The results show that the high-density fluid model of the MPS can qualitatively reproduce the submarine landslide phenomenon up to a flow distance of 50m in the case of pure sand. This presentation highlights a significant effect of submarine landslide flow occurring in coastal or marine areas around a shallow-water-depth-installed monopile type foundation.

Wave-Induced Liquefaction and the Stability of Offshore Structures in Seabed Soils in a Drum Centrifuge

JUNJI MIYAMOTO[1]*, TOYO CONSTRUCTION CO., LTD. (miyamoto-junji13@toyo-const.co.jp)
SHINJI SASSA[2], National Institute of Maritime, Port and Aviation Technology

Abstract

Wave-induced liquefaction of seabed soils is an increasingly important research subject concerning the stability of offshore wind farms, offshore platforms, submarine power cables or other such facilities. This study explores the relationships between wave-induced liquefaction in sand beds and the initiation and progress of instability of marine structures such as pipelines, monopiles, and suction buckets under severe wave loading, based on centrifuge modelling. Centrifuge wave tests in a drum channel were performed with viscous scaling introduced such that the time-scaling laws for fluid wave propagation and consolidation of the soil were matched.

The experimental results showed that the instability of the structures is attributed to the occurrence and progress of liquefaction of the sand bed around the structures. Under severe wave conditions, liquefaction occurred at shallow soil depth in the loose sand beds, and the liquefied zone propagated downwards in the course of wave loading. In the study of pipeline stability, upon the occurrence of liquefaction at a shallow soil depth, the buried pipe started moving upwards and the motion of the pipe increased markedly in association with the downward progress of liquefaction during wave loading. Similarly, in the cases of a monopile and a suction bucket, they started significant structural rocking, when liquefaction occurred and progressed downward to a certain depth. The residual displacement of the structures increased markedly with the downward progress of the liquefied zone, eventually leading to their collapse.

The effects of a gravel layer replacement over a sand bed on countermeasure against wave-induced liquefaction are also discussed. Specifically, the scour protection with gravel replacement around the monopile was used for countermeasures against wave-induced liquefaction leading to the pile instability. The experimental results showed that the scour protection increased liquefaction resistance, depending on the diameter ratios of the scour protection and the pile, however, it could not prevent the collapse of the monopile once liquefaction occurred.

Overall, we present several valuable insights into the complex interactions between wave, seabed, and structures, shedding light on the characteristics of the instability and mitigation strategies for marine structures such as buried pipes, monopiles, and suction bucket foundations relevant to offshore renewable energy systems in the context of wave-induced liquefaction.

Assessment of Submarine Geological Risks to Offshore Wind Power in Japan Coastal Areas

Koki KIMURA[1]*, Kiso-Jiban Consultants Co., Ltd. (kimura.koki@kiso.co.jp)
Hideo NOMURA[2], Kiso-Jiban Consultants Co., Ltd.
Kiichiro KAWAMURA[3], Graduate School of Science and Technology for Innovation, Yamaguchi University, Yamaguchi, Japan

Abstract

In recent years, offshore wind power is rapidly gaining momentum for development in the coastal areas of Japan. Foundations, anchors, and power cables of offshore wind farms are installed on the seabed, in which various geohazards exist. Therefore, it is important to identify geohazards and assess the geological risks relevant to the seabed for the development of offshore wind power. As Japan is in an active margin and seismically active regions, and the seabed in the coastal areas of Japan is characterized by steep topography, it is necessary to identify hazards specific to Japan's waters and evaluate the risks.

Potential submarine geohazards in Japan include: shallow gas, submarine landslides, active faults, submarine dunes and sand waves, gravity flows and their deposits, channels, mud volcanoes, tsunamis due to sector collapse, volcanic tsunamis, creep, submarine fans, old river channels and buried valleys, liquefaction, soft soil layers, deltas, tidal currents, etc. Amongst them, this paper focuses on five of the most influential geohazards and discusses their effects on wind turbines and cables, as well as the methodology used to identify the geohazards. In addition, examples of geohazards that have actually appeared in the coastal areas of Japan are presented.

Furthermore, this paper reports the methodology established to assess the geological risks for the development of offshore wind power that coexists with geohazards.

Seismic characteristics of Changyun Rise western offshore central Taiwan (eastern Taiwan strait) and their possible connections to Late Pleistocene - present Choshui River system

Yi Hao WANG[1]*, Institute of Oceanography, National Taiwan University (r11241309@ntu.edu.tw)
Jih-Hsin Chang[2], Institute of Oceanography, National Taiwan University

Abstract

In last decade, the seafloor bathymetry and geology of the western offshore central Taiwan (eastern Taiwan Strait) has been substantially surveyed because it has been considered one of the best sites for offshore wind power development in the world. A large amount of geophysical data has been collected especially high-resolution reflection seismic data (Sparker) for shallow part of sedimentary layers and stratigraphy. Presumably they are very likely to be landward linked to Late Pleistocene-present depositional system of the alluvial river (i.e., Choshui River, the largest river drainage system in western central Taiwan). In this study, we revisited the characteristics and structures revealed from selected sparker profiles and explored the possible relationships between submarine and terrestrial depositional systems. Major bathymetric feature offshore central Taiwan is Changyun Rise, which is composed of nearshore area, eastern swale, eastern Changyun Ridge, western swale, and western Changyun Shoal from east to west. In nearshore area, bathymetry is generally shallow (< 30m) and is dipping seaward, and the sparker profiles is mainly dominated by seaward dipping reflectors overlying on poorly continuous reflectors. Seawards, seafloor in eastern swale become being dominated by sandwaves overlying the poorly continuous reflectors. Further seawards, the bathymetry in eastern Changyun Ridge is distinct with layered, low amplitude, and gently dipping reflectors. Further west, the bathymetry and seismic features of western swale reflectors is very similar to those of eastern swale. The westernmost part of Changyun Rise is western Changyun Shoal. It is predominated by sandwave and most reflectors beneath sandwaves are generally indistinct. Only at the westernmost end of the Changyun Shoal we can recognize dipping reflectors. Consider that dipping reflectors and underlying poorly continuous reflectors are widespread outward of the Choshui River system in eastern Taiwan Strait, we propose that they most likely represents the distal clinoforms of the Choshui River system developed in response to various sedimentary processes during the Last Glacial Period.

Thermolithospheric Model (THERMOMAG) to Curie Isotherm Calculations

Suze Nei Pereira GUIMARAES[1]*, Federal Rural of Rio de Janeiro University
(suzeguimaraes@ufrrj.br)
Beatriz Lessa[2], National Observatory
Fábio Pinto Vieira[3], National Observatory

Abstract

The variation in temperature and pressure deep within the Earth's lithosphere directly affects a wide variety of rock properties and your physical processes. Performing a correlation of crustal thermal modeling from the analysis of the deep temperature can bring valued insights about the variation of temperatures at depth and magnetic petrology. In this work, we present a THERMOMAG thermolithospheric model, which is a method of geothermal investigation in the magnetizable crust, thus delimiting the Curie isotherm.

Two geothermal parameters related to the rock interfere directly in the 1D crustal thermal modeling, considering the steady state of heat transfer by conduction: the thermal conductivity (λ) and the radiogenic heat production rate (A) in the crustal layers. Considering a variation rate in these two parameters, the geothermal model of crustal temperature distribution becomes more significant in the geothermal gradient analysis.

The use of Curie depth from the spectral analysis of anomalous magnetic field data, considering the bottom of layers from deeper sources, as being the magnetic boundary of the crust, can to complementary the analysis of the crustal thermal distribution in a indirect way. Basing in the inclinations of the amplitude spectrum (fitting straight lines) and in the use of the combined filtering technique to verify the results of the spectral depth calculations and thus minimize errors.

Thus, the THERMOMAG thermos-lithospheric model is based on a cross-checking of geothermal and magnetometric Curie depth results. This check is carried out in each analysis cell, considering its geotectonic context. A thermomagnetic correction factor (β) is introduced for an improved approximation of the Curie isotherm depth results obtained indirectly. Thus (β) is adjusted for different geotectonic contexts, taking into account the geostructural provinces to which they were related. Therefore, the Curie isotherm data, corresponding to temperature of magnetization from magnetite (Fe3O4 - 580oC), which can be related to the magnetic basement in the lower crust can be determined by the Curie depth acquired through the spectral analysis of the aeromagnetometric data corrected by the thermomag factor acquired through the cross- check of direct measurements (geothermal) of crustal temperature. Future perspectives aim to improve the windowing in the spectral analysis of magnetometric data for the calculation of subsurface layers and to improve the script of this model encompassing the thermomagnetic correction factor adjusted to each geological context by new acquisitions of direct temperature data.

Significance of Strong Amplitude Reflectors Observed in Geothermal Areas for Deep Geothermal Resource Exploration

Jun MATSUSHIMA[1]*, The University of Tokyo (jun-matsushima@edu.k.u-tokyo.ac.jp)

Abstract

Seismic reflection surveying technology has evolved in the background of oil and natural gas exploration and is predominantly utilized in the field of elastic wave exploration. This method not only provides the highest-resolution underground structural information but also offers diverse characteristics of subsurface properties. However, when applying this technology primarily designed for sedimentary basins (stratigraphic structures) to geothermal zones mainly composed of volcanic rocks, its applicability is often questioned due to its lower effectiveness. This is partly because the layers constituting geothermal zones are heterogeneous rather than stratified, causing elastic waves to scatter, resulting in poor reflection waves being observed. Despite its less-than-optimal applicability compared to oil exploration, seismic exploration in geothermal zones has shown effectiveness in several aspects, one of which is observing strong amplitude reflectors. Fracture systems are characterized as low-velocity zones in elastic terms; thus, as fractures develop, the acoustic impedance in these systems decreases, leading to a significant contrast in acoustic impedance with surrounding layers. As a result, strong amplitude reflection waves are produced, making them easier to detect. Such strong amplitude events may suggest the presence of fracture systems. Furthermore, there are examples of strong amplitude reflection surfaces being observed at depths of several kilometers in geothermal zones, first discovered in Italy's Larderello-Travale geothermal area and also observed in the country's Amiata volcano-geothermal zone. Various discussions have been conducted on the causes of these strong amplitude reflectors, including theories involving critical fluid-containing fracture systems and brittle-ductile transition zones accompanied by high-pressure fluids. In any case, these strong amplitude reflectors at deep levels may serve as indicators for the development of deep geothermal resources. This presentation comprehensively introduces cases of strong amplitude reflection surfaces in geothermal zones and discusses the significance of observing these surfaces.

DEVELOPMENT OF THE RENEWABLE GEOTHERMAL ENERGY IN UZBEKISTAN

Elena Aleksandrovna GOLOVKO[1]*, Ministry of Mining Industry and Geology of the Republic of Uzbekistan (sidorovaelena87@gmail.com)
Irina Petrovna Sidorova[2], Institute Geological and Geophysics
Rasuljon Isomodinovich Sakhobidinov[3], Institute Geological and Geophysics

Abstract

Uzbekistan is among those states that have already achieved energy independence. The country's sources of electricity generation are natural gas and oil products. Geothermal energy, being a renewable energy source, can become an alternative to hydrocarbon resources, which will undoubtedly contribute to strengthening the energy security of the country in providing electricity, heat supply and drinking water to the population living in settlements remote from the central energy supply. Geothermal energy is the only source of carbon-free electricity that is both renewable and capable of delivering variable baseload power at the scale needed for the Uzbekistan energy transition. Preliminary studies already have been carried out. Following a multidisciplinary approach, it is necessary to carry out geological and geophysical studies of the selected areas with anomalous Heat Flow. The stage Exploration includes several research sub-stages:

1. Geological exploration;
2. Geophysical subsurface;
3. Pre-feasibility study.

The conductive anomalies that we have identified in the Earth's crust are associated with deep, weakened permeable zones, which provide increased heat and mass transfer. The use of a complex of geophysical methods in the exploration of the construction site and operation of the reservoir can significantly reduce the cost of deep heat resources and make petrothermal energy competitive compared to traditional energy.

Based on the results obtained, a 3D model of the Muruntau area with the geothermal station with a new settlement was built. This is practically very important, since the of the Muruntau quarry expansion is planned to the north-west and the old village needs to be removed. As a result of complex geophysical studies the places of optimal laying of geothermal wells and, accordingly, the construction of a geothermal station to provide the new village with electricity were identified. At the last years geothermal investigations were been carried out on the World Bank project REP-1/5 “Development of the renewable geothermal energy in Uzbekistan”.

Gabriel C. Rau[6], School of Environmental and Life Sciences, The University of Newcastle, Callaghan, Australia

Abstract

Heat transport in sedimentary aquifers has drawn attention for various applications in Earth Sciences, especially for sustainable geothermal system design and hydraulic property characterization of aquifers. Heat propagation in porous media is commonly described, assuming a simplification of the heat transfer mechanism between fluid and solid phases termed as local thermal equilibrium (LTE). While previous studies have illustrated that local thermal non-equilibrium (LTNE) may be present in the context of water flow through porous aquifers, experimental data is still lacking. To investigate LTNE effects, we conducted systematic flow-through experiments with temperature sensors inserted in different sized glass spheres (5 to 30 mm diameter) for solid temperature and sensors placed on the outside to measure the fluid temperature. Temperature breakthrough curves in response to steady-state flow with different seepage velocities from 9 to 61 m/d and a temperature step input were measured. Experimental results demonstrated stronger LTNE effects with increasing flow velocities and grain sizes. Crucially, the experiments also exhibited significant non-uniform flow which impeded investigation of subtle LTNE effects. The experimental data was therefore analyzed using a 2D numerical model to explore the impact of the heat transfer coefficient on LTNE in the presence of non-uniform flow. Integrating non-uniform flow into the model revealed the magnitude and nature of LTNE effects. These findings will contribute to the understanding of heat transport mechanisms in natural porous media and their relation to heat transfer coefficient and non-uniform flow.

Experimental investigation of formation damage potential during thermal water reinjection on Upper Miocene (Pannonian) sandstones from Szentes geothermal field, Hungary

Péter János KORONCZ[1]*, Doctoral School of Earth Sciences, University of Pécs
(pkoroncz@gamma.ttk.pte.hu)
János Kovács[2], Department of Geology and Meteorology, University of Pécs
Eszter Keresztény-Borbás[3], Doctoral School of Earth Sciences, University of Pécs
Ferenc Fedor[4], Department of Geology and Meteorology, University of Pécs

Abstract

Late Miocene sandstone formations in Hungary has been utilized for thermal water production for almost 150 years. Due to the intensive water production, pressure drawdown has increased in the geothermal systems. Although sustainable utilization would require the reinjection of cooled geothermal brine into the host formation, most of the geothermal sites suffer from reinjection issues. Despite of the high amount of production wells, formation damage processes during reinjection are less investigated and understood earlier.

To understand the link between formation damage mechanism and rock textural characteristics is crucial for a long-term water reinjection design.

In this study, it is aimed to characterize late Miocene friable sandstone reservoirs from Szentes geothermal field and investigate the formation damage potential of these formations.

Petrophysical interpretation of core data (porosity, permeability ultrasonic velocity, pore throat size distribution) was used to describe the physical properties of these reservoir sandstones. Grain size distribution, petrographycal thin section analysis and scanning electron microscope imaging were used to investigate textural and pore scale features (authigenic clay minerals) that can affect the permeability during the reinjection.

Laboratory core flooding experiments were performed on sandstone samples at reservoir conditions. The aim of these tests was the investigation of pore-clogging phenomena and subject long-term rock-water interaction.

Study of seasonal characteristics of near-surface geo-temperature obtained by long-term monitoring in Japan

Osamu MATSUBAYASHI[1]*, A.I.S.T. , Japan (o_matsubayashi@hotmail.com)
Hideki Hamamoto[2], Center for Environmental Science in Saitama

Abstract

The goal of our study is to help improve the performance of thermal energy utilization systems using ground source heat pump, by closely looking at near-surface geo-temperature changes as an environmental controlling factor for the energy extraction. Geothermal specialists including the present authors have jointly started to make long-term monitoring of 1m-depth geo-temperature at different sites in Japan (Ehara et al., 2021), and they have acquired data set of near-surface geo-temperature over a period up to 10 years. The initial purpose was to confirm the effect of global warming and/or heat island phenomena by the geo-temperature observations, while the high-frequency components should be attenuated and their daily change component automatically vanishes, in particular.

It is generally considered that the yearly change of near-surface geo-temperature may be explained by a sinusoidal periodicity basically (ex. Miyazaki, 2023). But we have a view that more detailed investigations could reveal some fundamental differences of the heat transfer mechanism which governs seasonal characteristics of near-surface geo-temperature among the seasons. In this work we divide our time-series data into four seasonal segments, i.e., spring, summer, fall and winter, to evaluate the relative intensity of different modes of heat transfer mechanism at/near the earth's surface for each of the segments. In spring and summer geo-temperature has a rising trend with time, whereas in fall and winter it has a falling trend, as we anticipated. But, those two trends are not symmetrical at all, as we found in this study.

So, we have compiled the season-average values of 1m-depth geo-temperature for consecutive years at our observation sites in Kanto Area, Japan, and found that the year-to-year variations in "summer" for most of the sites have a smaller standard deviation value comparing with other seasons. We interpret that this is caused by the effect of high bulk heat capacity in "summer" due to the contribution of enhanced latent heat by the presence of water on/near the ground surface. On the other hand, the ground surface is very dry in "winter" period, so that bulk heat capacity of the ground surface is generally substantially smaller than in "summer". The fact which we have found would help evaluate the near-surface geo-temperature behavior, especially when some practical geo-heat extraction systems with ground source heat pump are applied to a real field.

Application of play fairway analysis to identifying geothermal prospect areas in Sulawesi Island, Indonesia

Angga Bakti PRATAMA[1]*, Kyoto University (angga.pratama.84k@st.kyoto-u.ac.jp)
Katsuaki KOIKE[2], Kyoto University
Heru Berian PRATAMA[3], Kyoto University

Abstract

Numerous geothermal prospects exist in the Sulawesi Islands due to a variety of geological factors, plate subduction, seismic activity, and volcanic activity. However, development of the geothermal areas priority needs to be selected to acquire an effective and efficient development. This study aims to improve the accuracy and dependability of geothermal resource delineation using a Play Fairway Analysis (PFA) to identify areas suitable for geothermal resource development. This technique quantitatively assesses geothermal resources using geological data (surface geothermal manifestations, active faults, earthquakes, and volcanoes) combined with geophysical data, environmental-governance data, and expert judgment. In addition, potential heat source-related zones are estimated using data on surface manifestations and volcano locations. These heat source data are then combined with gravity and magnetic data to validate each other. The distributions of active faults and hypocenters detect the possibility of permeable zones that act as ascent fluid pathways. To provide factual identification of geothermal resources for development, the national parks and local government development plans were also considered. Furthermore, all the input data is integrated by normalization and weighting process. Finally, the highest potential areas are defined by high probability anomaly founded along the faults which located closed to the volcano and surface manifestation.

Incorporating Mineral Compositions in Shallow Wells into Multicomponent Geothermometer to Improve Reservoir Temperature Estimation in the Patuha Field, Indonesia

Brenda Ariesty Kusumasari[1]*, Kyoto University (brenda.kusumasari.e12@kyoto-u.jp)
Koki Kashiwaya[2], Kyoto University
Yohei Tada[3], Kyoto University
Koike Katsuaki[4], Kyoto University

Abstract

Geothermometry is known for determining reservoir temperature based on the following presumptions: (1) the fluid-mineral reaction reaches equilibrium, and (2) the fluid composition remains unchanged by near-surface reactions, mixing, or dilution. Restrictions on using geothermometry arise due to the constant occurrence of near-surface interactions, mixing, and dilution. This study aims to clarify the effectiveness of multicomponent geothermometry that considers potential surface processes for accurately estimating reservoir temperature. This technique uses a complete chemical study of water to estimate reservoir temperature more accurately. An evaluation technique for mineral selection is applied, aiming to achieve a more accurate estimation of reservoir temperature. One of the few vapor-dominated geothermal systems is the Patuha Geothermal Field (PGF) in West Java Province, Indonesia. The initial temperature value ranging from 180-260°C was obtained using basic multicomponent geothermometry computing, which automatically selects minerals assemblage from the thermodynamic database. This study later found that some of the automatically chosen minerals were not the best representative minerals. Therefore, minerals are manually selected and identified from the shallow wells at two points within the research area to evaluate the basic computing result. After this, the process demonstrates that quartz, andesine, albite, pyroxene, and muscovite are superior mineralogical assemblages. Using multicomponent geothermometry simulation, the reservoir temperature for the research region is estimated to be around 210°C. The comparable outcomes of solute and multicomponent geothermometry imply that both techniques can enhance one another rather than work against one another to produce a reservoir temperature estimate of the highest caliber.

The role of the upper crustal thermal structure in defining the global Golden Zone of hydrocarbons

Carlos Alberto Alberto Vargas[1]*, Universidad Nacional de Colombia (cavargasj@unal.edu.co)
Alejandra J. Angulo[2], Universidad Nacional de Colombia

Abstract

This study focuses on identifying hydrocarbon accumulation patterns of economic significance through the analysis of sedimentary sequences situated within a thermal range of 60 to 120°C, referred to as the "Golden Zone." Within this zone, there exists a conducive environment for the coexistence of petroleum system elements with minimal degradation or transformation of hydrocarbons generated from source rocks, particularly in the hydrocarbon expulsion zone ranging from approximately 120 to 200°C. To facilitate the delineation of regions with relevant hydrocarbon potential, we have developed global distribution maps of the Golden Zone. These maps are derived from a global geothermal gradient model, utilizing the Curie Point Depth (CPD) distribution, which is constrained by direct well temperature measurements, alongside a comprehensive model of sedimentary thicknesses compiled from data provided by various institutions. Our findings reveal significant variations in the distribution of the Golden Zone across different geotectonic settings. Depth intervals for the Golden Zone range from 500 to 3000 meters at the top and from 1000 to 5000 meters at the base, with thicknesses spanning from 5 to 3000 meters. Along active tectonic margins, sedimentary sequences tend to be thin, often displaying abrupt contrasts with the basement, and where one or both isotherms defining the Golden Zone lie beneath the basins, hindering optimal development. However, exceptions to this trend are observed in forelands and certain intermountain basins. In contrast, passive margins exhibit Golden Zone regions characterized by a wide range of sedimentary sequence thicknesses within basins of varying ages and extensions. This comprehensive mapping and analysis of the Golden Zone contribute valuable insights into hydrocarbon prospecting efforts, aiding in the identification of regions with significant economic potential for future exploration and development endeavors.

Turning point of geothermal resources development in the world

Yasukuni Okubo[1]*, Geothermal Energy Research & Development Co., LTD. (yasu-okubo@jcom.home.ne.jp)

Abstract

In descending order of geothermal installed capacity, the countries are US, Indonesia, Philippines, Turkey, New Zealand, Kenya, Mexico, Italy, Iceland, and Japan. Among these, Indonesia, Turkey and Kenya have been growing rapidly since 2010. In other countries, the growth in installed capacity has been slow. In particular, Japan is in a decline. The reasons are that it is difficult to develop a power plant in a national park and that there is a conflict with “Onsen”, a traditional tourism industry. Since the oil crisis in the 1970s, Japan has been promoting geothermal development. At the beginning, the potential was assessed using Curie point depth analysis. Following the success the Curie point depth analysis has become widely used around the world. Now Japan, to break away from stagnation, once again performs the Curie point depth analysis in order to develop a new type of power generation using supercritical CO2 and supercritical water. In the Kakkonda geothermal area, a strong reflector was discovered by seismic survey. A similar strong reflector was discovered at Larderello, Italy. Both are interpreted as an aggregation of fractures, where supercritical water resides. In non-volcanic countries such as Germany, which has begun geothermal power generation since 2000, binary cycle power generation is being actively developed, and its installed capacity is rapidly increasing. In Kenya, a large-scale geothermal power plant is developed in a national park where many natural animals live. As well as in Iceland, geothermal resources in Kenya are located on the divergent plate boundary. As geothermal resources are abundant, so further development is expected in the future. Surplus geothermal water and CO2 from geothermal wells are also used to grow flowers in greenhouses. This is a show case of integration of power generation, tourism and agriculture. Geothermal resource development faces a turning point. Going forward, we need to study the rapidly growing country, to develop new technologies, to utilize low-temperature hot water for binary cycle power generation and to promote integration with other industries such as tourism and agriculture.

Underground Resources and their Uses in the Energy Transition: Hydrocarbon exploration, geothermal energy, and natural gas, CO2 and H2 storage in the Polish Basin as a part of the Central European Permian–Mesozoic Basins.

JAROSLAW ZACHARSKI[1]*, Polish Geological Institute - National Research Institute (jzach@pgi.gov.pl)
ADAM WÓJCICKI[2], Polish Geological Institute - National Research Institute
RAFAŁ LASKOWICZ[3], Polish Geological Institute - National Research Institute
HUBERT KIERSNOWSKI[4], Polish Geological Institute - National Research Institute
MARIUSZ SOCHA[5], Polish Geological Institute - National Research Institute

Abstract

The European Union member states have adopted strategies to address climate change, including a gradual energy transition achieved by decreasing the share of fossil fuels to reduce manmade CO2 emissions. Such strategies promote the use of renewable energy sources (including geothermal energy) and natural gas as a low-carbon fossil fuel, as well as implementing CO2 and H2 storage (CCS/CCUS). Natural gas is also considered a source of blue hydrogen. In Poland, activities connected with the energy transition form part of government strategies and of geological and mining law, under which a framework for industrial-scale natural gas, CO2, and H2 storage is being implemented. It is also intended to serve the development of projects using geothermal energy. To fully utilise the available resources and storage potential, the studied area must be properly identified in terms of its geological structure, surface infrastructure, transmission pipelines, CO2 emission sources, social aspects, and environmental protection.

Poland currently has ten underground storage facilities, nine of which are used to store natural gas (working gas capacity: 3 bcm) and one used to store crude oil and other petroleum products. Seven were built using depleted hydrocarbon reservoirs and three in salt caverns.

In recent years, the Polish Geological Institute – National Research Institute (PGI-NRI) has conducted, coordinated, and participated in domestic and international research projects on the underground storage of natural gas, CO2, and H2, as well as on identifying opportunities for hydrocarbon exploration, and on the conditions for the development of geothermal energy in Poland. The most promising sites, including salt structures, working and depleted gas fields, and saline aquifers suitable for storing substances, have been identified in the Permian–Mesozoic formations located in western, northern, and central Poland.

This part of Poland is also known, as one of the best areas for the production of hydrocarbons (the south-eastern part of the Southern Permian Basin) and as an optimal area for the development of geothermal energy for both heating and recreational purposes (Mesozoic formations).

For these reasons, multi-energy firms have recently considered the development of new energy storage facilities in such locations, which PGI-NRI identified.

However, when conducting exploration work to use underground geological structures optimally, energy firms aim to minimise the technical and geological risks. Research currently conducted at PGI-NRI enables the identification of various possibilities for the use of underground structures

and resources, which is particularly relevant in the design and planning of works, especially in the Polish Basin.

PTA and TTA the fundamental difference in Geothermal prospect well test

Fathia ABDI ATTEYE[1]*, L'Office Djiboutien de Développement de l'Energie Géothermique (ODDEG) (fathiaabdiatteye@gmail.com)

Abstract

After completion and during exploration drilling, geothermal wells are subject to well testing. The objective of well testing is to determine the wellbore production capacity and condition. Well testing essentially include pressure and temperature logging of the wellbore. The data are then subject to analysis and interpretation. Pressure Transient Analysis (PTA) is the analysis of pressure of the well. For decades Pressure transient analysis has been considered as the most effective way for diagnosing a well situation. A new tool being currently developed is the Temperature transient analysis (TTA), also make diagnosis of the well condition. A Geothermal well test comprise three test, multi injection rate, pressure fall off and pressure build up. During multi injection the injectivity index is calculated from the pressure vs flow rate. This value give us an insight to the well productivity hence permeability. In the pressure fall off when there is no more fluid injection into well then the pressure suddenly falls. From the pressure fall off trend we can apply analytical graphical method to know the current reservoir condition. This is done by analyzing pressure change linearity with the logarithm of time. This association help identify parameters such as transmissivity, permeability, reservoir initial pressure, skin factor. This paper will be exploring the fundamental difference between PTA and TTA and how to use TTA to determine the reservoir parameters similarly to PTA.

Combination of Fuzzy Logic and Geostatistics for Detecting Potential Zones of Geothermal Resource over Java Island, Indonesia through Multi-Sensor Satellite Image Data

Tedi Atmapradhana[1]*, Kyoto University (tedi.atmapradhana.83a@st.kyoto-u.ac.jp)
Tedi Atmapradhana[2], Kyoto University
Asep Saepuloh[3], Bandung Institute of Technology
Koike Katsuaki[4], Kyoto University

Abstract

Indonesia, situated within the dynamic tectonic confines of the Ring of Fire, boasts a wealth of geothermal potential. However, the current total capacity of geothermal power plants is still limited. To increase the use of geothermal resources needs a cost-effective and accurate resource exploration technique. Thus, this study endeavors to refine our understanding of geothermal potential by employing a novel approach combining Weighted Fuzzy Logic (WFL) and geostatistics, termed Fuzzy Ordinary Kriging (FOK). Through this methodological fusion, we aim to detect and delineate areas with high geothermal potential. The datasets harnessed in this methodology encompass a diverse range of sources, including multisensor image data from Landsat 8 Operational Land Manager (OLI), nocturnal thermal data from ASTER Thermal Infrared Sensor (TIRS), as well as geophysical data such as aeromagnetic and gravity data, alongside mineral spectral data taken from field measurements. The analysis of ASTER TIR thermal imagery contributes to estimating the land surface temperatures, while Landsat 8 data, specifically bands 3, 4, 5, 6, and 7, facilitates the assessment of vegetation condition using the Vegetation Index Considering Greenness and Shortwave Infrared (VIGS) algorithm. Furthermore, aeromagnetic data aids in discerning the magnetic properties of rocks around volcanic formations, while gravity data is instrumental in identifying the Bouguer anomalies over the study regions. Based on the FOK, the highest potential areas are located in the western part of the island, around Mt. Gede, and a part of the eastern regions, around Mt. Arjuna. Some anomalies are also detected in the island's northern part around Mt. Muria.

Carbon emission reduction: Contribution of geothermal energy and practice in China

Liqiong JIA[1]*, Development and Research Center of China Geological Survey (jialiqiong1225@163.com)

Abstract

As a kind of natural energy from the earth's interior, geothermal energy is characterized by large reserve, wide distribution, good stability, high utilization coefficient, and positive effects of energy-saving and emission-reduction. It is of great significance for promoting green and low-carbon energy transition, reducing greenhouse gas emission, and achieving global climate goals and sustainable economic development. The potential of the global geothermal energy resource is estimated to be 1.25×10^27 J, equivalent to 4.27×10^16 t of standard coal. As a country with abundant geothermal resources, China accounts for about one-sixth of the global total. Shallow geothermal resources are widely distributed, especially concentrated in the central and eastern areas (including Beijing City, Tianjin City, Hebei Province, Shandong Province, Jiangsu Province, Anhui Province, Henan Province, Shaanxi Province) and some northeastern areas. The annual exploitable amount in over 336 cities at or above the prefecture level is approximately equivalent to 700×10^6 t of standard coal. 80% of the land in these areas are suitable for utilizing shallow geothermal energy and could be able to provide a cooling area of 32.575×10^9 square meter in summer and a heating area of 32.268×10^9 square meter in winter for building . Hydrothermal geothermal resources are mainly distributed in twelve large and medium-sized sedimentary basins, such as the North China Plain, Songliao Plain, and Sichuan Plain. The geothermal resource is equivalent to 1.02×10^12 t of standard coal and the annual exploitable amount is equivalent to 1.7×10^9 t of standard coal. Hydrothermal geothermal resources are relatively few in the uplift mountain areas. The high-temperature geothermal resources in the mainland are mainly distributed along the intensive hydrothermal activity zone, the southern Tibet-western Sichuan-western Yunnan region. The power generation potential of those high temperature resource is 7120 MW, accounting for 84.1% of the national total. The hot dry rock resource in China has huge potential and is considered to be the main direction for future geothermal exploration and development. It is estimated that the resource potential of the hot dry rock at a depth between 3 km and 10 km in the mainland is 2.5×10^25 J, equivalent to 856×10^12 t of standard coal. Calculated on 2% of exploitable resources, the exploitable heat energy from hot dry rock is equivalent to 17.2×10^12 t of standard coal. China's direct utilization of geothermal energy has consistently ranked first in the world for many years. By the end of 2021, the installed capacity for geothermal direct utilization had been equivalent to 100.2 GW and the total annual energy use had exceeded 820 PJ. The heating (cooling) area exceeded 1.33×10^9 square meter. According to the official targets set by National Energy Administration, by 2025, the heating (cooling) area of geothermal energy in China will increase by 50% and the installed capacity of geothermal power generation will double compared to 2020. By 2035, the heating (cooling) area and installed capacity will double

compared to 2025. It is expected that geothermal energy will play a more and more important role in contributing to the global sustainable development.

Colombia's natural hydrogen potential: first exploration insights

Valeria RAMIREZ JUYA[1]*, Ghent University (valeria.ramirez@ugent.be)
Felipe Gonzalez Penagos[2], Atlas Research Group
Alejandra Carrillo Ramirez [3], University of Pau
Isabelle Moretti[4], UPPA-LFCR

Abstract

The global energy landscape has been dominated by fossil fuels for several decades. Nonetheless, the world is currently routed on research on clean and sustainable energy sources including hydrogen. Most of the investigations have been focused on H2 from hydrocarbons (gray and blue H2) and water (green H2), besides, the discovery of substantial natural hydrogen gas reservoirs could represent a lucrative opportunity for the hydrogen economy.

In the particular case of Colombia, a geologically diverse country, there is a great potential for hydrogen accumulation in regions such as the ophiolites in the western Cordillera, characterized by the rich composition of Fe and Mg plus the proximity with the volcanic complexes of the central Cordillera which displays surface emissions of gases, hydrothermal fluids and intrusive igneous formations beneficial for fluid-rock interaction.

Colombia's numerous sedimentary basins, including the Cauca-Patía and Chocó, present an intriguing potential for hydrogen accumulation, including the Putumayo foothills with high concentrations of CO2 in wells and an increased 3He/4He ratio in the eastern foothills, indicating potential hydrogen presence. However, due to their status as border areas, there is limited foundational information for initiating research.

The regional geology of the Northern Andes, including the Romeral (western flank of the Central Cordillera) and Dagua (Western Cordillera) terrains, features basaltic rocks, tholeiitic MORB-affiliated complexes, mafic-ultramafic formations, and ophiolitic sequences. Complex fluid circulation related to hydrothermal systems, fumaroles, and intrusions along the Cordillera within the Pacific subduction tectonic framework further enriches the continent. High-pressure reactions in subduction zones could be the origin of potential natural hydrogen and abiotic methane generation, especially in the deeper depths associated with serpentinization processes. Current models lack deeper sources of H2 and CH4 abiotic, emphasizing the need for further research.

Aiming to start exploration of H2 in Colombia, the ophiolites were selected to make the first approximation of soil gas measurements. The zone of study is geologically composed of Ginebra ultramafic complex, Amaime formation, Ginebra Amphibolite, and the thrusting regime of the Guabas-Pradera fault system. The data collected showed high concentrations of H2, especially over the fault trace, surpassing 1000 ppm. This groundbreaking discovery confirms the presence of natural hydrogen emissions in the country and opens the door for future in-depth studies.

Abstract

The new model of economic development linked to the fourth industrial revolution and the need to achieve the objectives of containment of climate-altering emissions is determining a massive and continuously growing demand for mineral resources essential for the creation of green technologies and for the carbon footprint reduction. The growth in demand has given rise to an international race to acquire them, generating political and economic conflicts. The need for the supply of mineral resources is highlighting the critical aspects both fort the whole European and Italian industry, essentially linked to the strong dependence on imports. In this period, issues relating to mineral raw materials, in particular those considered critical/strategic, are at the top of the political agendas throughout the world, clearly reiterating what has characterized the entire history of humanity: who holds the ownership of raw materials holds the power. Based on this awareness, the EC declared its concern about raw materials and developed the regulation proposal for the safe and sustainable supply of critical raw materials, the so-called Critical Raw Materials Act (CRMA) which will come into force before summer of 2024. The CRMA will also oblige member states to undertake specific actions to achieve strategic targets aimed at reducing dependence on foreign markets. Among these, the development of the National Mining Plan for the definition of the mining potential of each Member State and the characterization of extractive waste deposits, including abandoned ones. The waste deposit may represent potential new deposit of critical and non-critical resources, which could be reused in a circular economy perspective. Italy has an important mining history, which began in pre-Roman times. Due to economic policy choices, the activity relating to the extraction of metal minerals ended by the end of the last century. This caused the decline of university education and loss of knowledge and training and lifelong learning of mining industry professionals. The closure of the most profitable mines, accompanied by the abandonment of large mineral research projects, also led to a rapid decline in interest in the whole value chain from university education, with the progressive closure of degree courses in Mining Engineering and in Geology of Mineral Resources, till the removal of large companies in the sector. ISPRA Geological Survey Dept., as part of the National Critical Raw

Materials WG (created in January 2022), is already preparing to address the new challenges imposed by the ecological and digital transition. In Italy as in Europe, the first action to be undertaken is the cultural one, dispelling three false myths such as the absence of critical strategic materials in the old continent, the passed vision that sees mining activity as always associated with environmental damage and disaster and the certainty that recycling and recovery can be sufficient to meet the growing demand for CRMs without which no green and blue transition will ever be possible. The aim of this work is to illustrate and start the debate on new paradigm of sustainable and ethical mining as a future model of development.

Research on the Effect of Pressure on Thermal Cracking of Immature/Low Mature Source Rocks

Fengtian BAI[1]*, Jilin Univerisity (baift@jlu.edu.cn)
Wei Guo[2], Jilin University
Youhong Sun[3], China University of Geosciences

Abstract

The effect of pressure on thermal cracking of source rocks has been investigated on different pressure using two typical immature/low-maturity hydrocarbon source rock (oil shale) samples from China. The thermal pressure simulation experiments were carried out through a cyclic heating method. With inert gas and water as the pressure transmission medium, three experimental conditions were studied: no water and no pressure, low water pressure (300 bar), and high water pressure (500 bar). A systematic organic geochemical study of the simulation experiment products was carried out, and the hydrocarbon generation characteristics of immature/low-maturity hydrocarbon source rocks at different evolution stages were obtained. The dynamic thermal cracking characteristics of hydrocarbon source rocks from immature/low-maturity to maturity to high maturity under pressure conditions were discussed. The results show that with the increase of thermal evolution degree, the maturity of the source rock (oil shale) gradually evolves from immature/low mature to mature to high mature, and the gas production of the sample gradually increases and reaches the maximum at the high mature stage, and liquid hydrocarbon production shows a trend of first increasing and then decreasing, and reaches the maximum at the mature stage, and the quality of the liquid hydrocarbon continues to improve, and the quality of the liquid hydrocarbon continues to improve, and the main peak carbon moves forward and the high carbon long chain hydrocarbons break continuously to form short-chain hydrocarbons, and the odd carbon advantage of medium high carbon number nC21~nC31 gradually weakens, and the hydrocarbon generation potential of the source rock gradually decreases. The influence of pressure on hydrocarbon generation and cracking is shown in the inhibition of volume expansion reaction, and the influence on the maturation process is shown in the inhibition of demethylation and dehydrogenation aromatization of organic matter structure. The pressure has little effect on the gas yield of immature low mature source rock (oil shale) samples, but will significantly inhibit the gas yield of low mature high mature samples. The increase in pressure can promote the generation of liquid hydrocarbons in the pyrolysis system of source rocks. The total production of liquid hydrocarbons in Huadian and Fushun samples increases with the increase of pressure, especially in the low evolution stage, the greater the pressure, the more significant the promotion. We hope this study can provide theoretical support for the hydrocarbon generation mechanism of shale oil, shale gas, and conventional oil and gas.

Oxidative pyrolysis characteristics and kinetic analysis of low-medium maturity organic rich shale

Sunhua DENG[1]*, Jilin university (denghua13@163.com)
Dongxue Yu[2], Jilin university
Wei Guo[3], Jilin university
Chaofan Zhu[4], Jilin university

Abstract

Organic-rich shale is abundant in China and holds potential as a supplementary energy source for conventional oil and gas. In-situ oxidation conversion technology is expected to enable large-scale development of this resource. This paper systematically investigates the oxidative pyrolysis behavior and kinetic characteristics of organic-rich shale with varying degrees of maturity under an air atmosphere, utilizing thermogravimetry-Fourier transform infrared spectroscopy.

The findings indicate that as the shale matures, the initial oxidative pyrolysis temperature of the organic matter decreases. However, at a medium maturity level, the expulsion of hydrocarbons reduces the content of organics inside the sample, which hampers the oxidation-assisted pyrolysis process. Consequently, there is a decrease in oil and gas yield and an increase in coke formation, leading to a corresponding decline in combustion performance. The oxidative pyrolysis kinetics of low-medium maturity organic-rich shale are calculated using the Friedman, Ozawa Flynn Wall (OFW), and Kissinger Akahira Sunose (KAS) methods. The results demonstrate that an increase in the degree of organic matter maturation effectively reduces the activation energy of organic matter oxidative pyrolysis reactions in low maturity shale. Similarly, once the organic matter reaches a medium maturity level, the activation energy of the oxidative pyrolysis of shale shows an increasing trend.

This study sheds light on the influence of organic matter maturation on the oxidative pyrolysis behavior of organic-rich shale. It aims to provide a theoretical foundation for the in-situ development of low-medium maturity organic-rich shale.

Design and simulation of a high-efficiency cooling system for high temperature drilling fluid

Rui JIA[1]*, Jilin University (jiarui@jlu.edu.cn)
Siyuan SUN[2], Jilin University
Haoxin FENG[3], Jilin University
Yihang KOU[4], Jilin University
Gege TANG[5], Jilin University

Abstract

Under the guidance of the goal of achieving carbon peak and carbon neutrality, the development and utilization of geothermal resources have been increased; at the same time, oil and gas drilling is developing towards deeper areas with the increasing demand for oil and gas resources in China's social development. These have led to increasingly prominent high-temperature issues faced by drilling fluids. Due to the large depth of deep oil and gas drilling and the high geothermal gradient in geothermal drilling, the bottom hole temperature may exceed 200 ℃, causing the temperature of the drilling fluid to exceed 180 ℃ after circulation. Continuous high temperature can deteriorate the mud performance, affect the service life of downhole mechanical drilling tools and underground instruments, reduce drilling speed, and pose a threat to the safety of drilling operations. Therefore, during deep oil and gas drilling and geothermal well excavation, timely cooling of the drilling fluid and reaching a suitable temperature is essential for drilling safety. Our research summarized the commonly used methods and characteristics of the current frequently-used high temperature drilling fluid. In regard to the energy-saving characteristics of air cooling and the advantage of high cooling efficiency of the coolant with forced cooling, a high-efficient cooling system for high temperature mud has been put forward. The air cooler and the tube and shell heat exchanger in the cooling system have been designedchecked and simulated, and the reliability of the design has also been verified. As a result, the high-temperature drilling fluid with an initial temperature of 80 ℃ and a flow rate of 1800 L/min can be cooled below 40 ℃. Compared to directly performing forced cooling on high-temperature drilling fluids, it saves 60.7% of energy consumption. At the same time, the cooling effect of the cooling system has also discussed at different drilling fluid temperatures, flow rates, and air temperature conditions. The results showed that as the initial temperature of the drilling fluid entering the cooling system increased or the flow rate decreased, the temperature difference between the inlet and outlet of the cooling system increased, demonstrating an improvement in cooling capacity, with the air cooler playing a more significant role. When the drilling fluid temperature or the flow rate is too high (drilling fluid temperature exceeds 90 ℃ or flow rate exceeds 2200 L/min), the selected parameters of the cooling system designed in this article cannot meet the requirements, and it is necessary to add equipment or adjust equipment parameters in the cooling system. As the temperature rises, the outlet temperature of the drilling fluid increases linearly, and the temperature difference between the inlet and outlet gradually decreases. The cooling capacity of

the cooling system decreases, mainly due to the rapid decrease in the cooling effect of the air cooler. The cooling capacity of the shell and tube heat exchanger gradually increases. When the temperature reaches 40 ℃, the shell and tube heat exchanger plays a dominant role.

Projection of natural gas demand in China based on a hybrid model from sector perspective under carbon-neutral strategy

Xiaoqian GUO[1]*, CAGS (xiaoqianGuo88@163.com)

Abstract

As a main substituted clean energy, natural gas is regarded as the main transition energy under the carbon-neutral strategy in China. In recent years, natural gas consumption in China has kept a 7% increasing rate and the projection of natural gas demand has received significant attentions for China's energy policymakers with the rapid increasing external dependence. A series of numerous theoretical and empirical analyses around the world focus on energy demand causal analysis and projection analysis. However, these causal analysis model and projection model are separated in most of the studies. In this research, we established a hybrid model to analyze the influencing factors and future demand together for natural gas in China. Firstly, causal analysis was adopted to investigate influencing factors for three main consumption sectors, including Industrial, Residential and Transport. According to the unit root tests and co-integration test, 6 factors with a closely relationship with natural gas consumption are chosen, including resident consuming level, urbanization, industrialization, per-capita GDP, GDP of transport and natural gas vehicle number. Then, grey model and regression analysis were combined to make projection based on the chosen factors for each sector. And the natural gas demand is 100.3, 340.7 and 44.3 billion cubic meters for Residential, Industrial and Transport sector, respectively, and the total natural gas demand for China is 581.86 billion cubic meters in 2030. Besides, two specific policy recommendations were put forward for nature gas in China: (1) As the biggest demand sector, technological innovation and structure optimization are necessary for Industrial sector to improve the natural gas utilization efficiency; (2) Infrastructure construction of natural gas is still important for Residential sector with the increasing sector consumption.

Magnetite powder as an enhancer in biogasification of phenolic pollutants

Minjae KIM[1]*, Pukyong national university (alswo274@pukyong.ac.kr)
Juyun Lee[2], Pukyong national university
Seonmin Kang[3], Pukyong national university
Joonyeob Lee[4], Pukyong national university

Abstract

Hydroquinone is a representative phenolic pollutant produced from various industrial organic wastewaters, such as those from coal gasification, chemical processes, and refining. Due to its toxicity, proper treatment of hydroquinone wastewater (HW) is necessary before its release into the environment. Anaerobic digestion presents a promising carbon neutral technology for treating organic waste and wastewater, achieving simultaneous reduction of organic pollutants and generation of energy-rich biogas. However, high-rate anaerobic digestion of HW poses challenges due to thermodynamic limitations on anaerobic hydroquinone degradation and inhibition of methanogenesis by hydroquinone.

Magnetite is recognized as one of the major types of naturally occurring iron ore on Earth. Magnetite powder (MP) can be derived from iron ore and recovered from waste such as steel slag through hydrothermal treatment. MP can act as a mediator, accelerating electron transfer between anaerobic bacteria and methanogenic archaea in anaerobic digestion. The addition of MP has the potential to be an effective strategy for enhancing the anaerobic digestion of HW, but relevant research on this topic has been seldom reported.

Thus, this study conducted sequential batch experiments with and without MP to investigate the effects of MP addition on anaerobic digestion of hydroquinone, focusing on anaerobic hydroquinone degradation and methane production. Results demonstrated that anaerobic degradation of hydroquinone was significantly improved in the MP-added reactors, with methane production rates in the MP-added reactors increasing by 238% compared to the control reactors. Further details will be presented in the conference.

This research was supported by Learning & Academic research institution for Master's, PhD students and Postdocs (LAMP) Program of the National Research Foundation of Korea (NRF) grant funded by the Ministry of Education (RS-2023-000301702). A spectroscopic assessment of the microstructural evolution in a suite of Indian coals and their potentiality for energy storage applications

Archchi Sarkar[1]*, Pandit Deendayal Energy University (sarkar.archchi@gmail.com)
Rincy Anto[2], Pandit Deendayal Energy University
Uttam Kumar Bhui[3], Pandit Deendayal Energy University
Sudip Bhattacharyya[4], Geological Survey of India

Abstract

The need for efficient energy conversion technologies and storage systems is being driven by the growing need for clean energy with little environmental effect. Coal being a cheap and plentiful source of carbon and carbon-based products, may offer a workable option for long-term, sustainable use in a variety of areas of human civilization. The key to producing various carbon-based nanomaterials is to chemically modify the crystallites present naturally in coals. In order to produce these next-generation biomaterials, it is also crucial to properly delineate the chemical moieties in coal, as the carbon concentration of coal changes with different rank. In the present study, an attempt has been made to understand the evolution of the macromolecular structure in a suite of Indian coals based on the characterization of their bulk and solvent-extracted compositions and their potential applications in the development of energy harvesting and storage systems, using the help of different spectroscopic techniques viz. FT-IR, UV-Visible and Total Synchronous Fluorescence spectroscopy (TSFS), and XRD analysis. Background-subtracted X-Ray Diffractograms exhibited an increment in the intensity of characteristic 002 band (indicated by a decreasing FWHM), which is consistent with the intensity of the coalification process and demonstrated by their corresponding vitrinite reflectance (VR) values. The lattice parameters indicate that lower rank coals are structurally less ordered than higher rank coals investigated in the study. The bulk and solvent-extracted compositions of the coals were determined using spectroscopic techniques, revealing the presence of different polycondensed aromatic ring structures, and their potentiality for energy storage has been discussed in accordance with their corresponding ranks. It was also observed that inorganic impurities present in the coal samples have minor effect on the efficiency while structural parameters are the major contributors on the potential properties in battery application.

Characterization of pore structure in semi-deep and deep lacustrine tight sandstones: A case study of the Triassic Chang 6 in Longdong area, Ordos Basin, NW China

Taping He HE[1]*, 710233010@qq.com (b22010021@s.upc.edu.cn)
Yaoqi Zhou[2], zhouyq@upc.edu.cn

Abstract

In recent years, tight oil, an important unconventional oil and gas resource, has become a research hotspot of global oil and gas exploration. The typical representative of the tight oil reservoir is the Chang 6 reservoir of the Yanchang Formation in Ordos Basin. Its lithology is tight, and the pore throat is small and complex, making it difficult to describe the microscopic pore throat characteristics. Under the influence of pore throat structure, tight sandstone reservoir seepage characteristics are also more complex, which is an important factor affecting oil and gas exploration and development. Therefore, how to effectively characterize the microscopic pore throat characteristics of tight sandstone reservoirs is a key issue in the study of unconventional oil and gas resources. To clarify the characteristics and influencing factors of Chang 6 reservoir in this area, the rock mineral composition, diagenesis, and physical properties of Chang 6 tight sandstone in the Longdong area of Ordos Basin were studied utilizing rock core photos, casting thin sections, field emission scanning electron microscope, high-pressure mercury injection and constant rate mercury injection, and the influence of diagenesis on pore throat was qualitatively analyzed. The results show that deep-water gravity flows mainly developed three types of sediments: sandy debris flows, turbidites, and seismic slide deposits. The reservoir pore types are mainly residual intergranular pores, dissolution pores, and micropores. The pore throats are mainly distributed in the range of 0.004-100 μm, less distributed less than 0.1 μm, and more than 1 μm. The pore radius of each sample is concentrated between 60-348 μm. The throat radius of each sample is dispersed between 0.12-1.5 μm, and the roaring type is fine-micro roar type, showing strong heterogeneity. The throat mainly controls reservoir permeability, and the proportion of small throat increases with the decrease of permeability.

Two decades of research on injection-induced seismicity: What have we learned?

David EATON[1]*, University of Calgary (david.w.eaton@ucalgary.ca)

Abstract

Injection-induced seismicity – earthquakes triggered by anthropogenic fluid injection into the subsurface – has been well documented for over half a century, including associations with hydrocarbon production. Yet, the past two decades have witnessed an explosion of research on this topic, commencing with seminal work on the relationship between injection, pore-pressure diffusion and induced seismicity. At about that time, it was recognized that induced seismicity poses a serious risk for enhanced geothermal systems (EGS), leading to the introduction of traffic-light systems for use as reactive-control protocols for operations. In the early 2010s, growing realization of the scale and scope of induced seismicity linked to massive saltwater disposal (SWD) in the U.S. midcontinent provided the impetus for considerably expanded research activity. Scientific debate ensued over the potential for hydraulic fracturing, as well as gigatonne-scale carbon capture and storage (CCS), to trigger felt earthquakes. In the case of hydraulic fracturing, it is now well established that the risk of induced seismicity is real, with notable published examples in North America and China. Basic screening tools have been developed, and widely deployed, to aid in the assessment of fault slip potential, but exhaustive mapping of potentially seismogenic fault systems remains a challenge even using modern 3D seismic data. Building on advancements in artificial intelligence, the seismological community has adapted machine learning methods for use in basic processing of continuous data from seismograph networks as well as to test hypotheses for intrinsic geological susceptibility to fault activation to better explain the patchy nature of seismic activity in unconventional hydrocarbon fairways. There have been debates about the relative importance of various triggering mechanisms, such as direct pore-pressure effect on fault strength, as well as variations in poroelastic stress that modify fault loading conditions. Out of this has emerged a recognition that slow (aseismic) fault slip could also play an important role. Vigorous scientific debates have focused on controls on the magnitude of injection-induced earthquakes, such as net injected volume and injection rate.

What have we learned from the past several decades of research, and what challenges remain? In situ measurements of pore pressure using downhole gauges have reasserted the importance and large spatially extent, of elevated pore pressure within disposal zones. Traffic light systems have been widely adopted by regulators, but with remarkable inter-jurisdictional variability in response thresholds. The advent of risk-based and adaptive approaches for traffic light systems offers significant promise. New monitoring methods, including satellite interferometric synthetic aperture radar (InSAR) and distributed acoustic sensing (DAS), are promising approaches for the detection of aseismic processes that could be important, including for related hazards such as casing deformation. In the context of the energy transition, the advent of competing uses for pore

space arising from growth of EGS, CCS, SWD and extraction of critical minerals from brines, poses challenges for understanding cumulative effects of these operations for induced seismicity.

Applications of low-field NMR techniques in CO2 sequestration in hydrocarbon reservoirs

Yanbin YAO[1]*, China University of Geosciences, Beijing (yyb@cugb.edu.cn)
Hao Wu[2], China University of Geosciences, Beijing
Chao Cui[3], China University of Geosciences, Beijing
Pengwei Mou[4], China University of Geosciences, Beijing

Abstract

Developing effective novel methods is crucial for global-scale carbon storage. One potential approach involves injecting CO2 into deep subsurface formations like oil and gas reservoirs. This solution is not only capable of reducing CO2 emissions, but also enhancing hydrocarbon recovery through effectively displacing oil and gas by CO2. However, some challenges need to be addressed when implementing CO2 storage in hydrocarbon reservoirs. These challenges include: 1) insufficient reservoir data, particularly regarding reservoir properties; 2) a lack of understanding of the short-term and long-term interactions between CO2 and reservoir rocks and fluids; 3) the integration of CO2 storage and enhanced hydrocarbon recovery. To overcome these research obstacles, it is crucial to conduct a comprehensive and accurate assessment of reservoir and caprock properties, as well as continuously monitor the dynamic interactions of fluids after CO2 injection. In recent years, Nuclear Magnetic Resonance (NMR) has emerged as a valuable and non-destructive experimental technique for studying hydrocarbon reservoirs. Numerous researchers have utilized NMR technology to comprehensively analyze various aspects of reservoir pore-fracture systems, and the presence and distribution of water and hydrocarbons in reservoirs. Overall, NMR technology holds immense potential in the study of CO2 geological sequestration and enhanced hydrocarbon recovery. It offers an efficient, accurate, economical, and sustainable method for monitoring CO2 sequestration processes, playing a vital role in understanding CO2 storage in hydrocarbon reservoirs. However, it is important to acknowledge that NMR technology still faces challenges, and future research should focus on addressing these issues and refining and promoting its application.

Advancements in the Exploration and Production of Coal-Associated Unconventional Natural Gas in China: Geological Insights and Technological Innovations

Dameng LIU[1]*, China University of Geosciences Beijing (dmliu@cugb.edu.cn)

Abstract

The global coal-associated unconventional natural gas (CAUNG) resources are widely distributed in Russia, Canada, China, the United States, and Australia etc. China has huge amount of CAUNG resources, mainly distributed in the Ordos Basin, Qinshui Basin, and Zhungeer Basin, which is an important foundation for promoting the development of clean energy and economics. In this paper, firstly, the sedimentary and basic geological characteristics of coal-associated reservoirs is summarized; the geochemical characteristics and gas-bearing research status of coal-associated reservoirs is discussed; the symbiotic combination mode and reservoir forming elements of coal-associated reservoirs is studied. On this basis, the geological genesis of stacked CAUNG systems and block scale CAUNG enrichment theory are summarized, and a comprehensive analysis technology system for multiphase fluids in CAUNG reservoirs based on the synergy of multiple technologies such as nuclear magnetic resonance (NMR) is summarized. Thirdly, the differential fracturing technology system based on the fracturability of CAUNG reservoirs is evaluated; the dynamic change prediction technology of permeability in CAUNG reservoirs is analyzed; the evaluation and prediction methods for favorable areas of CAUNG reservoirs are summarized. On the basis of summarizing the current research status, the main scientific problems that urgently need to be solved in the field of CAUNG in China are proposed: (a) The CAUNG migration and accumulation effect and the geophysics-based fine description technology; (b) co-development compatibility evaluation for stacked CAUNG and multiphase fluid characterization method; (c) Geological control factors for high-quality CAUNG layers and optimal selection of favorable areas. The resolution of these issues will be conducive to further promoting the development of geological theory and the efficient development and utilization of CAUNG resources in China.

Effect of intraformational mudstone on CO2 plume migration and distribution: Insights from Sleipner geological storage project

Huixing ZHU[1]*, Jilin University (zhuhx@jlu.edu.cn)
Tianfu Xu[2], Jilin University
Hailong Tian[3], Jilin University

Abstract

Stratification of strata is commonly observed in geological formations. For instance, sandstone reservoirs, which are frequently used for CO2 geological storage, often exhibit the presence of low permeable interlays such as mudstone or shale. However, existing numerical simulation studies tend to overlook the impact of these intraformational mudstone layers on the migration of CO2 plume, thereby compromising the reliability of simulation results. One of the primary reasons for this oversight is the limited exploration accuracy at most sites, which hinders the identification and accurate characterization of these mudstone interlayers within the sandstone. The Sleipner CO2 geological storage project, as the world's first commercial endeavor in this field, has conducted comprehensive geophysical exploration work that includes a detailed characterization of formation structure and CO2 plume migration. This project presents an exceptional opportunity to investigate and address this issue. The exploration results indicate that the sandstone reservoir at this site has a thickness exceeding 200 meters and is compartmentalized into nine sub-reservoirs by eight layers of thin mudstone, each with a thickness ranging from 1 to 2 meters. Additionally, within the thin mudstone, there exists localized permeable zones known as "feeders", which serves as conduits for CO2 migration towards the shallower region. To quantitatively investigate the influence of intraformational mudstone on the migration and distribution of CO2 plume, a geological model was constructed based on the latest Sleipner benchmark model, and the multiphase flow simulator TOUGH2 (ECO2N module) was invoked for simulation purposes. The simulation results demonstrate that the presence of thin interlayer mudstone and feeders exerts a significant influence on the spatial distribution of CO2 plume. Specifically, the combination of multiple thin layers of mudstone and "feeders" enhances the vertical homogeneity of CO2 distribution, thereby preventing its confinement to the injection horizon observed in the scheme solely comprising thin mudstone layers. Moreover, it prevents CO2 accumulation at the top of reservoir due to buoyancy effects as seen in the scheme lacking thin mudstone layers, consequently ensuring optimal utilization of middle and lower reservoir spaces. This comprehensive exploitation of vertical reservoir space effectively restricts horizontal migration range for CO2, thus minimizing potential leakage along concealed faults. Moreover, the presence of thin mudstone layers mitigates the pore pressure buildup at the interface between the top sandstone reservoir and the overlying mudstone cap, thereby ensuring the integrity of the primary cap and enhancing storage security.

Minhee LEE[4], Major of Environmental Geosciences, Division of Earth Environmental System Science, Pukyong National University

Abstract

Geological sequestration of carbon dioxide (GSC) is one of practical carbon capture and storage (CCS) technologies, having minimal adverse side effects. Research and technology development for the GSC is critical to improving the CO2 injection efficiency and increasing the storage capacity in geological CO2 reservoirs, particularly for countries with high CO2 emissions and limited storage sites. In this study, laboratory scale experiments were performed to evaluate the effect of the surfactant on the supercritical CO2 (scCO2) storage ratio increase in the storage formation under practical subsurface conditions.

For experiments, the stainless-steel column (diameter: 4.5 cm; height: 10 cm) packed with glass beads (diameter: 0.1-1.5 mm) was prepared to simulate the porous media of the CO2 storage formation. The column's pore spaces was saturated with distilled water or a nonionic surfactant solution (Tween 80: polyoxyethylene (20) sorbitan monooleate) and the scCO2 was injected into the column at the CO2 storage conditions (high temperature and pressure). The scCO2 storage ratio in pore spaces of the column was determined by measuring the amount of remaining scCO2 in pore spaces after the scCO2 flow in the column. Surfactant in pore water may affect the scCO2 storage ratio in porous media by changing interfacial tension, contact angle and viscosity in the pore water-scCO2 (two-phase system). Laboratory experiments were performed to identify these property changes in a two-phase system and to quantify the correlation between the property change and the scCO2 storage ratio change. The stainless-steel high-pressure reactor vessel (diameter: 6 cm; height: 6 cm) was saturated with distilled water (or surfactant solution). The scCO2 was injected into the reactor vessel under the actual CO2 storage conditions. The interfacial tension between the scCO2 and solution was measured by using the pendant bubble method. The contact angle between the scCO2 and solution at the boundary on the glass plate was measured by using the captive bubble method and the viscosity of the solution was measured by using a viscometer (CAS, CL-L2).

The scCO2 storage ratio showed an average improvement of over 50% as the surfactant concentration in pore water increased, compared to the distilled water-saturated column. As the pore pressure of the scCO2 was increased from 8 MPa to 20 MPa, the scCO2 storage ratio in the column's pore spaces was increased by over 20-30%. The interfacial tension decreased by over 50% due to the increase of surfactant concentration (0 to1.0 wt%). The contact angle increased by over 20% with the increase of surfactant concentration. From this study, the effect of the

surfactant on the scCO2 storage ratio in a two-phase system under practical subsurface storage conditions was quantitatively investigated, obtaining the correlation between the hydraulic property change due to the surfactant and the scCO2 storage ratio change and supporting important information to maximize the scCO2 storage capacity in the CO2 reservoir rock.

Material Balance Equation for CO2 Storage Capacity Estimation in Saline Aquifer

Sangkeon PARK[1]*, Seoul National University (skpark0111@snu.ac.kr)
Hyunmin Oh[2], Seoul National University
Hyunjee Yoon[3], Seoul National University
Yeongju Kim[4], Seoul National University
Byungin Choi[5], Computer Modelling Group
Wenyue Sun[6], School of Petroleum Engineering
Hoonyoung Jeong[7], Seoul National University

Abstract

Estimation of CO2 storage capacities is important in developing carbon capture and storage projects. Material balance equation (MBE) methods, which are widely utilized, offer a straightforward approach for estimating of CO2 storage capacities. However, previous MBE methods use an original fluid in-place volume that is calculated using volumetric methods without validation of the original fluid in-place volume. The accurate estimation of the original fluid in-place volume, indicative of the pore volume, is imperative as it substantially influences the CO2 storage capacity. In this study, we developed an MBE method that yields precise evaluations of CO2 storage capacities by validating the original fluid in-place volumes within saline aquifers. In the proposed MBE method, brine extraction for mitigating pressure buildup can be considered. The accuracy of the proposed MBE method was assessed by comparing with a commercial reservoir simulator in a synthetic aquifer example and the Sleipner model. In the synthetic aquifer example, the proposed MBE method yielded an accurate CO2 storage capacity estimate, achieving a relative error of 2.085% despite relying on short-term (1-year) injection data. Similarly, when applied to the Sleipner model, this method maintained its high accuracy, with the relative error of 1.6873%. The proposed MBE method also provided accurate estimation of CO2 storage capacities under various circumstances such as different horizontal grid sizes, porosities, horizontal permeabilities, CO2 injection rates, shut-in periods, OWIP estimation methods, numbers of input data points, brine extraction rates, heterogeneity of porosity and permeability.

Anisotropic reservoir characteristics influencing the CO2 sequestration behavior in shale with simultaneous enhanced gas recovery and a case simulation

Li LI[1]*, Sichuan University (lilill@stu.scu.edu.cn)
Jun Liu[2], Sichuan University

Abstract

CO2 injection into shale reservoirs serves a dual-purpose by facilitating the geological CO2 sequestration with enhanced gas recovery (CS-EGR). However, the mechanism of anisotropic reservoir characteristics (permeability and in-situ stress) determining the CS-EGR responses remains unclear. In this work, the shale-based CS-EGR behavior is simulated based on an integrated thermo-hydro-mechanical (THM) coupled model, where the interactions of gases (CO2 and CH4) in multi-phase (free/adsorbed) are clarified in a systematic manner. The results indicated that the stronger anisotropic in-situ stress enables more CO2 in the free phase to be trapped in the shale reservoir and ensures a more distinct decreased amplitude of matrix porosity. Besides, it is also concluded that anisotropic permeability has a greater influence than in-situ stress on the gas migration during CS-EGR – for both free and adsorbed gases. According to a single shale layer model, higher horizontal permeability or lower horizontal in-situ stress positively makes an improved CS-EGR performance – from the adsorbed gases perspective. By the comparison of 7 cases, the decrease in free CH4 is tender after CO2 flooding under greater difference between vertical and horizontal in-situ stress. It is also concluded that under sufficient CO2 flooding, constant ~65% and ~35% of free gases in shale reservoirs are free CO2 and free CH4 at most (mass fraction), respectively. In addition, this work simulated two contiguous shale layers with variable permeabilities or in-situ stresses, indicating that the gases competitive adsorption behavior during the CS-EGR is primarily determined by the horizontal permeability or in-situ stress of the lower layer. The two-layer model also suggests that greater horizontal permeability difference between the two layers enhances the magnitude of CO2 accumulation and CH4 desorption. Nevertheless, a case application of this work to the Longmaxi formation and its implications are also expressed. Hopefully, this work is helpful in enhancing the knowledge on the accurate forecast on a shale-based CS-EGR outcome under the objective reservoir anisotropies.

Abstract

CO2 Mineral trapping is one of the safest means of carbon sequestration in saline aquifers. When injecting supercritical carbon dioxide (sc-CO2) into sandstone reservoirs, the mineral components and in-situ conditions may significantly influence the CO2-water-rock interactions and the CO2 trapping mechanism. In this study, three series of hydrothermal batch reactions have been carried out to investigate the reactions between sc-CO2 and siliciclastic minerals (plagioclase, potassium feldspar, chlorite, and montmorillonite). The effluent sampling and scanning electron microscope (SEM) are used to monitor the changes in the fluid hydrochemistry and mineral surface morphology during the study. The results show that mineral dissolution in the CO2-water-plagioclase reaction system is more obvious than in other mineral systems at 18MPa and 120°C. Higher temperatures further promote the dissolution of plagioclase and the generation of secondary minerals. It is also found that calcium feldspar is more soluble than sodium feldspar when the temperature is below 120°C and sodium feldspar will be more soluble than calcium feldspar when the temperature is above 120°C. Moreover, the montmorillonite also promotes the reactions due to its large surface area. For the CO2-water-plagioclase-chlorite reaction system, the simultaneous dissolution of plagioclase and chlorite in CO2-saturated water would lead to competition for H+. These inhibit the initial mineral dissolution. As the dissolution of chlorite provides Fe and Mg, when the concentration of Ca2+ is increased to meet the requirements for ankerite precipitation, the demand for elements such as Fe and Mg will conversely promote chlorite dissolution.

Molecular simulation of CO2 injection in methane-bearing coal models with different pore structures

Ruikang CUI[1]*, China University of Petroleum (East China) (Ruikang_Cui@163.com)
Jianmeng Sun[2], China University of Petroleum (East China)

Abstract

Deep coalbed methane (CBM) is a new field of CBM exploration with great resource potential. CO2 injection enhanced coalbed methane recovery (CO2-ECBM) technology can not only improve the coalbed methane production rate and reduce the methane content of coal seam, but also achieve the storage of CO2 and achieve the purpose of greenhouse gas emission reduction, which has both economic and environmental benefits. Compared with the middle-shallow coal reservoir and the Longmaxi Formation shale reservoir in Sichuan Basin, the pore structure of deep coal reservoir is more complex. The pore type is dominated by micropores (pore size <2nm), and the specific surface area of micropores accounts for more than 99%. In order to study the effect of micro - and nano-scale pore structure on the process of CO2 adsorption and CH4 displacement, a minimum energy coal model containing adsorbed methane was determined by using the large canonical Monte Carlo (GCMC) simulation method. The desorption behavior of CH4 after CO2 injection in a microporous - mesoporous model (pore size 2-50nm) was studied. The results show that methane exists in the form of micropore filling, adsorption state and free state in mesoporous. CO2 drives out methane gas mainly by occupying the adsorption site. The micro-nano scale pore structure controls the process of CO2 adsorption and CH4 displacement and fluid migration behavior. The stronger the adsorption potential of micropores, the stronger the adsorption capacity of coal for the mixed gas of CO2 and CH4, which is not conducive to CO2 replacement of CH4. Mesoporous pores directly affect the diffusion and transport behavior of CO2 and CH4. By analyzing the types of diffusion in micropores and mesoporous pores, it is found that transitional diffusion and Knudsen diffusion are dominant in micropores, while transitional diffusion and Fick diffusion are dominant in mesoporous pores. This study reveals the methane desorption behavior and CO2 displacement mechanism in coal reservoirs, which is of significant importance for utilizing CO2 to enhance coalbed methane recovery and capture and sequestration of CO2 in coal reservoir pores.

Exploration of shale gas from lower Gondwana shale beds of Jharia Coalfield, India– a potential game changer in clean energy domain

KAUSIK KUMAR GHOSH[1]*, GEOLOGICAL SURVEY OF INDIA (kausik.ghosh@gsi.gov.in)
Krittibas Das[2], GEOLOGICAL SURVEY OF INDIA
Jitendra Kumar[3], GEOLOGICAL SURVEY OF INDIA
Sudip Bhattacharyya[4], GEOLOGICAL SURVEY OF INDIA

Abstract

Unconventional natural gases like shale gas are in focus for its sustainable clean and green energy field. Shale gas is chiefly composed of methane, which burns much more cleanly than other fossil fuels. The gas is generated from organic-rich shale through biogenic and/or thermogenic processes. Shale gas reservoirs act as both source and reservoir rock for hydrocarbons generation. Pursuing challenges in energy needs in a sustainable manner, shale dominated lower Gondwana litho-assemblages of Jharia Coalfield was explored through exploratory drilling to determine the shale gas potentiality and quantitative estimation of shale gas resources.

A total of 8951m of drilling through 7 boreholes was carried out. A comprehensive multi-parametric approach was undertaken through measurement of in-situ shale gas content by gas desorption study, petrography, Rock-Eval pyrolysis, adsorption isotherm study, pore analysis, SEM-EDX, XRD and gas chromatography for detailed characterization of shale reservoir. The estimated Gas-In-Place (GIP) of 24,200 million cubic meters (MCM) shale gas was assessed over 100 sq. km. area. Significant gas content upto 7.36 cc/gm (average: 1.51 cc/gm) from a total of 1010m thick carbonaceous shale was determined. This finding may open up a new vista for unconventional source of energy from lithounits, which are devoid of economic coal seams.

The calculated high palaeogeothermal gradient (up to 6.5˚C/100m) renders the maturation of the organic matter in the thermogenic stage. Source kerogen of carbonaceous shale reveals mostly Type-III & Type-IV (late mature to post-mature stage) with total organic carbon (TOC: 3.87-34.12%) and Hydrogen Index (HI: 4-148) indicating excellent source rock potentiality for gas generation. The maximum temperature corresponding to the maximum hydrocarbon yield (Tmax) ranges from 448°C to 606°C indicating excellent maturity for gas generation. Pore study indicates the dominant control of the mesopores on the gas adsorption capacity and pore interconnectivity. Dominance of quartz over the accessory clay minerals in these shales has rendered enhanced brittleness, suitable for better hydro-fracturing capability during production. The high-pressure N2 adsorption isotherm study also suggests the favorable condition for shale gas reservoir, where the gas saturation level increases with depth. High gas recovery factor (82-95%) also strongly implies excellent production potentiality. High proportion of CH4 within the combustible gas content (avg. 93.02%) is highly suitable for its use as fuel in Greenfield energy domain. Considering the excellent reservoir potentiality, the carbonaceous shale horizons of Jharia Coalfield may be the game changer, providing shale gas as a major share in the clean and green energy domain of the Indian energy mix in the near future.

Structural deformation and microstructure evolution of marine shale from the upper Yangtze region of China

Yiwen JU[1]*, University of Chinese Academy of Sciences (juyw03@163.com)
Hongjian Zhu [2], University of Chinese Academy of Sciences
Kun Yu[3], China University of Mining and Technology

Abstract

Tectonic stress may deform or damage the shale rocks, thus affecting their macro or micro structures to varying degrees. The Lower Paleozoic marine shale samples from the upper Yangtze region of China, were studied through focused ion beam scanning electron microscopy (FIB-SEM), gas adsorption, and mercury intrusion, to evaluate the effect of structural type and deformation mechanisms on the reconstruction of shale pore and fracture structures. Results indicate that shale in monoclines contains mostly organic matter pores, while shale in folds or faults resulted from strong tectonic activities contains largely mineral interparticle pores, dissolution pores and fractures. Comparatively, fold- related shale has more micro pores and fault-related shale has more macro pores than monoclinic shale. The pore difference in shale of different structural parts can be attributed to an uneven distribution of local structural stress. Brittle shale contains mainly micrometer- sized pores and fractures, which are conducive to gas migration and accumulation; while ductile shale is dominated by nanometer- sized pores, which are conducive to gas adsorption and occurrence. The total pore volume of the shale increases with brittle deformation and decreases with ductile deformation. The total specific surface area of the pores is loosely connected with brittle deformation, but has a positive relationship with ductile deformation. Based on these results, the paper discusses the controlling factors and evolution models of micro- nano shale pores and fractures under structural deformation, and concludes that the structural stress on shale results in the modification of shale compositions, the evolution of pores and fractures in shale, and the storage and migration of shale gas.

Fracture Diagnosis and Inter-Well Interaction Analysis - Correlating Fiber Optic Data with Coupled Geomechanics-Thermal-Flow Simulations

Chuanyao Zhong[1], University of Alberta
Juliana Leung[2]*, University of Alberta (juliana2@ualberta.ca)

Abstract

Recent advancements in fracture-diagnostic tools, particularly fiber optic technologies such as Distributed Temperature Sensing (DTS) and Distributed Acoustic Sensing (DAS), have enhanced real-time monitoring and analysis of fracture hits, stress shadowing, and temperature and production variations. However, integrating field DTS/DAS data with production responses remains challenging. This study employs numerical simulation, and its capability to address these coupled geomechanics-thermal-flow problems is systematically evaluated. The model is used to explore temperature-strain responses, subsequently assessing the impact of fracture network properties on temperature responses and to derive insights into fracture diagnosis. Finally, the simulation results are used to interpret observations from field DTS/DAS data. Very few prior studies have investigated the impact of fracture interference on the fracture development and production of child wells. Attempts to include DTS data in evaluating the production performance of these offset wells are limited.

Detailed mechanistic models are constructed to simulate various fracture distributions and fracture hits scenarios. 3D thermal flow models, incorporating detailed wellbore modelling, are integrated with geomechanical calculations. Multi-scale fracture responses are simulated, e.g., physical opening/closure of hydraulic fractures (HF), induced secondary fractures, and pre-existing natural fractures. A commercial simulator is used, and a systematic examination of available model setup options was conducted to attain the most accurate responses. This modelling framework is validated against both established numerical and analytical standards. Two innovative features have been integrated: first, the matrix apparent permeability is dynamically updated according to pore pressure to capture the impact of nano-scale flow behaviours; second, natural fracture properties are updated in response to the stress variations, capturing their dilation/closure. Several field cases based on the Montney Formation are replicated. Simulated temperature, strain rate and production responses are compared to field DAS/DTS supplied by an industrial partner.

The simulation outcomes reveal the near-wellbore temperature behaviours as they respond to various HF properties and secondary fracture network distributions. The thermal effects exert a significant influence on the strain responses around HF. The results also indicate that while fracture hits hinder the growth of adjacent new fractures, they also enhance the production of nearby stages, particularly during the early phases. Frac hits lead to slower cooling during injection and faster warm-back during shut-in and flowback near the wellbore. These effects become more pronounced with closer proximity but diminish as the intensity of frac hits increases.

This study is the first to identify and outline the optimal configurations for maximizing the potential of commercial software packages in representing the complex behaviours of hydraulic fracturing. A quantitative framework is introduced to correlate simulation responses with DAS/DTS data. This type of analysis proves beneficial across various geological energy applications. The results underscore the sensitivity of downhole temperature, strain/stress and production responses to fracture network properties and treatment-monitor well interactions. Various scenarios are simulated and compared with field data. The findings offer valuable insights into leveraging real-time DTS/DAS data from the field for fracture diagnosis, fracture hit analysis, and production data interpretation

Pore-scale Investigation of the Effect of Surfactant on Storage Efficiency in CO2 Geosequestration

Chan Hee KIM[1]*, Korea Institute of Geoscience and Mineral Resources, Daejeon, Republic of Korea (kchnice1@kigam.re.kr)
Kue-Young Kim[2], Korea Institute of Geoscience and Mineral Resources, Daejeon, Republic of Korea
Gidon Han[3], Korea Institute of Geoscience and Mineral Resources, Daejeon, Republic of Korea
Weon Shik Han[4], Department of Earth System Sciences, Yonsei University, Seoul, Republic of Korea
Jae-Hong Lim[5], Pohang Accelerator Laboratory, Pohang, Republic of Korea

Abstract

Geosequestration of carbon dioxide (CO2) plays a crucial role in mitigating atmospheric CO2 levels. Therefore, securing reservoirs for large-scale CO2 storage is essential to achieve emission targets. Given the limitations of utilizing pore spaces in storage systems, enhancing pore space utilization becomes crucial in CO2 geosequestration. Among the various proposed technologies, we here focus on the utilization of surfactants. Surfactants are used to reduce capillary forces. With their hydrophilic polar heads and hydrophobic aliphatic tails, surfactants effectively lower the CO2-water interfacial tension (IFT). This study experimentally investigates the effect of surfactants on CO2 flow and storage efficiency in a sandstone at pore-scale. Two-phase flow experiments were conducted under various pressure conditions (6-16 MPa) where CO2 transits from gaseous phase to supercritical state. High-resolution three-dimensional images were obtained during the experiments using synchrotron-based X-ray microcomputed tomography. We compared microscale parameters such as interfacial curvature and contact angles, and additionally assessed mesoscale parameters including capillary pressure and relative permeabilities. Our results showed that low surfactant concentration of 0.05 wt% can lead to an increase in CO2 saturation throughout the core sample. Moreover, the measured microscale parameters such as contact angle and IFT revealed a positive effect of surfactant on storage especially when CO2 was gaseous phase (< 7 MPa). Our study implies that the use of surfactant could effectively enhance CO2 storage capacity, especially in depleted gas reservoirs where CO2 is injected in gaseous phase at the early stage of injection.

A novel method to enhance hydrate production and CO2 sequestration in clayey silty reservoir via splitting grouting

Xiaochu WANG[1]*, Jilin University (wangxiaochu@jlu.edu.cn)
Wei Guo[2], Jilin university
Yuan Wang[3], Jilin university
Rui Jia[4], Jilin university
Pengyu Zhang[5], Jilin university

Abstract

During the pivotal period of energy transition between carbon neutrality and carbon peaking, it is crucial to develop technologies which integrate efficient fossil energy development and carbon sequestration. Unlike traditional fossil fuels (coal, oil and natural gas), natural gas hydrate (NGH) has the advantages of high energy density and non-pollution, recognized as the most promising clean energy source of the 21st century. However, the NGH production also faces several significant challenges that need to be addressed such as low production rate, low production range and short stable production period. Meanwhile, conventional CO2 storage technologies also face shortcomings such as low carbon storage efficiency, poor confinement effect and CO2 leakage.
Therefore, in this work, an environmental-benign method to enhance hydrate production and CO2 sequestration in clayey silty reservoir via splitting grouting is introduced. As a novel method for achieving the three goals of all reservoir skeleton reinforcement, permeability enhancement and CO2 sequestration improvement, is proposed to stimulate NGH reservoir. Herein, the formulation based on CO2 foamed ultrafine cement grout was established. The results showed that the grout has good fluidity with initial viscosity ~500 mPa·s and consolidation time in the range of 28-50 min. Meanwhile, the consolidation performance evaluation was studied, and it showed that the consolidation is with porosity in the range of 9.41%-46.59%, permeability in the range of 51.23 mD-789.07 mD, and compressive strength in the range of 3.31 MPa-3.88 MPa. The internal pore channels are uniformly distributed with a large number of stomatal strings, which can be used as a multistage seepage channel for gas and water production from hydrate decomposition. Meanwhile, CO2 is converted to carbide and permanently sequestered in the grout consolidation. To further examine the stimulating behavior, the effect of hydrate saturation, grouting well diameter, grouting flow rate, and in-situ stress on splitting pressure and grouting volume were analyzed, and it was found that the grout has good ability to split fracturing and grout diffusion under the conditions of axial pressure of 5 MPa, confining pressure of 4 MPa, and hydrate saturation not more than 0.30. In addition, an environmental-benign high-efficient reservoir stimulation method on a laboratory scale was proposed. The findings could provide fundamental insights and recommendations for the implementation of splitting grouting in NGH reservoirs.

Abstract

To achieve the net zero economy, energy transition is needed in whole Europe. Carbon capture and storage (CCS) is a promising way to decrease the emitted CO2. Subsurface hydrogen storage can be one of the key methods for the energy transition. In this study both technologies are under spotlight to show their viability in the Pannonian Basin, Hungary. The available formations of thick strata with regional extent marked by facies with varying porosity and permeability from excellent aquifers to low permeability aquitards. This represents an enormous potential to store and seal off large volumes of pore fluids. Porous rocks (e.g. sandstone) are among the most potential reservoirs to inject and store CO2 on geological time scale. This could be an option for short- or long-term hydrogen storage as well. However, the mechanisms of storage, and the effect of the CO2 or hydrogen for the reservoir are not straightforward. To understand the interactions in the rock-water-gas system, investigation of natural reservoirs, laboratory experiments and geochemical modelling with PHREEQC have been carried out.

In case of CO2 geological storage, natural CO2 occurrences (Mihályi-Répcelak) have been compared with sandstones of the same formation which have not been flooded by CO2 (Ölbő). The comparison of the petrographic and geochemical features revealed which processes are a response or partially connected to the CO2 flooding. Dawsonite [NaAlCO3(OH)2] is missing in the investigated Ölbő sandstone and siltstone samples. In Mihályi-Répcelak area dawsonite formation was induced by CO2 flooding. The CO2 that precipitated as dawsonite seems to be magmatic in origin (Cseresznyés et al. 2021). In contrast, the isotopic signature of siderite suggests that it was only partially formed as a response to CO2 flooding, the rest being an early diagenetic mineral. The isotopic composition of siderite present in the unflooded Ölbő sandstones also supports this scenario.

In case of underground hydrogen storage, abiotic reactions were investigated which can occur in the sandstone reservoir. Among the rock forming minerals, K-feldspar and pyrite were investigated. K-feldspar ($KAlSi_3O_8$) is one of the pH sensitive silicate minerals, meanwhile pyrite (FeS_2) is a redox sensitive accessory mineral of sedimentary rocks. Geochemical modeling and static batch reactor experiments have been conducted in the pressure and temperature range of subsurface hydrogen storage to track the effect of hydrogen on K-feldspar and pyrite (described in Gelencsér et al. 2023). Results show that K-feldspar behaves similarly both under hydrogen and nitrogen atmosphere. Pyrite can react with hydrogen resulting in partial alteration of pyrite surface (to pyrrhotite [FeS] precipitation) and hydrogen sulfide (H_2S) production, whereas the reference experiments with nitrogen did not show any H_2S or the appearance of pyrrhotite.

Acoustic Simulation Study of Coal Rock

Xiaojuan SUN[1]*, China University of Petroleum (East China) (Lavender6sxj@163.com)
Jianmeng Sun[2], China University of Petroleum (East China)

Abstract

Our country's coalbed methane reservoirs exhibit characteristics of "high stress, low permeability, and heterogeneity." The composition and physical properties of coal formations are highly complex and diverse. This study focuses on the mixed-phase fluid in coal reservoirs and simulates the dynamic propagation process of ultrasound in rocks, along with various acoustic parameters such as wave velocity, waveform, spectrum, amplitude, and attenuation coefficient. The aim is to investigate the variations in acoustic parameters with different saturation levels of gas and water in coal samples and summarize the relevant relationships between coal properties (gas content, water content) and acoustic response characteristics. Additionally, the study simulates the variations in acoustic parameters under high temperature and high pressure conditions. The research findings indicate a strong positive correlation between longitudinal and shear wave velocities and density of coal formations. As the water saturation of coal increases, both Vp and Vs exhibit exponential growth, with Vp showing a more significant response to changes in water saturation. Conversely, with increasing gas saturation (Sg), both Vp and Vs exhibit exponential decreases, with Vp being more sensitive to changes in water saturation. Under conditions without axial and confining pressures, as the pressure increases, the gas density, Vp, Vs, and amplitude increase while the attenuation coefficient decreases gradually.

Comparison of Gas-bearing Parameter Evaluation Methods for Deep Shale Based on Pressure-holding Coring Technique

Xiao LI[1]*, China University of Petroleum (East China) (392052416@qq.com)
Xianguo Zhang[2], China University of Petroleum (East China)
Shuangfang Lu[3], Northeast Petroleum University
Wenbiao Li[4], Northeast Petroleum University

Abstract

Gas-in-place (GIP) content and adsorbed gas ratio of deep shale under stratigraphic conditions are two key parameters for the objective assessment of shale gas resource potential, screening of sweet spots, as well as the formulation and optimization of development plans. Over the past decades, relevant scholars and engineers both at home and abroad have carried out various researches and explorations for the evaluation of the above key parameters. So far, direct methods based on field degassing data have been proposed and widely used, including the USBM method, polynomial fitting method, Amoco curve fitting (ACF) method, improved curve fitting (MCF) method, and the newly proposed process analysis method and carbon isotope fractionation (CIF) model. However, different methods have their own advantages, disadvantages and applicable conditions. There are many differences in the results of the evaluation of gas-bearing parameters for the same sample (especially for deep shale samples), and there is still a lack of systematic and convincing comparative studies on the evaluation methods of shale gas-bearing parameters. Pressure-holding coring technique is currently recognised as the most effective means of validation and offers the possibility of resolving the above scientific controversies and industry pain points. In this study, the Well P1 in Luzhou area, Sichuan Basin, was selected, and one conventional and three pressure-holding coring were carried out at different depths. The GIP content of the above samples was evaluated using the USBM method, polynomial method, ACF method, MCF method, process analysis method and CIF method respectively, and the applicability and accuracy of the above methods were verified based on the comparison of the pressure-holding coring measured data.

The results demonstrate the gas content obtained is significantly higher because pressure-holding coring samples have excellent sealing and minimal lost time. (2) The GIP content is underestimated by the USBM method, while the polynomial fitting, ACF, and MCF methods overestimate it. The process analysis and CIF methods can evaluate the GIP content of deep shales more accurately. Based on the comparative results of the adsorbed gas ratio calculated using the process analysis and the CIF methods (33.49% and 24.53%, respectively), it is recommended that the CIF method be given priority when evaluating deep shale gas-bearing.

Pressure-holding coring technique can not only be used as an effective support for the results of gas content standard calculation, but also can be used to design the coring process to explore the isotope fractionation characteristics of shale gas in the complete output process, which can help to better understand the mechanism of isotope fractionation, and help the rapid and efficient

development of shale gas exploration and development.

Preliminary assessment of CO2 storage capacities in the northern portion of the offshore Orange Basin, South Africa.

Nangamso DUNGA[1]*, Council for Geoscience (ndunga@geoscience.org.za)
Nigel Hicks[2], Council for Geoscience
Andrew Green[3], University of KwaZulu-Natal

Abstract

Separation between the South American and African plate's occurred along the present day Atlantic margin during the Middle to Late Jurassic leading to the formation of the volcanic passive margin along the west coast of Southern Africa. The margin then later developed into the large Orange Basin flanking the west coasts of South Africa and Namibia.

Carbon dioxide capture, utilisation and storage (CCUS) has been identified as one of the fundamental approaches to mitigating global climate change through the capture and injection of anthropogenic CO2 into suitable geologic reservoirs. South Africa hosts three offshore sedimentary basins which have potential for industrial-scale (>1 million tons) CO2 storage. The Orange Basin on the country's west coast represents the largest and most promising CO2 repository in South Africa, as it covers an area of 145000 km2 to the 2000 m isobath and hosts known, but currently unexploited, hydrocarbon accumulations indicating suitable trapping and reservoir mechanisms. The study aims to further CCUS, sedimentological, petroleum geology and sequence stratigraphic knowledge through the mapping and definition of geological aspects of a 28000 km2 area along the continental shelf in the northern portion of the basin.

Within offshore frontier sedimentary basins, legacy data are important tools in basin-scale exploration for potential CO2 storage. Based on single-channel 2D seismic reflection data and well data, six seismic units (A-F) are revealed, separated by major sequence boundaries. Internal seismic reflector geometries and sedimentology suggest depositional regimes from syn-rift structurally defined sedimentation, followed by incipient ramp development, and lastly progradational sedimentary shelf propagation. Single-channel 2D seismic reflection data and well log data are further utilised to provide evidence of reservoir/seal pairs in saline aquifers that may represent potential storage sites for CO2 injection, stratigraphic and structural traps have been identified. These include continental sediments, fluvial to lacustrine sandstones, of Late Hauterivian-Early Barremian, developed within syn-rift graben systems formed during early continental breakup and the opening of the Atlantic Ocean, and the laterally extensive shelf-bound shallow-marine-sheet and deltaic sandstone packages of Middle Albian-Cenomanian and Turonian. These systems are correlated with analogous hydrocarbon-bearing sequences of the Orange Basin and other mapped and known systems throughout South Africa and Namibia. Using conservative assumptions, at P10; P50 and P90 scenarios, the total CO2 storage capacity is 178Mt at a P90 probability level (355Mt at P50; 607Mt at P10) for shelf and syn-rift sandstone reservoirs. Furthermore, structural closures within the study area have capacities of 22Mt at a P90 scenario (44Mt at P50; 75Mt at P10).

Nano-petrophysical studies for energy geosciences in the context of carbon neutrality.

Qinhong Hu[1]*, China University of Petroleum (East China) (huqinhong@upc.edu.cn)

Abstract

The research on nano-petrophysics, namely the study of rock properties and their interactions with fluids (gas, liquid hydrocarbons, and aqueous solutions) in nanopores of tight rock formation, has been receiving much attention because of the utilities of a range of tight rocks (e.g., mudrocks, granite, salt rock; basalt) in emerging energy and resources geosciences in terms of carbon management. This presentation will cover micro-scale pore structure and its emergent effect on macro-scale fluid flow and chemical transport in porous and fractured media for geological and engineering applications, such as the remediation of contaminated sites, geological repository for high-level nuclear waste, shale petroleum development, enhanced geothermal systems, and underground carbon and hydrogen storage. These systems commonly need effective reservoirs (sandstones, carbonates) for large-volume storage (e.g., effective porosity) and impermeable cap rock (mudrocks and salt rock) for containment (e.g., permeability, diffusivity, and tortuosity). This work studies 10+ representative rock samples from typical geological formations encountered at CCUS, such as Berea sandstone, Crab Orchard sandstone, Guelph dolomite, and Indiana limestone (as depleted sandstone or carbonate oil/gas reservoirs & saline aquifers) with Woodford claystone and Himalayan salt rock as cap rocks. Various and integrated experimental approaches are presented about important processes of diffusion, imbibition, and sorption and associated parameters (e.g., effective vs. “isolated” porosity, tortuosity), as well as ongoing coupled thermal-mechanic-hydrological-chemical processes under reservoir-relevant setting, for a cost-effective and confident utilization of these tight rocks for the storage or storage of fluids.

Carbon fixation mineral—Geological characteristics and synthetic experiments of Dawsonite

Yangchen ZHANG[1]*, China University of Petroleum (East China) (807545537@qq.com)
Xiyu Qu[2], China University of Petroleum (East China)
Qian Li[3], China University of Petroleum (East China)

Abstract

Carbon dioxide mineralization capture is the most durable and stable form of geological storage, and has become a hot spot for carbon sequestration research in recent years in the context of "dual carbon". As a natural carbon dioxide tracer mineral, the formation of dawsonite is closely related to carbon dioxide infusion, and it may also be an important carbon fixation mineral for carbon dioxide geological storage. The condition of massive and stable presence of dawsonite in geological background is a key issue that constrains the carbon dioxide mineralization capture, and is also an important influencing factor in the search for carbon dioxide geological burial sites. In order to explore the conditions for the rapid synthesis of dawsonite by using carbon dioxide, we conducted a series of experiments for the three main influencing factors of temperature (100/120/140/160/180/200°C), pH (8.5/9/9.5/10/10.5) and reaction time (6/12 hours), and based on scanning electron microscopy (SEM), X-ray diffraction analysis (XRD) to clarify the optimal conditions for the synthesis of dawsonite. The experiments suggests that: In the range of pH 8.5–10.5 and temperature 100–180°C, the products were all pure dawsonite, and the synthesis amount showed a trend of increasing and then decreasing with the increase of pH and temperature, at the temperature of 200°C, the crystallinity of dawsonite decreased and the content of pseudo-boehmite increased. The prolongation of reaction time did not have an obvious promotion effect on the quality of the products, and the prolongation of reaction time at the temperature of 200°C would accelerate the dissolution of dawsonite instead. Overall, 140°C and pH 9.5 are the best conditions for the synthesis of dawsonite using carbon dioxide and probably the ideal conditions for geological sequestration of carbon dioxide.

Multi-objective optimization of impure CO2-EOR implementation using CNN-GRU neural network and NSGA-II algorithm: a case study on H59 block of Jilin oilfield China

guangxu CHEN[1]*, Jilin University (chengx22@mails.jlu.edu.cn)
Hailong Tian[2], Jilin University

Abstract

For approaching the maximum benefits, various optimization methods for CO2-EOR projects have been used to co-optimize CO2 storage and oil production. However, few methods are capable of simultaneously considering all the three concerned objectives (i.e., carbon storage, oil production and economic efficiency). In addition, the impact of CO2 impurity on the optimization objectives was rarely reported in previous works. The target of this work is to access the optimal operation parameters with which the CO2-EOR projects are expected to simultaneously obtain the maximum cumulative oil production, net present value, and minimum cumulative gas production.
The convolutional neural network (CNN) was combined with the gate recurrent unit (GRU) neural network to build a novel robust proxy model (CNN-GRU). An intelligent optimization technique coupling CNN-GRU neural network and the Non-dominated Sorting Genetic Algorithm II (NSGA-II) algorithm was proposed to optimize the impure CO2-EOR implementation. Numerical model based on the H59 block of Jilin oilfield, China was employed to generate data for training and testing the built proxy model. The proposed optimization method in this work was applied to obtain the optimal operation parameters (including CH4 fraction in CO2 injection stream, gas mixture injection rate, and producer back-pressure).
The built CNN-GRU proxy exhibits higher prediction accuracy than the GRU proxy and the proposed optimization technique finds the Pareto Front of the optimum solutions. The cumulative oil and gas production increase with the fraction of CH4 in the CO2 injection stream. Considering the global warming potential, the co-injection of CH4 with CO2 improves carbon storage efficiency. Whereas, in terms of economic efficiency, the CH4-CO2 co-injection will increase the disposal cost of produced gas and water, resulting in a lower net present value. This work is desired to provide significant insights for decision-makers in carrying CO2-EOR projects.

Geochemical Characterization of Pimienta Formation, Mexico as a Potential Hydrogen Source

Alexis Rosa NUMMER[1]*, UFRRJ (rosanummer@gmail.com)
Ana Paola Silveira Martins[2], casada
Douglas J. Betancourt[3], casado
Efrain J. Betancourt[4], casado
Efren Solorzano[5], casado
J. L. P Rabe[6], casado

Abstract

The key objective of the geochemical analysis in this study is to describe shale resources system in terms of their organic geochemical characteristics. The target is the Pimienta formation. This is calcareous shale located in the southern portion of the Burgos Basin, in Mexico, located in the upper Jurassic portion. The stratigraphic column of Pimienta fm. consists of the Lower Oligocene, which is made up of calcareous light gray shale, the Lower Eocene is constituted by light, gray, shales, in which at the bottom of formation traces of light gray sandstones, with fine to medium quartz grains and dark lithics been identified. The mineralogy analysis indicated that mudstone, wackestone and packstone constituted 72% of the carbonate and 11% of clay containing illite, montmorillonite, glauconite and kaolinite. Permeability in the reservoir ranged between 1,600 to 2,000 nD, with total porosity ranging between 5.2 and 9.6%, a median Young's Modulus of 40^106 GPa, a static Poisson's Ratio of 0.25. The present study has been performed to understand the geochemical properties of this formation as a potential source of hydrogen using underground in-situ gasification processes. The main findings of the Geochemical analysis are: Gas Chromatography – Oil/gas ratio in Pimienta Formation shows gas contains 1,302 ppm-23,138 ppm methane, and a small amount of ethane87ppm-3,471ppm) and trace amount of propane, ranging from 60ppm to 542ppm. Drying coefficient of natural gas (C1/C1+) is ranging from 0.9975 to 0.9985. The results show that through the analysis the TOC present in Pimienta is a good rock quality (Quality Generating Rock sources). In average is superior to 2%. As a result of the evaluation the type of Kerogen is II / III and hydrocarbon as oil /gas. Vitrinite reflectance (VR) - The results indicated that hydrocarbon was identified all over the formation. It was possible to establish this formation as hydrocarbon generator system for the Superior Jurassic Play. Rock Eval pyrolysis - Analysis were conducted on the initial and pyrolysis non-extracted and extracted rocks from the sequential experiments. The study of pyrolysis provides knowledge about the chemical composition and maturity of the organic matter contained in the generating rock. The laboratory tests indicated that the water saturation is about 25.5%, oil saturation is about 55.7%, gas saturation is about 18.8%. Dry helium porosity % is about 7.7%. Hydrogen Index (HI) and Oxygen Index (OI) - It is an indicator of the presence of non-oxidized hydrogen in the system, a high HI indicates a greater potential for oil generation. The type of Kerogen can also be inferred from this index. Hydrogen can be classified between 50-200 for gas, between 200-300 for gas and oil and superior 300 is only for oil. Pimienta Shale went through three maturation windows (oil

window, transition between oil and gas windows and gas windows) as it dips south. The results shows that zones of high TOC with hydrocarbon > 1,200 ppm, kerogen type II-III. The study was able to identify sweet spot in the studied unconventional reservoir.

Comprehensive division of exploration and development units: case studies from three blocks in the southern Qinshui Basin

HUI WANG[1]*, North China University of Science and Technology (huiwang90@ncst.edu.cn)

Abstract

Coalbed Methane (CBM) reservoirs typically exhibit significant heterogeneity, leading to the simultaneous presence of high-yield wells and low-efficiency wells within the same geological unit. To address this issue, it is urgent to require the development of a systematic approach to segment exploration and development areas. This study examines three blocks of Anze, Mabi, and Zhengzhuang in the SQB's slope region. The key metrics, such as the 'conversion depth of coal adsorption saturation' and 'lateral pressure coefficient', were calculated to delineate the boundaries of the study area. These calculations facilitated the division of the study area into five primary geological units. Further refinement was achieved by considering additional other factors like structure, lithology, and hydrogeology, resulting in the subdivision into 11 secondary units. Building upon these subdivisions, the study proposes an evaluation methodology for CBM recoverability, tailored to the specific characteristics of CBM resources, desorption, and reservoir transformability. As a result, the study area was divided into three unique units for CBM development, namely Type I, II, and III. These categories align with regions of high, medium, and low yield respectively. This classification is substantiated by the history production data gathered from approximately 1000 CBM wells collected from the study area .

Evaluation of Multi-scale Natural Fractures in Coalbed Methane Reservoirs

Yidong CAI[1]*, China University of Geosciences Beijing (yidong.cai@cugb.edu.cn)

Abstract

In this work, the seismic, well logging, core and thin section data were used to evaluate the multi-scale natural fractures. Herein, take Shanxi Formation 3# and Taiyuan Formation 15# coal seams in Zhengzhuang block of southern Qinshui Basin as an example, the multi-scale natural fractures were identified and characterized. The plane distribution characteristics of natural fractures were revealed, the characteristic parameters of natural fractures were defined, and the main controlling factors of natural fractures were discussed. The results showed that natural fractures of coal reservoir in the study area can be divided into large-scale fractures, meso-scale fractures, small-scale fractures and micro-scale fractures according to multi-scale characteristics. Large-scale fractures are mainly developed near the eastern fault zone but are less developed in the middle zone. Meso-scale fractures are developed near the central and eastern fault zones, and the least developed in the northwest and southwest. Small-scale fracture development area mainly concentrated in the middle, and the fracture development degree in other areas is generally poor. Micro-scale fractures are relatively developed in the central part and less developed in the southwest. The comprehensive prediction shows that the multi-scale fracture development is generally poor, and the fracture development is in the central and eastern part of the study area. The fracture characteristic parameters are generally low, the fracture opening is mainly between 0.5-1μm, the fracture porosity is mainly 0.02%, the fracture permeability is mainly between 0.01-0.02mD, and the fracture permeability only a small range of high value area exists in the middle of the study area. Tectonic stress, coal lithotype, vitrinite content, vitrinite reflectance, and rock mechanical properties should have important effects on fracture development, among which tectonic stress and rock mechanical properties were deemed as the main factors controlling fracture development.

Numerical Simulation Study on the Effect of Horizontal Well Reservoir Stimulation for Gas Hydrate Production

Xiaoyang LI[1]*, Institute of exploration techniques, China Geological Survey (770613273@qq.com)
Xiaohang LIU[2], Nankai University
Yongqin Zhang[3], Institute of exploration techniques, China Geological Survey

Abstract

According to the analysis of technical bottlenecks in marine gas hydrate production, one new kind of gas hydrate reservoir stimulation method for improving reservoir permeability and compressive strength was proposed. In this method, the chemical reagents of three components were developed and injected into hydrate reservoir by hydraulic fracture. Through the lab tests, it was found that the chemical reaction could release transient heat to increase the decomposition rate of hydrate. In addition, the chemical reaction product had the honeycomb structure to support fractures and increase permeability at least 60 times. Based on the geological condition of marine hydrate in the South China Sea, three hydrate development models were simulated to study hydrate production capacity. And these three models included horizontal well(HW), horizontal well with fractures(HWF), horizontal well with the stimulation of chemical reagents(HWS). Compared with HW, the simulation results showed that the total gas production of HWF in one year was 7 times of HW, while the cumulative gas production of HWS was 12 times of HW, significantly enhancing the daily production and development efficiency. Furthermore, the evolution patterns of hydrate saturation, temperature-pressure field in production time for three production methods were studied, and the influencing factors of fracture conductivity, fracture half-length and fracture number on hydrate production enhancement were explored. Through the simulations, it provided the new method and theoretical support for the optimization of marine hydrate reservoir stimulation scheme.

Early-Stage Risk Assessment for a Potential Commercial-Scale Geological Carbon Storage Site in Utah, USA

Ting XIAO[1]*, University of Utah (xiaotinguu@gmail.com)
Brian McPherson[2], University of Utah
Hailong Tian[3], Jilin University

Abstract

Carbon capture, utilization, and storage (CCUS) in geological formations is playing a key role in mitigating CO2 emissions and achieving the “net-zero” goal for greenhouse gas emissions. Risk assessment is critical for CCUS projects, especially in early stage, because it influences the development and quantitative analyses of reservoir simulations, as well as the subsequent plans for monitoring, characterization, and external communications. This study summarizes the early-stage risk assessment developed and applied to the Uinta Basin Carbon Storage Assurance Facility Enterprise (CarbonSAFE) Phase II project sponsored by the U.S. Department of Energy (DOE), located in the east Uinta Basin, Utah, USA.

The Uinta Basin CarbonSAFE Phase II project seeks to establish the technical and economic feasibility of commercial geological carbon dioxide storage (GCS) with high-resolution characterization data, technical analysis, economic evaluation, and environmental analysis. Identifying constraints and risks that might prevent commercial-scale CCUS development is a key component of this project. To date, the project team has evaluated risks to project values including economic, environmental, legal, social, technical, operational, and management aspects. With a feature, event, and processes (FEP) list that summarizes potential risks for a typical CCUS project, project members, CCUS experts, and external advisory board members identified risks that might potentially impact the project deployment and their likelihood and severity. The results are valuable for subsequent risk evaluations by considering key risk factors for this specific CCUS site and the strategies of community engagement.

Microscale gas occurrence mechanism in coalbed methane reservoirs

Fengrui SUN[1]*, China University of Geosciences Beijing (sunfengrui@cugb.edu.cn)
Dameng Liu[2], China university of geosciences Beijing
Yidong Cai[3], China university of geosciences Beijing
Yongkai Qiu[4], China university of geosciences Beijing

Abstract

At present, the exploration and development of major coalbed methane (CBM) fields in the world continues to strengthen. Elucidating the gas occurrence mechanism in coalbed methane reservoirs is one of the basic tasks before carrying out numerical simulations. The academic community generally agrees that methane is mainly in the adsorption state in CBM reservoirs, with some free gas and dissolved gas, and has developed the single-layer adsorption theory and the multi-layer adsorption theory represented by the Langmuir model and the BET model. Until now, the molecular force field superposition mechanism of gas occurrence in microscale pores under different coal rank conditions is still unclear, and there is still a lack of systematic research on the differences of gas occurrence mechanism in different adsorption layers and the nature of adsorption/desorption between adjacent adsorption layers. In this paper, the macroscale coal rank control mechanism of adsorbed gas is firstly studied, and the statistical nature of the Langmuir model is revealed. It is found that gas molecules show the duality of "Newtonian mechanics-Vibration dynamics" in the surface control field; the gravitational field model can well explain the phenomenon of gas stratification under different coal rank conditions, and reveal the nature of adsorption/desorption between adjacent layers; the residual pressure is relatively low in low-rank and high-rank coal matrix, and relatively high in medium-rank coal matrices; the residual pressure equation can also provide theoretical analysis basis for the enhanced gas recovery of low-pressure CBM wells.

Effect of SCCO2-H2O-Coal Reaction on the Pore Structure of High-rank coal

Junyan Jun ZHANG[1]*, 1060247389@qq.com (1060247389@qq.com)
Qiang Gui Zheng[2], +8615110084688
Sheng Lin Gao[3], +8615350715799
Ji Li[4], +8615128438350

Abstract

Coal reservoirs using for CO2 geological sequestration not only reduces greenhouse gases, but also promotes the development of coalbed methane (CBM), which has dual significance in protecting the environment and improving CBM extraction. In this experiment, temperature and pressure at different depths of the geological strata were used as experimental variables. Supercritical CO2 (SCCO2) and distilled water were injected into the 3# anthracite coal sample from the southern part of the Qinshui Basin to observe the changes in the pore structure of the coal sample pre and post experiment. The pore structure characteristics of the coal samples were measured by the mercury intrusion tests (MIP) and low temperature N2 adsorption methods (BET) . The surface morphology changes of coal samples can be observed through scanning electron microscopy experiments (SEM). The experimental results show that the SCCO2-H2O-Coal reaction has a significant effect on the modification of mesopores or mesopores (pore size of 2-50nm) in coal samples,but has almost no effect on micropores (pore size<2nm) or macropores (pore size>50nm). The causes of the phenomenon can be summarized as follows: 1. the original pores in coal were expanded during the SCCO2-H2O injection; 2. the closed pores in the coal were opened, increasing the connectivity of the coal; 3. the minerals in coal, especially carbonate minerals, are dissolved, resulting in the formation of more pores. In addition, SCCO2 can physically extract small molecule organic matter from coal. The acidic environment formed by the injection of SCCO2-H2O into coal seams can also disrupt the connection bonds between the basic structural units of coal molecules and other functional groups on the side chains, thereby promoting the development of pores and fractures in coal. In summary, the transformation effect of SCCO2-H2O-Coal reaction on the pore structure of high rank coal reservoirs will affect the adsorption and desorption performance of coal seams, thereby affecting the recovery rate of CBM.

Monitoring methane gas emissions in coal mine areas of North Korea based on Sentinel-2 satellite data

Minju KIM[1]*, Dong-A University (330140@donga.ac.kr)
Jeongwoo PARK[2], Dong-A University
Chang-Uk HYUN[3], Dong-A University

Abstract

As abnormal climates such as extreme heatwaves and heavy rainfall occur worldwide due to the increase of greenhouse gases, the importance of reducing greenhouse gas emissions is emphasized. Methane, a greenhouse gas with a significant impact on climate change, has a global warming potential approximately 82.5 times that of carbon dioxide over a 20-year period. Reduction of methane gas emissions, which cause relatively strong global warming effects, is essential for mitigating climate change, and it is important to identify and manage emission sources and quantities through continuous monitoring. Satellites can effectively detect methane emissions in inaccessible or extensive areas by providing periodic and global data. In particular, Sentinel-2 satellites, with their short revisit period and relatively high-resolution images covering various bands from visible to shortwave infrared, can be effectively utilized for methane gas detection. Previous researches have been conducted on methane detection using shortwave infrared bands of satellites such as GHGSat and WorldView-3 for known methane emission sources. In this study, we utilized Google Earth Engine (GEE), a cloud platform for efficient analysis of large-scale satellite data, and Sentinel-2 satellite data to detect and monitor methane gas emissions from coal mines in the vicinity of Suncheon, South Pyongan Province, North Korea, including the 2.8 Jikdong Coal Mine, a region with restricted access. The results of this study are expected to contribute to international efforts aimed at reducing methane emissions globally and to be utilized as foundational data for sustainable environmental management and climate change mitigation. Furthermore, it demonstrates the practicality of methane emission monitoring using remote sensing technology.

Simulation study of the high-temperature nitrogen injection in-situ conversion process: a case study in Songliao Basin shale formation

Chaofan ZHU[1]*, Jilin University (chaofan_zhu@jlu.edu.cn)
Wei Guo[2], Jilin University
Qiang Li[3], Jilin University
Sunhua Deng[4], Jilin University
Yuan Wang[5], Jilin University
Rui Jia[6], Jilin University

Abstract

China’s oil shale reserves are 739.1 billion tons and 45 per cent of which are in Songliao Basin. Therefore, a pilot project is conducted in Songliao Basin, aimed at technical preparation for commercial in-situ oil shale processes production. Because N2 is readily accessible and has no damage to the formation, the high-temperature nitrogen injection in-situ conversion process (HNICP) is the most basic convection heating technique, which is used in the pilot project. In this study, the Wellington reaction model is adjusted to describes the pyrolysis behavior and characteristics of shale in Songliao Basin, China. Based on the geological data and production date of the pilot project in Songliao Basin, a simulation model matching the production test scheme is established to investigate subsequent production performance and the evolution of reservoir physical properties for 550 days. Finally, the effect of injection temperature, total organic carbon (TOC), and enclosing area on the recovery factor is analyzed. The results show that the oil production rate can be divided into four stages for the HNICP of oil shale. In the third stage, prechar accumulation is very severe in the main fracture. However, the prechar accumulation relieves the heat short problem in the main fracture. The high temperature is beneficial to the production of oil, HC, and prechar. The formation plugging in the low TOC shale formation is more serious. Because of the spontaneous imbibition of oil in the formation away from the main fracture, the small enclosing area is beneficial to the production of oil.

Numerical Simulation of Oil Recovery Performance and Long-term CO2 Storage Potential after Different CO2-EOR Operations

Zejin FAN[1]*, Jilin University (3030966868@qq.com)
Huixing ZHU[2], Key Laboratory of Groundwater Resources and Environment, Jilin University
Tianfu XU[3], Key Laboratory of Groundwater Resources and Environment, Jilin University

Abstract

The CO2-EOR (Enhanced Oil Recovery) technology has emerged as a crucial approach for achieving carbon neutrality, enabling simultaneous carbon sequestration and oil production, thereby enhancing its economic viability. Recent studies on CO2-EOR have provide valuable insights into the optimization of oil production. However, the fate of injected CO2 has often been disregarded. In this study, the oil components were incorporated into the reactive transport simulator TOUGHREACT to achieve a comprehensive description of multiphase flow, multi-component miscible process, and geochemical reactions involved in CO2-EOR. Therefore, the evolution of CO2 in different phase states (gas/supercritical, dissolved, and solid) can be effectively characterized. A CO2-EOR project in Jilin Oilfield in China was used to verify the model, and gained a good match between pressure and oil production rate with actual data, then the oil recovery efficiency and CO2 sequestration efficiency of several typical CO2-EOR operations were compared. The results showed that miscible WAG (Water Alternating Gas injection) method (CO2-water slug ratio 1:1) can obtain the best oil recovery factor (92%) when injecting the same volume of CO2, followed by continuous miscible CO2 injection (83%), immiscible WAG injection (gas-water slug ratio 1:1, recovery factor 76%) and continuous immiscible CO2 injection (66%). Similar results were seen in the CO2 sequestration efficiency when CO2-EOR operations were stopped, which were 94% of miscible WAG, 92% of immiscible WAG, 77% of continuous immiscible injection and 65% of continuous miscible injection, respectively. Due to the horizontal flow of the fluid is limited, and the presence of hydrocarbon components in the gas phase further reduces the CO2 dissolution amount, the injected CO2 in continuous injection cases mainly gathered in gas phase around the injection well during the 500 years' sequestration period. The dissolution rate of CO2 into the water was controlled by the consumption rate of the CO2-water-rock reaction. In the CO2 gas-water phase zone, minerals such as calcite and albite are constantly dissolved under the acidic condition, resulting in a maximum increase of 0.1% in porosity. In compared, WAG injection stored more CO2 (70%) in liquid phase in the formation, effectively reducing the risk of CO2 gas breakthrough. The CO2 involved in the water-rock reaction to form the minerals could be up to 5% of the total sequestrated amount through 500 years, which improved the stability of the entire system.

Autothermic Pyrolysis in situ Conversion Process for Oil Shale Recovery

Wei GUO[1]*, Jilin University (guowei6981@jlu.edu.cn)
Chaofan Zhu[2], Jilin University
Qiang Li[3], Jilin University
Sunhua Deng[4], Jilin University
Yuan Wang[5], Jilin University

Abstract

In China, oil shale has not been applied in large-scale industrial processes owing to its poor efficiency and high energy extraction costs. The autothermic pyrolysis in situ conversion process (ATS) is an oil shale high-efficiency heating extraction method that uses the residual potential heat after kerogen pyrolysis.

Herein, a large-size oil shale (Φ: 100 mm, L: 500 mm) in situ pyrolysis experimental apparatus, which considers the overburden pressure, was designed to study the feasibility, characteristics, and energy efficiency of ATS. Two ATS pilot tests were conducted at different depths (approximately 70 and 480 m) in the Songliao Basin, China. The pilot tests were performed for nine years, from 2013 to the present.

The results demonstrate that the ATS of oil shale is successfully triggered at 300 °C. The autothermic pyrolysis reaction is steadily advancing, proving the feasibility of the method in laboratory-scale experiments. According to their optical characteristics and chemical composition, ATS reaction zones can be divided into residue, autothermic, pyrolysis, preheating, and virgin zones. Compared with the high-temperature nitrogen in situ conversion process, pyrolysis oil obtained from ATS contains more light components. When the oil recovery via ATS reaches 69.1%, the energy efficiency reaches 3.46, which is much higher than 0.51 by nitrogen.

The cumulative oil and gas production of the shallow-ground pilot test was 1.6 ton and 1500 m3, respectively. In addition, the cumulative oil and gas production of the deep-ground pilot test was 3.0 ton and 18,000 m3, respectively. During the two pilot tests, long-life downhole heating technology and equipment were developed and applied. The compound reservoir reconstruction technology, which includes shock wave fracturing, hydraulic fracturing, and acid fracturing, was studied. To improve the pyrolysis efficiency, oil recovery and quality to the oil shale oil was studied.

This study shows the advantages and feasibility of ATS using experiments and pilot tests, which can be used for the large-scale commercial development of oil shale.

Study on promoting mechanism of electric field on pyrolysis and seepage of oil shale products

Qiang LI[1]*, College of Construction Engineering, Jilin University (lqiang1982@jlu.edu.cn)

Abstract

The in-situ exploitation technology of oil shale is environmentally friendly and is an crucial means to solve the energy crisis in the world today. The degree of pyrolysis of kerogen, fluidity of heavy oil and its state of occurrence in pores of oil shale in the process of exploitation seriously affect the production efficiency. In situ exploitation technology of High Voltage - Power Frequency is to break down the oil shale layer by applying high voltage to the formation, and then pyrolysis the oil shale through the processing frequency electricity. It can centrally heat the oil shale layer and has the characteristics of high energy utilization. It is worth noting that, different from traditional electric heating, the electric field of High Voltage - Power Frequency technology occurs in the oil shale layer, the electronic structure of the molecules is changed and the polar molecules are deflecting under the electric field, thus, the physical and chemical properties of oil and gas products are changed, affecting the production efficiency of in-situ exploitation technology of oil shale. In this study, the fluidity and chemical properties of oil and gas products under the electric field are studied on a multi-scale by combining experimental and theoretical analysis. The macroscopic fluidity and chemical properties of the product under high temperature electric field are studied by Viscosity Test, Fourier Transform infrared spectroscopy (FTIR) analysis and Gas chromatography-Mass spectrometry (CG-MS) analysis. The electronic structure, band structure and interfacial adsorption of oil and gas molecules under electric field are simulated by Density Functional Theory (DFT) and Molecular Dynamics (MD), and their chemical properties and physical properties such as adsorption and infiltration Angle at different mineral interfaces are analyzed. Based on the physicochemical properties obtained from the study at molecular and macro-level studies, the mesoscopic transport model of oil and gas products in the pores of oil shale is established by finite element method. Combined with the multi-scale study, the mechanism of electric field to promote the production efficiency of oil shale is revealed.

Altering Pore Morphology of Organic-Rich Shale through SC-CO2 Exposure

Ogochukwu OZOTTA[1]*, University of North Dakota (ogochukwu_ozotta@yahoo.co.uk)
Oladoyin Kolawole[2], New Jersey Institute of Technology
Chioma Onwumelu[3], University of North Dakota

Abstract

The alteration of pore structures in organic-rich shale through the interaction with CO2 is a topic of significant interest due to its impact on various projects. This study focuses on investigating the effects of supercritical CO2 (SC-CO2) exposure on samples obtained from the Upper Bakken (UB) and Lower Bakken (LB) formations. The duration of exposure was set at 3, 8, 16, 30, and 60 days, and a comprehensive evaluation of chemical and structural changes during this process was conducted using multiple techniques such as X-ray diffraction (XRD), gas adsorption (N2) isotherm, and fractal theory.

The findings revealed notable transformations in the composition of the shale samples following CO2 saturation. Specifically, the concentration of quartz increased in the UB samples, while it decreased in the LB samples. Clay minerals and other minerals exhibited a decreasing trend in both UB and LB samples after exposure to CO2. Additionally, the pore size distributions (PSDs) displayed a shift towards smaller pore sizes at all diameters, indicating a reduction in the number of pores because of the reaction with CO2.

The fractal dimension, which characterizes the complexity and roughness of pore surfaces, demonstrated an increasing trend as the samples were exposed to CO2. This suggests that the pore structure became rougher and more intricate after 8-16 days of CO2 saturation. However, after 30-60 days of saturation, the fractal dimension decreased, indicating a transition towards a more homogeneous pore structure.

Furthermore, the dissolution of clay minerals contributed to an increase in pore volume, while carbonate dissolution resulted in an augmentation of the specific surface area. These empirical findings provide valuable experimental evidence to further examine the mechanisms involved in the geological storage of CO2 in organic-rich self-sourced plays.

In summary, this study sheds light on the pore structure alterations that occur in organic-rich shale when exposed to SC-CO2. The findings highlight changes in mineral composition, pore size distribution, fractal dimension, and the impact of clay and carbonate dissolution. This research contributes to our understanding of the geological storage of CO2 in self-sourced plays and provides a foundation for further investigations in this field.

Unveiling the Sub-10 Nanometer Realm: Innovative FIB-HIM Approach to Shale Nanopore Characterization

Jianguo WU[1]*, Institute of Geology and Geophysics, Chinese Academy of Sciences (IGGCAS)
(wujianguo@mail.iggcas.ac.cn)
Guoliang Li[2], Institute of Geology and Geophysics, Chinese Academy of Sciences (IGGCAS)

Abstract

Nanopores in shale serve as crucial storage sites and transportation channels for oil and gas. However, characterizing shale nanopores, especially those below 10 nanometers (sub-10 nm), poses significant challenges with current technologies. In response, we have developed an innovative scheme using focused ion beam-helium ion microscopy (FIB-HIM) to capture 2-D and 3-D digital rocks of shale pores down to the sub-10 nm level. Taking Longmaxi shale samples from the Sichuan Basin as a case study, the application of the novel FIB-HIM approach in the characterization of shale nanopores is introduced. The imaging results reveal the morphology of sub-10 nm pores and demonstrate three types of spatial relationships of nanopores in 2-D: independent, touching or merging, and nesting. A 3-D digital core with a precision of 3 nm is reconstructed, showcasing the pore connectivity patterns under the involvement of sub-10 nm pores. Quantitative results rectify errors in traditional methods, highlighting the significant impact of sub-10 nm pores on the evaluation of resource reserves and productivity. For experimental samples, the surface porosity increases by 10.73%, the pore circumference by 43.02%, and the specific surface area by 76%. The novel approach revises the unimodal pore size distribution obtained from traditional methods into a multimodal distribution, consistent with the multi-stage formation model of organic nanopores. The 3-D digital core reveals that the pores unveiled by FIB-HIM exhibit higher coordination numbers and a higher proportion of internal connectivity volume, indicating greater connectivity probability and providing more flow pathways. Compared to conventional focused ion beam-scanning electron microscopy (FIB-SEM) techniques, the novel approach offers several key advantages: (1) Enhanced resolution for visualizing morphological features of sub-10 nm pores. (2) Revised pore size distribution curves, along with recalculated parameters such as porosity, pore circumference, and specific surface area. (3) Improved accuracy in reconstructing the 3-D connectivity of nanopores, elucidating the positive impact of sub-10 nm pores on connectivity. Our novel FIB-HIM scheme provides robust technical support for a comprehensive understanding of shale nanopores. It also furnishes experimental models for both resource assessment and research into fluid transport mechanisms, thereby showcasing significant potential applications in the field.

Formation dry-out from CO2 injection into coal seam: Salt precipitation and injectivity alteration

Xiaoxiao SUN[1]*, China University of Geosciences, Beijing (xsun90@cugb.edu.cn)

Abstract

Sequestering CO2 into deep coal seams stands out as a leading method to mitigate anthropogenic CO2 emissions. This is primarily due to the significant storage capacity afforded by CO2 adsorption to coal under high pressure. However, within deep coal seams, groundwater typically exhibits exceedingly high salinity levels. As water evaporates during CO2 injection, salt precipitates from the aqueous phase, leading to alterations in the porosity and permeability of the coal. Our objective is to specify how serious salt precipitation is for CO2 storage into coal seam and whether its importance has been overlooked. In this study, we injected supercritical CO2 into a coal core fully saturated with NaCl brine to investigate salt precipitation induced by the evaporation process under varying gas types (CO2 and nitrogen), gas flow rates, and formation water salinity. Scanning electron microscopy was employed to analyze the location and morphology of salt precipitation crystals under both static and gas flow conditions. Additionally, measurements of water saturation, porosity, and permeability within the core samples were conducted concurrently during gas injection to displace formation water. The results show that gas flow displaces a portion of movable water, leading to the drying of residual water under gas flow conditions. Gas flow within fractures significantly impacts salt crystallization, while the salt within the matrix experiences comparatively minor effects due to gas infiltration limitations. Monitoring of nuclear magnetic resonance-T2 spectra during gas flow reveals a reduction in moisture content within fractures, with moisture gradually migrating from the matrix to the fractures as drying progresses. The presence of salts within coal markedly decreases porosity and permeability, particularly evident with increasing formation water salinity. Gas flow velocity inversely correlates with the magnitude of these effects, with a weaker impact observed at higher gas flow rates. Interestingly, in high-pressure CO2 gas environments, salt precipitation effects are less pronounced compared to nitrogen gas environments.

Influence of sediment properties on methane hydrate enrichment in fine-grained sediments

Chenyang BAI[1]*, China University of Geosciences at Beijing (baicy@cugb.edu.cn)

Abstract

Methane hydrates predominantly accumulate in silt-clay sediments, where sediment characteristics such as particle size and mineral composition critically influence their accumulation. The northern South China Sea (SCS) hosts significant fine-grained methane hydrate reservoirs, representing a key area for study. This study analyzed the particle size and mineral composition of 597 sediment samples from methane hydrate reservoirs and adjacent layers across seven sites in the Dongsha, Shenhu, and Qiongdongnan areas of the northern SCS, describing the properties of fine-grained methane hydrate reservoirs. Scanning electron microscopy (SEM), specific surface area (SSA) measurements, and irreducible water saturation tests were employed to elucidate the influence of sediment properties on methane hydrate accumulation in fine-grained sediments. Results indicate that mineral composition significantly impacts both methane hydrate reservoirs and non-methane hydrate layers. The methane hydrate reservoirs exhibit low illite-smectite (I/S) mixed layers and high felsic mineral content, attributed to the adsorption and constraint of gas and fluid by the complex microstructure of I/S mixed layers. Sediment particle size plays a crucial role in determining methane hydrate saturation and morphology within fine-grained methane hydrate reservoirs. Methane hydrate reservoirs with sediment particle sizes above 16 μm primarily feature dispersed, low-saturation methane hydrates formed by pore filling. Conversely, methane hydrate reservoirs with sediment particle sizes below 8 μm predominantly contain visible, high-saturation methane hydrates formed through particle displacement. This study elucidates the mechanisms of methane hydrate enrichment in fine-grained sediments, offering significant insights for exploration, development, and understanding environmental impacts.

The Geochemical characteristics and Genetic mechanism of tight gas in Shahezi Formation,North Songliao Basin, China——Take Xujiaweizi Fault Depression as an example

YiXuan RAN[1]*, National Key Laboratory of Deep Oil and Gas, China University of Petroleum (East China), Qingdao 266580, China (ran18645949951@163.com)
Jian Wang[2],
National Key Laboratory of Deep Oil and Gas, China University of Petroleum (East China), Qingdao 266580, China

Abstract

In recent years, the tight gas exploration and development of Shahezi Formation in the northern Songliao Basin has made strategic breakthroughs, and the long-term test production has achieved remarkable results, which has become an important replacement field for Daqing oilfield. Among them, The tight gas in Shahezi Formation in Xujiaweizi fault depression has become a new and important exploration field for deep gas exploration in the basin and has made continuous breakthroughs. In order to understand the generation and distribution law of tight gas in deep-layer of North Songliao Basin, this study focuses on the geochemical characteristics and accumulation period of tight gas, based on analysis of geochemical data such as tight gas compositions, carbon isotopes and Inclusion homogenization temperature. According to the result of these analysis, the tight gas in Shahezi Formation is dominated by methane with a light portion of heavy hydrocarbons and generally non-hydrocarbon, such as carbon dioxide and nitrogen. There is a widely distribution of $\delta^{13}C_1$ which is ranges from -33.2‰ to -27.8‰, while $\delta^{13}C_2$ is higher and have a relatively intensive distribution from -29.2‰ to -22.4‰. Carbon isotopic distribution of tight gas is characterised by a normal pattern, some partial reversal of carbon are observed. The identification of tight gas shows that the main type of tight gas in Shahezi Formation are coal-formed gas and there are two accumulation periods including Nenjiang period and Qingshankou period. The mix of high maturity coal-formed gas in Nenjiang period and relatively low maturity coal-formed gas in Qingshankou Period is the major cause of carbon isotope reversal. In addition, it is notable that carbon dioxide in study area are inorganic origins and distributed nearby the basement faults, resulted from the magma degassing in Yingcheng Period volcanic magma activity.

Abstract

The steam assisted gravity drainage (SAGD) method, which is the most popular method in Canada, utilizes steam to reduce bitumen viscosity. However, natural gas use for steam generation significantly contributes to greenhouse gas (GHG) emissions (ECCC, 2023). A total of 85 Mt-GHG came from the oil sands industry in Canada in 2021, which is 45% of Canada's oil/gas sector GHG emissions. Aligning with the recent carbon-neutral trend, the province of Alberta in Canada has implemented a policy to limit GHG emissions from the oil sands industry to 100 Mt-GHG. Green and Jackson (2016) anticipated that this emission cap would lead to a decrease in Alberta's total oil production by approximately 3.34 billion barrels due to constraints on steam generation. Thus, there is a need for more eco-friendly thermal methods.

The steam and gas push (SAGP) method, developed by Butler in 1999, is suitable for such improvement. This method differentiates from SAGD by additionally injecting non-condensable gas (NCG) along with steam. SAGP alleviates the issue of heat loss to thief zone compared to SAGD and allows for more effective maintenance of temperature and pressure of the steam chamber. This reduction in unnecessary steam usage ultimately reduces the cumulative steam-oil ratio (cSOR), enabling more efficient utilization of steam in the oil sands thermal process.

This study investigated the sensitivity analysis of the SAGP method according to the type and mole fraction of NCG in three-dimensional heterogeneous oil sands reservoirs. The reservoir model has a grid system of 100x860x43m with a grid size of 2x10x1m, comprising a total of 184,900 grids. Production simulation was implemented over 15 years using CMG's STARS software. Methane (CH_4), nitrogen (N_2), and carbon dioxide (CO_2) were used as NCGs, with their mole fraction at 0, 0.5, 1, 2, and 4 mol% for sensitivity analysis. The results showed that lower mole fraction leads to a decrease in cSOR and an increase in cumulative oil production regardless of NCG type. Specifically, at 0.5 mol%, all NCG types reduced cSOR compared to the SAGD method, promoting eco-friendly oil sands production. CO_2 exhibited a relatively lower cSOR than one of CH_4 and N_2 except 0.5 mol% case. These findings propose the possibility of eco-friendly

production of oil sands resources through the SAGP method, especially by utilizing CO_2 as NCG, further reducing GHG emissions.

Abstract

CO2 flooding is a tertiary oil recovery technology with broad application prospects. Many oil fields at home and abroad have incorporated carbon capture, utilization and storage (CCUS) projects into the green and low-carbon strategic development system.

Since 2007, the pilot experiment of CO2 miscible flooding has been carried out in the G89 well area of Shengli Oilfield. There are 11 CO2 injection wells and 23 production wells in the core area. The study area has good storage and flooding conditions: 1) The cap layer is oil shale with stable deposition; 2) The reservoir is beach-bar sand with low porosity and low permeability, which requires CO2 flooding to improve EOR; 3) There are two large faults in the north and south of the study area, which are good for sealing and conducive to carbon dioxide storage. In 1992, 2011 and 2021, three rolling exploration with non-repeated acquisition were carried out, which provided data conditions for the dynamic monitoring of carbon dioxide flooding. In particular, in the data of 2021, the aspect ratio of the geometry is 0.72, which belongs to wide-azimuth exploration. Besides rich offset information, there are also original azimuthal information suitable for determining the dominant direction of CO2 injection.

In our research, firstly, well seismic calibration and analysis are carried out, and then forward simulation of CO2 flooding is carried out on the basis of petrophysical experiment. The forward modeling shows that: 1) After CO2 flooding, the basic characteristics of seismic reflection remain unchanged, which are "two strong and one weak"; 2) After CO2 injection, the amplitude of the reservoir section is significantly enhanced, and the time is about 4ms down; 3) In different orientations, the amplitude changes according to azimuth after CO2 injection, with azimuthal anisotropy. The model study provides a theoretical basis for our practical application. When the actual data is applied, the OVT gathers is extracted from the high density data after normal moveout by inline and crossline, and then stacked according to the azimuthal information of the data. Considering that the stratum above the injection layer is not affected by carbon dioxide plume, the caprock-T7 standard layer is used to carry out amplitude consistency during stack. After consistency processing, the max-amplitude information of the target layer is extracted, the data is arranged according to polar coordinates, and the ellipse fitting is carried out. The direction of the long axis is the dominant injection and production direction. The prediction agrees with the post-stack difference attribute extracted by time-lapse seismic data (2011 and 2021), and also

agree with the tracer in well.

Investigation of Characteristics of Gas Hydrate Decomposition under Microwave Stimulation

Yue Zhu[1], Changchun Institute of Technology
Baochang Liu[2]*, Jilin University (liubc@jlu.edu.cn)

Abstract

As a kind of clean fuel with huge reserves, the exploitation of natural gas hydrate has become one of the research hotspots in the world. Among many exploitation methods, depressurization combined with heating stimulation is considered as one of the most promising methods. As a unique bulk heating method, microwave could heat gas hydrate quickly and efficiently.

In this paper, the decomposition characteristics of methane hydrate by microwave stimulation were studied under continuous and intermittent microwave heating. Under continuous microwave stimulation method, the decomposition rate of methane hydrate was higher at the initial stage, and the decomposition heat mainly came from microwave volume heating. With the hydrate decomposed, the free water content increased, the microwave penetration depth of the reservoir decreased. The macroscopic heat transfer became the main mechanism of hydrate decomposition in the remote microwave source regions. With the increment of microwave power, the average gas production rate increased from 0.303 L/min to 0.882 L/min. The decomposition time of hydrate decreased with microwave power increased. Intermittent microwave heating could improve the energy efficiency ratio effectively. When the intermittent heating cycle was 5+1 min, the energy efficiency ratio was 2.103, which was 59.32% higher than that of the continuous microwave heating.

Furthermore, the experiments of microwave hydrate decomposition enhanced by different microwave absorbent were studied. C (conductive graphite), TiO2 and Fe3O4 with powder particle size of 1 μm were added into the reservoir as microwave absorbents. The experimental results showed that the average gas production rate and the energy efficiency ratio of C, TiO2 and Fe3O4 groups were increased by 48.5%, 24.3% and 93.5% compared with the blank control group, respectively.

The characteristics and laws of gas hydrate decomposition under microwave stimulation were revealed. The research results could provide theoretical basis and guidance for the process of gas hydrate exploitation in the field.

Fatigue life analysis of oil shale in-situ conversion combustion heater

Shui haoche[1]*, jilin university (shuihc21@mails.jlu.edu.cn)
Wang yuan[2], jilin university
chen zhilin[3], jilin university
guo wei[4], jilin university

Abstract

Oil shale, as an unconventional oil and gas resource, can generate the required oil and gas through high-temperature pyrolysis. In-situ conversion technology is the most commonly used method for oil shale exploitation, which involves injecting a high-temperature heat carrier directly into the oil shale layer using downhole heaters to achieve oil and gas recovery. Components of the combustion heater are made of metal materials, and the uneven temperature distribution experienced by these materials during the beginning, process, and termination of operations can lead to fatigue conditions such as high-temperature creep, micro-cracking, and micro-deformation. To prevent these occurrences, fatigue life analysis of downhole combustion heaters is necessary to provide practical guidance for engineering operations. This study combines actual operational experiments of combustion heaters with finite element simulations to analyze the influence of temperature, structure, and stress amplitude on the fatigue life of the heaters. The findings suggest that the fatigue life of the heater is most significantly affected by the metal gasket, with lower fatigue life observed at higher tail gas temperatures. Heating operations notably reduce the fatigue life of the heater, while cooling operations have minimal impact. Circular metal gaskets exhibit higher fatigue life compared to square ones, and thicker gaskets generally result in longer fatigue life. Stress amplitude has the most pronounced impact on the fatigue life of the heater, as doubling the stress amplitude quickly leads to fatigue failure of the metal gaskets.

Numerical Simulation Study on the Influence of Intermittent Gas Injection on the in-situ Conversion Development Effect of Oil Shale Autothermic Pyrolysis

Yijian ZENG[1]*, Jilin University (1304520112@qq.com)
Chaofan ZHU[2], Jilin University
Yanwei LI[3], Jilin University
Wei GUO[4], Jilin University

Abstract

Autothermic pyrolysis in situ conversion process is a method that utilizes the internal heat of oil shale to thermally decompose it, characterized by its environmentally friendly, low pollution, and high energy efficiency features. The autothermic in situ conversion technology initiates the thermal reaction by injecting air into the formation after thermal triggering, resulting in the appearance of ineffective heating zones, oil and gas oxidation, and so forth. This paper introduces the intermittent gas injection approach to control the autothermic stage and employs numerical simulation methods to investigate the temperature field, kerogen concentration field, and oil saturation field in oil shale formations under intermittent gas injection conditions, as well as to analyze the energy efficiency. The results demonstrate that (1) injecting 20,000 m^3/day of nitrogen at 550°C continuously for four months in the preheating stage, followed by injecting 10,000 m^3/day of air at 25°C to trigger autothermic reactions, leads to substantial oil production one year later. During this stage, intermittent gas injection is implemented, with one month of gas injection cessation alternating with one month of injecting 10,000 m^3/day of air at 25°C, repeated for two years. This intermittent gas injection method yields the best development effect, reaching an energy efficiency peak of 3.51 in the 3.7th year, while conventional autothermic conversion reaches an energy efficiency peak of 3.22 in the 5.3rd year. (2) Intermittent gas injection for autothermic in situ conversion of oil shale results in a 2% reduction in cumulative oil production compared to conventional autothermic in situ conversion, a slight decrease of 1% in cumulative natural gas production, and a significant decrease of 30% in cumulative injected compression energy. However, the energy efficiency is improved by 0.29. This study provides valuable guidance for optimizing the autothermic in situ conversion process for oil shale.

Abstract

In-situ conversion of oil shale is an environmentally friendly, economically efficient, and high energy conversion rate method of extraction. Oil shale formations are characterized by developed fracture, current simulations of oil shale in-situ conversion have not taken into account the impact of fracture pattern.This paper focuses on the oil shale of the Xunyi region in China's Ordos Basin as the research subject. By employing the statistical method of stochastic fracture modeling, a discrete fracture model is developed. Integrated with numerical reservoir simulation software, a comprehensive coupled model of seepage, heat transfer, and chemical reactions is constructed. The study examines the effects of hydraulic fracture permeability, fracture density, fracture length, fracture production, and the fracture dispersion on the concentration of kerogen, the production of oil and gas, and the energy efficiency rate during the in-situ conversion process. The results indicate that higher permeability of hydraulic fracture can lead to thermal shortcuts. An increase in fracture density has a significant impact on early stage production. When the power-law exponent D of fracture length approaches 2,extreme channeling phenomena may occur. The optimal fracture trend is parallel to the well direction. The greater the dispersion of fractures, the more achievable it is to attain uniform and stable heating. The optimal scheme selected for the Xunyi oil shale target area is a main fracture permeability of 50 md, fracture density of 0.00015 m3/m3, fracture length power-law exponent D of 2.5, a fracture trend of 90°, and a Fisher K of 50.This research can provide guidance for enhancing the exploitation of oil shale in targeted areas of the Ordos Basin, Xunyi region.

Abstract

Hydraulic fracturing, as an effective reservoir stimulation technology, is critical in the process of oil shale in situ conversion. In this study, the Nong'an Oil Shale In-situ Conversion Pilot Project is taken as the research object, which examines the generalized changes in reservoir stimulation volume and microfracture density in the stimulated area during hydraulic fracturing and gas injection. The findings revealed that hydraulic fracturing resulted in a greater reservoir stimulation volume, with permeability in the stimulated area increasing to 324.6 mD. Water replacement in the stimulated area was achieved by injecting lower-temperature nitrogen, which helped to reduce reservoir stimulation volume shrinkage and close microfractures. However, permeability dropped by 80.54%, and seepage area fell to 2660.7 m3.

The gas injection and mining procedure is separated into two phases: warming and cracking. The former is to accelerate the drying of the formation in the stimulation area, while the permeability of the stimulated area is restored to 22.87% of the original area. The latter aims to increase the permeability of the reformed area to 704.842 mD through the process of hydrocarbon expulsion by organic matter cracking. The reservoir stimulated area can be classified as cracking, high seepage, or low seepage based on the difficulty of the injected gas flow and the range of high-temperature influence.

Carbon Dioxide Storage Potential of Cenozoic Saline Aquifers in the South Yellow Sea Basin

Yong YUAN[1]*, Qingdao Institute of Marine Geology (yuany010@126.com)
Jianwen CHEN[2], Qingdao Institute of Marine Geology
Jianqiang WANG[3], Qingdao Institute of Marine Geology
Ke CAO[4], Qingdao Institute of Marine Geology

Abstract

Geological carbon dioxide (CO2) storage refers to the engineering approach of injecting captured CO2 into deep geological reservoirs to achieve the long-term isolation of CO2 from the atmosphere. CO2 storage in underwater reservoirs is a valuable method of reducing carbon emissions. Saline aquifers such as those in the South Yellow Sea Basin (SYSB), have great potential for geological CO2 storage. Thus, we use the recommended calculation method of USDOE and a formation volume model to determine the geological conditions for CO2 storage and estimate the CO2 storage capacity of the Cenozoic saline aquifers in the SYSB (depth: 800–3200 m). Overall, the SYSB exhibits weak fault activity and seismicity, medium and low geothermal fields, four types of source sandstone reservoir, and four sets of carbon reservoir–caprock assemblages developed from the Cenozoic strata, providing relatively good geological conditions for CO2 storage. The estimated capacity of the Cenozoic strata ranges from 39.59 Gt to 426.94 Gt (average: 155.25 Gt). The Yantai Depression has a lower geothermal gradient and terrestrial heat, weaker seismic activity, and double the storage capacity of the Qingdao Depression, indicating that it is the most suitable area for Cenozoic CO2 storage in the SYSB, whereas the Laoshan Uplift is not suitable for storage. This study provides a scientific basis for the selection of offshore CO2 storage sites.

Experimental Study and Numerical Simulation of Rock Fracturing Based on High Voltage Electric Pulse

LI XIAOLE LI XIAOLE[1]*, College of Construction Engineering, Jilin University
(lxl22@mailes.jlu.edu.cn)

Abstract

In the process of in-situ transformation of oil shale, the reservoir needs to be heated, and the permeability of the reservoir needs to be improved in order to transfer the heat effectively. Moreover, the process of replacing the oil and gas from the cracked oil shale to the extraction wells also puts high demands on the reservoir, which also needs to be modified.

High-voltage pulsed discharge reservoir fracturing as a promising new technology applied to oil shale .formations.This technique of pulsed discharge in water generates a powerful shock wave. In a short period of time, it will produce a strong destructive force on the rock structure, causing damage to the rock body until it is destroyed,.and finally forming a network of volumetric seams in the reservoir, which can effectively improve the permeability of the reservoir.Through the combination of physical experiments and simulation analysis, we analyze the extension law of reservoir cracks under different discharge parameters and analyze its correlation.ABAQUS software was used to establish a finite element model of oil shale, and numerical simulation of impact fracturing was carried out to analyze the fracturing effect of reservoirs under different discharge parameters, and to provide a theoretical basis for the further development of reservoir fracturing technology.

Abstract

Korea National Oil Corporation(KNOC) is developing the 1st large-scale CCS demonstration project in Korea using the Donghae-1 (East Sea) depleted gas field to pursue the greenhouse gas reduction roadmap by the Korean government. The CCS demonstration project aims to inject 1.2 million tons of CO2 per year into Donghae-1 depleted gas field. In an effort to the government roadmap on carbon reduction, additional storage potentials near the Donghae gas field are required for future scale-up.

In this study, CO2 storage potentials of Donghae-1 gas field and the vicinity area were explored based on the previously acquired data such as seismic, logging, core, production data and the additional stratigraphic and sedimentary environment analysis. Also. Geophysical property analysis and seismic inversion work were performed to build an integrated geological model and dynamic model for capacity estimation.

KNOC evaluated the storage capacity of 1) Donghae-1 depleted gas field where proven containment and sealing capacity as the main CO2 storage, 2) the lower saline aquifer layers extended from the depleted gas reservoirs, 3) the saline aquifers above the gas reservoir with the similar geological concept which is shale-filled canyon, and 4) the saline aquifers in the vicinity of the gas field as an upside potential candidates.

Evolution of fluid occurrence states during oil shale pyrolysis under inert and oxidative conditions

Junfan PAN[1]*, Jilin University (panjf22@mails.jlu.edu.cn)
Wei Guo[2], Jilin University

Abstract

The occurrence state of different fluids in the complex pore space determines their distribution and migration in the reservoir. Revealing the evolution law of fluid occurrence state under different pyrolysis conditions is of vital significance for the efficient exploitation of oil shale. In this paper, oil shale pyrolysis under inert and oxidative conditions at different temperatures (200-800 ℃) was conducted. Rock eval pyrolysis and X-ray diffraction (XRD) were used to determine the composition changes of pyrolysis residue, while low-temperature N2 isotherm adsorption/desorption analysis (LTNA) was used to characterize the evolution of pore space. Nuclear magnetic resonance (NMR) measurements were carried out on solid samples saturated with oil and water, and T2 spectra were calibrated according to LTNA results. The component decomposition method based on Gaussian fitting was used to identify the occurrence state of fluid. The results show that with the increase in temperature, the content of organic matter decreases, and the clay minerals transform into an amorphous form at high temperatures. The pore volume and pore size tend to increase with temperature. The porosity of solid residues produced by oxidative pyrolysis is larger than that of residues generated from inert pyrolysis. NMR spectra can be decomposed into three to five independent component spectra, respectively characterizing micropores (< 10 nm), small pores (10-100 nm), mesopores (100-1000 nm), macropores (1000-10000 nm) and microcracks (>10000 nm). Bound fluid and irreducible fluid are distributed in the micropores and small pores, while movable fluid exists in the mesopores, macropores, and microcracks. The content of movable fluid increases with the increase in temperature, and the content of movable fluid under oxidative conditions is higher than that under inert conditions. The variation trend of the contents of oil and water with the same occurrence states is basically identical. In micropores, clay-bound water is the main fluid while movable oil dominates in microfractures.

Research on the inherent mechanism of rock mass deformation of oil shale in-situ mining under the condition of thermal-fluid-solid coupling

Shuo ZHANG[1]*, College of Construction Engineering, Jilin University (961978810@qq.com)

Abstract

In situ exploitation of oil shale is the focus of future research. Since the mechanical properties and pore structure of oil shale will change after heating, it may face some problems such as land subsidence during its exploitation. At present, few people have studied the deformation of oil shale mining process. In this paper, the structure of oil shale heated at different temperatures was tested by MICP, SEM and CT experiments, and the mechanical tests in parallel and vertical bedding directions were carried out. Combining mechanical properties with structural changes, the constitutive model of in-situ mining deformation of oil shale is established for the first time by using statistical damage mechanics and fracture mechanics. The thermal-fluid-solid coupling model of oil shale in-situ mining was established by COMSOL, and the deformation caused by oil shale mining with a depth of 200m and a thickness of 1m was studied. The results show that before 300 ℃, the mechanical properties have increased due to the expansion of mineral particles and the increase of the continuous enhancement of particles. After 300 ℃, due to the thermal stress and the pyrolysis of organic matter, there are many macro fractures parallel to the bedding direction in the oil shale. This anisotropic structure causes its mechanical properties to decline in different degrees in the vertical and parallel bedding directions. The established constitutive equation considering the parallel bedding fracture and damage can well reflect the stress-strain relationship of oil shale in vertical and parallel bedding directions at different temperatures. The final simulation shows that the oil shale with a depth of 200m and a thickness of 1m will have a settlement of 6.5cm after mining, but combined with the overlying strata and size effect, it is estimated that the final surface settlement will be less than 6.5cm. This article provides important data and theoretical support for the study of the mechanical performance of oil shale and the geological effect

Effect of decrease in pore water salinity induced by depressurization in clayey silt gas hydrate reservoirs on the migration characteristics of illite

Jiang LEI[1]*, Jilin University (leijiang20@mails.jlu.edu.cn)
Wei Guo[2], Jilin University
Yuan Wang[3], Jilin University

Abstract

Achieving long-term efficient production in clayey silt hydrate reservoirs with low permeability and high clay content is challenging, with fines migration being one of the main influencing factors. Illite has a high percentage in the reservoir, and the effect of the decrease in pore water salinity caused by hydrate depressurization on its migration characteristics cannot be ignored. This work investigated the fines migration characteristics of illite under the condition of pore water salinity decreased, and the effect on reservoir seepage characteristics was analyzed by the pressure difference, pore size distribution, clay content and zeta potential. The decrease in pore water salinity induced by hydrate decomposition has a significant contribution to illite migration, even under conditions where the fluid dynamics are insufficient to make a difference. A critical salinity of 3.21% exists for illite migration. A critical salinity of 3.21% exists for illite migration. When the salinity has not decreased to the critical value, the damage of illite migration to the seepage capacity of the reservoir is limited; once the salinity decreases below the critical value, illite is released in large quantities, and the damage to the seepage capacity of the reservoir is worsened. Under low decomposition pressure, illite is more likely to form flocculated structures and lead to reservoir seepage capacity impairment in the form of clogging, while at high decomposition pressures it is more likely to be in the form of bridging. This work suggests that considering the impact of fines migration during hydrate production is critical to achieving commercial exploitation in the future.

Enhancement on the development of methane hydrate in the clayey silty reservoir by stratified split grouting

Hangkai Chen[1]*, Jilin University (chenhangkai@foxmail.com)
Wei Guo[2], Jilin University
Xiaochu Wang[3], Jilin University
Jinsheng Sun[4], China National Petroleum Corporation

Abstract

During the transition period between carbon neutralization and carbon peaking, methane hydrates tend to be the most promising energy resource for replacing the coal resources. In the last two decades, past experiences on field trials have shown that low-permeability and low-strength of clayey silty reservoir are the main barriers to realize the commercial production on hydrates. At present, split grouting is expected to become a new generation of reservoir stimulation for clayey silty reservoir with the better effect, which means to inject a specific slurry into the reservoir, wait until the slurry solidifies inside the reservoir. The consolidated body then would become mass transfer channels with high permeability as well as the high strength reservoir skeleton.

However, the current studies for split grouting have some limitations such as low injection volume, difficulty in injection, and short stimulation range. In other words, there is still a lot of work need to be done before large-scale application for commercial production.

Therefore, in this study, to further discuss the performance of the stratified split grouting in the stimulation of clayey silt reservoir, a three-dimensional experimental system was adopted. The hydrate-bearing sediments were prepared according to the physical properties of clayey silt samples obtained from Shenhu area in South China Sea. To study the influence of stratified split grouting, different grouting pipe designs were adopted to realize the changes of grouting morphology, distribution and other factors. For the in-situ samples after stratified spilt grouting, computed tomography was used to observe the morphology of consolidation in samples and explore the slurry diffusion mode. In addition, the permeability and pore distribution characteristics of in-situ samples were analyzed by nuclear magnetic resonance (NMR).

Overall, this work further proved the feasibility of stratified split grouting with ultrafine cement slurry to stimulate the clayey silt reservoir. Meanwhile, it elucidated the diffusion mechanism of the foamed cement slurry in the sediment during the stratified splitting grouting process. In addition, the in-situ NMR tests of cement-sediment coupler further demonstrate the exceptional effect in terms of permeability. Finally, the analysis of the gas production behavior of grouting parameters revealed the mode of influence of each stimulation parameter. This work will serve as a reference for the selection of suitable stimulation parameters, and grouting equipment design solutions in the development of methane hydrate.

Fracture propagation and evaluation of dual wells, multi-fracturing, and split-time in Fuyu oil shale

Bin Zhu[1]*, Jilin University (zhubin20@mails.jlu.edu.cn)
Qiang Li[2], Jilin University
Wei Guo[3], Jilin University

Abstract

Reservoir stimulation is crucial for in-situ exploitation, it can promote a fracture network and increase the heat transfer area. Therefore, it directly affects heat injection and products transportation efficiencies. Conventional reservoir stimulation techniques, such as hydraulic fracturing are widely used. However, hydraulic fracturing in a vertical well tends to generate simple fractures that are unfavourable for heat transfer, and real-time fracture propagation is difficult to monitor, thus failing to precisely control the hydraulic fracturing scale. In addition, there are few qualitative and quantitative criteria in reservoir-scale fracture evaluations for interpreting the overall hydraulic fracturing effect. Consequently, in this study, dual wells, multi-fracturing, and split-time technology (DMS) were designed and conducted based on microseismic monitoring in field experiments to find real-time fracture propagation. Furthermore, based on Hugot's research on connecting microseismic events by spatiotemporal sequences, we proposed a step-index and path intensity considering microseismic event intensities to evaluate the effect on hydraulic fracturing. The results showed that a three-dimensional fracturing zone with a 60×30×8 m length, width, and height was generated at a 476–484 m depth, which corresponded to the designed hydraulic fracturing and facilitated heat transfer and product migration. Higher pump pressure and rate harmed hydraulic fracturing, blocking proppant migration during which the FK1-4 coefficient of viscosity reached 70 N·s/m2, 1.4 times greater than that of FK1-2 and FK1-5 according to Poiseuille's law. The hydraulic fracturing effect in FK1-4 was superior than that in FK1-2 and FK1-5. This study serves as a reference for monitoring oil shale exploitation via in-situ pyrolysis.

Calculation method and application of cap rock's effective thickness of X Gas Reservoir

Zhengchun SHEN[1]*, China university of petroleum,Geophysical Research Institute,Shengli oilfield,SINOPEC (shenzhengchun.slyt@sinopec.com)
Cunfei MA[2], China university of petroleum
Chengyan LIN[3], lcydcm@upc.edu.cn
Chunmei DONG[4], China university of petroleum
Hongwei HAN[5], Shengli oilfield branch company,SINOPEC

Abstract

A method of computing cap rock's effective thickness is proposed based on that cap rock's heterogeneity may result in different capillary sealing ability within cap rock. Using data of thin section, SEM, breakthrough pressure, porosity, permeability and other test data of argillaceous cap rock and sandstone reservoir, the boundary between cap rock and reservoir can be defined, which includes breakthrough pressure limitcritical lithology(grain size) and petrophysics limitSubsequently the evaluation criteria of cap rock's capillary sealing ability is established. With gamma ray curve, interval transit time curve and test data, a logging interpretation model
is established to quantitatively recognize cap rock's lithology and to calculate porosity, permeability and breakthrough pressure.
A comprehensive evaluation on capillary sealing ability of cap rock has been made to first remove the cap rock with no capillary sealing ability and then to obtain the effective thickness. Our results show that between cap rock and reservoir of X gas reservoir
the breakthrough pressure limit is 2 MPa; the critical lithology(grain size) is argillaceous coarse siltstone; the porosity limit is about 6%and the permeability limit is about 0.02×10-3μm2. Cap rock's capillary sealing ability has been divided into five grades from Ⅰ to Ⅴ. By removing grade Ⅳ and Ⅴ which correspond to no capillary sealing ability, the effective thickness of single cap rock is obtained between 4 and 10 m. Correlation between the height of gas column and the effective thickness suggests the robustness of the method. Based on the effective thickness, a weighted average of breakthrough pressure has been taken to obtain equivalent breakthrough pressure, and the whole capillary sealing ability of cap rock has been evaluated as moderate effectively
The Calculation method for cap rock's effective thickness introduced in the article has guiding significance for the CO2 Geological Sequestration, and has application value for evaluating the potential of CO2 Sequestration.

Hydrocarbon migration and accumulation in shale play

Rujiao CHENG[1]*, China University of Petroleum (Beijing) (crj666666aj@163.com)
Feiyu WANG[2], China University of Petroleum (Beijing)

Abstract

Since 2000, significant breakthroughs have been achieved in the exploration and development of shale oil and gas in North America, prompting an increasing number of countries to focus on the exploration and development of unconventional oil and gas resources such as shale oil. Traditional views suggest that shale oil (or tight oil) is generated in situ from source rocks and remains in place or is preserved in adjacent tight reservoirs through limited short-distance migration. However, in recent years, with the accumulation of global data on shale oil and gas exploration and development, more and more researchers have recognized the existence of large-scale and long-distance migration of oil and gas in unconventional reservoirs. Here, we present a case study of the large-scale migration and accumulation of shale oil from the Paleogene upper Xiaganchaigou formation (E32) in the western Qaidam Basin, China.

The study established a three-dimensional geological framework of the shale reservoir in the study area using the petroleum system simulation software of Trinity, characterized the spatial thermal maturity variation of the shale reservoir based on the actual temperature data of wells, and calibrated the organic maturity of the shale reservoir using measured source rock residual hydrogen index (HI). In this shale reservoir, characterized by a significant thickness (approximately 1-2 km), source rocks ranging from immature to whole oil generation window stages are distributed. Along a dipping geological profile, as burial depth increases, the maturity of the source rocks progressively increases. Extensive shale oil discoveries and extractions have been produced at different depth intervals. Interestingly, oil-source correlation reveals that although the crude oil originates from E32 shale, there are significant differences in maturity indicators (such as biomarker parameters and concentrations) between the crude oil and the in-situ shale. The crude oil maturity is notably higher than that of the indigenous source rocks. Furthermore, mature crude oil has been discovered in shallow, immature shale areas, indicating significant hydrocarbon migration and accumulation in the E32 shale play.

The physical characteristics of crude oil also support this understanding. Along a dipping geological profile, as burial depth increases, the API gravity and gas-oil ratio (GOR) of the crude oil also systematically increase. However, based on kinetic simulations of hydrocarbon generation from organic facies and maturity of source rocks, the predicted GOR values of hydrocarbon fluids generated in situ source rocks are much lower than actual GOR values of production fluids. Therefore, we are more confident in the existence of large-scale hydrocarbon migration and accumulation within the E32 shale reservoir in the study area. According to estimates based on crude oil biomarker concentrations, the lateral migration distance of crude oil exceeds 5 km, while the vertical migration distance exceeds 1 km. This study provides valuable insights: the hydrocarbon generation from organic-lean source rocks in-situ may be a small quantity, and

migration facilitates the enrichment of shale oil, forming sweet spots, which significantly expands the scope of unconventional oil and gas resource exploration, enabling shale oil exploration in low maturity even in immature shale areas.

A novel approach for predicting in-situ stress in coal reservoirs based on acoustic emission: Analysis, comparison, and application

Shuheng TANG[1]*, China University of Geosciences, Beijing (tangsh@cugb.edu.cn)
Kaifeng WANG[2], China University of Geosciences, Beijing
Songhang ZHANG[3], China University of Geosciences, Beijing
Zhaodong XI[4], China University of Geosciences, Beijing

Abstract

In-situ stress is a crucial parameter in the field of coalbed methane (CBM) geology and development, involving various aspects such as evaluating favorable development zones, engineering drilling and completion, hydraulic fracturing, and CBM production process. Accurately predicting in-situ stress has been a long-standing scientific challenge. To develop an effective and precise method for predicting in-situ stress, this study focuses on coal reservoirs in the southern Qinshui Basin. Rock mechanics and acoustic emission (AE) experiments were conducted based on directional compression of coal specimens, providing an in-depth analysis of the stress-strain process and characteristics of AE signals. A method for identifying apparent Kaiser point (AKP) and predicting in-situ stress based on wavelet analysis (WA) of AE signals was established. Comparative analyses were performed with traditional methods in the CBM field, such as hydraulic fracturing (HF) and well logging inversion (LI). This novel approach was applied to predict in-situ stress in the Shizhuangnan block coal reservoir. The results indicated that, the stress-strain characteristics of directional coal specimens are typically delineated into four stages, exhibiting a strong alignment with the stage characteristics observed in AE. The points of AE energy release during compression-induced damage generally occur in the mid-late stage of elastic deformation, the crack propagation stage, and the fracture instability stage. WA of AE signals enables precise identification of the sought apparent Kaiser point (SAKP) corresponding to the current in-situ stress, typically observed as the first relatively strong energy release point. The novel method proposed in this study achieves an average accuracy of 91.4%, surpassing conventional AE slope analysis (87.7%) and well logging inversion (78.0%). HF method, in principle, provide two-dimensional stress measurements and neglect the mechanical heterogeneity of coal reservoir, resulting in significant errors in predicting the maximum horizontal principal stress. Both HF and LI methods are constrained by engineering factors and are costly, making large-scale in-situ stress prediction during early exploration impractical. In contrast, AE method is easier to implement and account for the heterogeneity and mechanical anisotropy of coal reservoir, resulting in higher predictive reliability. The new method proposed in this study was applied to predict in-situ stress in the Shizhuangnan block coal reservoir in the southern Qinshui Basin. The stress state of vertical stress (σv), maximum horizontal principal stress (σH), and minimum horizontal principal stress (σh) undergoes two transitions at depths of 660 m and 950 m, with a predominance of strike-slip ($\sigma h < \sigma v < \sigma H$) and normal faulting stress state ($\sigma h < \sigma H < \sigma v$). The lateral stress coefficient (K) undergoes a transition at a depth of 923.6 m, with vertical stress

becoming the dominant factor. Hydraulic fracturing indicates the development of vertical fractures. The method proposed in this study offers a novel approach for predicting in-situ stress in coal reservoir, providing valuable insights for similar studies in other regions and deep coal reservoir.

Identifying Miocene sedimentary rocks for CO2 storage in the Gunsan Basin

CHANGYOON LEE[1]*, Korea institute of Geoscience and Mineral resources
(chngynlee@kigam.re.kr)
SUN-YOUNG PARK[2], Korea institute of Geoscience and Mineral resources

Abstract

We investigated the Gunsan Basin, also known as the northern South Yellow Sea Basin, to assess its potential for CO2 storage, with a focus on the sedimentary basin's history for facies modeling. The Gunsan Basin was formed during Cretaceous and underwent multiple tectonic events. Its initial formation was associated with rifting processes followed by subsidence due to thermal contraction. The study area is located close to a strike-slip fault, which significantly influenced the accommodation of depositional systems. Following the final syn-rift or uplift-related stage, the basin entered a post-rift or post-uplift stage characterized by thermal subsidence in Early Miocene. Although the post-rift units are typically characterized by coarse-grained sediments, the basin experienced relatively deep subsidence near the strike-slip fault due to local tectonics. This tectonic activity led to the formation of the lake environment from the previous alluvial plain. This transition in the Early Miocene occurred over a relatively short period, resulting in the localized development of the lake near the strike-slip fault. The presence of the lake environment is crucial for CO2 sealing, with the littoral area retaining coarse-grained sediments suitable for CO2 storage. Using 2D-attribute seismic data, we generated trend maps to understand lateral rock variations and applied geo-statistical methods to determine their properties.

Geological Surveys in Ibero-America and land use planning

Enrique Armando CASTELLANOS ABELLA[1]*, Ministry of Energy and Mines
(eacastellanos@gmail.com)
Vicente Gabaldón[2], ASGMI

Abstract

Geological knowledge is vital for territorial planning. It has always been used intuitively and, more recently, it is carried out in coordination with the national geological surveys. Geology and land use planning are mutually dependent. The granting of geological and mining concessions, the management of geosites and geoparks, studies of hazard, vulnerability and risk, and other geological works must always be verified with land uses for approval or not. On the other hand, investments, both in buildings and roads, national, strategic or regional land use planning, take into account the geological information generated by geological surveys.

This work presents a summary of how these national organizations contribute and, at same time, benefit from land use planning. Examples from Ibero-America presented in a workshop of the Association of Ibero-American Geology and Mining Surveys (ASGMI) on the role of geological surveys in land use planning and management are analyzed. Some countries that have assigned land-use planning functions to their respective national geological surveys are highlighted. Other countries, with smaller or even no geological surveys, have less significant land use planning roles. Although deficiencies still persist in practice, there is an institutional framework that has achieved great progress in the region.

The need to implement communication actions to more effectively disseminate geoscientific knowledge of the territory is recognized, with greater emphasis on risk reduction, geological heritage, and mineral and hydrogeological resources. It is concluded that it is important that geological surveys incorporate in their lines of action a holistic transdisciplinary vision of geodiversity, which includes not only strictly geological knowledge of the territory, but also that which contributes to adaptation to climate change, including active processes. Biodiversity and the impact of anthropogenic activity on ecosystems. Finally, it is very convenient to share experiences and information related to regulations and legislation as a guide for the support and consolidation of the activity of geological surveys in relation to land use planning and management and as elements of support for the energy and ecological transition.

Developing QGIS Plugins for 3D Geological Modelling

Michel M. NZIKOU[1]*, Center of Exploration Targeting - UWA
(michel.nzikoumamboukou@uwa.edu.au)
Mark Jessell[2], Center of Exploration Targeting - UWA

Abstract

As the demand for advanced geological analyses and visualizations increases, the integration of three-dimensional elements within GIS platforms becomes essential. This initiative seeks to enhance the usability of existing Loop3D algorithms by leveraging recent developments and innovations within QGIS to address the complexities associated with 3D geological modelling.

To achieve this goal, a QGIS plugin has been developed to provide a user-friendly interface for industry, geological survey and research projects. The plugin focuses on several key areas, including data processing and integration, visualization techniques, and the incorporation of field and knowledge-based geological parameters into the QGIS ecosystem. These enhancements aim to streamline the various processes involved in map deconstruction that provide inputs for 3D geological modelling codes.

Furthermore, extensive 3D modelling calculations have been integrated to facilitate the transition to 3D geological modelling, whether conducted remotely or locally using docker technology.

This project explores the evolving landscape of QGIS development, specifically targeting the enhancement of its capabilities for 3D geological modelling. Through practical applications, our work demonstrates the enhanced QGIS 3D geological modelling capabilities and their relevance in real-world scenarios. Additionally, we outline potential future directions for QGIS development in the realm of 3D geological modelling, underscoring the importance of ongoing collaboration, innovation, and the integration of cutting-edge technologies.

This exploration contributes to the broader discussion on open-source GIS platforms, highlighting their adaptability to meet the evolving needs of the geospatial community in the context of three-dimensional geological modelling.

Abstract

A more precise understanding of a nation's geology is a necessary first step to better address many policy issues related to finding and exploiting its resources. In this context, the Saudi Arabian government, through the Saudi Geological Survey, has commissioned a decade-long remapping of the exposed Precambrian geology of the Arabian Shield at 1:100,000 scale. As part of this process an Arabian Shield Stratigraphic Commission has been assembled and tasked with developing a new lithostratigraphic and lithodemic code (ASLLC) to act as a guide for mapping.

During 2023, the commission made three traverses across the Shield. Through these, and a subsequent workshop, the new ASLLC was developed. We present it here for the first time. The ASLLC builds from the existing Saudi Arabian lithostratigraphic code, which it updates, and merges aspects of both the North American and British Geological Survey codes. During this process, we addressed a number of issues that have emerged over the use of these codes in low-grade accretionary orogens, such as the Saudi Arabian Shield. One innovation is to define a new class of "highly deformed rocks" within which, structural lithodemes are defined that are collected within higher ranked "shear zone" and "shear zone system" or, for rocks exclusively deformed by brittle deformation, "fault/fault zone" and "fault system".

The Arabian Shield has been split into various terranes over the last decades. A primary task of the ASSC is to test the veracity of each terrane as more mapping and geochronological data is released over the project's life. Fourteen terranes have been initially defined. These are the Midyan, Jiddah, Hijaz, Bidah, An Nimas, Al Qarah-Malahah, Tathlith, Hulayfah, Nuqrah, Ha'il, Suwaj, Ad Dawadmi, Ar Rayn and Siham-Khida terranes. A geochronology database for these terranes has been audited and revised, and the existing stratigraphy has been compiled with stratigraphic code issues and scientific questions identified for all terranes.

In this presentation we will present the ASLLC and use examples of terranes from the Arabian

Shield to illustrate its applicability to discuss how it will guide mapping. Although designed for the Arabian Shield, we suggest that this code has considerably wider application. The integration of new mapping with up-to-date stratigraphic techniques and methodologies, a new generation of geophysical data and a targeted geochronological program, provides a unique opportunity to obtain a better scientific understanding of the development of the Saudi Arabian Shield, and of arc-terranes in general. It is aimed at ensuring that the mineral prospectivity of the Arabian Shield becomes better understood, and will guide future land use policy in Saudi Arabia as the Kingdom develops its mineral resources.

[Keynote] The Australian national geological survey organisation's (Geoscience Australia) provision of geoscience data to inform national policy and decisions using the Digital Atlas of Australia

Steve HILL[1]*, Geoscience Australia (steve.hill@ga.gov.au)

Abstract

Geoscience Australia hosts Australia's national geological and geographic capability enabling national-scale, evidence-based decisions by government, community and industry. A new means of delivering geospatial data, the Digital Atlas of Australia, brings together, curates and connects trusted national geospatial datasets from across government into an interactive, secure, and easy-to-use online platform. As part of this, the Digital Atlas will be the single access point to Australian Government data on geography, people, economy, and the environment. Exploring data by location will empower governments, businesses and communities to make better data-driven evidence-based decisions about planning, infrastructure and investment at the local, regional and national level.

On 31 March 2023, The Digital Atlas beta prototype government environment was made available to select stakeholders from across federal government. As a whole of government geospatial capability, the Digital Atlas for government enables authenticated government users to explore, visualise and analyse readily available, curated, open, location data alongside their own data in a secure environment. By 30 June 2023, the Digital Atlas of Australia beta prototype will be made available to the public—representing the initial operating capability. The final "go live" release of the Digital Atlas of Australia is then planned for the first half of 2024. The sustainment and incremental development of the platform and data links will then continue. Digital Atlas of Australia can be accessed at www.digital.atlas.gov.au

Contribution of geoheritage and geoconservation research to land use planning and new policies in the post-eruptive recovery phase of 2021 Tajogaite volcano (La Palma Island, Spain)

Juana VEGAS[1]*, Geological Survey of Spain (IGME-CSIC). Spain (j.vegas@igme.es)
Gonzalo Lozano[2], Geological Survey of Spain (Instituto Geológico y Minero de España, IGME-CSIC). Spain
David Sanz-Mangas[3], Geological Survey of Spain (Instituto Geológico y Minero de España, IGME-CSIC). Spain
Nicolás Ferrer-Valero[4], , Institute of Oceanography and Global Change. Las Palmas de Gran Canaria University (IOCAG-ULPGC). Spain
Inés Galindo[5], Geological Survey of Spain (Instituto Geológico y Minero de España, IGME-CSIC). Spain
Nieves Sánchez[6], Geological Survey of Spain (Instituto Geológico y Minero de España, IGME-CSIC). Spain

Abstract

From September 19th to December 19th in 2021, a hybrid volcanic eruption with strong fissural control and some phreatomagmatic pulses (magnitude VEI 3) occurred on the northwest slope of the Cumbre Vieja volcanic ridge on the island of La Palma (Canary Islands, Spain). More than 200 Mm3 of volcanic material was emitted through a main eruptive alignment N130ºW trend. This main fissure had more than a dozen eruptive vents, of approximately 0.5 km-length, which generated a volcanic cone with a maximum height of 200 m with respect to the pre-eruptive topography. The eruption produced tephrite-basanite lavas over more than 1200 ha, with a majority of a'ā type lavas and a minority of pāhoehoe type lavas, with an estimated maximum thickness of 70 m. The last days of the eruption also saw the opening of eruptive fissures disconnected from the main cone, with the emission of pāhoehoe lava flows. Two main lava deltas have also formed, with a subaerial surface area of 48 ha and an estimated submarine area of 21 ha. The accumulated tephra deposit ranged up to 2.7 m thick in the areas close to the main cone, reaching the whole island and even the rest of the western Canary Islands in the phases of greatest explosivity. The lava flows and accumulated tephra have had a direct impact on the most inhabited area of the island. The scientists call it an ‘urban eruption’, as it seriously affected several villages and over 3000 buildings, roads and banana and vineyards farms.

On the other hand, this latest eruption on La Palma Island in 2021 has highlighted the scientific challenge of determining the most valuable volcanic features for protection. The present work reports the methodology specially designed to identify the EVIs (Spanish acronym for Volcanic Elements of Interest) and assess their scientific and touristic value. The results have allowed to select EVIs that should be legally protected to ensure a sustainable socioeconomic development that does not endanger the conservation of the most valuable features of this volcano. The identification and mappings of EVIs have been used this methodology have been used by the Canary Islands Government (Decree Law 9/2023, of December 18), on the adoption of "territorial and urban planning measures for the economic and social recovery of the island of La Palma after

the volcanic eruption of Cumbre Vieja", where they are protected and recognised in the category of 'land for precautionary protection' as an initial procedure for their inclusion in the Cumbre Vieja Natural Park. Over this two-year period, leading up to the adoption of the Decree-Law by the Regional Government, strong damages and impacts caused irreversible loss of the most valuable volcanic elements. This fact shows the importance of quick scientific assessment of geoheritage in order to include the most valuable areas in the new territorial and urban plans to be carried out after the eruptions have ended. This is the best guarantee for geoconservation in volcanically active areas.

The European Critical Raw Materials Act – How can geoscience programmes support the Act and build collaborations

Ana Luisa Luísa LAVADO[1]*, Geological Survey Ireland (analuisa.lavado@gsi.ie)
Dina Carrilho[2], Fundação para a Ciência e a Tecnologia
Koen Verbruggen[3], Geological Survey Ireland
Aoife K. Braiden[4], Geological Survey Ireland

Abstract

In 2023, the European Commission published the Critical Raw Materials (CRM) Act. This document sets the foundation to (i) strengthen the EU's capacities along all stages of the value chain by strengthening domestic supply chains, (ii) improving resilience by increasing preparedness, reducing dependencies, and promoting supply chain sustainability and circularity, and (iv) reinforcing international engagement to develop mutually beneficial partnerships. The Act also sets 2030 benchmarks for Strategic Raw Materials:

• Extraction: at least 10% of the EU's annual consumption for extraction.
• Processing: at least 40% of the EU's annual consumption for processing.
• Recycling: at least 15% of the EU's annual consumption and recycling.
• External Sources: not more that 65% of the EU's annual consumption of each strategic raw material at any relevant stage of processing from a single third country.

To effectively implement the Act and achieve the 2030 benchmarks for Strategic Raw Materials, the European Union will strengthen the uptake and deployment of breakthrough technologies in CRM by investing in research, innovation, and skills. The establishment of a large-scale European public-public partnership to provide funding and promote skills development relevant to the CRM value chain and circular economy is one important tool to be implemented. Critically, this will rely on a joint effort from Member States and non-EU countries to tackle the transnational/cross-border/international supply chains necessities, demands, and problems addressed by the Act.

To support the Act, a large scale pan-European Partnership on Raw Materials for the Green and Digital Transition will continue the successful work of the 3 ERA-MIN networks (2011-2025) as a funding instrument complementary to Horizon Europe, across all areas of the non-fuel, non-food raw materials research and value chain, which will actively contribute to the implementation and objectives of the CRM Act and to the EU Joint Research Centre Raw Materials Information System (JRC RMIS).

This presentation will summarise the contribution and efforts of European networks, including geological surveys and researchers across all sectors, and how we can support the implementation of the CRM Act while strengthening international collaborations and partnerships.

Geological Survey Ireland, supporting national policy through geoscience on land and at sea.

Koen M VERBRUGGEN[1]*, GEOLOGICAL SURVEY IRELAND (koen.verbruggen@gsi.ie)
Ray Scanlon[2], GEOLOGICAL SURVEY IRELAND
Aoife Braiden[3], GEOLOGICAL SURVEY IRELAND
Monica Lee[4], GEOLOGICAL SURVEY IRELAND
Sean Cullen[5], GEOLOGICAL SURVEY IRELAND
Eoin McGrath[6], GEOLOGICAL SURVEY IRELAND
Sarah Blake[7], GEOLOGICAL SURVEY IRELAND

Abstract

Geological Survey Ireland is a division of the Irish government Department of Environment, Climate and Communications, and has typical origins as a geological survey founded to map the nation's natural resources, in 1845. In recent years it has changed focus from more traditional geological mapping activities and methods to carrying out major projects of national societal value, supporting and developing policy initiatives, many of which also support Land Use Planning. Programmes include; one of the world's largest seabed surveys INFOMAR, which is delivered jointly with the Irish Marine Institute, is supporting Offshore Renewable Energy policy and marine spatial planning; a national groundwater mapping and protection programme supporting the EU Water Framework and Drinking Water Directive and policies, which has produced maps of Aquifers, Groundwater Protection Schemes and Source Protection Zones as well as online tools use by decision makers on land use planning; modern geophysical and geochemical mapping under its Tellus programme, which is supporting agricultural soil, radiological protection and mineral development policies as well as updating the fundamental geological maps which underpin all land based products; and a minerals programme supporting construction, aggregate and mining policies, including Aggregate Potential Mapping online resources and databases of mineral occurrences. The minerals programme is also dealing with Historic Mine Site rehabilitation as a safety, water quality, remediation, and land-use issue. In addition, the survey has helped develop a new national Geothermal Roadmap and subsequent Geothermal Energy Policy and supporting scientific programme, which is working to develop deep geothermal in Ireland to support decarbonising of heating systems. Geological Survey Ireland has also developed a successful geoscience research programme, supporting international and national research policies, including those on Geoscience research supporting land use policies. By maintaining an awareness on policy development, particularly from a European Union perspective, often by working closely with EuroGeoSurvey the umbrella organisation, and focussing on stakeholder engagement, effective communication of the value of geoscience and maintaining scientific rigour, geological surveys can play a vital role in land use and marine planning and national policy.

Geoscience information in Dutch land use planning: showcase for comprehensive planning?

Rob van der KROGT[1], TNO - Geological Survey of the Netherlands
Tirza van van DAALEN[2]*, TNO Geological Survey of the Netherlands (tirza.vandaalen@tno.nl)

Abstract

In the Netherlands, knowledge about hydrology and subsoil conditions has always been supporting land use planning. But the use and content of this knowledge in planning practices shifted over time. For centuries, the Dutch gained experience with the subsoil creating new land, 'engineering' hydraulic systems (canals, ditches, wind mills) and building dykes. On the 'old' land, planning was often guided by common knowledge about local hydrology and subsurface conditions. The 20th century brought urbanization and high ambitions to create prosperity for growing populations; natural conditions regarding water and the subsurface were often ignored or 're-shaped' to enable large housing and infrastructure developments. The last few decades, spatial planning is facing new grand challenges, such as climate adaptation and the energy transition. These challenges enforce better utilisation and integration of subsurface conditions in spatial planning, for example to create (future) resilience to flooding, drought and subsidence or to enhance use of geothermal potential. This raises awareness of spatial planners and politicians that solid subsurface knowledge is (again) key for sustainable planning.

Knowledge base for the subsurface
Over many decades, geoscientific experts and organizations such as the Geological Survey of the Netherlands have created a huge knowledge base for the subsurface. Since early 90s, they invested in digitizing their paper archives. They replaced the production of geological maps by systematic digital and nationwide 3D subsurface modelling. Next, and still ongoing, they are improving data and IT-infrastructures along professional standards. Since the early 2000s serious attempts were made to connect to the spatial planning domain. This process evolved from performing advisory tasks for public boards, then providing geoscience data as public open data and concluded by the development of a key register for the subsurface: a single national database for subsurface data and information, which Dutch government bodies are obliged to use when making policies or decisions that pertain to, or can be affected by the subsurface. This key register is legally governed by a national law. And recently, the Dutch Government issued a formal policy guideline, stating that 'water and subsoil should be guiding spatial planning choices'. This unique proposition combining (legal) policies, geoscientific expertise and information management is now largely in place.

Towards more effective use of subsurface data
This proposition is not the end stage, but a starting point for the spatial planning community to develop deeper understanding how to utilize geoscience information most effectively and how to

fulfill their new role as data suppliers for the key register. On their side, the geoscience community, with the survey as its prominent party, is learning step by step how to present geoscience data for the planning domain. This involves for example rethinking or adding various data types, use and interpretation of the 3D/4D models, scale and resolution issues, and integration with aboveground data and models. Good practices can already be presented, where geoscience information contributes to more comprehensive land use planning, dealing with actual challenges related to urban development, water management, energy storage and infrastructure planning.

OneGeology Projects: Climate Action, Geohazards and of course, the Global Geological Map

James Patrick Johnson[1], Geoscience Australia
Steve Hill[2]*, Geoscience Australia (steve.hill@ga.gov.au)
Verity Normington[3], Geoscience Australia

Abstract

OneGeology is a membership coalition that provides opportunities for collaboration between national geological survey organisations around the world. The collaborative nature of OneGeology is such that despite no official directive to work together, through strong relationships and a common goal, accessibility of geological data has been, and continues to be, improved. OneGeology is championing the adoption of new approaches and best practices are encouraged to the benefit of all. Sharing of experiences and expertise from geological surveys around the globe, allows for smaller organisations to benefit from capabilities and networks of larger organisations and, as such, programs of common interest promote common and interoperable data standards, formats and methods.

Through the OneGeology portal, geoscience information, such as geological maps, are accessible for all continents on a single platform. This portal showcases that through common standards and protocols, data can be shared and work interoperably, independent of platform. Using the lessons learned to enable the sharing of global geological maps, OneGeology is expanding the platform to share information from the member organisations regarding climate change and natural hazards.

Climate change and natural hazards affect everyone on this planet and, as such, OneGeology is endeavouring to make information accessible to all through a portal that provides direct links into organisations' webpages to provide information about a country's Climate Action scientific programs, and its Natural Hazards programs. These new examples will be a springboard for new relationships, collaborations and greater promotion of geoscience education and outreach through accessible and findable online resources.

Public geoscience: a foundation for strategic land use decisions in Canada

Sonia TALWAR[1]*, Geological Survey of Canada (Natural Resources Canada)
(sonia.talwar@nrcan-rncan.gc.ca)
Daniel Lebel[2], [Retired] Geological Survey of Canada (Natural Resources Canada)
Philip Hill[3], Geological Survey of Canada (Natural Resources Canada)

Abstract

In Canada, public geoscience has found broad application in support of land use planning and land management by governments since the Geological Survey of Canada was established in 1842.

Here we present some recent examples where geoscience knowledge was developed to inform land decisions in Canada in a variety of national level contexts. We review geoscience programming at the Geological Survey of Canada (GSC) to highlight multiple innovative applications that were developed in response to various national policy needs regarding land management.

GSC geoscience activities have grown in applications to address national policy needs from specific land areas (such as defining new national parks), regional scale (e.g. developing northern mineral deposits and road infrastructures), to the entire Canadian offshore territory (e.g. undertaking offshore resource assessments to help define 30% of marine conservation areas by 2030).

Many of the federal level policies that drove the demand for geoscience over the last decade are derived from Canada's commitment to international conventions and treaties, namely: UNCLOS (oceans), UNCBD (biodiversity), and UNDRR (disasters). To a lesser extent, public geoscience also has been driven by UNSDGs (sustainability) and will most certainly be, by UNDRIP (Indigenous). Taken together, these federal policies and international commitments are fundamental to the new GSC Strategic Plan 2023-2028. We believe that there are potentially many lessons to be learned from a comparison of the GSC with other national geological survey organizations in how they manage domestic lands and engage in international partnerships.

However, each country varies in governance and we recognize that the Canadian experience is likely difficult to replicate elsewhere. Land management responsibilities and associated political and administrative processes between the various levels of governments is complex. From the federal to the municipal levels, each government often contends with a multitude of evolving and conflicting public and private issues and interest groups competing over the rights of use of a given land area at the surface and extending to the subsurface. In such a context, it can be a further challenge to bring the weight of scientific advice and data to bear on the decisions.

One of the more far reaching changes that has influenced land use and decision in Canada started when Canada adopted a proactive policy of Indigenous reconciliation, following a number of major judicial decisions and constitutional changes that affirmed Indigenous rights. The country fully adopted UNDRIP in 2016 after simply endorsing it in 2010. With this adoption, Canada is engaged in the work to enable Indigenous peoples to exercise their inherent rights, including the right to own, use, develop and control lands and resources within their territories. This, in turn, creates a challenge and an opportunity for geoscientists in Canada to engage with Indigenous Peoples to build capacity to manage the natural resources in line with their world view.

Navigating Extreme Landslide Events: Insights from Slovenia's August 2023 Disaster and the Role of the National Geological Survey

Miloš BAVEC[1]*, Geological Survey of Slovenia (milos.bavec@geo-zs.si)
Jernej Jež[2], Geological Survey of Slovenia
Mateja Jemec Auflič[3], Geological Survey of Slovenia
Andrej Novak[4], Geological Survey of Slovenia
Tina Peternel[5], Geological Survey of Slovenia
Ela Šegina[6], Geological Survey of Slovenia
Špela Kumelj[7], Geological Survey of Slovenia
Klemen Teran[8], Geological Survey of Slovenia
Jasna Šinigoj[9], Geological Survey of Slovenia

Abstract

In August 2023, Slovenia experienced unprecedented rainfall leading to severe floods and numerous landslides, predominantly in the Southeastern European Alps and its foothills. The Savinja, Meža, Kamniška Bistrica and Poljanska Sora valleys in northern Slovenia were particularly affected. The Geological Survey of Slovenia (GeoZS) played a crucial role in mitigating its impact.

GeoZS, the largest (public or private) geoscience organization in Slovenia, has evolved its mission from mineral resource exploration to understanding Earth's dynamics, environmental changes and issues and geohazards throughout its near 80-year history. Leveraging its expertise, GeoZS swiftly responded to the crisis.

Using MASPREM, a national landslide warning system, GeoZS collaborated with civil protection services and meteorological offices to issue timely warnings, contributing to relocate of thousands of inhabitants and prevent immediate casualties.

Immediately after the floods, GeoZS deployed landslide experts to advise intervention teams on temporary mitigation measures and relocation efforts. Additionally, GeoZS facilitated the acquisition of Copernicus Rapid Mapping results and used high-resolution orthophoto scans of affected areas, aiding in rapid damage assessment. Initial estimates suggest that approximately one-tenth of the 10,000 landslides triggered may require mitigation measures, with potential costs exceeding €1 billion.

Furthermore, GeoZS promoted the use of e-Plaz, a citizen science application, to gather data on landslide occurrences, resulting in the registration of nearly 2000 landslides by municipalities. This data serves as a valuable resource for disaster assessment and prioritizing mitigation efforts.

In response to the disaster, the government enacted the Act on Reconstruction, Development and the Provision of Financial Resources, mandating among others the creation of a centralized database for geological and geotechnical information. This marks a significant step towards proactive risk management and underscores the importance of maintaining comprehensive geological databases.

GeoZS advocates for the establishment and maintenance of such databases as a fundamental

responsibility of national geological surveys. In pursuit of its vision, GeoZS endeavors to establish practices within the geological surveys community that maximize the benefits for the public. Through initiatives like the Geological Service for Europe project (GSEU), GeoZS aims to optimize practices to ensure the public derives the greatest possible value from geological surveys, thereby enhancing disaster preparedness and response capabilities.

In conclusion, the August 2023 landslide disaster in Slovenia highlighted the indispensable role of a geological survey organizations in crisis management. By leveraging its expertise and resources, GeoZS not only facilitated immediate response efforts but also contributed to long-term risk mitigation strategies, emphasizing the importance of proactive geological data management in safeguarding communities against natural hazards.

U.S. Invests in Foundational Geoscience Data Collection, Mapping, and Analysis to Inform Infrastructure Policy

David APPLEGATE[1]*, U.S. Geological Survey (applegate@usgs.gov)
William L. Cunningham[2], U.S. Geological Survey
Geoffrey S. Plumlee[3], U.S. Geological Survey

Abstract

The mission of the U.S. Geological Survey (USGS) is to deliver actionable information on complex human and natural Earth system interactions at scales and timeframes relevant to decision makers. As the science arm of the U.S. Department of the Interior, which manages one-fifth of the nation's lands, the USGS produces policy-relevant science that informs environmental, natural resource, and public safety decision.

In 2021, the Infrastructure Investment and Jobs Act provided the USGS with major investments in areas common to many geological survey organizations: geologic mapping, geophysical surveys, geochemical assessments, hyperspectral imaging, high-resolution digital elevation data, and geoscience data preservation. Several USGS programs have been enhanced through these investments: the Earth Mapping Resources Initiative (Earth MRI), the 3D Elevation Program (3DEP), and the National Geological and Geophysical Data Preservation Program (NGGDPP).

The USGS launched Earth MRI as a collaborative effort with U.S. states' geological surveys, tribal nations, and private-sector entities to modernize the surface and subsurface geologic mapping of the nation. The USGS and partners jointly identify, prioritize, and acquire new geoscience data. The primary focus is on geographic areas that have potential to host a variety of mineral resources. Such foundational data also benefits studies of energy resources, groundwater resources, natural hazards, and infrastructure planning. Earth MRI currently focuses on critical minerals and industrial minerals including construction materials. As one example, over the past 5 years, Earth MRI has conducted high-resolution airborne geophysical surveys in areas covering over 1 million square kilometers to yield an improved understanding of the Nation's critical mineral potential. The evaluation of mine waste as a potential resource for critical minerals is a unique aspect of Earth MRI. The USGS is developing a national mine waste inventory and conducting targeted research to characterize this potential resource, a potential "win-win" for mineral supplies and the environment. From all of this data collection and research, the USGS develops assessments quantifying mineral resource potential both from in-ground deposits and from mine waste.

Detailed topographic mapping provides valuable insight toward understanding geologic processes. 3DEP was created in 2016 to respond to growing needs for high-quality elevation data to inform critical decisions that are made across the USA every day, ranging from immediate safety of life, property, and environment to long-term planning for infrastructure projects. 3DEP collects lidar data nationwide with a vertical accuracy of 10 centimeters that can produce high-resolution models of ground elevation. At the end of fiscal year 2023, 94.7% of the Nation has available or

in-progress elevation data that meet 3DEP specifications for high accuracy and resolution.
The NGGDPP is providing resources that enable the USGS and U.S. state geological surveys to create more uniform physical and digital infrastructure to properly store the geological and geophysical data and samples needed to understand critical minerals, and making these data and samples available to all who need them for generations to come.
These investments are allowing the USGS and its partners to collect and synthesize data on natural resources that will inform land use planning and decision-making for generations.

EU International Centre of Excellence on Sustainable Resource Management in support of the United Nations Resource Management System

Meta Dobnikar[1], Geological Survey of Slovenia
Snježana Miletić[2], Geological Survey of Slovenia
Miloš BAVEC[3]*, Geological Survey of Slovenia (milos.bavec@geo-zs.si)
Zoltan Horvath[4], Supervisory Authority of Regulatory Affairs, Hungary

Abstract

Sustainable, efficient and integrated use of raw materials, needed for energy storage, power generation and the transition to climate neutrality, may be achieved by harmonization and attentive management of data on its reserves and resources. These circumstances created an opportunity to build on EU level mineral intelligence by developing a capacity building and knowledge centre in support to the sustainable resource management.

With such a motivation, the Horizon Europe project Geological Service for Europe is creating an EU International Centre of Excellence on Sustainable Resource Management (EU ICE SRM). The objective of the EU ICE SRM is promotion and capacity building of an international scheme for the classification and management of resources – the United Nations Framework Classification for Resources (UNFC), that considers the degree of confidence, technical feasibility and social-economic-environmental aspects of each project. The UNFC assists the implementation of the United Nations Resource Management System (UNRMS). UNRMS is a comprehensive resource management system for sustainable development, represented by the principles and requirements on sustainable resource management, set by the United Nations Economic Commission for Europe.

The first steps towards the creation of the EU ICE SRM have been made. Capacity building trainings on UNFC have been organized to support the implementation of the European Critical Raw Material Act, which aims to enhance the resilience of EU critical raw material supply chains. The EU ICE SRM will also further develop and maintain a European Network for UNFC experts and will tend to achieve a common understanding of UNFC, expanded to other resources, including secondary raw materials, water and energy.

By this approach the EU ICE SRM supports UNRMS through capacity building and promotion of the resources needed to accomplish the goals of the UNs 2030 Agenda for Sustainable Development. It intends to operate as a network of partners and experts to assist the decision makers and key stakeholders in resource management.

Subsurface environment, a key asset for the global ecological transition

Christophe POINSSOT[1]*, BRGM (c.poinssot@brgm.fr)
Patrick D'HUGUES[2], BRGM
Francis CLARET[3], BRGM
Alain DUPUY[4], BRGM

Abstract

Global climate change is certainly one of the most challenging issue the humankind has ever faced. In order to mitigate its potential impact, reducing greenhouse gas emissions is mandatory and will require developing low-carbon technologies and societies, while preserving the biodiversity is crucial for the overall livability of earth. Although often neglected in the public debate, subsurface environment is the core of many solutions that will play a significant role either for reducing the overall impact, or for adapting to the changing environment.

On the one hand, decarbonising the economy will rely on an intensive electrification of usages that will require developing new energy infrastructures which are highly metals intensive: windmills, solar panels or electric vehicles will for instance require very large amounts of critical mineral resources such as rare earths, nickel, lithium or even copper. The anticipated explosion of the mineral demand will not be covered by the sole recycling, and extracting new metals will be mandatory. Developing new exploration programs and new mines will be needed but will have to be meet the highest environmental and social standards for being sustainable and acceptable, the so-called responsible mining.

On the other hand, low carbon heat will also have a key role to play to optimize the overall efficiency and reduce the electricity demand. Among others, geothermal heat has most likely a key role to play for meeting the demand in residential or tertiary buildings heating or geocooling. Beyond the overall reduction of electricity consumption, it will efficiently contribute to reduce peak demand which has a very strong impact on the grid dimensions. Storing fatal heat underground may also easily be implemented with such geothermal systems, paving the way for inter-seasonal heat storage. Quantitative illustration of the huge potential for decarbonization will be illustrated based on the French case.

Finally, water is both a prerequisite for human livings but also mandatory for many powerplants and industries. Example of powerplants shutdown due to summer drought is a clear illustration of the nexus between water and energy. Aquifers currently represent a very high share of the overall water used in many countries, (e.g. 40% for industries and 70% for potable water in France). Ensuring a sustainable supply of water will only be achievable by a better knowledge and management of underground water in order to compensate for the likely reducing of precipitation and the increase of intermittency.

Altogether, subsurface is at the core of many essential solutions to be implemented on our pathway towards net zero and sustainable societies. In such context, politization and governance

of subsurface environments will have to be renewed and improved based on a better knowledge of subsurface. Geosciences have never been so necessary for the future of our societies!

The key role of NGSOs and transnational associations in supporting policy making process for mitigating and adapting to the global climate change

Christophe POINSSOT[1]*, BRGM (c.poinssot@brgm.fr)
Philippe FREYSSINET[2], BRGM

Abstract

Global climate change is certainly one of the most challenging issue the humankind has ever faced. In order to mitigate its potential impact, reducing greenhouse gas emissions is mandatory and will require developing low-carbon technologies and societies, while preserving the biodiversity is crucial for the overall livability of earth. Although often neglected in the public debate, subsurface environment is anticipated to provide solutions that will play a significant role either for reducing the overall impact, or for adapting to the changing environment: critical mineral resources, geothermal energy, water resources, storages… Geological environments also bring risks such as eathquakes, sea level rising, erosion and landslides, clay swelling, which are for many of them sensitive to the overall climate change.

In such a context, developing and sharing a better knowledge and understanding of the subsurface is a mandatory step for an optimized usage of the underground resources and a better anticipation and prevention of the risks. It is the core mission of the National Geological Surveys association to develop such a knowledge in each country. Although invested for decades or centuries, the current knowledge is as such still far from being completed and often limited either to large scale structures or to upper subsurface. A first challenge to face is therefore to improve the subsurface knowledge and make it available to the overall societies not only by geological maps, but also by large set of databases and 3D numerical models. Essentially, geology remains an model-driven interpolation science from a huge large number of data coming from satellites, geophysical surveys, boreholes, samplings, geochemical analyses… As such, it represents a fantastic playground for model-driven AI which is typically designed for such challenges! NGSO are most likely at the eve of a new revolution to come 50 year after plate tectonics.

Supporting policy making processes and governments require providing qualified datasets and 4D models to be able to assess the usable resources while preventing the potential risks and preserving the biodiversity. However, underground has no frontiers and many issues are cross-cutting frontiers. That was one the key driver for launching in 1971 an association of all the EU NGSOs in the so-called EuroGeoSurveys non-profit association (EGS). The aim was to gather and share the subsurface knowledge, the know-how and provide EU with a large set of experts. From time to time, the core of a EU numeric platform was developed, European Geological Data Infrastructure (https://www.europe-geology.eu/) which provide EU scale maps and sets of data. EGS also developed under a dedicated EU funding, a trans-national geological service for Europe (GSEU). EGS is currently supporting the development of new and innovative EU policy for improving land planning, resources usages and risk mitigation. Key role in the i:!implementation of the Critical Raw Material Acts from 2023 is a good example.

With the anticipated increasing role of geoscience for facing the near-future issues, NGSOs and transnational organization such as EGS have a clear front-stage role to play in supporting policy making process.

The Important of Geoscience Data for Land Use Planning in Malaysia

Zamri bin RAMLI[1]*, Department of Mineral and Geoscience Malaysia (zamri@jmg.gov.my)
Amir Mizwan bin Mohd Akhir[2], Department of Mineral and Geoscience Malaysia
Abd Rahim bin Harun[3], Department of Mineral and Geoscience Malaysia

Abstract

In Malaysia, the development and adoption of mineral and geoscience data has emerged as an effective tool for providing geological information for land use planning and decision-makers. The geoscience data in land use planning is accomplished for the local agencies to develop sustainable urbanization based on environmental sensitive areas. Malaysia, alongside other nations, understands the criticality of managing mineral and geoscience data efficiently by the association values of geological hazard, natural resources, and natural heritage which is used in the evaluation of rational planning and government policy. To meet the increasing demand for accurate and up-to-date information, the Department of Mineral and Geoscience Malaysia (JMG) has developed the mineral and geoscience digital data platform since 2008 until 2024 using the system known as Mineral and Geoscience Geospatial Information System (MINGEOGIS) or with the commercial name of MyGEMS.

The development of MyGEMS encompasses all JMG's activities to produce easily accessible and shared geospatial products in compliance with the government policy and the prescribed of Geological Survey Act 1974. JMG also has separate systems such as the National Terain and Slope Geospatial System (NaTSIS), Marine Geological Database (NOSRIM), Quarry Operational Dust and Noise Pollution Index System (QPINS), National Mineral Commodity Database System (PESMIN) and Mobile Heritage Geological Site Information Application (MYGEOTAPAK). Such as NaTSIS, is developed specifically to assist local authorities and stakeholders in the process of managing landslide and slope information in the aspect of physical development and management of landslide geological disasters. There are more than 6000 number of landslides is recorded in the NatSIS system and currently used to develop landslide forecasts and landslide geological disaster notifications. Based on statistics from MyGEMS through NaTSIS in 2023, the Malaysian government has suffered economic losses of RM4 billion in 62 years (1961-2023) due to geological disasters. JMG has been appointed as the leading agency (Working Group 1) in the Inter Governmental Committee on Slope Management (ICSM) which is responsible for the aspects of Hazard Mapping and Slope Risk under the National Slope Master Plan program.

JMG is well-known as one of the External Technical Agencies in the One Stop Centre (OSC) platform by the Local Government Department under the Ministry of Housing and Local Government Malaysia, extended to all 98 Local Authorities in Peninsular Malaysia. The role and responsibility of JMG is to verify geological input and assess the risk of geological disasters for the impact of development on the environment, which coincides with the Survey Investigation Act

Earth 1974, Part IV (14). In line with geoscience information requirements, JMG is also involved in providing geoscience technical input for the Environmental Impact Assessment (EIA) Committee under the Department of Environment Malaysia. This EIA is used to identify, predict, and evaluate the impact on the environment of proposed development activity and to detail the mitigating measures prior to project approval and implementation in accordance with the requirements of the Environmental Quality Act 1974.

Role of Czech Geological Survey in Siting of Deep Geological Repository of Radioactive Waste

Zdenek Venera[1]*, Czech Geological Survey (zdenek.venera@geology.cz)

Abstract

Identifying the best available site for installation of deep geological repository of radioactive waste is an issue of utmost importance for land use planning at a national scale. Czech Geological Survey (CGS) has been involved in this matter since 80-ies of the 20th century. In the Czech Government, a responsible body in this matter is Radioactive Waste Repository Authority which signed an agreement with CGS on long-term collaboration. CGS carried our research on 9 pre-selected sites in crystalline - mostly granitoid massifs based on archive data, previously produced maps, and new geophysical profiles accompanied by 1:10.000 geological mapping in zones along these profiles, and produced 3D geological models of the areas. A matrix composed of 13 characteristics of each site, including lithological homogeneity, geochemical, structural, tectonic, volcanological, seismic, geomorphological, hydrogeological, mining, and environmental aspects, was applied resulting in proposal of 4 best suitable sites to be approved by the Government. The approval in 2020 launched the next phase of research and prospecting. Current activities in 4 sites are aimed at geological and hydrogeological mapping at a scale 1:25.000 in 25 km perimeter of repository, detailed mapping at 1:10.000 of area under exploration licence (ca 30 km2), remote sensing interpretation, structural analysis comprising discrete fracture network, geophysical survey, drilling and well logging, installation of hydrogeological and seismic monitoring network, and production of detailed 3D models. Some activities can be performed only when licences are issued by the Ministry of Environment, expected by the end of this year. Current phase is planned till 2028 when 2 best suitable site should be proposed for approval of the Government: one as principal, the other as backup. That will start the final stage of exploration with even more detailed focus, drilling and geophysics. After the best site selected, repository of radioactive waste will built at a depth 500 m and shall be in operation by 2050. For decades this topic has been and will continue to be one of the major tasks of national importance for Czech Geological Survey.

The importance of raw materials for the Energy Transition

Teresa PONCE DE LEÃO[1]*, LNEG (teresa.leao@lneg.pt)

Abstract

Raw materials are becoming increasingly important for the competitiveness of Europe's industry, for innovation and for the transition to a low-carbon, more circular economy.
Many new enabling technologies rely on materials that are predominantly produced outside of the European Union, such as cobalt for Lithium-Ion batteries powering low-emission mobility or rare-earth elements for energy-saving electronics.
International competition for such raw materials is becoming more intense.
EU imports most of the materials it uses rather than mining them itself. It is a net importer of raw materials, in which it has had a trade deficit since 2002. Last year (2019) that trade deficit stood at €31 billion
Europe still has many resources. Europe mines more than 42 different metals and minerals, plus ornamental stones, sand and gravel and aggregates"
European Commission is now focusing on collecting information about the deposits available in Europe – not necessarily for new mines, but also to expand existing mines or use them more efficiently
End-of-life circuit boards, certain magnets in disc drives and electric vehicles, EV and other special battery types, and fluorescent lamps are among several electrical and electronic products containing critical raw materials
Recycling most of the products rich in CRMs is not commercially viable, with low and volatile CRM prices undermining efforts to improve European CRM recycling rates, which today are close to zero in most cases.
A lot of efforts are underway:
Survey data (geophysics, geochemistry, geochronology, remote sensed data) Energy Transition
Knowing and understanding the subsurface environment (MAPS)
Understanding the metallogenic processes that give rise to ore deposits (MODELS)
Inventorying the subsurface for (CRM & SRM) mineral deposits (INVENTORY)
Turning individual small data packages into large data packages (DATA HOMOGENISATION)
UNFC classification
UNMRS
These are some of the effort methodologies for a transparent and ethic way to contribute to a low-carbon, more circular economy.

Professionals in Earth Sciences in municipal administrations, a contribution to the development of the territory: a case study in Colombia, South America

Clemencia GOMEZ[1]*, Universidad Nacional de Colombia, sede Bogotá (clgomezgo@unal.edu.co)

Abstract

The geographical location, economic vulnerability of a large portion of the population, lack of teaching of Earth Sciences in schools, lack of territorial planning, illicit extraction of resources, and lack of public policies adapted to the reality of the territories are the perfect breeding ground for what is observed daily in the news: loss of lives and economic losses due to lack of harmony between public policies, knowledge, geo-hazards, and environmental degradation in the regions.

In this scenario, a legislative initiative has been proposed in Colombia that allows for the presence of a professional in Earth Sciences in the territory, who can permeate the social fabric and have a positive impact on the well-being of the population. This initiative has been accompanied by research projects at the National University of Colombia, Bogotá campus, including undergraduate theses, academic internships in a municipality, a short documentary, as well as more than 50 presentations in national and international events of different kinds, campaigns led by professional associations (Colombian Geological Society and Colombian Association of Petroleum Geologists and Geophysicists), communications and meetings with government officials and lawmakers, news coverage in national and local press, campaigns on social media, among others.

The current reality calls for ensuring the presence of professionals in Earth Sciences in municipalities, with the aim of contributing to sustainable development through the application of technical knowledge in the exercise of oversight, advisory, and validation of issues related to geo-hazards, groundwater prospecting and identification, and mining-energy resources present in the territory, supporting the development and review of territorial planning and schemes, and promoting social appropriation of knowledge in Earth Sciences. We face challenges such as climate change and its consequences for society, energy transition, carbon neutrality, and all of them have in common the knowledge acquired by geologists in their academic training.

In this sense, the initiative also seeks to generate more and better knowledge of topics related to geology and its importance for society. The lack of knowledge in Earth Sciences prevents proper and optimal territorial management, resulting in conflicts in land and subsurface use, lack of timely mitigation of potential risks in communities, and ignorance of potential water resources.

Therefore, building a country involves putting the knowledge acquired in the university at the service of society, and thus professionalizing decision-making in the territory with technical information support can lead to progress on the right path towards sustainable development.

OneGeology's impact: shaping the development of digital cartography in the Polish Geological Survey

Katarzyna JÓŹWIK[1]*, Polish Geological Institute - National Research Institute (kjoz@pgi.gov.pl)
Urszula Stępień[2], Polish Geological Institute - National Research Institute
Marcin Słodkowski[3], Polish Geological Institute - National Research Institute

Abstract

The Polish Geological Institute (PGI) was established in 1919 and has been the primary provider of geological maps in Poland ever since. According to the Polish Geological and Mining Law, the PGI acts as the Polish Geological Survey, and therefore, conducting geological mapping in the country is one of its statutory tasks.

The beginnings of digital cartography at the PGI date back to the 1990s when the first computer system (based on the Silicon Graphics Computer Systems - SGCS) for digital compilation of the Detailed Geological Map of Poland at a scale of 1:50,000 was introduced. Other digital map production systems for maps at different scales were implemented in subsequent years. The main focus of these systems was on delivering a printed map as the final outcome, and the structures of appropriate GIS databases were designed accordingly. Information on the age, lithology, and genesis of geological units was organized in a way that allowed the systems to produce complex literal and color symbols for map printouts but made spatial data analyses difficult.

Engaging in the OneGeology initiative in 2007 was a turning point for digital cartography at the Polish Geological Survey, initiating a gradual transition from printout-oriented systems to those focused on providing spatial data and services for applied geology uses.

The OneGeology initiative aimed to establish an interoperable geological distributed system for Europe and the world, utilizing the GeoSciML (Geoscience Markup Language) for data exchange. The 1:1,000,000 scale Surficial Geological Map of Poland was the first map compiled according to the OneGeology guidelines and was published by the OneGeology-Europe project in 2010. Subsequent projects, such as the Glaciotectonic Map of Poland and the Bedrock Geological Map of Poland, further reflected PGI's commitment to digital cartography. These maps, developed between 2011 and 2013, utilized the GeoSciML data model and set new standards for digital map compilation. Notable changes included improving the description and storage of information on the genesis and lithology of geological units and separating layers for surficial and bedrock units to provide a full picture of the geological structure and avoid data redundancy.

The OneGeology initiative laid the groundwork for digital geological cartography, with GeoSciML standards later forming the basis for INSPIRE schemas. Both initiatives emphasize compliance with metadata standards, such as ISO19115, ISO 19119, and ISO 19139. PGI's achievements include providing INSPIRE-consistent metadata using GeoNetwork software and offering maps compliant with the GeoSciML model. Notably, the Geological Map of Poland at a scale of 1:500,000 was fully harmonized with INSPIRE schemas using HALE software.

Currently, PGI is focused on modernizing geological maps on larger scales, such as the Detailed

Geological Map of Poland or the Geological Map of Poland at a scale of 1:200,000. The next steps will involve introducing standardized hierarchical vocabularies, enabling further harmonization and linking of data from geological maps at different scales. Finally, the Polish Geological Survey plans to use API services and AI to facilitate interaction with users through natural language queries.

PanAfGeo: A unique pan-African training programme for African Geological Surveys

Nicolas CHARLES[1]*, French Geological Survey - BRGM (n.charles@brgm.fr)
Jean-Claude GUILLANEAU[2], French Geological Survey - BRGM
Rokhaya SAMBA DIENE[3], Geological Survey of Senegal / OAGS
Julie HOLLIS[4], EuroGeoSurveys
Céline ANDRIEN[5], EuroGeoSurveys
Mosa MABUZA[6], Council for Geoscience / OAGS

Abstract

The African Mining Vision and the European Green Deal set out certain objectives that can be addressed through initiatives between the European Union and the African Union, e.g., Governance of mineral resources; Sustainable exploitation of non-energy mineral resources; Prevention and mitigation of natural and man-made disasters; and Development of local mining private sector. These goals are clearly linked to the geosciences. To help to meet these challenges, a partnership between the Organisation of the African Geological Surveys (OAGS) and its European sister-organisation, EuroGeoSurveys (EGS), was initiated in 2015, leading to the creation and implementation of a pan-African action, PanAfGeo, an initiative that has developed into a long-term strategic cooperation between African and European Geological Surveys.

PanAfGeo for “Pan-African Support to Geological Sciences and Technology Africa-EU Partnership” is a project in two three-year phases (2016-2019 and 2021-2024), training geoscientific staff from African Geological Surveys. The action is cofunded by the European Union and a consortium of 13 European Geological Surveys, coordinated by BRGM, the French Geological Survey. PanAfGeo contributes to a more sustainable management of natural resources and tackling climate change based on science and technology.

In concrete terms, PanAfGeo is an innovative training programme in different geoscientific skills, i.e. geoscientific mapping, mineral resources assessment, artisanal and small-scale mining, environmental management of mines, geohazards, geoheritage, geothermal energy, geoscientific information management; and communication and dialogue in geosciences. It aims to make the African Geological Surveys and the OAGS more effective in supporting national, regional and continental policy-making and planning. From 2016 to 2024, PanAfGeo carried out almost 60 training sessions exclusively in Africa, in English, French, and Portuguese, and thanks to the support and involvement of more than 20 host-countries. More than 1,800 geoscientists from geological surveys or similar bodies from across the African continent (54 countries) were trained, making PanAfGeo a unique pan-African geoscience-training programme. Courses were carried out by African and European experts from geological surveys, universities and also environmental authorities, such as Global Geoparks. It is noteworthy that many stakeholders are involved, including UNESCO, the Geological Society of Africa, the African Minerals Development Centre, the African Minerals and Geosciences Centre, and the Association of Women in Mining in Africa.

In the wake of this unprecedented pan-African project, a geoscientific network now exists on both

continents. This network can contribute to sustainable management of geological resources in Africa and promote EU-African partnership in geosciences and, in particular, raw materials. Looking ahead, a planned successor project aims to strengthen Africa-EU institutional partnerships on Geosciences at continental, regional and national levels; continue to strengthen African Geological Surveys and the OAGS in terms of geoscientific intelligence and national, regional and continental support to policy making and planning processes; create OAGS Expert Groups; and promote EU-Africa economic partnerships on raw materials value chains.

IGME's contribution to the Critical Raw Materials pan-European map: GSEU project

Iván MARTÍN-MÉNDEZ[1]*, IGME-CSIC (i.martin@igme.es)
Egidio Marino[2], IGME-CSIC
Concepción Fernández-Leyva[3], IGME-CSIC
Francisco Javier González[4], IGME-CSIC
Ester Boixereu[5], IGME-CSIC
Susana M. Timón-Sánchez[6], IGME-CSIC
Paula Adánez[7], IGME-CSIC
Virginia Rodríguez[8], IGME-CSIC

Abstract

The GSEU project (Horizon-CL5-2021-D3-02-14), has as its main objective to establish a Geological Survey for Europe, as an entry point to a permanent collaborative network of geological surveys and partner organizations, to provide European institutions, companies, and citizens with high-quality and up-to-date information about the earth beneath our feet and the geological resources it harbors. One of the main areas of the project is dedicated to raw materials. Its main objective is to re-evaluate both primary mineral resources - in the terrestrial and submarine domains - and mining waste, focusing on the strategic and critical raw materials needed for the energy transition, digital transformation, and sustainable development. To this end, after harmonizing the available information, a complete update of the pan-European mapping of strategic and critical mineral resources (reference of both maps) has been prepared. This mapping will serve as a starting point to assess the European potential in mineral raw materials based on known resources and resources to be known, in a harmonized and standardized way. In addition, this study has served to identify and characterize the gaps in the information at European level, which will allow proposing future lines of research, in order to strengthen the supply of critical raw materials in Europe.

The Geological Survey of Spain (IGME-CSIC) is actively contributing with the provision of its mineral resource databases (BDMIN onshore) and (GeoERA-MINDeSEA offshore) developed throughout its history and with the progress of its current mineral exploration work which is focused on the exploration of the strategic and critical materials defined by the European Union in its latest list, based on the Study on the Critical Raw Materials for the EU 2023 – Final Report.

What we have learned from operating OneGeology Portal

Amaya FUENZALIDA VELASCO[1]*, BRGM (a.fuenzalidavelasco@brgm.fr)
James Passmore[2], BGS
Christelle Loiselet[3], BRGM
Hajatiana Ramambazafy [4], BRGM
Valentin Raille[5], BRGM
Marcus Sen[6], BGS

Abstract

The OneGeology portal allows sharing geoscience international data via web services using common standards and protocols. Based on interoperability principles (GeoSciML). Geological services from around the world deliver map data through a standard OGC web service (WMS / WFS). The list of metadata of maps/services is collected into a catalogue of services managed centrally. Currently, 126 countries display 797 datalayers from 146 web services. The Platform code (Portal) is also an opensource facility proposed by OneGeology project, which is available from Github to be widely distributed. This free access to data and digital resources is available for anyone with internet access around the globe, and allow a unique opportunity to approach geosciences to the global community.

Working at worldwide scale is accompanied of important challenges, technical and on cooperation. In this work, we present the operational side of the One Geology functioning. That means how the international team coordinate the operational activities for make the portal work and evolve. We will present visitors statistics for the five years of the portal, such as their geographical distribution and main consulted services. We will analyze how the Covid crisis affected our portal and the main technical issues that we have need to overcome.

To finish our presentation, we will present the work perspectives for the next years in terms of technological implementation and new proposed services.

The national geological service of Senegal : an instrument for managing geoscience data that benefits policy makers.

Raymond SAGNA[1]*, Service Géologique National du Sénégal (SGNS)
(raymond.sagna@sgns.gouv.sn)
Rokhaya SAMBA[2], Organisation Of African Geological Survey (OAGS)
Alla DIAW[3], Service Géologique National du Sénégal (SGNS)

Abstract

Since its independence, the State of Senegal has adapted its mining policy to the state of geological knowledge. This policy was implemented through mining law, the implementation of this policy resulting in action plans with activities such as improving the legislative and regulatory framework (Mining Code), knowledge of the mineral potential , etc.

Indeed, if since independence until 2000, the State has played a leading role in the mining sector because it is the main investor in the sector assisted in this by external or (FAC, KFW, FED, MRE, CRDI, UNDP, UNIDO, World Bank, IDA, etc.) internal (mining companies such as: CSPT, SSPT; PROCHIMAT, etc.) financial partners and from 2004 it is rather the mining companies which take over the acquisition of geoscientific data. However, it should be noted that the State has updated its geological infrastructure with the support of the European Union through the 9th EDF. The quantity and quality of data produced has led to an an evolution in its policy by increasingly returning to the operator in another form.

Thus, the State, through the provisions of article 114 of law n°2016-32 of November 8, 2016 relating to the Mining Code, creates a sector development fund which receives 20% of mining revenues on the one hand and on the other hand, the State has set up a public industrial and commercial establishment (EPIC) called the National Geological Service of Senegal (SGNS) whose main mission is the establishment of an efficient acquisition system, processing, interpretation and dissemination of geoscientific data by decree no. 2022-1358 of July 7, 2022.

To achieve this mission, the SGNS after several consultations is in the process of setting up a National Geological Mapping Program (PNCG). This plan, the first phase of which is devoted to the production of a general inventory of available geoscientific data, will make it possible to generate thematic maps but also a global map of the country on the one hand and on the other hand to guide the

survey campaigns data acquisition for geophysics as well as for cartography and geochemistry.

SOCIAL REPORT OF THE GEOLOGICAL SERVICE OF BRAZIL, AN ESG TOOL

Patricia DURINGER Jacques[1]*, cprm (patricia.jacques@sgb.gov.br)
Ana Cláudia aguiar Accioly[2], CPRM
Ana Cristina Peixoto[3], CPRM
Samanta Bittencourt Suprani[4], CPRM
Juliano Souza Oliveira[5], CPRM

Abstract

The Geological Survey of Brazil - CPRM, is a public company, linked to the Ministry of Mines and Energy, whose mission is “to generate and disseminate geoscientific knowledge with excellence, contributing to the quality of life and sustainable development in Brazil”. To carry out its mission, CPRM receives a budget from the Federal Government through actions in the Annual Budget Law linked to State public policies, in accordance with the Federal Constitution, with its Multi-Year Plans (renewed every four years). The CPRM's Social Report aims to render accounts to society, through an accounting statement, of how much the institution's actions in the social, environmental, economic and governance axes are reflected in effective improvements for the country's population, for development sustainable and for society, highlighting the public benefits generated. It is an ESG (Environmental, Social and Governance) tool that demonstrates the social profit generated in an organized and auditable way. The first social report of CPRM is related to the base year 2021 and was published in 2022 (https://rigeo.sgb.gov.br/bitstream/doc/22837/3/balanco_social_sgb_v_final_atualizada.pdf). The methodology is based on the accounting statement using the standard table of the Brazilian Institute of Social and Economic Analysis - IBASE. Additionally, the economic impacts of projects and services carried out during the base year are evaluated and detailed. In the first social report, seven economic impacts were evaluated, which promoted a social profit of R$ 2,707,980,195.94. The projects and services that had their economic impact calculated were: hydrological alert system, studies of hydromineral sources, distribution of didactic collections of minerals and rocks, consultations with lithotheca collections, courses and training for external public, geological mapping and resource assessment minerals and mineral heritage. In the second social balance, base year 2022 (https://rigeo.cprm.gov.br/bitstream/doc/24259/1/balanco_social_2022.pdf), new products and services evaluated for their economic impacts were included, totaling 13 products, which promoted a social profit of R$ 2,051,325,816.52. The products included were: fossil workshops for children, MEV analyzes for external users, maps of geophysical anomalies, cartography for disaster prevention and the use of aerogeophysical data in theses and dissertations. Despite the inclusion of new products and services, the value of social profit recorded was lower, which is mainly explained by the decrease in the value of the iron commodity, used in one of the calculation methodologies. Fluctuation in the value of profit obtained annually is common, as it is a balance sheet. It is important to highlight to society that the document demonstrates the use of

the product or service in a given year. The future goal is to use this statement as an instrument to consolidate society's trust in the Geological Survey of Brazil, as well as to demonstrate publicly and in accessible citizen language its public value and its socio-environmental and governance performance. The geological service is preparing its third social report (base year 2023) in the expectation of being able to further expand the economic accounting of the products and services it delivers to society, in the form of public policies.

Geothermal energy research supporting national policy and regulation; a European case study from Ireland

Aoife K. BRAIDEN[1]*, Geological Survey Ireland / RML ltd (aoife.braiden@gsi.ie)
Sarah Blake[2], Geological Survey Ireland
Koen Verbruggen[3], Geological Survey Ireland

Abstract

Across Europe there has been a renewed focus on evidence for policy and regulation, in particular to support energy and climate adaptation strategies. For example, Geological Survey Ireland (GSI), in collaboration with partners in academia and industry, has been providing geoscience data and information for the development of new geothermal energy policy and regulations for Ireland.

New data and related products have been delivered through (a) a research funding programme established in 2015 which has been driving the research and directly supporting geoscience researchers, and (b) Geological Survey Ireland's technical staff providing open databases, collating external research outputs and developing expert knowledge. These joint activities have improved our understanding of Irish geothermal resources but have also provided essential information for decision makers for management, planning and regulation of geothermal energy in Ireland. In addition, the research has also ensured innovation and best practice through international collaborations.

A key element of the research both carried out and supported by GSI, is the delivery of open access data and products. These follow GSI, and national, open science policies and encourage the development and use of high quality national and international accessible and interoperable online databases. These databases are also the basis for planning and GIS tools currently being developed to support local and national authorities in relation to surface land use and subsurface utilisation.

In July 2023, the Irish Government published a policy statement for the development of geothermal energy in Ireland. The objective's are to support Ireland's climate action commitments by setting out;

i. the preferred approach to regulation, and

ii. the scope of a strategy to promote the sustainable development of Ireland's geothermal resources to decarbonise the heating and cooling of buildings and for industrial uses and power generation.

The development of both the regulation, further policy and the wider geothermal energy sector will require continued, bespoke research outputs and increased geological information to derisk the subsurface., and also close collaboration between academia, policy makers and expert national organisations such as geological surveys.

Geoscience Policy Advocacy for the Public Good: Making an Impact through Policy!

Munira Raji[1]*, University of Plymouth, United Kingdom (munira.raji@plymouth.ac.uk)

Abstract

Geoscience research enhances our understanding of the Earth's complex systems and processes, including the atmosphere, hydrosphere, cryosphere, biosphere, and geosphere. Policy decisions and frameworks influence and shape how we manage Earth's resources, conserve environments, and assess and mitigate environmental degradation, geological hazards, climate change, and rising sea levels. However, gaps and limitations in current policies can hinder geoscientific advancement, innovation, and discovery - ultimately impacting societal well-being. This presentation highlights the integral role of geoscience policy across multiple fronts - from addressing climate change, transitioning to renewable energy from fossil fuels, implementing carbon capture mechanisms, and sustaining natural resources to building resilience against climate change, geological hazards, and environmental risks.

As experts in their field, geoscientists have some obligation and responsibility to advocate for evidence-based policies and policy reforms that support geoscience research that benefits society. The presentation will discuss why geoscientists should get involved in policy advocacy, why active engagement in policy reform is a crucial responsibility for geoscientists and how they can make a difference by doing so. Geoscientists are knowledgeable about best practices and effective methods to manage and prevent pollution, minimise the consequences of volcanic eruptions and mining activities on human well-being and the environment, and ensure sustainable exploitation of essential resources such as minerals, wind energy, geothermal energy, and groundwater in the face of rising global demand. Their input can inform policy to reduce resource overexploitation and destruction, and policies that expand funding for climate modelling research that could lead to improved predictions about the pace and impacts of climate change. In disaster management, geoscientific research on earthquakes and floods underpins policies that minimise risks and build preparedness.

By bridging the gap between the geoscience community, policy-makers, communities and other stakeholders, geoscientists can translate their technical knowledge into actionable, impactful policies that encourage sustainable extraction of natural resources, reducing community vulnerabilities, strengthening resilience to global challenges, and serving the public good.

Geoscience for Sustainability – A new initiative to promote the role of geosciences in society

Jonathan ARTHUR[1]*, American Geosciences Institute (jarthur@americangeosciences.org)
Chris Keane[2], American Geosciences Institute
Ed Robeck[3], American Geosciences Institute

Abstract

The American Geosciences Institute (AGI) has embarked on the Geoscience for Sustainability (GfS) initiative as a long-term and multi-faceted project to highlight the critical role that geoscience plays in developing a sustainable world. Having begun in 2023, GfS is designed to build on the effective framing of societal issues provided by the United Nations Sustainable Development Goals (SDGs) and views the geoscience nexus with these goals as means to strengthen the global geoscience community internally and externally. Not only do geosciences bring understanding of the Earth system to enable effective stewardship, but geoscience is prominent at the intersection of the planet and humanity.

AGI envisions that the GfS initiative will empower geoscientists with the knowledge to understand how the environmental, social, and economic impacts of their geoscience work contribute to developing a sustainable world as a core ethos of the geosciences. AGI's mission in this endeavor is to build a framework of actions, tools, and programs that enable and coordinate the efforts of individuals and organizations in our professional community to support the SDGs, thereby empowering the geosciences as central to the successful development of systems that achieve sustainable development.

Importantly, GfS also responds to global concerns about the role of the geosciences, such as in terms of supporting all of society, its relevance to daily life, and the novelty of its expertise. Some elements of the public perception of the geosciences negatively impact public support for geoscience. This has many effects, including decreasing geoscience enrollments in higher education. Geoscientists fully understand these concerns are misconceptions, but they are nonetheless an indictment on the geoscience enterprise's ability to promote understanding of its role in supporting humanity.

Goals of the GfS initiative include 1) collaboratively leading the transformation of the geoscience profession into one whose members integrate sustainability into their daily work, especially with positive actions and impacts to environmental, social, and economic considerations, including people and societies affected by their work, 2) supporting awareness of sustainability as part of the daily activities of geoscientists, and 3) positioning the geoscience profession as the exemplar of a community of practice committed to developing a sustainability-focused society.

Insights on the evolution of mineral policies, acts, rules and their association with mineral targeting geosciences in India

Debkumar BHATTACHARYYA[1]*, Geological Survey of India (debkumar@gsi.gov.in)
D S JEERE[2], Geological Survey of India
K V MARUTHI[3], Geological Survey of India

Abstract

This abstract discusses the progressive efforts made to achieve economic growth in the mineral sector for non-fuel, non-atomic minerals and their association with mineral-targeting geosciences in India. The deposit discovery follows mineral block development and mining. Mines and Mineral (Development and Regulation) Act, 1957 (MMDR Act) is the main statute for the regulation of mineral sector. The Mineral Concession Rules, 1960 outline the procedures and conditions for obtaining a Prospecting Licence (PL) or Mining Lease (ML). The National Mineral Policy (NMP), 1993 and subsequent reviews undertaken in 1994, 1997, 1999 and 2000 facilitate both private and foreign investment in exploration and mining. Later, amendments to MMDR Act in 1999 introduced the concept of a Reconnaissance Permit (RP) before the PL. The RP holder has the preferential right for obtaining PL, and then ML with the required conditions. In 2008, a revised NMP mentioned the grant of RP, PL and ML transparently, seamless and easy to transferability. The private sector would be the main source of investment in RP and PL and government agencies would focus on areas where private sector investments are less. The MMDR Act amendments in 2015 brought several reforms as mandating the auction of mineral concessions to improve transparency, establishing National Mineral Exploration Trust for enhancing regional and detailed mineral exploration through funding. E-Auction was made mandatory for the grant of mineral concession to ensure a transparent method of allotments of mineral wealth.

The Government brought out a National Mineral Exploration Policy (NMEP), in 2016 to give further momentum to exploration efforts. NMEP stated a structured framework for comprehensive exploration with a judicious interplay of government support and private innovation and enterprise. It emphasised the acquisition and interpretation of baseline geoscience data for the exploration process. The policy assured that baseline geoscience data comprising geology, geochemistry, and geophysics will be generated as a public good and will be made available in the public domain for free access. National Geoscience Data Repository will be set up which will collate and make available all baseline and mineral exploration information generated by various central, state government and others.

Geological Survey of India (GSI) established in 1851, is a premier government geoscience agency involved in mineral exploration, fundamental geoscience studies and research. GSI generates a large repository of the finest quality geological database and would be responsible for allowing the data to be made freely available in the public domain and upgrading India’s geological potential

areas with new mineral exploration information. Following the NMEP 2016 and MMDR amendments, GSI is covering and disseminating the geoscience data namely., seamless geological maps on a 50K scale, geochemical data, ground gravity & magnetic data, aero geophysical and remote sensing data with priority on geological potential areas for the whole country. A significant number of potential mineral exploration blocks and the blocks with estimated mineral resources were passed on to the State Governments for auctioning as per the new MMDR Amendments of 2015, 2016, 2020 and 2021.

Integrated geoscience mapping toward minerals and energy development: a case study for lithium prospectivity in the Northern Cape of South Africa

Taufeeq DHANSAY[1]*, Council for Geoscience (tdhansay@geoscience.org.za)

Abstract

The Council for Geoscience is mandated to undertake fundamental and applied geoscience research toward the sustainable development of South Africa. This includes development within the themes of minerals and energy, groundwater and environment, and infrastructure and land use. It aims to achieve this mandate through the collection and integration of several fundamental geoscience data and information. The Council for Geoscience has embarked on strategy to cover the country on a scale of at least 1:50,000 of various geoscience datasets. This includes geology, tectonics, geophysics, geochemistry, remote sensing, and economic geology. This strategy was initiated in 2017 and, to date, has increased South Africa's 1:50,000 scale geological coverage by 13%. Much of this increased coverage is focussed on regions that are defined to have significant mineral potential. It is envisioned that the development of these data and information may increase South Africa's share of the global exploration budget and contribute toward the country's development imperatives. This paper presents findings of how an integrated geoscience approach was applied to define lithium-bearing sequences in the Northern Cape Province of South Africa. Integration focused on the extraction of key lithological signatures from multi- and hyperspectral satellite imagery and specific geochemical indicators from regional and targeted geochemistry. These data were further corroborated and defined by field-based geological mapping and ground geophysical investigations. The integration of these findings has elaborated on the overarching tectonic evolutionary characteristics of the region and how these have enabled and controlled the emplacement of these mineralised sequences. Furthermore, this information has increased the prospective region of these sequences by at least 10,000 square kilometres. Targeted sampling has yielded lithium concentrations of up to 3-4%. Finally, mineral extractive studies were undertaken and suggest that at least 93% of the spodumene-bearing lithium can be economically liberated. It is proposed that these findings attain expression in the development of innovative mining and post-mining strategies for the region, including aspects of knowledge-driven exploration and extraction, downstream mineral beneficiation and sustainable mine closure practises.

Communicating with Non-Scientists: A Review of Select EU Horizon Projects and their Degree of Public Transparency

Maureen Gallagher[1]*, European Federation of Geologists (maureen.gallagher@eurogeologists.eu)
Anita Stein[2], European Federation of Geologists
David Govoni[3], European Federation of Geologists

Abstract

Geology and the geosciences are the most important professional sector to safeguard the Earth and humanity's future. The changing climate, advancing technology, and human migration have all increased the need for more geologists to 1) find and extract critical raw materials for the green transition, 2) predict, prepare, and avoid natural disasters, and to 3) slow and/or reverse the effects of greenhouse gas emissions, to name a few. Yet as more are needed, fewer individuals are interested in the sector and its myriad of professions. Further, the global public has little understanding of the profession's value to society.

For more than two decades, the European Federation of Geologists (EFG) has provided expertise in the development, execution, and communication of more than two dozen European Union (EU) funded projects under the 7th Framework Programme, Horizon 2020, and Horizon Europe. These research projects span topics from critical raw materials to natural hazards, hard science to social science, and primary students to advanced career professionals. A common thread among projects is communication of results and impact. Target audiences are professionals, students and prospective students, and society (non-scientists to include policy-makers).

In 2024 the European Federation of Geologists embarked on an analysis of communication success as a means of reflection on meeting desired communication objectives for their projects and building strategies to improve communication for currently active and future EU funded projects in which EFG has involvement. In comparing ongoing projects (CRM-geothermal, CEEGS, Tripgift, TIMREX), recently closed projects (REFLECT, SUMEX, ROBOMINERS) and historic projects (INTRAW, ENGIE, CROWDGEOTHERMAL) we developed a Communication Transparency Index (CTI) to be used as a guide in maximizing transparency for our three audiences. Through these and future projects, EFG will be a leader in reversing the trend of disinterest and misunderstanding of the profession and the impact of the science for society. Maximizing our transparency is essential to meeting our objectives and promoting the value of the EU investment in these projects.

IGCP 735 project: Rocks and the Rise of Ordovician Life

Wenhui Wang[1]*, Central South University (whwang@csu.edu.cn)
Bertrand LEFEBVRE[2], Université Lyon 1
Yves CANDELA[3], National Museums Scotland
Khadija EL HARIRI[4], Cadi Ayyad University
Mansoureh GHOBADI POUR[5], Golestan University
Elena RAEVSKAYA[6], JSC "Geologorazvedka"
Oive TINN[7], University of Tartu
Beatriz WAISFELD[8], National University of Córdoba

Abstract

Deciphering the complex interactions between climate change, biodiversity and ecosystem structuration is a major societal issue for future generations. The geological record offers the unique opportunity to document the impact of environmental changes in the biosphere in the past, and thus to provide some clues for the future. Early Palaeozoic interval embraces major evolutionary events such as the Cambrian Explosion and the Great Ordovician Biodiversification Event, but also major shifts in climate with a dramatic impact on the biosphere. Recently, the development of large-scale collaborative palaeontological databases promoted high-resolution analyses of biodiversity patterns, which could be compared using different environmental proxies. However, most available data are so far strongly biased towards some geographic areas (Europe, North America) and time intervals (lower-middle Cambrian, Middle-Upper Ordovician). Through a multidisciplinary approach, and in close collaboration with the International Subcommission on Ordovician Stratigraphy, our IGCP 735 project aims at filling the numerous knowledge gaps in most regions of the world (e.g. Africa, Asia and South America), with a special focus on less-documented time intervals (e.g. late Cambrian to early Ordovician). The IGCP 735 was approved and started in 2021. Until now, more than 220 scientists from 42 countries have participated to the project. Three annual meetings including an online meeting have been held since 2021. Three thematic volumes in the international journals Palaeogeography Palaeoclimatology Palaeoecology, Frontiers in Earth Sciences and Geobios about the scientific topic have been published in 2023. The IGCP 735 project has been very enthusiastically welcomed by the scientific community and has been acknowledged in almost two hundred publications in international journals. More details about the project can be found on our website: https://rocksnrol.wordpress.com/.

Intergovernmental Action on Sustainability and the Role of Geoscience

Janice Lachance[1]*, American Geophysical Union (AGU) (jlachance@agu.org)
Lisa Graumlich[2], American Geophysical Union (AGU)
Mark Shimamoto[3], American Geophysical Union (AGU)

Abstract

In 2015, countries around the world adopted the United Nations Agenda 2030 which contains the Global Goals for Sustainable Development. 17 Goals, 169 targets, 230 indicators. Each collectively aimed at ensuring a healthier and more sustainable global society both now and into the future. While some goals explicitly align strongly with the geosciences, such as 13: Climate Action, 14: Life Below Water, and 6: Clean Water and Sanitation, the geosciences do have a role to play in all 17. AGU's strategic plan builds on the bedrock of discovery science and emphasizes the necessity of greater advancements in solution science for the benefit of humanity. It charges the community to collaborate and innovate ways their science can inform solutions to society's greatest challenges laid out in the U.N. Global Goals. This includes partnering with local communities, other disciplines of science and engineering, as well as engaging with policymakers and the public to co-produce science that ensures it moves from usable to used. This presentation will highlight how AGU through partnerships and intergovernmental outreach, is addressing knowledge co-creation and information sharing for a more sustainable and just future. Specific examples include AGU's leadership in science policy and diplomacy, open science, community science, and scientific ethics.

The Brazilian Geological Survey: Unveiling a World of Geodiversity and Scientific Expertise for Global Collaboration

Deborah MENDES[1]*, SGB/CPRM (deborah.mendes@sgb.gov.br)
Rafael Pinto DUARTE[2], SGB/CPRM

Abstract

Brazil boasts a remarkable geodiversity within its vast territory, encompassing rocks of all ages, structural features, mineral deposits, landscapes, soils, fossils, and other elements that narrate the story of our geological evolution. Unique features include the 3.65 Ga Mairi Gneissic Complex in Bahia, the oldest rocks in Brazil, and the 2.4 Ga banded iron formations of the Iron Quadrangle in Minas Gerais, one of the world's largest deposits of its kind. The Sugarloaf Mountain in Rio de Janeiro, at 560 Ma, stands as a testimony to the amalgamation of the Gondwana Supercontinent during the Neoproterozoic. The Mesozoic reactivation of the Brazilian Platform led to the formation of the Paraná-Etendeka Magmatic Province, the second largest volcanic province on the planet. Cenozoic depositional environments are found throughout the country, exemplified by the Pantanal Basin, the largest floodplain on Earth with active fluvial fan sedimentation. Given Brazil extensive geodiversity, the SGB boasts a team of highly skilled professionals in various geoscience fields, including geology, geophysics, geochemistry, mineral resources, hydrology, hydrogeology, and territorial management. Our mission is to generate and disseminate geoscientific knowledge, contributing to the improvement of the quality of life and sustainable development of Brazil. As per the 2022 Social Balance, the company generated a social profit of approximately R$2 billion, demonstrating the significance of our products and services. As a scientific research institution of the federal government, the Brazilian Geological Survey provides data and information to support decision-making by government agencies, public and private companies. Our work includes the production of Geological Risk Area Maps and Susceptibility Maps to Mass Gravitational Movements and Floods, which effectively contribute to reducing losses from natural disasters. In the agricultural sector, we highlight research on agrominerals for soil remineralization, which aims to improve soil conditions and plant health through the use of minerals and rocks, thus optimizing food production in a sustainable manner. Recognized as a Science, Technology, and Information Institution and with extensive institutional representation, the Brazilian Geological Survey has unique position among its global counterparts allows us to contribute to the generation and transfer of scientific and technological knowledge to virtually any country in the world. Therefore, our international agenda aims to simultaneously provide access to geoscientific knowledge and, through international cooperation, seek the capabilities, competencies, technologies, and expertise needed to develop our human resources and infrastructure. This paper presents the Brazilian Geological Survey internationalization strategy, highlighting consolidated geoscientific information and its relevance to the needs of other countries. We are open to partnerships that foster scientific exchange towards sustainability and rational use of natural resources worldwide, in line with the UN Sustainable Development Goals

for 2030.

East to West collaboration for a gender equality in Geosciences

Minha LEE[1]*, Kangwon National University (minha_lee@kangwon.ac.kr)
Heejung Kim[2], Kangwon National University
Lola Pereira[3], University of Salamanca

Abstract

Gender disparity is a global issue affecting every scientific fields. The disparity is higher when dealing with STEM subjects, including Geosciences. Governments are adopting several corresponding measures continuously at various times, levels, and sectors to diminish the gender gap, but all regions should collaborate because it should be common effort. For example, in South Korea, large campaigns and promotion were conducted at the national level in early 1990s to improve female enrollment in the science and technology related fields, including geoscience, as such gender disparity involved cultural aspects. Furthermore, the gender quota systems were widely encouraged and adopted in major national projects, government offices and companies. As the results, recent statistics demonstrate much improved gender equality in science and technology field at the youth level such as university admissions (50% in science, 22% in technology), new recruitments (6.5% gender disparity), and junior positions (20% in science, 10% in technology). Unfortunately, however, the number drops dramatically by age 40 and diminishes at the higher ranks. Many survey and statistical reports conclude that while the main causes of resignment at the age 30-40 are sociocultural imbalance issues (marriage, pregnancy, and childcare), after 40 the cause is mainly organizational restrictions. Thus, it is critical to connect sociocultural measures on gender disparity in households (housework and childcare) and organization reform in institutions (glass ceiling) to achieve overall gender equality in professional fields like geoscience. Previous work shows that promoting women's leadership in STEM (including Geosciences) can help in closing the gender gap in STEM, increasing the role models for female students. We will analyze successful good practices, like collaborating in developing strategies through ERASMUS+ projects with western countries like Spain and eastern countries like South Korea. Closing the gender gap in Geosciences should transcend borders, with a multilateral and international focus to build networks that will reduce the gap in academia and research fields, also in higher roles by supporting women carriers towards the new, equal paradigm in Geoscience.

GeoLatinas: six years embracing, empowering and inspiring Latinas in Earth and Planetary Sciences

Monica Alejandra GOMEZ-CORREA[1]*, University of Hamburg & GeoLatinas – Latinas in Earth and Planetary Sciences (moagomezco@gmail.com)
Rocío Caballero-Gill[2], George Mason University & GeoLatinas – Latinas in Earth and Planetary Sciences
Daniela Navarro-Perez[3], Universidad de Magallanes & GeoLatinas – Latinas in Earth and Planetary Sciences
Sofía Barragán-Montilla[4], GeoLatinas – Latinas in Earth and Planetary Sciences & MARUM –Center for Marine Environmental Sciences, University of Bremen, Germany

Abstract

Since 2018, GeoLatinas has promoted Latina women's work and contributions to the advancement of Earth and Planetary Sciences worldwide. GeoLatinas is an international, inclusive, member-driven, circular organization that gathers students, academics and professionals in the public and private sectors. We aim to foster community and co-leadership, providing tools and opportunities to help GeoLatinas members succeed at all stages of their careers while inspiring future generations to pursue careers in Earth and Planetary Sciences.

Since its inception, our community has relied on several initiatives to translate our GeoLatinas mission and vision into actions. As such, we tackle barriers to women's advancement via representation and language barriers while promoting our community members' professional and personal growth. For example, one of GeoLatinas' first initiatives, #FridayFeatureInGeo, has been used to promote the life and work of Latinas in Earth and Planetary Sciences within all our social media platforms, enhancing their visibility and increasing representation in our fields. Beyond highlighting our members' contributions, we aim to embrace different backgrounds while decreasing the language barrier. One of the initiatives that aligns with this vision is the GeoLatinasBlog, a multilingual platform where members learn to be bloggers, editors, and translators as our writers communicate their science and perspectives. In line with this purpose, GeoTraductores is an initiative that translates science communication articles from the Eos.org platform from English to Spanish, increasing access to the Spanish-speaking audience and developing the technical skills of bilingual geoscientists. Furthermore, Conversando con GeoLatinas has been supporting the development of our members while improving their conversational English and Spanish skills.

Many of our initiatives promote our community members' professional and personal development, providing the necessary tools to thrive in their careers. This includes the Mentoring initiative, offering a variety of mentoring modes and opportunities, including a tailored pair program and resources for all members' growth within a safe space. The GeoSeminarios initiative offers a spotlight platform to showcase our research, allowing us to improve science communications

skills by focusing on a wider audience. The Impetu initiative motivates members to co-work in a supportive online community 24/7, providing ad hoc mentoring and promoting a sense of belonging. Lastly, the PERLA initiative offers webinars and workshops on technical and “soft” skills for various work sectors like industry and academia and even the transition to other career paths.

Through the labor and dedication of members in our organizational units, along with the focused initiatives above and many others, GeoLatinas has become an important online networking platform for Latinas and other demographics for which our mission and objectives resonate. At the end of 2018, GeoLatinas had 8 members in 2 countries; today, we have over 1300 members in 59 countries. This abstract summarizes 6 years of experience creating a community that works towards a more diverse and inclusive Earth and Planetary Sciences worldwide. Beyond our rapid growth in followers (over 25,600 as of February 2024) and sustainable community, our most important achievements relate to having had the privilege of supporting and mentoring each other along our journey.

[Keynote] Advancing Earth Science and women's equity through research, community building and professional societies

Carol FINN[1]*, US Geological Survey (cfinn@usgs.gov)
Wonsuh Song[2], Waseda University
Young-Seog Kim[3], Pukyong National University
Rie Hori[4], Ehime University
Gaku Kimura[5], JAMSTEC

Abstract

The pursuit of gender equity isn't solely the burden of women; it's a collective duty that encompasses all scientists. Research shows that the more diverse a science team, the more innovative it is. Exclusion of groups, including women who comprise ~50% of potential Earth scientists, diminishes the potential of science to serve society and promote a sustainable future. Studies show that women will study science if they see women as scientists. For example, in the US in the 1970's-1990's school children were asked to draw a scientist. At that time, only 1% drew a female scientist. Last year, 60% drew a female scientist. However, recent AI generated images of scientists are almost exclusively men. In 2019, in US science and engineering universities, women received ~50% of Bachelor's Degrees, ~45% of master's, 41% of Ph.D's, 37% of postdocs and only 29% were employed in their fields. The US ranks 18th globally in the percent of women research scientists of 34%. Korea ranked 28th with 20% and Japan 29th with 17%. Women make up ~30% of the membership of the American Geophysical Union and 32% of the Geological Society of Korea. In many places, hostile work environments, unequal opportunities and retaliation for reporting discourage women from entering and staying in Earth Science. Harassment and assault while doing field work is a serious issue as well. While the cultural change required for a more equitable and diverse workforce takes time, measures can be taken to provide the building blocks for change. An example of a building block is the Earth Science Women's Network (https://eswnonline.org/), which offers programs that pair early-career scientists with experienced professionals, organizes networking events, provides opportunities for professional development including grant writing, scientific writing and leadership skills and fosters a sense of community among women through online forums, social media groups and local chapters. Men participate in achieving the goal of scientific excellence through equity by including women in science teams, authorships on papers and principal investigator roles on grants and mentoring on how to advance in the systems, confronting wrong-doing, noting the accomplishment of women in public forums, using their voice to elevate the voices of women, telling women that they matter, and nominating them for honors, to name a few. Professional societies can play a role in advancing women through awarding honors, assigning committee appointments and leadership positions and providing resources on career advancement and overcoming barriers to advancement. For example, the American Geophysical Union, requires that elections and all committees have gender, geographic, career stage and ethnic diversity. Leadership and anti-harassment training is available for these activities. On a larger scale,

supporting research on how to advance gender equity to improve science has a large impact. The US National Science Foundation has awarded over $350M in grants to research ways to improve equity and increase participation in science. The Japan Geoscience Union has a committee on diversity management and talent pool. How will you contribute to equity, and therefore, excellence, in science? Our planet needs us all.

Africa-Europe: working together to close the gender gap in Geosciences.

Josefina Hamutoko[1], Geosciences, University of Namibia
Ndivhuwo Cecilia Mukosi[2], Council for Geoscience, South Africa
Lydia Olaka [3], Technical University of Kenya, Kenya
Lola PEREIRA[4]*, University of Salamanca (mdp@usal.es)
Lesego Peter[5], Botswana Geoscience Institute, Botswana
Yamirka Rojas-Agramonte[6], Institut für Geowissenschaften, Christian- Albrechts-Universität zu Kiel, Germany

Abstract

During the last International Union of Geological Sciences Executive Committee (IUGS-EC) meeting that took place in Kenya (Nairobi, 19-23 February 2024), it was clear that the gender gap is still a big problem in Geosciences. Bigger if we consider female leadership in decision-making areas. Even if there are enough female students graduating in Geosciences from the different universities, they are missing in leadership positions. By the exchange of ideas and information among African and European colleagues, it was made clear that the gap is not a geographic-limited issue. In both continents a lack of gender diversity is found where the decisions are taken. This is also a common place in other areas around the Globe, and we believe the solution is in the discussion and comparison of good practices where the gap has started to close by implementing specific policies. As a result, the colleagues that met in Kenya decided to start a network of female researchers from Africa and Europe, to study the root cause of the problem. This network will seek to establish the gender inequalities in the involved countries to start with. It will analyze the possible causes of such differences, including politics, social measures, and other tools that governments may or may not be using to close the gender gap. We will use medium-term tools to get a sustainable amount of data that can help in getting a reasonable response to our research question, including the elaboration of an ERASMUS+ proposal in the line of Capacity Building projects, in the frame of the European Union. Data for analysis will include some African Geological Surveys institutions to assess rations of graduates' intake up to leadership positions (e.g., example in Botswana). This will be the response to the demand of encouraging collaboration and action-oriented plans that was requested during the Nairobi meeting by some contributors. First, promotion of the African Geology should be a priority, helping to publish the research in high-impact journals. Also, the presence of female geologist in international conferences should be promoted, using gender quotas if needed when organizing the conference committees (a must in the IUGS-IGC meetings). Finally, promoting female researchers to be part of the editorial boards of those journals.

With these actions, a commitment to change and advance in a diverse path for geoscience will be ensured and will help female researchers to build a pipeline of young females with outstanding role models to follow in the geoscience career.

Inversion of Barcelona Basic Model Parameters for Thermo-Hydro-Mechanical Simulation of High-Level Radioactive Waste Disposal System

Yeongju KIM[1]*, Seoul National University (yzoo1008@snu.ac.kr)
Kwang-Il KIM[2], Korea Atomic Energy Research Institute
Minseop KIM[3], Korea Atomic Energy Research Institute
Changsoo LEE[4], Korea Atomic Energy Research Institute
Hoonyoung JEONG[5], Seoul National University

Abstract

For the safety and performance assessment of a high-level radioactive waste (HLW) disposal system, predicting and analyzing the coupled thermo-hydro-mechanical (THM) behaviors of bentonite, a candidate buffer material in the engineered barrier system, is crucial. The Barcelona Basic Model (BBM) is a constitutive model used to describe the geomechanical behaviors of partially saturated soils. Directly measuring BBM parameters of bentonite requires complicated tests. This study demonstrates that probable BBM parameters can be estimated by calibrating the BBM parameters to match simulation results with observed data from a simple test, the swelling pressure test, instead of the complicated direct tests.

The swelling pressure test was conducted using Gyeongju bentonite, a buffer candidate material in the improved Korean reference disposal system (KRS+). A numerical model was developed to emulate the swelling pressure test using COMSOL Multiphysics software. Optimal BBM parameters that reproduce the observed swelling pressures in hydro-mechanical simulations were determined using a particle swarm optimization method.

The optimal BBM parameters from the inversion process were used to predict the THM behaviors of the engineered barrier system (EBS) in KRS+. A numerical model was developed using TOUGH2-MP/FLAC3D software to conduct the performance assessment of coupled THM processes in KRS+. Temperature and saturation changes were evaluated at seven locations within the disposal system. Decay heat from high-level radioactive waste increases the temperature of the repository and decreases as decay heat diminishes. The maximum repository temperature reaches about 82℃ 15 to 20 years after the disposal of HLW, remaining below the maximum temperature criterion of 100℃. The saturation of the bentonite buffer near the canister decreases initially because of pore water evaporation induced by temperature increase. However, the bentonite buffer becomes saturated 100 years after the disposal of HLW, as groundwater from the surrounding rock mass flows in.

Micro CT and NMR studies in the very compact Boda Claystone, in connection with the Hungarian HLW project

Ferenc FEDOR[1]*, Department of Geology and Meteorology, University of Pécs
(fedor.ferenc@geochem-ltd.eu)
János Geiger[2], GEOCHEM Ltd.
Péter János Koroncz[3], Doctoral School of Earth Sciences, University of Pécs
Catarina C. Castro[4], Doctoral School of Earth Sciences, University of Pécs
János Kovács[5], Department of Geology and Meteorology, University of Pécs

Abstract

The Boda Claystone Formation, which has been studied in detail since the early 1990s, is one of Hungary's target rocks of the HLW repository project. The rock is highly compact, with very low porosity and permeability, characterized primarily to nanopores and microcracks. Therefore, laboratory analysis has been challenging and has required several improvements (PPD permeameter, more accurate porosity determination, cryodesiccation, etc.). New methods that have appeared in recent years (micro CT, nano CT, NMR), complemented and calibrated with improved conventional methods, offer the possibility of gaining insight into the rock structure and understanding its behaviour under reservoir conditions. They also allow investigation of the possibility of upscaling specific rock physical properties (REV determination). From studies carried out since the second half of the 2010s, it appears that water in the nano/microstructure of rocks forms a coherent volume that is practically immobile. This water is often not bound to the surface of the clays but trapped in the nanopores. This volume of this trapped water can be several times larger than the free water recoverable from the pores. This water mass, along with the clay content, may explain the self-sealing/self-healing capacity and the extreme physical character of the rock. However, the available theoretical and modelling background is unsuitable for describing such problems and needs improvement.

Microbial Reactions by Bentonite Indigenous Microbes under Varied Temperatures and Irradiation Conditions

Kanghyun PARK[1]*, Korea University (parkkh831@korea.ac.kr)
Man Jae Kwon[2], Korea University

Abstract

Bentonite is a promising buffer material for engineered barrier system in deep geological repositories (DGRs) of spent nuclear fuel (SNF). With its indigenous microbes, bentonite also serves as a potential microbial source that can mediate microbial interactions with surrounding materials, which can critically impact repository stability. Over the long term, bentonite and the indigenous microbes within the repository system can be subjected to both heat and irradiation resulting from radionuclide decay. In our previous study, we investigated microbial reactions by indigenous microbes in bentonite at 18 and 50 °C under Fe(III) and sulfate reducing conditions. Building upon this foundation, we conducted two batch experiments with bentonite indigenous microbes to 1) evaluate the temperature effect under more detailed conditions, and 2) assess the microbial activity and viability under irradiation.

Microcosms comprised WRK bentonite and artificial groundwater amended with lactate as an electron donor, along with Fe(III) (in form of ferrihydrite) and sulfate as electron acceptors. To determine temperature effect, microcosms were incubated under six different temperature conditions ranging from 18 to 70 °C. For assessment of irradiation effect, microcosms were exposed to gamma-radiation at varying dose rates of 2 to 200 Gy/h for 11 days.

Under different temperature conditions, microbial lactate utilization exhibited a transition near 40 °C. At lower temperatures, lactate was metabolized to acetate and propionate via fermentation, whereas at higher temperatures transformed solely into acetate. Microbial Fe(III) reduction extent appeared higher at low temperatures (18 and 30 °C), while rapid sulfate reduction was observed at higher temperature conditions. In the irradiation experiment, abiotic lactate decomposition and Fe reduction were detected during irradiation period, which were proportional to irradiation doses. After irradiation, microbial activity was observed stepwise up to a medium dose rate (10 Gy/h) and extreme-short dose condition (200 Gy/h for 1 day). Which revealed the survivability of bentonite indigenous microbes under gamma irradiation, albeit suppressed microbial activity. However, there was no indication of microbial viability for higher dose rates. Microbial community structure and composition in both experiments will be analyzed using 16S rRNA gene sequencing and further will be correlated with the geochemical data.

Investigation of Characteristics of Bentonite Samples in Natural Analogue Study Sites

Yoonah BANG[1]*, Korea Atomic Energy Research Institute (yoonahbang@kaeri.re.kr)
Ji-Hun Ryu[2], Korea Atomic Energy Research Institute

Abstract

Bentonite, primarily consisting of montmorillonite, plays an important role as an engineering barrier component in deep geological repository. Its properties, such as swelling, adsorption, ion exchange, and water retention capacities, make it an effective buffer to physically and chemically isolate high-level waste disposal facilities from the surrounding environment. This study aims to compare and analyze the fundamental characteristics of bentonite rock samples (W-B and NA-B) collected from natural analogue study sites in Jianping Xian, Chaoyang Shi, Liaoning Sheng, China, and Yeongnam, Gyeongju, Gyeongsangbuk-do, Republic of Korea. We explored the analysis methods and experimental results of bentonite, including its physical properties (color, particle size distribution, water content, density), mineralogical characteristics (mineral identification and quantification through X-ray diffraction, structure and surface properties through fourier-transform infrared and raman spectroscopy, thermogravimetric analysis, transmission electron microscopy and scanning electron microscopy), geochemical properties (chemical composition through X-ray fluorescence, total surface area, cation exchange capacity, and leaching solution), and pore water properties (pore water chemistry and anion accessible porosity). The findings of this study are expected to provide fundamental data for understanding the changes in the characteristics of bentonite under geological environment conditions, which is crucial for ensuring the safety of deep disposal systems over geological time.

3D and 4D insights into barrier behaviour

Katherine DOBSON[1]*, University of Strathclyde (katherine.dobson@strath.ac.uk)
Zoe Shipton[2], University of Strathclyde
Andrea Kozlowski[3], University of Strathclyde
Rebecca Lindsey-Halls[4], University of Strathclyde
Joanna Renshaw[5], University of Strathclyde

Abstract

Understanding the behaviour of natural and engineered barriers for nuclear waste repositories requires us to know their properties, and more importantly how these properties evolve through time. That evolution need to include impact of the barrier on the geology and the geosystem on the barrier. Here we present a range of 3D and 4D experiments that highlight how the latest in situ imaging techniques are allowing us to investigate both the short and long-term mechanical and chemical performance of a range natural and engineered barrier materials.

We present time series x-ray computed tomography of small dimeter cores from a range of potential barrier materials. Using simulated long–term deployment conditions,we encompass the key leaching, heating and loading conditions likely to be found. We performed tomography over the duration of the experiments, and integrated the quantitative tomography data (e.g. porosity and density evolution, fracture propagation, localised shrinking and swelling) with XRD (for mineralogy), SEM analysis and a range of other analytical techniques. We will show how this combined multi-modal analysis can shed new light on the mechanical and chemical performance of potential barrier materials, and the rocks that surround them; and will discuss how these tools could be applied in the design of future repository systems and their geosphere interactions.

Analysis of the Current Status of Siting Criteria and Factors for High-Level Radioactive Waste Disposal in Leading Countries

Taeyoo NA[1]*, Korea Institute of Geoscience and Mineral Resources (tyna@kigam.re.kr)
Byung-Gon Chae[2], Korea Institute of Geoscience and Mineral Resources

Abstract

The necessity of deep geological disposal for high-level radioactive waste is crucial for ensuring safe protection of human and environment from the radionuclide. It demands optimal siting criteria considering each country's specific geological conditions and societal contexts.
The current status of siting criteria and factors for deep geological disposal of high-level radioactive waste in leading countries including Sweden, Finland, Switzerland and United States was analyzed in this study. The analysis of siting criteria and factors carried out in this study has shown that all countries prioritize long-term safety and social acceptability. Specifically, they apply factors such as geological stability, groundwater flow, and environmental elements in assessing site suitability. These factors encompass various aspects including the characteristics of the bedrock, the presence of active fault zones, uplift and erosion, seismic and volcanic activity, geothermal gradient and hydraulic conductivity, pH and Eh, future climate change and natural resources, as well as transportation and costs. The analysis reveals that the detailed criteria employed by each country reflect their geological, environmental, and socio-economic characteristics. Through these varied criteria, it has been determined that each country is adopting a customized approach to ensure the safe isolation of radioactive waste and the protection of the environment.
The outcomes of this study are anticipated to set up appropriate siting criteria and factors for high-level radioactive waste disposal and will also be used to identify safe locations for deep geological disposal in Korea.

Characterization of Ca-type bentonite in contact with corrosion product of copper canister

Gha-Young Kim[1]*, KAERI (gkim@kaeri.re.kr)
Mihye Kong[2], Chonnam National University
Seok Yoon[3], KAERI
Jin-Seop Kim[4], KAERI

Abstract

Copper canister is one of the key components of an engineered barrier for deep geological disposal (DGD). It is the final stage of separating and isolating high-level radioactive waste from biosphere. The corrosion mechanism occurring at the surface of copper canister and the nature of associated corrosion products change as the DGD environment evolves from aerobic to anaerobic condition. The corroded copper products may present either dissolved forms or precipitates. Dissolved forms of copper corrosion product can diffuse away from the canister surface and interact with the buffer, resulting in the susceptibility of affecting the buffer performance. The purpose of this study is to understand characteristics of Ca-type bentonite (buffer material) in contact with dissolved form of copper corrosion product. In this study, we carried out the reaction experiment and evaluation of Ca-type bentonite (Bentonil-WRK) with CuCl2 (i.e., dissolved form of copper corrosion product) at room temperature. The concentration range of CuCl2 used in this study is from 0.1 uM to 0.1 M. The characteristics of CuCl2-treated bentonite such as chemical and mineral composition, element concentration, and swelling index were investigated. As a result of Ca-type bentonite treated with CuCl2, there were no significant effect on mineral alteration and no change in the swelling index in this study.

Site Characterization and Investigation Requirements (draft) for High-Level Radioactive Waste Disposal Facilities

Hyeondong Woo[1]*, Korea Institute of Nuclear Safety (hdwoo@kins.re.kr)
Seung Gyu Hyun[2], Korea Institute of Nuclear Safety
Taekmo Shim[3], Korea Institute of Nuclear Safety
Ohsang Gwon[4], Korea Institute of Nuclear Safety

Abstract

The imminent saturation of storage for high-level radioactive waste (HLW) necessitates a critical review and reformulation of current regulatory requirements outlined in the Nuclear Safety Act of the Republic of Korea. Presently, these regulations do not fully comply with the stipulations of the IAEA SSR-5 'Disposal of Radioactive Waste'. An R&D project titled 'Development of safety criteria for site characterization and site investigation for HLW disposal facility' was conducted from 2018 to 2022 to develop a regulatory framework for this matter. The primary objective of the project is to develop a draft guideline notice for the report on site characterization of the disposal facility for high-level radioactive waste.

This study analyzes the results of site investigation and evaluation related to the characterization of deep geological conditions for high-level radioactive waste disposal facilities in other countries. Detailed requirements related to the site description model, design, construction, operation, and long-term safety of geological disposal facilities for HLW are presented to develop the draft notice for the report on site characterization for high-level radioactive waste disposal facilities.

The general guidelines of the draft notice for preparing the site characterization report for high-level radioactive waste disposal facilities were developed, along with their purpose and scope of application. Additionally, the development of the draft guideline notice for the report on site characterization for high-level radioactive waste disposal facilities and its rationale were presented, along with the site description model, design/construction/operation, and long-term safety of deep geological disposal facilities. The requirements for detailed investigations and assessments related to site characterization include:

a. Geological and geophysical characteristics
b. Hydrogeological characteristics
c. Hydrogeochemical characteristics
d. Mechanical and thermal characteristics of rock mass
e. Transport characteristics of radionuclide through groundwater
f. Characteristics of the ecosystem

R&D of KAERI for development of base technologies for demonstration of the deep geological system

Geon Young KIM[1]*, KAERI (kimgy@kaeri.re.kr)
Jang-Soon Kwon[2], KAERI
Jin-Seop Kim[3], KAERI

Abstract

The second basic national plan of 2021 for HLW management of Korea contains important milestones of construction and operation of URL as well as phased siting process, interim storage and final disposal facility, and suggests 37 years until starting final disposal. Therefore, it is very urgent to develop demonstration technologies at the URL by the early 2030s and a new multi-ministerial 9-year R&D project (Ministry of Science and ICT, Ministry of Trade, Industry and Energy, and Nuclear Safety and Security Commission) was launched in 2021 for the development of core technologies to demonstrate the performance and safety of SNF disposal system prior to URL demonstration phase in the national SNF management program.

KAERI is carrying out two major projects in the field of deep geological disposal of the integrated governmental project. In this paper, we introduce a 'Development of base technologies for demonstration of the deep geological system' which is one of two KAERI R&D projects. The main objective of the project is development of key element technologies to identify the coupled interaction of the disposal system according to the long-term evolution and to demonstrate the performance of the disposal system at URL. The project consists 3 tasks based on the multi-barriers system components, which are development of long-term safety evaluation technology of EBS (Task 1), development of an assessment technology for the performance of long-term evolution of the natural barrier (Task 2), and development of base technologies for demonstration of the radionuclides behaviors in geological disposal environment (Task 3).

The main objective of Task 1 is to develop a long-term safety evaluation technology and in-situ validation of EBS performance in KURT and the main R&D contents are preparation of design requirement of EBS, characterisaiton of interactions of EBS components, identification of coupled THMC behaviors, and development of key technologies for in-situ demonstration of EBS performance.

The main objective of Task 2 is to develop an assessment technology for the performance of long-term evolution of the natural barrier and its demonstration methodology at URL. The main R&D contents are assessment of long-term change of geological environment, development of the long-term evolution of the natural barrier performance, development of integrated model of hydro-mechanical model and surface water-groundwater model, and development of assessment methodology on the long-term evolution of natural barrier at URL.

The main objective of Task 3 is to develop an evaluation technology of nuclide behavior within multi-barrier and conducting URL demonstration with the evolution process of disposal environment. The main R&D contents are Identification of nuclide dissolution and presentation of

dissolved chemical species in disposal environment, characterization of nuclide sorption/diffusion mechanisms within multi-barrier in disposal environment, characterization of accelerated and delayed transport of nuclide, and development of fundamental technology for on-site demonstration of nuclide behavior in disposal environment.
This project will be carried out in 3 stages for a total of 9 years and the first stage has been finished successfully in 2023.

Enhancing HLW Disposal Safety Through Global NA Study insights

HunSuk IM[1]*, KAERI (ihs95@kaeri.re.kr)
Dawoon Jeong[2], Korea Atomic Energy Research Institute
Min-Hoon Baik[3], Korea Atomic Energy Research Institute
Ji-Hun Ryu[4], Korea Atomic Energy Research Institute

Abstract

This research explores the role and strategy of Natural Analogue (NA) studies in enhancing the long-term safety and reliability of Deep Geological Disposal (DGD) systems for high-level waste (HLW) across several advanced countries, including Finland, Canada, the United States, and Spain, with a focus on their applicability to Korea's nascent NA program. NA studies utilize analogues substances and sites to investigate and analyze the long-term alteration processes of disposal system components. These investigations contribute as supplimentary data for the safety assessment (SA) of DGD systems over extensive periods.

The Finnish, leveraging the crystalline bedrock similar to that considered in Korea, is pioneering with the construction of a permanent DGD facility based on the KBS-3 concept, integrating general NA study data into its safety case. Canada's studies draw parallels between the natural uranium ore body at Cigar Lake and artificial DGR systems, using NA information on radionuclide transport behavior to refine predictive models and databases for SA. In contrast, the United States focuses on the temperature-dependent behavior relevant to HLW disposal, incorporating high-temperature studies around waste disposal containers. Spain, uniquely positioned with a state-owned nuclear policy, emphasizes comprehensive NA and SA studies, leading to the publication of extensive NA catalogs and the promotion of public understanding through simplified syntheses.

For Korea, where the HLW disposal concept remains under development, adopting a general NA study approach similar to Finland's is suggested. However, it's crucial that such studies reflect Korea's specific disposal concept and environmental conditions. This involves continuous NA studies from the development phase through to repository operation, emphasizing the need for a strategy that incorporates insights from the reviewed countries. International collaboration and domestic research organization are recommended to address diverse environmental conditions and long-term safety concerns efficiently. This strategy would benefit from engaging with global research groups and international Natural Analogue Working Groups (NAWGs).

Moreover, the study highlights the importance of interdisciplinary cooperation, particularly with archaeology, to understand the alteration processes of metal container materials and secure access to natural and archaeological analogues. Establishing a NA information system, as seen in Spain, is vital for improving social acceptance of disposal facility safety. This encompasses developing both a physical research center for tangible trust-building and a software database system for easy access to relevant NA information by facility designers and safety case developers.

This study also underscores the leadership role of nuclear regulatory agencies (e.g., CNSC, NRC,

CSN, STUK) in conducting NA studies, with operators like POSIVA and ENRESA playing key roles alongside regulatory bodies. It suggests establishing a domestic NA study system through organic cooperation among the nuclear regulatory agency, disposal facility operators, and research institutes.

In conclusion, leveraging the insights and strategies from NA studies in advanced countries can significantly inform and enhance Korea's approach to ensuring the long-term safety and reliability of its HLW disposal system, with a focus on international collaboration, interdisciplinary research, and the development of comprehensive information systems for societal engagement and regulatory support.

Integrating Advanced Technologies and Safety for a Susainable Spent Nuclear Fuel Waste management

HunSuk IM[1]*, KAERI (ihs95@kaeri.re.kr)
JungHo Hur[2], Korea Atomic Energy Research Institute
Hong Jang[3], Korea Atomic Energy Research Institute
Won Il Ko[4], Korea Atomic Energy Research Institute

Abstract

South Korea's approach to spent nuclear fuel (SNF) disposal is evolving towards a secure and environmentally responsible future, integrating advanced nuclear waste management techniques with rigorous safety protocols. The 1970s marked the inception of deep geological disposal as the paramount safe disposal method, influenced by extensive evaluations and international research spearheaded by entities like BNWL (Battle North West Laboratory). Emphasizing the critical importance of adapting to native geological conditions, South Korea, through the Korean Atomic Energy Research Institute (KAERI), has embarked on developing a domestic disposal system since 1997. This initiative encompasses the design and safety assessment of high-level radioactive waste disposal, culminating in the creation of the KAERI Underground Research Tunnel (KURT) for in-depth technological validation within granite bedrock.

Parallel to policy discussions on the High-level Radioactive Waste Special Act, technical advancements are mirroring successful international models, notably Sweden and Finland's SKB KBS-3V multi-barrier deep geological disposal system, tailored to South Korea's environmental context. Such models utilize dual protective barriers, combining engineered and natural defenses to contain and isolate SNF within deep geological formations, thereby mitigating potential ecological and human health risks. This strategy ensures the long-term decay of radioactive isotopes within the disposal canisters to levels comparable to natural uranium, despite geological evolution or container corrosion.

Despite the common adoption of deep geological disposal for spent nuclear fuel (SNF), the need for efficient disposal area use and future nuclear fuel supply considerations for advanced reactors have renewed interest in alternative disposal options. The deep borehole method, benefiting from recent technological advancements, offers potential for safe and efficient disposal by enabling tailored management of SNF. This approach involves separating SNF by radionuclide groups, processing it to fit specific disposal methods, thereby optimizing safety and minimizing disposal area. The strategy focuses on developing a disposal-coupled radionuclide management system that optimizes the radionuclide management and waste form production processes. Such a system aims for an integrated structure that facilitates rapid adaptation to process or system changes and provides strategic ease in establishing effective SNF management strategies. This is crucial for reducing environmental burdens and ensuring safety through varied and adapted disposal methods. Korean research emphasizes processing cooled SNF according to radionuclide characteristics, aiming for safer and more efficient disposal. The disposal-coupled radionuclide management

system represents a strategic approach, integrating radionuclide separation, waste form production, and disposal options to optimize SNF management, focusing on environmental impact, efficiency, and safety. This holistic method offers a pathway to improved SNF disposal, highlighting the importance of technology development and strategic integration across disposal processes.

Investigating Measurement Methods for Grain Bulk Modulus of Sandstone: An Experimental Approach

Min-Jun KIM[1]*, Korea Institute of Geoscience and Mineral Resources (kimmj@kigam.re.kr)
Junhyung CHOI[2], Korea Institute of Geoscience and Mineral Resources
Eui-Seob PARK[3], Korea Institute of Geoscience and Mineral Resources
Byung-Gon CHAE[4], Korea Institute of Geoscience and Mineral Resources

Abstract

Grain bulk modulus is a basic property characterizing the hydraulic-mechanical coupled behavior of rock frame. It affects rock response of deep subsurface to changes in pressure, temperature, and pore fluids. In addition, as an input parameter for numerical analysis, it is significantly related to the performance of natural barrier in deep geological repository. Nevertheless, a standardized procedure or method for measuring the grain bulk modulus has not yet been suggested. This study presents a measurement method for grain bulk modulus, which is important hydraulic-mechanical properties of rock, and conducts the experiment to obtain the grain bulk modulus of sandstone. The factors affecting the grain bulk modulus were investigated, comparing volumetric characteristics of rocks with different properties. As a result of the experiment, the grain bulk modulus of Berea sandstone was determined to be 28.9 GPa, while that of Idaho sandstone was measured to be 32.8 GPa. In the case of Berea sandstone, the value was 1.2% similar to the results of previous studies, whereas for Idaho, it showed a 17.6% difference compared to the theoretical estimate. The potential causes of the discrepancy were examined, highlighting the presence of non-connected pore spaces from rock particle structure. The experimental results demonstrated that the measurement method proposed in this study can reliably predict the grain bulk modulus of sandstone.

Abstract

High-level radioactive waste, containing radioactive nuclides with half-lives spanning tens to hundreds of thousands of years, requires isolation from human habitation for over 100,000 years. Selecting a geologically stable disposal site involves considering factors like topography, faults, seismic activity, and hydrological properties. Especially, brittle structures within the bedrock, such as faults, not only could serve as potential flow pathways but also significantly influence bedrock stability. However, studies on fault behavior and deformation, which is key components for site characterization, in underground are relatively scarce compared to studies at surface investigation.
This study was carried out within the KAERI Underground Research Tunnel (KURT) which is the sole experimental tunnel crucial for comprehending structural evolution and designing nuclear waste disposal sites. Before conducting a detailed geological survey, a preliminary lineament analysis was carried out through length-weighted lineament analysis, producing an overview of faulting in the study area. By inputting fault slip data encompassing strike, dip, slip direction, and slickenline into stress inversion programs, we derived the most suitable stress tensor. Further analysis of cross-cutting relationships allowed us to reconstruct the deformation history of the study area.
We identified three distinct brittle deformation stages in the study area from a strike-slip to an extensional environment, associated with the clockwise rotation of maximum horizontal stress from ENE-WSW, WNW-ESE/NW-SE to NNE-SSW. This study highlighted that the proper refinement and combination of lineament analysis, field survey, and paleostress analysis can improves previously proposed methods for the selection of deep geological repositories.

This research was supported by a grant(2022-MOIS62-001(RS-2022-ND640011)) of National Disaster Risk Analysis and Management Technology in Earthquake funded by Ministry of Interior and Safety(MOIS, Korea).

[Keynote] Current Status and Future Outlook on IAEA Safety Standards Development and Research Regarding the Site Safety for Nuclear Facilities

Paolo CONTRI[1], International Atomic Energy Agency
Heanu LEE[2]*, International Atomic Energy Agency (H.W.Lee@iaea.org)

Abstract

Feedback by IAEA Member States (MS) from IAEA safety reviews and technical meetings recently highlighted a number of topical areas which deserve special coverage in the research community and in the IAEA activities on the development of Safety Guides and relevant technical guidelines, in order to improve the installation safety in relation to external events, in particular: refined hazard modelling, time dependent and with improved uncertainty management and event combinations, design of advanced reactor types in relation to external events, and safety assessment of nuclear installations in relation to low probability events beyond their design basis. More in detail, many projects have been launched, specifically addressing the following:

1. Hazard modelling and installation PSA: special focus will be dedicated to the challenges brought by climate change, especially in estimation of time-dependent weather-related hazards and new types of threats, including sandstorms, desertification, permafrost, biological fouling, landslides and wildfires. A large number of documents on management of uncertainties in seismic hazard and on probabilistic fault displacement hazard assessment was planned. Volcanic hazard scenarios, using tephra dispersal models, Probabilistic Safety Assessment (PSA) in relation to coastal and riverine flooding hazard, and PSA for tsunami hazards were also addressed.
2. Design and safety assessment of nuclear installations in relation to external events: the estimation of design robustness against extreme external hazards is covered by studies on the evaluation of the safety margin assessments for beyond design basis extreme events (BDBEE) of all nature. Other guidelines are in advanced stages of development on optimization of protection against external hazards for facilities other than nuclear power plants and on seismic soil liquefaction assessment. The development of a Seismic Experience Database supports the seismic qualification of systems and components by similarity, which is faster and more cost-effective compared to shaking table testing.
3. The deployment of innovative nuclear technologies raises important questions about sustainable safety approaches to site selection, evaluation, and site-specific hazard assessment for Small and Modular Reactors (SMRs), including transportable reactors, and fusion reactors. A risk informed performance-based (RIPB) approach for siting and design may well support a graded siting framework for SMRs, focused on technology-specific design features to ensure safety against both natural and human-induced hazards. The safety assessment of the so-called passive safety features of small modular reactors (SMRs) and evaluations on the Emergency Planning Zone (EPZ) size are crucial for supporting the safe and sustainable deployment of advanced reactors worldwide. A Standard Review Plan should provide specific guidelines to the regulatory bodies on the site license review process.

The improvement of the effectiveness of the IAEA SEED review service, of the capacity building programs offered by the IAEA, and the operation of the real time external event monitoring system (EENS) on earthquakes, floods, tsunamis, volcano eruptions and wildfires boost the support capabilities of the IAEA to the nuclear safety of operating and future nuclear plants.

Volcanic Tephra-Fallout Hazards and the Safety of Nuclear Installations

Hyun Woo LEE[1]*, International Atomic Energy Agency (h.w.lee@iaea.org)
Shinsaku Nishizaki[2], International Atomic Energy Agency
Paolo Contri[3], International Atomic Energy Agency

Abstract

Tephra fallout presents unusual challenges for assessing external hazards at nuclear installations. Despite some nations lacking capable volcanoes within their borders, tephra-fallout hazards can occur from eruptions outside their territories because it may reach 100s to 1000s of kilometres downwind from an erupting volcano, depending on the energy of the eruption, its volume, and the nature of the wind field. The heavy, abrasive, and corrosive nature of volcanic tephra deposits can potentially affect the performance of Structures, Systems and Components (SSCs) in nuclear installations. Although tephra fallout events are infrequent, they typically offer days-to-months of warning, facilitating timely mitigation measures. Even though tephra eruptions typically last for hours-to-days, the persistence of tephra deposits for extended periods after an eruption distinguishes tephra fallout from other natural hazards.

In this regard, to provide practical guidance for assessing volcanic tephra-fallout hazards, designing nuclear installations, and implementing operational measures, drawing from Member States' experiences and providing recommendations for mitigation, the IAEA is currently in the process of developing a technical document that focuses on the characteristics and potential effects of volcanic tephra fallout on nuclear installations, as well as considerations for mitigative design and operational actions. Major contents of the document are as follows:

1. Characteristics of Tephra Fallout. A thorough examination of volcanic tephra's essential characteristics is presented and discussed. It encompasses the diverse spectrum of particle attributes generated during volcanic eruptions, critical factors necessary for evaluating deposits from past tephra-fallout events, and the long-lasting presence of tephra-fallout deposits after an eruption. Representative eruption magnitudes and types are summarized, and relevant characteristics of active tephra eruptions and deposits are discussed.

2. Current Approaches for Tephra-Fallout Hazard Assessment. Various methodologies and approaches for assessing volcanic tephra-fallout hazards are discussed with special attention on real-world examples of recent hazard assessments, providing practical insights into the hazard evaluation processes. Discussions include details on empirical observations for the past events in site regions, overview of numerical models for calculating tephra-fallout hazards, comparisons of modelled deposits to tephra fallout, and examples of monitoring applications.

3. Considerations of Potential Effects of Hazardous Tephra Fallout on SSCs. Experiences from Member States are described to secure a concise summary of design and performance considerations aimed at mitigating volcanic tephra-fallout hazards at nuclear installations. Recognizing the shortage of specific data on this subject, the discussions also include design and performance considerations derived from industrial facilities with SSCs that are analogous to

nuclear installations.

4. Considerations for Potential Operator Mitigation Strategies. Many of the potentially adverse effects of volcanic tephra fallout can be mitigated by pre-planned operational actions. Drawing upon parallels from analogous industrial contexts and SSCs, this section offers considerations for minimizing the potential effects of tephra fallout hazards on operational safety.

In conclusion, this technical document highlights the need to assess potential tephra-fallout hazards within appropriate Member States' regulatory frameworks, given the limited operational experience with tephra fallout events, especially those hazards originating from larger-magnitude eruptions.

Abstract

The establishment of a deep geological repository for radioactive waste requires a homogenous geological environment. An ideal location consists of granitoids unaffected by any significant fault zones or extensive brittle deformation. Evaluation of a potential repository site needs the careful integration of several geological disciplines. Here we present five main methods used to investigate the site of a potential repository in the Czech Republic – Březový potok.

The repository will be located in the Variscan granitoids of Central Bohemian Plutonic Complex, which intruded into high-grade basement of the Moldanubian.

The suitability of Březový potok as a deep geological repository site will be evaluate through: i) geological and structural mapping - to provide necessary surface information about petrological and structural configuration; ii) photogrammetry of selected outcrops (by geologists or drones), enabling the creation of 3D geological and DFN models and structural data processing using 3D software; iii) core drilling, core scanning, and borehole logging, revealing in-situ information's about the rock types and structural record, which can be analyzed by logging software; iv) geophysical methods with variable depth reach allowing for non-invasive study of the geological situation and possible comparison with core drilling and other data; and v) hydrogeological mapping, providing the information about potential fault zones with enhanced hydrogeological activity and drainage systems.

Except the methods described above we also use results of in-situ research project of Underground Research Facility Bukov, a former uranium mine, now used for scientific purposes, also located in Moldanubian Unit, Czech Republic.

The integration of these main five research approaches, alongside in-depth data from ongoing research at Bukov, which is located in the similar depth as the planned deep geological repository,

provides a unique opportunity to compare and evaluate data regarding Březový potok. This presentation aims to demonstrate how the integration of multiple approaches allows us to comprehensively study, describe, and understand the overall geological and structural situation of potential site. It facilitates the selection of safe and stable repository locations and offers insight into the complex geological and structural record at the projected depth for future underground construction.

GeM-DB – A searchable database, linking exploration objectives and geoscientific methods for the German nuclear waste repository siting process

Thies BEILECKE[1]*, BGR (thies.beilecke@bgr.de)
Raphael Dlugosch[2], BGR
Tilo Kneuker[3], BGR
Lukas Pollok[4], BGR
Lisa Richter[5], BGR
Nicole Schubarth-Engelschall[6], BGR
Ralf Semroch[7], BGR

Abstract

The site selection procedure for a high-level radioactive waste repository in Germany is defined by a German law, the Repository Site Selection Act (StandAG, 2017), which comprises three phases. During phase 2, the implementing authority, the Federal Company for Radioactive Waste Disposal (BGE), carries out surface exploration. Based on the exploration results, the so-called further-developed preliminary safety analyses, defined requirements and criteria, and socio-economic potential analyses will be applied feeding into proposed sites for subsequent underground exploration.

Commissioned by BGE, the Federal Institute for Geosciences and Natural Resources (BGR) is contributing to this procedure with two projects. Their common goal is to develop recommendations for surface exploration of siting regions. For this purpose, BGR has developed a systematic approach that includes (1) the derivation of exploration objectives, (2) the compilation of geoscientific and geophysical exploration methods, and (3) the development of a database "GeM-DB" with an interactive web-interface. Information from an associated analysis of case studies of national and international exploration programmes for high-level radioactive waste disposal was incorporated in the database.

The exploration objectives are based on the common criteria and requirements as defined by the StandAG. The identified exploration objectives (Kneuker et al., 2020) were integrated and linked with a large number of geoscientific and geophysical exploration methods within the database GeM-DB. All exploration methods were evaluated according to their suitability and applicability for (a) the three potential host rocks in Germany (crystalline rock, claystone, rock salt) and (b) the previously defined exploration objectives.

BGR is currently developing a methodology to generate host rock specific sequences of exploration methods from the database contents and the results of the analyzed surface exploration programs. These sequences of methods provide a basis for the exploration programs to be planned by BGE.

Integrated analysis of deep brittle structures using borehole images and drill cores for high-level radioactive waste disposal

Ji-Min CHOI[1]*, Korea Atomic Energy Research Institute (jiminchoi@kaeri.re.kr)
Soolim Jung[2], Korea Atomic Energy Research Institute
Nak Kyu Kim[3], Korea Atomic Energy Research Institute
Kyung-Woo Park[4], Korea Atomic Energy Research Institute
Young-Seog Kim[5], Pukyong National University

Abstract

High-level radioactive waste repositories depend on multi-barrier systems, incorporating both natural and engineered barriers, to ensure long-term safety. The efficacy of natural barriers requires comprehensive evaluation through continuous field investigations and laboratory experiments. Natural barriers, categorized by lithological and structural characteristics, with a particular focus on structural features such as fracture and fault, can influence groundwater flow paths, constituting critical considerations in performance assessments. In light of the deep disposal site's location, borehole data assumes significance. Consequently, the systematization of brittle structure analysis at depth utilizing borehole data becomes imperative. The boreholes utilized in this study were drilled to an approximate depth of 200 meters and are located within the site, around KURT (KAERI Underground Research Tunnel) at KAERI (Korea Atomic Energy Research Institute). To elucidate the distribution of the deep brittle structure, we employed borehole images and physical drill cores. Borehole images were analyzed using WellCAD software to assess fracture density at various depths. Within the drill cores, samples were selectively procured to discern the distribution of fault rocks, employing techniques such as thin sections through optical characteristic analysis. Through a comprehensive approach, we jointly analyzed the data to validate the distribution and interrelation between deep fault zones and fracture zones. The findings of this study will contribute to the development of three-dimensional models for deep brittle structures within natural barriers.

Soolim JUNG[2], Korea Atomic Energy Research Institute
Ji-Min CHOI[3], Korea Atomic Energy Research Institute
Kyung-Woo PARK[4], Korea Atomic Energy Research Institute

Abstract

Countries considering or in the process of constructing high-level radioactive waste repositories are actively engaged in studying bedrock for planning the repository and safety assessment. The Korea Atomic Energy Research Institute (KAERI) has designated a research area within its premises to develop site characterization technology for high-level radioactive waste disposal, conducting extensive geological studies to comprehend the deep geological environment. The KAERI Underground Research Tunnel (KURT), completed in 2006, serves as a crucial tool for identifying the deep geological characteristics of the research area. To gain insights into the long-term evolution of the natural barrier within the repository and construct a comprehensive geological model, a thorough examination of rock distribution and bedrock in the study area is indispensable. The crystalline bedrock of KURT is known to have been derived by igneous activity associated with the continental collision between the North and South China cratons during Jurassic. While previous studies have concentrated on granitic rocks, the post-geological process and evolution of the bedrock has been inadequately explained.

In this study, we examined the lithology of the bedrock and its intrusive rock, using core rocks extracted from four boreholes (GE-1, GE-2, GE-3, and GE-4) at a depth of approximately 200 meters at the KURT site. Comprehensive geochemical composition analysis, including Sr-Nd-Pb isotopes, is conducting to explore the age and petrogenesis of the rocks. Furthermore, zircon U-Pb and whole-rock Ar-Ar geochronology techniques are planned to get the ages of the rocks. This study contributes significantly to understanding the geological evolution of the bedrock in the KURT area and can be used as a basis for the construction of a deep geological model. It is also expected to be applied as an evaluation technique for disposal performance demonstration and the long-term evolution of natural barrier.

Abstract

The energy sector of the Czech Republic relies on nuclear energy for approximately 35% of its needs, with plans for further expansion in the future. However, meeting the European Commission's regulations requires the construction of a deep repository for radioactive waste by 2050. The Czech Republic is currently in the process of identifying a suitable location, with geological conditions being a crucial criterion. Based on Swedish KBS-3 model, the crystalline rocks should provide geologically safe and stable environment for such a project.

Traditional remote sensing methods, typically successful in arid regions, prove less effective due to the characteristics of the Central Europe landscape, heavily influenced by intensive agricultural and industrial activities, vegetation cover, and weathered crystalline rocks. However, methods based on digital terrain modeling (DTM), particularly morphostructural analysis (MSA) utilizing Light Detection and Ranging (LIDAR) data, offer promising insights.

The high-resolution (1×1 meter) LIDAR-derived DTM enables the identification of morphostructures crucial for delineating of lithological boundaries, foliations, beddings, brittle deformations, and especially faults. MSA results contribute to creating detailed geological maps, providing precise information on the distribution, shape, and boundaries of lithological bodies, fault type and positions, and brittle deformation characteristics. Moreover, these findings are applicable in hydrogeological studies, aiding in locating brittle aquifer zones and validating medium-scale Discrete Fracture Network (DFN) models.

Furthermore, the integration of the morphostructural analysis with structural geological modeling enhances the understanding of the geological context, facilitating the development of accurate 3D structural geological models. These models are indispensable for subsequent hydrogeological, geotechnical, DFN, and other related analyses, ensuring comprehensive assessment and planning for the deep geological repository construction.

GPR, a fundamental tool for 3d mapping of the complex internal salt structures by investigations in drifts and boreholes

Volker Gundelach[1], BGR
Thies BEILECKE[2]*, BGR (thies.beilecke@bgr.de)

Abstract

For the exploration of salt deposits in the subsurface the method of electromagnetic reflection or ground penetrating radar (GPR) as a non-destructive measuring technique is an important tool. It can be used to detect complex geological structures in low electrically conductive rock salt by identifying the distance and the direction of reflecting objects. With this information a three dimensional model of the deposit can be created. This is essential for the exploration and appraisal of sites that are candidates for high-level nuclear waste disposal.
In mine drifts, the German Federal Institute for Geosciences and Natural Resources (BGR) mainly uses shielded antennae with center frequencies from 30 - 200 MHz to detect the distance to reflecting structures like anhydrite or clay. The measurements are carried out with two polarizations at the roof, on the floor and at the walls of a drift. Inclination measurements of 360 degrees around a drift provides information about the direction of objects using inclination, travel time and amplitude of the reflected signal. Additional, direction finding antennae like a Rhode & Schwarz antenna and an Adcock antenna can be used to gain more detailed the information about the direction of reflections. In boreholes, we use direction sensitive cross frame antennae with the center frequency of 50 MHz. Based on the spatial position of the antenna system and the comparison of amplitudes from the perpendicular frame antennae with the dipole signal allows calculating the direction of reflections around a borehole. The combined information of the distances and directions from reflections allows a spatial migration using wave front reconstruction. This provides a structural database to create three-dimensional geological models.

Investigation of host rocks and geotechnical barriers for the disposal of radioactive waste by means of Electrical Resistivity Tomography (ERT)

Markus Furche[1], BGR
Thies BEILECKE[2]*, BGR (thies.beilecke@bgr.de)

Abstract

DC geoelectrics (here referred to as ERT) belongs to the classical geophysical potential methods. In addition to many other fields of application, it is used in the Federal Institute for Geoscience and natural Resources (BGR) as a method of exploration of rocks and geotechnical barriers for the disposal of radioactive waste. This includes fundamental studies on rock characterization with a focus on the variability of rock properties, but also the long-term observation of processes using modern monitoring techniques. The result of ERT measurements, the spatial distribution of the electrical resistivity, cannot be unequivocally attributed to the distribution of a single parameter, but depends on different factors such as water content or lithology. For the interpretation of the measurement results, additional information from other geophysical measurements such as ground penetrating radar (GPR) or seismic methods, but also geological responses of the rock or further results from laboratory experiments on representative sample material are therefore necessary. The results of the ERT can also be used in subsequent model calculations, e. g. for security analyses.
Selected recent examples of ERT measurements at the Mont Terri rock laboratory in Switzerland are shown
a) In the so-called sandwich experiment, the effect of a specially constructed sealing structure in a semi-scale in situ experiment has been monitored by ERT measurements for several years. Here, the process of saturation of the sealing material can be mapped in three dimensions.
b) In the so-called CD-A experiment, the effect of seasonal changes in humidity on the stability of the rock mass is investigated by comparing two identical niches, however with different exposition to the atmosphere. The ERT provides decisive indications of seasonal de-saturation or re-saturation processes in a cross-section by means of long-term observations over several years.

Comparison of geological and mechanical properties of crystalline and sedimentary rocks through deep drilling cases

Dae-Sung Cheon[1]*, KIGAM (cds@kigam.re.kr)
Kwangmin Jin[2], KIGAM
Won-Kyong Song[3], KIGAM
You Hong Kihm[4], KIGAM

Abstract

Crystalline rocks and sedimentary rocks are mainly considered as the host rock for geological disposal of high-level radioactive waste(HLW) around the world. In Korea's geology, crystalline rocks such as granite and gneiss occupy 60% of the country’s land area, and sedimentary rocks occupy 25%. This study compared and presented the geological and mechanical characteristics of the two rock types based on the deep drilling cases conducted in crystalline and sedimentary rock areas. Drilling for crystalline rocks was conducted at one location each in the Gyeonggi Massif, Okcheon Massif, and Yeongnam Massif, and for sedimentary rocks, drilling was conducted at three locations within the Gyeongsang Basin. From a geological perspective, the origin of the formation, lineament, and fault zone and fractures were investigated, and from a mechanical perspective, in-situ stress, uniaxial compressive strength, and elastic wave velocity were investigated. The origin of formation and lineament were investigated in a certain scale area including the deep borehole and drilled cores were used for the investigation of fault zones and fracture. In-situ stress was measured by hydraulic fracturing method in a field, and uniaxial compressive strength and elastic wave velocity were measured through laboratory test using a drilling core. It is expected that the results of this investigation through deep drilling cases will be useful in selecting a disposal site for high-level radioactive waste in Korea in the future.

Applying deep learning to detect fractures from GPR data

Ain LEE[1]*, Kangwon National University (dldkdls6912@kangwon.ac.kr)
Seokhoon Oh[2], Kangwon National University
Hyoung-Seok Kwon[3], Kangwon National University

Abstract

High-level radioactive waste (HLW) is disposed of in a deep geologic repository consisting of a multi-barrier system to ensure safe isolation from the ecosystem for tens of thousands of years or longer. Fracture zones in natural barriers are the primary fluid flow pathways for radionuclides, so it is essential to characterize the faults and fractures distributed in the bedrock. The distribution characteristics of fractures are investigated through various site surveys and experimental studies, and the performance of natural-barrier can be verified through fracture network modeling. Borehole image scanning methods and observation the excavation in Underground Research Laboratory (URL)s can be used to characterize the fractures in the deep underground. However, borehole imaging only provides fracture information from a specific point, and visual observation at the URL is also limited to the characterize the fractures on the excavation face. In contrast, ground penetrating radar (GPR) surveys in the URL can characterize the fractures at depths of several meters or more beyond the excavation face. During the site survey of a deep repository in Finland, a borehole radar survey was conducted to overcome the spatial limitations of borehole imaging techniques. A study on the GPR method at the Äspö Hard Rock Laboratory (HRL) in Sweden demonstrated the possibility of characterizing fractures up to a depth of approximately 8 meters inside the rock excavation. Recently, researchers have applied machine learning algorithms to extract faults and fractures from outcrop photographs or seismic profile images. This study applies the Convolutional Neural Network (CNN) technique, commonly used to extract faults from seismic data, to GPR data containing fractures. To create a CNN algorithm suitable for GPR data, it is necessary to generate training data. The study utilized GPR modeling software, GPRSIM, to generate training data and labeling data was generated based on the model data. The underground medium was set to a constant velocity similar to that of deep bedrock, and noise was added randomly to simulate field data. After applying data processing, such as gain recovery, band-pass filtering, and migration, to the modeling data, the training data was converted into images. The training data were generated under various conditions by varying the distribution of one or multiple fractures, as well as the extension, slope direction, and complexity of fractures. Using the GPR training data, we developed a CNN algorithm to identify fractures and examined the limitations of GPR method based on the fracture's distance, extension, and inclination angle. Finally, the deep learning algorithm was applied to GPR data collected in the exposed bedrock of the Daecheong Dam in Korea to assess its applicability to field data.

Abstract

To ensure the safe disposal of radioactive waste, understanding the characteristics of deep groundwater is crucial, including its recharge processes, movement patterns at regional and local levels, and hydrochemical evolution over time. The objective of this study is to determine the residence time, recharge mechanisms, and origins of deep groundwater by utilizing environmental isotopes such as δ18O, δD, δ13C-DIC, and 14C, alongside hydrochemical parameters. To identify potential recharge areas for deep groundwater, we utilized GIS to perform DEM-based landform classification, subsequently combining this terrain analysis with residence time data (14C) and stable water isotopes (δ18O, δD) from deep groundwater for comprehensive interpretation. Through an in-depth evaluation of hydrochemical and isotopic characteristics employing GIS, we propose that a considerable volume of paleo-recharge from Mountain Block Recharge (MBR) forms the basis of deep groundwater through slow-moving regional flow. This finding highlights the necessity of not only conducting detailed studies in near-field areas to ensure the long-term safety of High-Level Waste (HLW) disposal sites but also considering the regional deep groundwater system. It is anticipated that these studies will be instrumental in delineating the management boundaries for HLW disposal facilities and in projecting the impact of future climate variations on the deep groundwater system. Characteristics of radiogenic heat production rate in fractured rock mass

Yeonguk JO[1]*, Korea Institute of Geoscience and Mineral Resources (joy@kigam.re.kr)
Myungsun KIM[2], Korea Institute of Geoscience and Mineral Resources
Tae Jong LEE[3], Korea Institute of Geoscience and Mineral Resources
Changhyun LEE[4], Korea Institute of Geoscience and Mineral Resources

Abstract

This study aims to estimate the radiogenic heat production rate of a fractured subsurface rock mass using wireline logging techniques in a 1 km deep borehole. To achieve accurate heat production evaluations, natural gamma-ray logging and gamma spectrometry logging were conducted simultaneously, along with laboratory mass spectrometry analysis on drill-cores retrieved from the borehole for verification purposes. We used a well-known empirical correlation to estimate the radiogenic heat production rates using the total gamma-ray counts. Additionally, we calculated the heat productions based on the spectral gamma logs by examining the relationship between heat generation constants of major radioisotopes (uranium, thorium, potassium) and their concentrations.

The logged natural gamma-ray emissions ranged from approximately 0 to 800 API, corresponding to heat production magnitudes of 0.65 to 11 $\mu W/m^3$. However, the heat production rates estimated from natural gamma-ray logs at several intervals differed markedly from those evaluated from spectral-gamma methods. This discrepancy is likely due to the presence of natural fractures at those depths and the effects of groundwater flow and mineral alterations on heat production rate evaluations.

This study provides a comprehensive comparison of methods for estimating radiogenic heat production rates in fractured rock formations, highlighting the influence of subsurface fractures on heat production evaluations. The findings contribute valuable data for the assessment and utilization of subsurface geothermal energy resources, indicating the need for more precise heat production rate evaluations considering these variables in future studies.

Ching-Yuan Liu[6], National Central University

Abstract

The continued use of nuclear energy in Taiwan has come into question due to the difficulties in safety managing and disposing radioactive waste, and public opposition and disagreement for final repository has increased since the Fukushima nuclear disaster in March 2011. Since deep geological disposal is currently the preferred way of disposing nuclear waste, the state-run Taipoewr Company (TPC), owner of three nuclear power plants, initiated a long-term spent-fuel disposal program in the 1980s to prepare a geological repository for operation in 2050. To assess the long-term performance of this repository, it is necessary to deal with the problem of high-level radioactive waste (HLW) considering its long half-life and the associated risk of trans-porting radionuclides into the environment. Some geological investigations and research and development (R&D) efforts into radionuclide migration have been completed, and the experimental, numerical and safety assessment presented in this study are a part of this disposal program. Recently, to determine the relationship between the atomic-scale adsorption structure and the environmental behavior by using extended X-ray absorption fine structure (EXAFS) is a major and important tool, and we applied EXAFS to analyze several environmental samples including host rock and bentonite. Cesium ion adsorbed on clay minerals are dehydrated and hydrated, which are called inner-sphere (IS) and outer-sphere (OS) complexes, respectively. Cations forming OS complexes are more easily desorbed by cation exchange reaction than IS complexes. Thus, Cs+ is strongly adsorbed on clay minerals, making its extraction challenging, while other REE (i.e Eu3+) are weakly adsorbed, causing their high extraction rates by the cation exchange reaction.

Assessment of Water-Rock Interactions of Uranium through Laboratory Batch and Column Experiments

Sung-Wook JEEN[1]*, Jeonbuk National University (sjeen@jbnu.ac.kr)
Hakyung Cho[2], Jeonbuk National University
Soyeon Lim[3], Jeonbuk National University

Abstract

Understanding uranium behavior is crucial for the deep geological disposal of high-level radioactive waste. Given that the interaction of rocks and groundwater significantly influences uranium behavior, we conducted laboratory batch and column experiments to assess water-rock interactions involving uranium. The rock samples (coaly slate) for these experiments were sourced from a natural analogue study site (Okcheon Metamorphic Belt) in Korea, and artificial groundwater simulated the compositions of the groundwater at the study site. In the batch experiments, the initial pH levels rapidly declined after the reactions started, consistently falling below 4.5. This decline was attributed to the absence of carbonate species capable of buffering the pH and the generation of hydrogen ions from the oxidation of iron sulfide. In an experiment with an initial pH of 7.9, changes in uranium concentration increased and then decreased over time. The initial increase was attributed to the dissolution of uranium minerals (uraninite and ekanite), while the subsequent decrease was considered to be caused by the adsorption or surface complexation of uranium with SiO2 and iron (hydr)oxide, such as ferrihydrite. For column experiments simulating flow-through conditions in the field, two columns were prepared: one filled with coaly slate (0.025 ~ 2 mm grain size) and another with a mixture of coaly slate and limestone (10 wt.%) to provide pH buffering. The pH in the column with coaly slate only initially exhibited the highest value at 0 cm but gradually decreased to below 4.5. This was attributed to the insufficient carbonate buffering capacity to neutralize hydrogen ions generated by the oxidation of iron sulfide in coaly slate. In the column with the mixture, in contrast, the pH remained around 8. Uranium concentration in the mixture column increased gradually with distance. Subsequently, the released uranium formed uranium aqueous complexes with dissolved F or SO4 induced by iron sulfide oxidation. This study contributes to understanding the transport and reaction characteristics of uranium in groundwater, ultimately aiding in the management of high-level radioactive waste in a deep geological disposal site.

Characterization of radionuclide mobilization using environmental tracers at natural analogue site in Boeun, South Korea

Ye Ji KIM[1]*, Seoul National University (yejikim55@snu.ac.kr)
Jaeyeon Kim[2], Seoul National University
Dugin Kaown[3], Seoul National University
Kang-Kun Lee[4], Seoul National University

Abstract

Uranium bearing geological formations can be used for natural analogue studies which can provide insight to the long-term subsurface radionuclide mobilization characteristics. Uranium within the groundwater can be a direct indicator of mobilization, but hydrogeological characteristics such as redox conditions can hinder the single use of uranium for the analyzation of migration patterns. Hence, this study aimed to characterize the transport of uranium and its daughter product within the groundwater, along with the characterization of the groundwater flow regime using groundwater age tracers. The study was conducted in Boeun, South Korea, where coaly slate and black slate are situated which contain abundant amounts of uranium. Significant amounts of radiogenic helium were only observed at the deepest sampling depth of 80 m (OB3-80). This was in correlation with the fact that this point not only showed the highest uranium concentration, but also showed the highest groundwater age evaluated by the 14C age tracer. A more specific analysis of groundwater age was conducted through a multitracing approach using 4He, 14C, and 3H, and clarified the groundwater flow regime and uranium transport mechanisms of this area. Overall, this study provided the basic flow characteristics of this area and showed the potential for He to be used as a tracer for the analyzation of uranium transport.

Abstract

The Leakage during the operation of nuclear facilities can result in radioactive contamination of the soil at a decommissioning site. A large amount of soil waste contaminated with Cs-137, Sr-90, Co-60, and H-3 has been generated during the decommissioning of international commercial Nuclear power plants. The geological and radionuclide transport characteristics of a nuclear facility site are known to be important factors in determining a remediation strategy. In this study, we investigate the geological characteristics and radionuclide migration of the nuclear facility site to develop a methodology for the optimal remediation strategy. We establish a methodology for the selection of strategic sampling points by horizontal or vertical points on the site. We establish the procedure for building a geological model and establish the procedure for permeability testing to investigate radionuclide migration. Based on the sampling soils, the non-radioactive isotopes of cesium (Cs), strontium (Sr) and cobalt (Co) are used as single isotope or multiple isotope to predict the isotope mobility and select the optimal remediation strategy for each isotope for the migration and desorption results through the permeability and leaching tests. This study is expected to predict isotope migration and improve the efficiency of site remediation, taking into account isotope mobility and geological characteristics in the soil and groundwater of nuclear facility sites.

A current status of natural analogue studies in Korea for high-level radioactive waste disposal

Ji-Hun RYU[1]*, Korea Atomic Energy Research Institute (jryu@kaeri.re.kr)
Wanhyoung Cho[2], Korea Atomic Energy Research Institute
Yoonah Bang[3], Korea Atomic Energy Research Institute
HunSuk Im[4], Korea Atomic Energy Research Institute
Sanghoon Lee[5], Korea Atomic Energy Research Institute

Abstract

High-level radioactive wastes (HLW) must be isolated from the ecosystem until their radioactivity decreases to natural background radiation. Given the maximum time period of decay processes of various nuclides in spent fuel, the components of DGR (Deep geological repository) have to maintain their capabilities for the period to restrain the nuclides. To demonstrate the safety of DGR, current approaches of long-term stability of the system largely rely on short-term experiments in laboratory or engineering scaled facilities. In addition, complicated computer simulations have been developed to predict the future behaviors of DGR up to the maxium decay time covering most nuclides using various inputs from the experiments.

Due to the lack of competence in calculating the long-term processes, we try various approaches to minimize the uncertainties of simulation caused from fast laboratory experiments mimicking complexities of natural systems and low rates of processes involved. Natural analogue (NA) provides quantitative and/or qualitative information about the occurrence of various processes related to DGR to allow testing of individual processes over geologic time and space scales. Especially, for some processes such as thermal, NA study may be the only means of providing the required understanding of long-term and large-scale behavior needed to provide scientific confidence in performance assessment of DGR.

Several countries have been operating radioactive waste disposal programs to develop their own DGR and performing NA studies to have reliability of the long-term safety of the system. The Korea Atomic Energy Research Institute has launched an NA national R&D program for the first time in Korea on 2021. NA study can be an intuitive way to give reliability of the long-term safety of DGR. And the studies provide important elements or conceptual models in simulating DGR in many cases. For example, NA studies of geological systems can elicit information about the migration of nuclides in multi-barrier system of DGR.

In this study, we discussed some cases of NA studies in Korea as well as other countries for HLW disposal. We examined the differences among them and their roles in reflecting the country's own DGR. This study aims to develop the national NA program by establishing the basic concepts of NA studies.

Multiple sulfur and uranium isotope compositions of uraniferous slates in the Bibong Formation of the Okcheon Metamorphic Belt

Eunje OH[1]*, Seoul National University (dodosis97@snu.ac.kr)
Dong Kyun WOO[2], Seoul National University
Dongbok SHIN[3], Kongju National University
Min Sub SIM[4], Seoul National University

Abstract

Sulfur and uranium isotopes have been widely used to investigate the redox transformation of these elements in geological and biological processes, including the dissimilatory reduction of their oxyanions. Uraniferous slates in the Bibong formation of the Okcheon Metamorphic belt can be divided into black and coaly slates, of which the latter shows a higher grade of metamorphism and are usually more enriched in uranium. Although both sedimentary and metamorphic processes have been suggested to be involved in the formation of uraniferous slates, the mechanisms for uranium enrichment are not yet fully understood. In this study, we utilize the ratios of multiple sulfur isotopes (^{32}S, ^{33}S, and ^{34}S) and uranium isotopes (^{238}U and ^{235}U) to reconstruct the initial enrichment of uranium and its later alteration, coupled with changes in the biogeochemical cycle of sulfur. Samples were obtained from an outcrop (PJ Outcrop) located in Hoenam-myeon, Boeun, South Korea. The preliminary data collected from the outcrop show that the uraniferous coaly slates are enriched in ^{238}U compared to the black slates, suggesting that uranium was concentrated by reductive precipitation. Pyrite formation likely involved the reduction of seawater sulfate as a sulfur source, as indicated by the relatively high $\delta^{34}S$ values of pyrite, which range up to 14‰. In addition, the depleted $\Delta^{33}S$ values of pyrite in the uraniferous coaly slates can be attributed to the mixing of biogenic sulfide, which is strongly depleted in ^{34}S, with sulfide produced by the reduction of seawater sulfate with negligible sulfur isotope fractionation. The results of this study support the possibility that initial enrichment by microbial reduction, as well as later diagenesis and alteration, has contributed to the formation of uraniferous slates.

Examining Uranium Behavior Through Column Experiments Using Artificial Groundwater and Coaly Slate from a Natural Analogue Study Site in Korea

Soyeon LIM[1]*, Department of Environment and Energy, Jeonbuk National University, Jeonju-si, Jeollabuk-do, 54896, Republic of Korea (dlathdus0311@naver.com)
Hakyung CHO[2], Department of Environment and Energy, Jeonbuk National University, Jeonju-si, Jeollabuk-do, 54896, Republic of Korea
Sung-Wook JEEN[3], Department of Earth and Environmental Sciences & The Earth Environmental System Research Center, Jeonbuk National University, Jeonju-si, Jeollabuk-do, 54896, Republic of Korea

Abstract

Deep geological disposal methods are primarily employed for the management of high-level radioactive waste containing uranium. Understanding the behavior of uranium under different hydrogeochemical conditions is crucial, as any corrosion or breach of multiple barriers could lead to the potential migration of uranium into groundwater through fractures in the rock. To this end, we assessed the behavioral characteristics of uranium in the subsurface environment by analyzing temporal and spatial changes in uranium concentrations, as along with other geochemical parameters, through column experiments. Coaly slate, containing uranium minerals with a high radiation level (≥ 400 cpm), was collected from a natural analogue site of Okcheon Metamorphic Belt, Korea, and two columns (NA-PJ1 and NA-PJ2) were prepared. The columns were prepared by crushing the rock to a size of 0.025 to 2 mm and sieving it. NA-PJ1 was filled with coaly slate only, while NA-PJ2 was filled with a mixture of coaly slate and 10 wt% limestone to serve as a pH buffer. Artificial groundwater, designed to reflect the composition of the monitoring well, was injected into the column. Before the experiment, the artificial groundwater was purged with Ar gas to simulate the reducing environment. The solution was injected at a constant rate of 0.5 mL/min (720 cm/day). Temporal and spatial changes resulting from the reactions between artificial groundwater and the medium in the column were observed through profile sampling. Sampling was conducted at 0, 5, 10, 15, 20, 25, 30, 35, and 40 cm from the influent end of the column. Dissolved oxygen (DO), pH, Eh, electrical conductivity (EC), and alkalinity were measured, and cations and anions were analyzed. In both columns, DO consistently maintained a low concentration. The pH exhibited its highest value (8.5 ~ 8.93) at 0 cm in both columns. However, in NA-PJ1, it gradually decreased and fell below 4.5. This was attributed to the insufficient carbonate buffering capacity to neutralize the increased hydrogen ion concentration resulting from the oxidation reaction of iron sulfide in the coaly slate. In contrast, NA-PJ2 maintained a pH of approximately 8 at all distances. As for the uranium concentration, in NA-PJ1, it increased with distance (0.5 /L ~ 67.2 /L), primarily due to the dissolution of uranium minerals (i.e., uraninite and ekanite). Moreover, uranium formed aqueous complexes with dissolved F or SO4 generated from the oxidation reaction of iron sulfide, with the concentration gradually increasing with the flow of groundwater. Close to the column influent in NA-PJ1, uranium formed a UO2CO3(aq) complex. However, with increasing distance, uranium transitioned to form a UO2SO4(aq) complex with

SO4. The experimental results indicate that when uranium dissolves under low pH conditions, it may form complexes with other anions in the groundwater and subsequently migrate with the groundwater flow. This study can contribute to the interpretation and evaluation of uranium transport and reaction characteristics within groundwater flow systems.

Hydrochemical Characteristics of Deep Groundwater by Depth in Granite site for Disposal of High-Level Radioactive Waste

JIWON PARK[1]*, GeoGreen21 Co., Ltd. (jwpark@geogreen21.com)
JUN-YOUNG AHN[2], GeoGreen21
SEONG-CHUN JUN[3], GeoGreen21
JEONG-YONG CHEON[4], GeoGreen21
MYEONG-JAE Yi[5], GeoGreen21

Abstract

In this study, we investigated the hydrochemical characteristics of deep groundwater at various depths in a granite area, which is one of the rock types considered for the disposal of high-level radioactive waste, to evaluate the suitability as disposal depths. The groundwater was collected at the fractured zone (281~291, 310~320, 485~495, 612~622 m bgs) of 1,000 m depth borehole installed in the KURT study area. Comparing the hydrochemical properties of groundwater collected at different depths, it was observed that as the depth increased, the pH increased while DO and ORP decreased, indicating a reducing environment with increasing depth. The EC values ranged from 50~500 uS/cm, and the concentrations of Cl- were below 10 mg/L at all depths, indicating uncontaminated groundwater such as natural. As the pH of deep groundwater increased, the dissolution of carbonate minerals occurred, increasing the concentration of HCO3- as the depth increased. The concentrations of NO3- and SO42- decreased with deeper depth, indicating a reducing environment in deep groundwater. The increase of Na+ concentration was estimated to occur as the reducing properties in groundwater became stronger as the depth increased. Conversely, the concentration of Ca2+ decreased with depth, which is presumed to be due to the formation of calcite. Based on the results of this study, it was confirmed that the underground environment at a depth more than 500 m bgs is predominant the reducing environment, which is an appropriate level for the disposal of high-level radioactive waste.

Abstract

The transport of uranium through bentonite buffers within high-level radioactive waste repositories under various environmental conditions is crucial, particularly due to the predominance of uranium in waste package. To simulate this complex migration process, a reactive transport model is frequently utilized which can incorporate the multi-physical processes that potentially affect uranium migration, including groundwater flow, heat flow, and geochemical reactions. In this study, a COMSOL-IPhreeqc coupled model was developed, validated, and applied to simulate the uranium migration process under diverse conditions.

Initially, the transport of uranium through a one-dimensional bentonite-granite column, without any significant environmental change was simulated to serve as a standard scenario (BG-1). This model scenario includes a column consisting of 0.5 m of bentonite and 29.5 m of granite. Uraninite was assigned at the left end of the bentonite, assuming the canister failure. Given the absence of notable environmental events, the reactions in the bentonite was induced by the porewater mixing with the adjacent granite. Subsequent simulations, BG-2 and BG-3 investigated the impacts of temperature variations due to the heat generated from the canister and seawater intrusion through fractures, respectively. These changes in temperature or porewater composition significantly altered the environmental conditions, affecting aqueous speciation, adsorption dynamics, and mineral composition within the system. Future research will further elucidate the implications of these environmental evolutions on uranium migration, providing an insight into the long-term safety of high-level radioactive waste repositories.

Investigation of geochemical evolution and radionuclide migration in engineered barrier systems using an adaptive process-based total system performance assessment framework

Jeonghwan HWANG[1]*, Korea Atomic Energy Research Institute (KAERI) (hwangjh@kaeri.re.kr)
Jung-Woo Kim[2], Korea Atomic Energy Research Institute (KAERI)

Abstract

The long-term safety of engineered barrier systems (EBS) for the disposal of high-level radioactive waste is crucial for assessing the safety performance of deep geological repositories. Developed by KAERI, an adaptive process-based total system performance assessment framework (APro) simulates the long-term geochemical evolution of repositories and its impact on radionuclide migration. APro couples COMSOL and PHREEQC through a sequential non-iterative approach for the reactive transport modeling. In addition, the inclusion of non-water hydrogen (H), non-water oxygen (O), and charge balance in the coupling process significantly improves the accuracy and stability. This setup enables a radionuclide transport model to involve detailed geochemical reactions, such as mineral dissolution/precipitation, cation exchange, surface complexation, and sorption. This study conducted APro simulations to evaluate uranium migration within the EBS, considering the effects of redox changes and seawater intrusion.

The simulations confirmed that diffusion is the dominant mechanism for the migration of uranium and other dissolved ions within the bentonite buffer due to the concentration gradient between the EBS and the host rock. Additionally, the redox condition within the EBS was changed from oxidative to reductive states due to the oxidation of pyrite, which significantly influenced uranium migration through precipitation reactions. Seawater intrusion caused significant change of geochemical condition in the EBS throughout the long-term evolution, such as the dissolution of gypsum followed by the precipitation of calcite, dolomite, and siderite, thereby altering the porewater chemistry. However, this had only a minor effect on uranium transport.

Abstract

Cesium-137 (Cs), the byproduct of the uranium and plutonium fission processes, has the relatively long half-life (30 years) and the high solubility in water, making it particularly concerning for environmental pollution in the event of a leak. Although many Cs sorbents have been studied, they have disadvantages such as the high cost of sorbent materials and the low Cs removal efficiency in solution with low Cs concentration and/or high ionic strength. Additionally, the use of powdered sorbents for treating contaminated water in the real field is unrealistic because there is no convenient method to collect sorbents after treatment.

In this study, a new environmentally friendly Cs sorbent showing the high Cs sorption efficiency (named as 'Na-S-CMDS') was developed by adding sodium (Na) and sulfur (S) to the coal mine drainage treatment sludge (CMDS), which was produced during the treatment of drainage originated from abandoned coal mines. The physicochemical and mineralogical properties of the Na-S-CMDS were analyzed by various analyses including XRF, XRD, SEM/EDS, and XPS to confirm the successful Cs-sorbent development. To evaluate the Cs removal efficiency and the Cs sorption mechanisms of the Na-S-CMDS, sorption batch experiments with different Na-S-CMDS dosages, pH values, initial Cs concentration, and reaction time were duplicated. Results of sorption batch experiments indicated that the Na-S-CMDS exhibited the rapid sorption rate (< 1 hour) and the high sorption efficiency (> 90.0%) even at the low Cs concentration (< 0.5 mg/L). Additionally, the Na-S-CMDS maintained the high Cs removal efficiency (> 80.0%) across a wide pH range (pH 2 to 11). The primary sorption mechanisms of the Na-S-CMDS were attributed to the strong binding affinity of S-Cs, as proposed by the 'hard soft acid base (HSAB) theory', as well as the active ion exchange between Na+ and Cs+.

Additionally, the powdered Na-S-CMDS was synthesized into granules by using the biopolymer to facilitate the separation of the sorbent from an aqueous system. The Na-alginate was used as the biopolymer material, and batch experiments were conducted to evaluate whether the alginate-granulated Na-S-CMDS exhibits high Cs removal efficiency under the same experimental conditions or not. From this study, it was suggested that the less toxic and the low-cost Na-S-CMDS could be used as an effective sorbent for the Cs removal from radioactive wastewater with high ionic strength and at low initial Cs concentration.

Abstract

The quantitative understanding for the migration of gas and radioactive nuclide in the deep geological repository (DGR) is very important to minimize the radioactive nuclide spreading in the multi-barriers. Because gases originated from the spent nuclear fuel (SNF) disposal site are very mobile and may affect the migration of radioactive nuclides in the SNF disposal site. Thus, characteristics of gas-nuclide migration in the multi-barriers and their influences on the safety of the disposal site should be sufficiently investigated before the construction of the final SNF disposal site.

In this study, hydro-dynamic properties of gas-nuclide migration in barrier medium were investigated through laboratory experiments at the practicable SNF disposal site environment, and the numerical gas (or nuclide) migration modeling in buffer medium was performed by using input parameters acquired from experiments. For the simulation of the gas-nuclide migration in experiment and modeling, the gas-nuclide migration scenarios were classified into two stages according to the hydrogeological evolution process in the DGR: ① the migration of gas phase nuclide in the unsaturated and saturated buffer medium (only gas phase), and ② the migration of dissolved phase nuclide in the saturated buffer medium.

Hydro-dynamic and gas migration properties of the buffer material such as density, porosity, gas/water permeability, gas injection flux, gas diffusion coefficient, and gas dispersion coefficient were determined based on the experimental results. Migration properties of dissolved nuclide (Cs+ and I-) such as the average advection velocity and diffusion/dispersion/retardation coefficient at various repository conditions (injection pressure, pore pressure, confining pressure, temperature, water saturation, etc.) were also determined by experimental results including the concentration breakthrough curves. The H2 gas, Cs+ and I- were selected for the gas and the nuclide migration experiment (0.3% of H2; 132.9 ppm of Cs+; 126.9 ppm of I-).

Modeling and experimental results from this study will be more useful as the important data for the long-term modeling of radioactive nuclide-gas (multi-phase) migration, and will support idea to develop the technology, controlling radioactive nuclide migration and evaluating the safety of the SNF disposal site.

Abstract

Groundwater colloids play a crucial role in the dynamics of colloid-facilitated radionuclide transport within deep geological repositories. Groundwater colloids include various inorganic and organic substances; thus, understanding the physicochemical properties of groundwater colloids is crucial for assessing the fate and transport of radionuclides. To investigate the role of colloidal phases in colloid-facilitated radionuclide transport, characterization of colloids for elemental composition, mineralogical characteristics, size distribution, and surface charge is required. For this purpose, samples were collected from two boreholes, DB-1 and DB-3, at the KAERI Underground Research Tunnel (KURT), representing oxidizing and reducing conditions, respectively. A Teflon-lined metal container was used to preserve the original hydrochemical condition of the groundwater. The collected samples were stabilized in a glove box system and filtered through a 0.45 μm PTFE membrane filter. Due to the low concentration of groundwater colloids, the pre-filtered samples were concentrated using a tangential-flow ultrafiltration system equipped with 3 kDa cartridges. Dynamic light scattering, particle size analysis, scanning electron microscopy, energy-dispersive X-ray analysis, and X-ray diffraction techniques were applied to characterize the groundwater colloids. The results revealed diverse colloids consisting of inorganic and organic substances, providing useful insights for understanding the potential transport of radionuclides. Therefore, the results of this study are expected to be used as one of the fundamental case studies for predicting the formation of pseudo-colloids and the migration of radionuclides in granitic environments.

Abstract

The safe management of spent nuclear fuel (SNF) and associated contaminated by-products, which are classified as high-level radioactive waste (HLW), has emerged as a serious concern in numerous countries operating nuclear power plants. In south Korea, there have been productive R&D activities and societal discussions regarding the direct disposal of HLW without reprocessing, where the concept of deep geological disposal (DGD) stands out as the most proven technological option to prevent significant release of radionuclides into biosphere and ultimately secure the long-term safety of entire disposal system. Within the DGD system, comprised of multiple engineering and natural barriers, bentonite-based buffer and backfills play the key hydrogeochemical roles in 1) suppressing the intrusion of groundwater and reactive chemical substances that may expedite the corrosion of waste canister and 2) retarding the transport of released radionuclides to biosphere by providing abundant chemisorption sites. Montmorillonite is a primary mineral component in the bentonite, and it predominates the swelling and sorption capabilities of the clay material. Therefore, in terms of reducing the uncertainty in a performance assessment of DGD system, it is crucial to comprehensively understand the mechanisms of chemical interactions between dissolved radionuclides and montmorillonite. The chemisorption of dissolved species onto mineral adsorbents has been described and quantified based on the definition of sorption-desorption distribution coefficient (Kd). However, since the simple Kd concept does not incorporate any mechanistic essence of the surficial interaction, an empirical Kd value is eventually dependent on the experimental conditions (pH, temperature, S/L, etc.) under which it was assessed. In this framework, the application of thermodynamic sorption modeling (TSM), based on the chemical principle of mass action laws, has been suggested and actively investigated to geochemically parametrize the sorption phenomena more reliably under a wide range of aquatic conditions, especially in the context of modeling radionuclide migration within the DGD environment.

In 2021, the disposal performance demonstration R&D division of Korea Atomic Energy Research Institute (KAERI) adopted a new reference Ca-type research bentonite clay, Bentonil-WRK (Clariant Korea), and we conducted experimental and modeling works on the purification of Ca-montmorillonite from Bentonil-WRK and its chemisorption behaviors with major radionuclides and other relevant substances. This presentation provides an overview of the utilization of TSM in an operation of process-based total system performance assessment framework, and the resulting reaction models and stability constants of surface Cs(I), Sr(II),

Se(IV), and I(-I) species, which are highly soluble major fission products contained in the HLW, onto the Ca-type Bentonil-WRK montmorillonite under ambient conditions were discussed.

Assessing nuclides migration across multi-barrier interfaces using reactive transport models

Heewon JUNG[1]*, Chungnam National University (hjung@cnu.ac.kr)
Sunwong Lim[2], Chungnam National University
Yehoon Kim[3], Chungnam National University

Abstract

Performance assessment of a geologic nuclear waste repository requires numerical modeling to understand the long-term migration of nuclides through engineered and natural barriers, because the timescale of interest extends well beyond the typical range of direct estimation methods. Additionally, the processes governing the long-term safety of the repository occur across various scales in space and time, often surpassing the capabilities of conventional observables. Overcoming such limitations requires a numerical approach, capable of providing insights into the intricate processes associated with conventional observables over a geologic time scale. In this regard, reactive transport models, which mathematically integrate hydrological and geochemical processes, provide unique opportunities for evaluating the long-term fate of nuclides in repository environments. Here, we focus on hydrological evolution induced by geochemical reactions at the pore-scale near a concrete-granite interface of a multi-barrier system using a novel pore-scale reactive transport modeling framework, CompLaB. Along a fracture across a concrete-granite interface, we characterize the evolution of porosity and permeability as a result of dissolution and precipitation reactions under various flow conditions. As dissolution and precipitation reactions expose new surfaces for nuclides to interact with, we also investigate the intricate nature of nuclide breakthroughs in the evolving subsurface system. This numerical study provides a building block for developing a field-scale macroscopic model that explicitly takes into account the hydrogeochemical evolution at the pore-scale.

Interrogating reactive surface distribution at the pore-scale using dual tracer breakthrough curves

Sunwong LIM[1]*, Department of Earth, Environmental & Space Sciences (Geological Sciences) Chnungnam National University (sunwong@g.cnu.ac.kr)
Heewon Jung[2], Department of Geological Sciences, Chungnam National University

Abstract

Understanding the fate of nuclides and dissolved chemicals in subsurface environments hinges on intricate interactions between transport and reaction processes at the pore scale. However, fully resolving such fine-scale phenomena in a large field system is practically infeasible. Hence, many investigations rely on field-scale observables such as breakthrough curves (BTCs) and macroscopic modeling techniques that simplify pore-scale transport and reaction processes. This simplification introduces significant uncertainties in quantitatively estimating and predicting hydrogeochemical processes in heterogeneous subsurface environments, hindering the direct application of advanced laboratory observations to field systems. To bridge the gap between pore-scale processes and macroscopic observables, this study investigates the effects of reactive surface distribution on tracer BTCs. A total of 48 simulations were conducted, injecting both conservative and reactive tracers into three simulation domains characterized by different dead-end pore volumes and reaction surface distributions, while maintaining the same porosity. The reactive tracer is consumed at predefined reactive surfaces, while the conservative tracer is used to extract reaction rate BTCs from the tracer BTCs. Analysis revealed two distinct types of peaks (Type I and Type II) in the time derivative of reaction rate BTCs, indicating advection- and diffusion-controlled surface reactions, respectively. Employing curve fitting techniques using two skewed Gaussian curves successfully reproduced the simulated reaction rate BTCs, with parameters systematically varying depending on the flow and reaction surface distribution conditions. This finding suggests a novel approach for extracting reaction surface distributions in heterogeneous subsurface environments from multi-tracer BTCs, allowing potential advancements in understanding hydrogeochemical processes in complex subsurface systems.

Minhee LEE[5], Major of Environmental Geosciences, Division of Earth Environmental System Science, Pukyong National University, Republic of Korea

Abstract

The deep geological repository (DGR) is regarded as a viable solution for the permanent disposal of the spent nuclear fuel (SNF). Ensuring the safe and permanent SNF disposal requires the comprehensive understanding of the hydrogeological evolution processes during the SNF disposal and of the leaked radionuclide reaction behavior in the DGR. The DGR is composed of various barrier systems and the compacted bentonite buffer is considered to be used as a crucial engineering barrier. Characterized by high swelling capacity and low permeability, the compacted bentonite buffer plays an important role in preventing groundwater infiltration and radionuclide spreading in the DGR. Throughout the hydrogeological evolution of the DGR, various gases such as H2, H2S, CO2 and He can be generated and properties of the bentonite buffer also could be influenced and modified by these gases. These transitions finally affect the behavior of released radionuclides as well as the alteration in groundwater properties.

In this study, we simulated the dissolution of active representative gases (CO2 and H2S) and the geochemical reaction in the groundwater-gas-bentonite system at the repository's oxidative (or reductive) environment. Property changes of bentonite and adsorption capacity changes of Cs (I) and Sr (II) on bentonite due to gas were mainly investigated in batch experiments. The Korean bentonite (‘Bentonil-WRK’) used in the experiment is a Ca-type bentonite intended to be used as a buffer material for the Korean SNF disposal repository. The artificial solution was prepared with the initial Cs (Sr) concentration of 20 ppm and at pH 9 for batch experiments. Powdered bentonite was mixed with solution in a sealed glass vial, and the remaining space was filled with CO2 or H2S gas. The vial was stirred at 100 rpm for 0.08, 0.5, 1, 2, 6, 12, 24, 72, 168, and 336 hours at 60℃. At the same experimental condition, the geochemical reaction modeling for the bentonite-water-gas system was performed using a program of GWB (‘Geochemist’s Workbench’) and modeling results were compared with experimental results. In this study, the effect of active gases (H2S and CO2) on the sorption property of Cs (I) and Sr (II) on the bentonite was investigated and the feasibility of the Korean bentonite (‘Bentonil-WRK’) as the buffer material to prevent the nuclide spread in the SNF disposal site was also evaluated by both of experiments and

geochemical modeling.

Experimental Investigation into Nuclide Diffusion on Compacted Bentonite under the Influence of Reactive Gas

Jin-Seok KIM[1]*, Disposal Performance Demonstration R&D Division, Korea Atomic Energy Research Institute (jskim84@kaeri.re.kr)
Sang-Ho Lee[2], Disposal Performance Demonstration R&D Division, Korea Atomic Energy Research Institute
Seung Yeop Lee[3], Disposal Performance Demonstration R&D Division, Korea Atomic Energy Research Institute
Jang-Soon Kwon[4], Disposal Performance Demonstration R&D Division, Korea Atomic Energy Research Institute

Abstract

Spent Nuclear Fuel (SNF) is destined for final disposal in a deep geological repository. The SNF is encapsulated within a metal canister made from cast iron insert and copper, which is designed to provide long-term containment of the radionuclides. The canister forms part of a multi-barrier disposal system that combines both engineered and natural barriers, offering a basic layer of protection to prevent the leakage of radionuclides. Radionuclides may leak from the canister at the end of its service life, with colloids and gases acting as mediators that can facilitate this process. These mediators can influence the behavior of radionuclides and accelerate their migration. Therefore, it is crucial to consider these factors when assessing the long-term stability of a deep disposal repository.

To better understand the behavior of radionuclides, an experimental setup was designed to simulate a deep geological environment. The experiment aimed to observe the diffusion of nuclide due to dissolved gas diffusion under specific temperature and pressure conditions, similar to those of a deep disposal repository. The experiment simulated gas diffusion within an engineered barrier, reflecting conditions that would be present 1000 years after the closure of the repository. The barrier material chosen for the experiment was bentonite WRK, which was compacted to a dry density of 1.61 g/cm^3. The compacted bentonite was subsequently saturated under a water pressure of 5 MPa, equivalent to the hydrostatic pressure found 500 meters underground. The evaluation of nuclide behavior, as it diffuses into bentonite along with dissolved CO2 gases, was carried out by injecting gas into saturated bentonite at a pressure of 5 MPa to balance with the hydrostatic pressure. The experiment was designed to allow nuclides to diffuse into compacted bentonite under pressures equivalent to 500 meters below ground level. Cesium iodide was used in the experiment, and diffusion reactions were conducted over periods of 10, 20, 30, and 50 days. Most of the cationic nuclides were adsorbed onto bentonite and diffused at a very slow rate. The dissolved carbon dioxide formed trace amounts of precipitated minerals and affected the porosity.

In scenarios high-pressure gas is generated at the interface of the canister and the buffer, diffusion of the dissolved gas into the buffer can occur. This can lead to cationic nuclides such as cesium and strontium adhering to the bentonite particles and becoming fixed. Additionally, the dissolved gas, dissolved elements from accessory minerals, and nuclides can form a new mineral, preventing

the migration of the radionuclide outside of the buffer. However, the high mobility and difficulty of fixation by mineralization of anions necessitate further investigation.

Preliminary results of nuclide migration and retardation in engineering-scale natural fractured rock

Seonyi NAMGUNG[1]*, Korea Atomic Energy Research Institute (synamgung@kaeri.re.kr)
Ki-Jong Jang[2], Korea Atomic Energy Research Institute
Jang-Soon Kwon[3], Korea Atomic Energy Research Institute

Abstract

Ensuring the safety of managing high-level radioactive waste (HLW) in deep geological disposal sites is of paramount importance prior to the construction of the final disposal facilities. This safety assessment requires a comprehensive understanding of how radionuclides interact with geological materials and groundwater in the disposal environment. However, predicting the migration characteristics of radionuclides in the deep geological environments is challenging due to the intricate interplay among various physicochemical processes. In this study, we preliminary evaluated the nuclide behavior at an engineering-scale fractured granite rock to establish the foundational data for future field evaluations. We analyzed the mineralogy and chemical compositions of the primary and the fracture filling minerals to characterize the fractured rock. In addition, the aperture distribution of the fracture was determined based on the results of the hydraulic testing. Migration experiments were then conducted using five nonradioactive cationic and anionic nuclides (i.e., Cs, Sr, Ni, Cl, I) dissolved in deuterium water (D2O). The deuterium water was used as a criterion for evaluating the retardation factors of various nuclides based on their chemical properties. Our results showed distinct differences in the nuclides behavior with the chemical properties in this engineering-scale fractured rock. The detailed results will be presented and discussed.

Accelerating geochemical calculations in reactive transport simulations with an artificial neural network based surrogate model for nuclear waste repository management

Yehoon KIM[1]*, Dept. Earth, Environmental & Space Sciences, Chungnam National University (wnsla7323@naver.com)
Horim Kim[2], Korea Institute of Geosciences and Mineral Resources
Heewon Jung[3], Chungnam National University

Abstract

Reactive transport modeling is a powerful framework integrating chemical transport and geochemical reactions in subsurface environments, finding wide applications in subsurface utilization such as nuclear waste repository management. However, the applications of this modeling approach are often hindered by its substantial computational costs, a challenge that has restricted many model setups to one or two dimensions with coarse spatiotemporal discretization. The computational bottleneck resides in the geochemical reaction calculations, which typically consume approximately 90% of the total computational time. Recognizing this bottleneck, this study introduces a surrogate modeling approach that replaces the geochemical sub-process with an artificial neural network (ANN). The training data were prepared using PHREEQC considering the dissolution of carbonate minerals and surface complexation of uranium species. Preliminary ANN results demonstrate mean squared errors of less than 0.5% when compared to the full-physics PHREEQC calculations. Although this promising level of agreement suggests the potential of the proposed surrogate model in alleviating the computational burden associated with reactive transport simulations, small errors propagate in successive iterations ultimately leading to substantial deviation in surrogate model predictions and yielding unphysical results. This suggests the need for future work, a smart surrogate algorithm that is capable of identifying the error propagation and rejecting inaccurate surrogate predictions informed by full physics representation of geochemistry.

The Basal Emsian boundary – the only pending stage issue in the Devonian stratigraphy

Ladislav SLAVÍK[1]*, Institute of Geology of the Czech Academy of Sciences (slavik@gli.cas.cz)
Hedvika Weinerová[2], Institute of Geology of the Czech Academy of Sciences
Tomáš Weiner[3], Institute of Geology of the Czech Academy of Sciences
Jindřich Hladil[4], Institute of Geology of the Czech Academy of Sciences

Abstract

The Devonian system has well defined stage boundaries. There is one exception only – the problematic lower boundary of the Emsian Stage. The current basal Emsian GSSP was defined in the Zinzil'ban Gorge (Kitab State Geological Reserve, Uzbekistan) based on the FAD of conodont Polygnathus kitabicus Yolkin et al. According to detailed correlations with Mauro-Ibero-Armorican, Rheno-Ardennan and Barrandian faunas it lies far below the base of the classical Emsian in German sense (Carls et al., 2008). At the same time, the GSSP correlates with a level in the lower part of the Praha Formation (Slavík et al., 2007; Carls et al., 2008), but the Pragian Stage has been originally devised to correspond entirely lithologically and biostratigraphically confined Praha Formation (i.e. "the original Pragian"). In 2019, the Subcommission on Devonian Stratigraphy decided to search an alternative section with stratigraphically appropriate level for the new basal Emsian GSSP. The most promising candidates are situated in the Spanish Central Pyrenees and in the Prague Synform. In the past decades, Lower Devonian successions in the Prague Synform were extensively studied for biostratigraphy and palaeontological, sedimentological, geochemical and petrophysical record. Slavík & Hladil (2020) summarized the conodont data from the Early Devonian from the Prague Synform and established conodont zonation in this area. The gracilis Event represents an alternative marker that approximately corresponds to the traditional boundary between the originally defined Pragian and Emsian stages. Our team concentrated on the Pragian-Emsian sections in the Prague Synform in order to obtain large biostratigraphical, geochemical and petrophysical datasets. The beds of the Bohemian Graptolite Event (BGE) form a correlation horizon in the upper parts of the Praha Formation. It is formed by dark grey mudstone layers alternating with carbonate beds, and characterized by close entries of conodont taxa Polygnathus excavatus excavatus Carls & Gandl and Latericriodus bilatericrescens gracilis Bultynck, which might be critical for potential definition of new basal Emsian GSSP. The data from the most promising sections with presence of the BGE with good accessibility and diverse sedimentology will be presented. The Pod Barrandovem, Mramorka Quarry and Požár 3 Quarry sections were sampled for microfacies study and faunal content, magnetic susceptibility logs, geochemical analyses (δ13C and δ18O stable isotopes, INAA, EDXRF) and GRS measurements. The most eligible section for the prospective GSSP redefinition in the Prague Synform will be presented.

The research was financed by the Czech Science Foundation (21-21829S) and was conducted within institutional support RVO 67985831 of the Institute of Geology of the Czech Academy of

Sciences.

Building a numerical high-resolution geological timeline

Shuzhong SHEN[1]*, Nanjing University (szshen@nju.edu.cn)
Shuhan Zhang[2], Nanjing University
Junxuan Fan[3], Nanjing University
Xiangdong Wang[4], Nanjing University

Abstract

The Earth has a history of ~4.5 billion years and a geologic timeline is the only common language available to unravel the evolutionary history of the Earth. Since the 1960s, the International Commission on Stratigraphy (ICS) aims to establish a universal standard timeline for intercontinental and regional correlations. The ICS currently uses the Global Stratotype Section and Points (GSSP) method to define geologic time boundaries. However, we have all recognized that there are some obstacles to precisely placing the stratigraphic horizon of a GSSP. The most common challenge is that all fossil records are far from complete, and it is theoretically impossible to identify the absolute first occurrence of an index fossil species, and thus the previously defined GSSP can be frequently overthrown by subsequent earlier “first” occurrences of index fossils. In addition, the GSSPs defined by biostratigraphy commonly contradict with other physical or chemical markers (e.g., volcanic ash beds, isotope excursions, geochemical anomalies, etc.) that are of isochronous significance. All geological records have temporal and spatial properties and thus should be valuable for intercontinental and regional correlations. The 21st century has entered an era of the widespread application of big data and artificial intelligence. Building a high-resolution geological timeline based on big data of all geological records is an urgent mission for stratigraphy in the next decade. The new geological timeline we are expected should be supported by global stratigraphic databases. We could apply statistics, artificial intelligence algorithms, etc. to correct the incomplete nature of fossil records and to obtain statistically optimal solutions for the ordering of stratigraphic information and combine to use geochronology, magnetostratigraphy, chemostratigraphy and cyclostratigraphy data. The new digital timeline, once established, will greatly promote the quantitative study of the detailed timing, duration, and rate of a given event in Earth history.

Heterogeneous selectivity and morphological evolution during the Permian-Triassic mass extinction

Xiaokang Liu[1]*, China University of Geosciences (xkliu@cug.edu.cn)
Haijun Song[2], China University of Geosciences
Daoliang Chu[3], China University of Geosciences
Xu Dai[4], China University of Geosciences
Fengyu Wang[5], China University of Geosciences
Daniele Silvestro[6], University of Fribourg

Abstract

Morphological disparity and taxonomic diversity are distinct measures of biodiversity, typically expected to evolve synergistically. However, evidence from mass extinctions indicates they can be decoupled. Mass extinctions lead to a drastic loss of diversity, but their impact on disparity remains unclear. Here, we evaluate the dynamics of morphological disparity and extinction selectivity across the Permian-Triassic mass extinction (PTME). We developed a new approach based on the extraction of morphological features from fossil images using a deep learning model (DeepMorph) and applied it to a high-resolution temporal dataset encompassing 599 genera across six marine clades. While five clades experienced strong taxonomic losses, we detected different patterns and magnitudes of morphological change during the PTME, including evidence of selective extinction of specialized forms in some clades. The presence and intensity of morphological selectivity likely reflect the variations in environmental tolerance thresholds among different clades. In clades affected by selective extinctions, the intensity of diversity loss promoted the loss of morphological disparity. Conversely, in clades experiencing non-selective extinctions, the magnitude of diversity loss had a negligible impact on disparity. Our results highlight that the PTME had heterogeneous morphological selective impacts across clades, offering new insights into how mass extinctions can reshape biodiversity and ecosystem structure.

A Deep Learning Approach to Synthesizing Phanerozoic Paleoclimate and Biogeochemical Cycles

Dongyu ZHENG[1]*, Chengdu University of Technology (zhengdongyu@cdut.edu.cn)
Andrew S Merdith[2], University of Adelaide
Yves Goddéris[3], CNRS–Université de Toulouse III
Yannick Donnadieu[4], Aix Marseille Univ
Khushboo Gurung[5], University of Leeds
Benjamin J.W. Mills[6], University of Leeds

Abstract

Databases of 3D paleoclimate simulations are increasingly integral to global biogeochemical models across the Phanerozoic Eon, enhancing the accuracy of surface process representations. However, the method's utility is constrained by the limited availability of comprehensive paleoclimate simulations across various pCO2 levels and continental configurations. Our study introduces the application of the Frame Interpolation for Large Motion (FILM) Deep Learning technique to enhance the temporal resolution of paleoclimate model simulations from an interval of approximately 25 million years to every 1 million year (Myr).

Our methodology's efficacy was validated through tests on a set of continental configurations with a 5 Myr time resolution, accurately reconstructing intermediate frames over periods up to 40 Myrs. Applying this technique, we successfully refined the temporal granularity of the paleoclimate data within the SCION climate-biogeochemical model. This refinement enabled the SCION model to predict previously undetected climate shifts, overcoming the limitations imposed by sparse datasets and simplistic linear interpolations previously employed.

We posit that a ~10 Myr resolution might be optimal for exploring the long-term carbon cycle, with Deep Learning playing a pivotal role in achieving this resolution efficiently. Furthermore, these methods open avenues for developing continuous models for 3D continental processes like species distribution over geological timescales. However, the heterogeneous nature of runoff distribution poses challenges to Deep Learning's interpolation accuracy, underscoring the necessity of validating interpolated climates with dedicated paleoclimate model runs for rigorous scientific conclusions.

[Invited] Reconstructing High-Resolution Biodiversity Patterns in Deep Time: Innovations, Challenges, and Future Directions

Junxuan FAN[1]*, Nanjing University (jxfan@nju.edu.cn)
Shuzhong Shen[2], Nanjing University

Abstract

One crucial aspect of studying the Earth's life history is the reconstruction of deep-time biodiversity patterns. With the emergence of large databases such as the Paleobiology Database (PBDB), the massive compilation of paleontological data has enabled the statistical analysis of fossil records at various hierarchical levels, including family, genus, or species, over continuous time intervals. This approach has been widely adopted, offering an important means of inferring long-term biodiversity history. However, in long-term, large-scale studies, the temporal resolution is often on the order of millions to tens of millions of years, limiting our understanding of rapid, significant events affecting the evolution of life. Over the past decade, we have explored non-traditional methods, such as using the CONOP approach of quantitative stratigraphy, coupled with artificial intelligence and parallel computing, to construct higher temporal resolution marine biodiversity history. With the continued accumulation of data from large stratigraphic databases such as the Geobiodiversity Database (GBDB) and OneStratigraphy, we have investigated several significant biotic events during the Phanerozoic. Future developments focus on two main directions. First, we will try to apply this methodology to the terrestrial fossil records to construct high-resolution biodiversity curves for terrestrial life and to compare them accurately with marine curves. Second, as sedimentary geochemical databases continue to improve, high-resolution time series data of key environmental proxies will emerge, allowing more reliable mechanisms of environment-life interactions to be established in deep time.

[Keynote] Mesozoic origin and evolution of coccolithophores documented by their biodiversity and calcification

ELISABETTA ERBA[1]*, University of Milan, Dept. Earth Sciences (elisabetta.erba@unimi.it)

Abstract

Paleoclimate episodes preserved in the geological record are valuable sources of information about how ecosystems and species functioned in much warmer conditions than today. Paleontological data, thus, inform us about the impacts of global changes on the biosphere and ecosystem dynamics. Long-term time-series can be used to derive the tempo and mode of biota adaptation and recovery.

Calcareous nannofossils include the coccoliths/nannoliths produced by coccolithophores and nannoliths of unknown provenance. They are the low-Mg calcite remains of calcareous nannoplankton that have populated the oceans since Triassic times. The rise of coccolithogenesis is one of the most profound ecological innovations in the oceanic ecosystem, and Early Triassic nannofossils from South China are important for delineating the circumstances that prompted (or allowed) a group of phytoplankton to mineralize calcite, effectively dating the birth of the modern ocean. The origination of coccolithophores in the aftermath of Earth's most catastrophic mass extinction at the end of the Permian imposed a reset of marine ecosystems and forced biota to adapt to, and perhaps take advantage of, extreme climatic and chemical conditions in the ocean and novel niches.

The origin of coccolithophore biocalcification—a spectacular example of the intimate coupling between geological processes and life evolution—began to change oceanic ecosystem dynamics, biochemical processes, and sedimentation in the oceans. The onset of coccolithogenesis marked the beginning of the long and successful evolutionary history of coccolithophores. The Mesozoic evolution of calcareous nannoplankton is characterized by a general increase in diversity, punctuated by speciations, mass extinctions, and turnovers. Times of accelerated rates and/or drops in nannofossil diversity partly correlate with global changes in the geosphere, hydrosphere, and atmosphere, suggesting that the evolutionary patterns are linked to environmental modifications that are interconnected with and determined by processes operating inside the Earth.

During the Mesozoic, calcareous nannoplankton diversification led to the development of 25 coccolith/nannolith families and 5 groups Incertae sedis. In Late Cretaceous times, nannofossil diversity reached a total of 149 species and 115 genera. At a broad scale, nannofossil diversity does not show a clear relationship with climate changes or paleoenvironmental perturbations.

The long-term trends in biodiversity and abundance/calcification of coccolithophores allow for the analysis of their resilience and resistance. In terms of resilience, the biodiversity of calcareous nannoplankton during the Jurassic and Cretaceous shows high resilience, as they were able to maintain their diversity and recover to their pre-perturbation state after disturbances. Possibly, nannofossil diversity is not a suitable parameter for measuring resilience or resistance. Instead, nannoplankton calcification patterns provide valuable insights into their ecological resilience and

resistance. Indeed, based on coccolithophore abundance and calcification, their resilience was more moderate, and different taxa displayed varying levels of sensitivity and resistance.

Unraveling Marine Biodiversity Dynamics in North China during the Middle-Late Cambrian: Insights from a High-resolution Species-level Richness Analysis

Yujie Shi[1]*, Nanjing University (yujieshi795@outlook.com)
Yukun Shi[2], Nanjing University
Aihua Yang[3], Nanjing University
Hanhui Huang[4], University of Oxford
Zhengbo Lu[5], Nanjing University
Yiying Deng[6], Hefei University of Technology
Xiaofang Teng[7], Nanjing University
Junxuan Fan[8], Nanjing University

Abstract

The Cambrian represents a significant milestone in Earth's evolutionary history, marked by pivotal changes in biology and the environment. Despite this, marine biodiversity during the Middle to Late Cambrian remains poorly understood, with dynamic patterns still subject to debate. North China, existing as an independent tectonic plate during the Cambrian, possesses a unique geological background and biota from that time, making it crucial for unraveling deep-time biodiversity history.

In this study, we compiled a dataset based on published biostratigraphic sections of the Middle-Late Cambrian in North China, sourced from the OneStratigraphy database (http://onestratigraphy.ddeworld.org/). Utilizing a constrained optimization algorithm, a high-resolution, multi-phyla, species-level marine richness curve was constructed. This curve reveals richness patterns among different fossil groups and life modes, shedding light on the evolutionary events of marine animals in North China. These events include evolutionary radiation from the Wuliuan to the Guzhangian, extinction events in the early Guzhangian and late Guzhangian to early Paibian, and recoveries in the late Guzhangian and Paibian to Stage 10.

Our detailed analysis reveals that fossil groups with different life modes, such as benthic and nektonic groups, exhibited diverse patterns during these events. Trilobites, the best-recorded marine group from this period, underwent detailed analysis, with richness curves constructed for distinct taxonomic orders. Further investigations unveiled shifts in trilobite dominance across stages and compared these with those of South China to reveal diverse responses under different geological backgrounds. By decomposing fauna composition and turnovers in these bio-events, we explored potential biotic drivers. Proxies of marine physical environments, including carbon isotopes, strontium isotopes, I/Ca ratio, and others, were scrutinized to elucidate their relationships with biodiversity dynamics.

Overall, this study enhances our understanding of Cambrian marine fauna biodiversity dynamics

in the North China Block. It offers preliminary insights into the intricate relationships between biotic and abiotic factors during this pivotal period in Earth's history.

An enigmatic macrofossil from the terminal Ediacaran Liuchapo Formation in South China

Qing TANG[1]*, Nanjing University (qingt@nju.edu.cn)
Lang Xue[2], Nanjing University
Haizhou Wang[3], China University of Petroleum (Beijing)
Bin Wan[4], Nanjing Institute of Geology and Paleontology, Chinese Academy of Sciences
Ke Pang[5], Nanjing Institute of Geology and Paleontology, Chinese Academy of Sciences

Abstract

The terminal Ediacaran is key for the rise of modern ecological system that featured by complex eukaryotes, including animals. Molecular clock data suggest that major groups of metazoans diverged in the Ediacaran or even earlier. However, among the many complex macrofossils reported in the Ediacaran, only a few are arguably metazoans. To achieve a better understanding on the diversity of complex eukaryotes in the Ediacaran, here we report a new group of enigmatic macrofossils from the terminal Ediacaran Liuchapo Formation in Changde city, Hunan Province, South China. Our investigation, using reflected light microscopy, scanning electron microscopy, energy-dispersive X-ray spectroscopy, and micro-CT, reveals that the Liuchapo specimens are preserved as domal casts and molds. Their morphology varies from round or polygonal to starlike in line with their size growth. A pyritized membrane is usually preserved on outer margin of the specimens, occasionally accompanied with pyrite clusters and organic particles within the body. Moreover, multiple concentric spherical structures are occasionally observed within the specimens. Collectively, these observations indicate a biogenetic origin for the Liuchapo specimens, likely presenting a novel Ediacara-type macrofossil and morphologically similar to some Phanerozoic medusae. Although the metazoan interpretation of the Liuchapo specimens requires future studies with more robust evidence, their discovery contributes to the growing diversity of complex eukaryotes in the terminal Ediacaran ecosystem.

Palaeo-environmental insights into late Ediacaran "mass extinctions"

Brennan O'Connell[1]*, University of Cambridge (bo295@cam.ac.uk)
William J. McMahon[2], University of Cambridge
Catherine E. Boddy[3], University of Cambridge
Alex G. Liu[4], University of Cambridge

Abstract

Observed shifts in taxonomic diversity between three biotic assemblages of the Ediacaran biota–the Avalon (~575–560 Ma), White Sea (~560–550 Ma), and Nama (~550-539 Ma)–strongly influence current understanding of early animal evolution and are considered to evidence trends of diversification and extinction. However, the influence of local palaeo-environmental controls on Ediacaran taxonomic diversity is not adequately accounted for in existing datasets. Brief or highly generalised palaeo-environmental descriptions for key localities, limited study of non-fossiliferous units, and differences in interpretation of strata by various research teams complicate palaeo-environmental reconstructions and global site comparisons. Here, we apply consistent, field-based sedimentological and stratigraphic methods to reconstruct the palaeo-environmental context of key sites representing each Ediacaran biotic assemblage (from Australia, Canada, and Namibia), considering both fossiliferous and non-fossiliferous intervals. Our approach permits direct comparison of similar palaeo-environments between assemblages and through time, permitting recognition of potential palaeo-environmental controls on the observed distribution of Ediacaran macrobiota. Preliminary findings suggest broad overlap in palaeo-environments between key sites, with deltaic, shoreface, and offshore shelves represented in all studied basins. However, subtle but important differences between sites have the potential to influence interpretation of true organism diversity and community structure. For example, a higher prevalence of transported biota in the Nama assemblage compared to the White Sea or Avalon assemblages, and far more extensive deltaic deposits in the Avalon (100s of meters thick) than in the White Sea or Nama (10s of meters thick) may account for some variation in community composition, ecosystem maturity, and organism size. Comparisons of taxonomic diversity through time that rely on comparisons between biotic assemblages must account for facies-scale palaeo-environmental variability, to distinguish ecological or environmental controls from evolutionary patterns. Macrofossils are strongly facies- and environment-dependant in all studied sections, with implications for the magnitude of proposed late Ediacaran extinction events.

Morphological complexity as a potential predictive indicator of evolutionary rates in ammonoids

Luyi Miao[1]*, State Key Laboratory of Biogeology and Environmental Geology, School of Earth Sciences, China University of Geosciences, Wuhan 430074, China. (miaoluyi@cug.edu.cn)
Arnaud Brayard[2], Biogéosciences, UMR 6282, CNRS, Université de Bourgogne

Xu Dai[4], State Key Laboratory of Biogeology and Environmental Geology, School of Earth Sciences, China University of Geosciences
Haijun Song[5], State Key Laboratory of Biogeology and Environmental Geology, School of Earth Sciences, China University of Geosciences

Abstract

The heterogeneity of evolutionary rates is a key issue in the field of macroevolution. The origination and extinction rates are controlled by abiotic factors such as climate and geography, as well as biotic factors such as species diversity and competitive interactions. However, the possible relationship between morphological complexity and evolutionary rates is largely unknown.

To explore the link between morphological complexity and evolutionary rates in ammonoids, we propose a new method, the Ornamentation Index (OI), for quantitatively describing the ornamentation complexity of ammonoids through 3D models. This new approach was applied at the genus- and species-levels on 462 Cretaceous genera and 212 Early Pliensbachian species and. The results show that ammonoids with a high complexity (strongest and more complex ornamentation) have generally a short longevity, whereas those with a simpler or less pronounced ornamentation persist over longer periods. In addition, ammonoids with a more complex ornamentation tend to exhibit higher origination and extinction rates compared to those with a simpler morphology.

As the development of ornamentation in shelled animals is often related to ecological habits, and affect functions such as hydrodynamic properties, anti-predation, shell building, sensory function, it may also indirectly influence the ecological niche of organisms. The potentially increased energy requirements of strongly ornamented groups may favor their presence in ecosystems with a higher species richness and a greater energy availability, which in turn may facilitate a more rapid pace of evolution within these niches . Additionally, for the Cretaceous case studies, the analyse of the relationship between the ammonoid ornamentation complexity and their latitudinal distribution shows that low paleolatitudes contained more strongly ornamented forms, whereas higher paleolatitudes tend to harbour species exhibiting a weaker shell ornamentation. Furthermore, complex species possess greater phenotypic plasticity and a broader range of variation, which can have led to possible more rapid morphological divergences and thus, to a higher propensity for speciation for some ammonoid groups.

Recognition and timing of Early-Middle Devonian extinction events in South Polar regions

Cameron Roy PENN-CLARKE[1]*, Evolutionary Studies Institute, University of the Witwatersrand, Johannesburg (Cameron.Penn-Clarke@wits.ac.za)
David Harper[2], Palaeoecosystems Group, Department of Earth Sciences, Durham University, Durham, UK
Clarisa Vorster[3], PPM Research Group, Department of Geology, University of Johannesburg, Johannesburg, South Africa

Abstract

Multiple biocrises are recognised throughout the Devonian, of which those from the Late Devonian are perhaps most well-studied. Biocrises from the Early-Midde Devonian have received comparatively less attention. Growing evidence suggests that a number of these biocrises, namely the “Kačák” (terminal Eifelian) and “Taghanic” (middle Givetian), were of such severity that both rank in the 10 largest mass extinction events of the Phanerozoic and are part of a long-term declining biodiversity trend which culminated in the Late Devonian mass extinctions. Eifelian and Givetian biocrises are noteworthy in that they are associated with the collapse of endemic bioregions and a shift towards cosmopolitan faunas, typified by the progressive invasion of warmer-water taxa into higher latitudes, termed the “Great Devonian Interchange”. The extent of Eifelian and Givetian biocrises has recently been recognised at south polar regions, making them global phenomena. Here, these events are suspected to be associated with the collapse of the Malvinoxhosan bioregion and extinction of its endemic biotas. In South Africa the extinction of the Malvinoxhosan biotas show a stepped decline in biodiversity correlated with changes in local base-level at varying orders of magnitude, with high survivorship among cosmopolitan taxa. Although changes in sea-level seems to be responsible, there is no appreciable change in overall environment suggesting a complex extinction mechanism at play.

Detrital zircons from the Devonian System in South Africa have been utilised to link changes in base-level with tectonic activity and constrain maximum ages for biotic turnover events. At least two proximal detrital sources are identified, the Neoproterozoic-Cambrian Pan-African Belts and post Pan-African Cambrian-Ordovician supracrustals, with distal sourcing from the Cambrian-Ordovician Famatinian Belt and Silurian-Devonian aged Patagonian massifs. Zircons from Famatinian and Patagonian sources show a trend of younging and increasing frequency and are almost always associated with the stratigraphic range of the Malvinoxhosan biotas, peaking in frequency during major transgressive phases. Maximum ages from youngest zircons from strata associated with biotic turnovers returned maximum depositional ages of 405±14 Ma, 394±5 Ma, and are in range of the Zlichov, Daleje, and Choteč events whilst the final appearance of the Malvinoxhosan biotas is associated with of 387±7 Ma and 382±15 Ma zircons, in range of the Kačák and Taghanic events. Following the extinction of Malvinoxhosan biotas, detrital zircons are almost always exclusively from Pan-African sources. This further coincides with an overall regressive stacking pattern into the overlying Witteberg Group. Time-sliced palaeogeographic

reconstructions further show reorganisation of basin morphology, notably shifts in palaeoshoreline orientation, coincident with base-level changes suggesting lithospheric flexure. Collectively the convergence of Patagonia with Gondwana affected tectonics, palaeogeography and allocyclicity in the Cape Basin (and associated West Gondwana depocentres). Such changes in tectonics and palaeogeography suggest that the convergence of Patagonia with Gondwana might have also broken-down allopatric barriers to speciation, such as circumpolar currents, perhaps influencing extinctions at a global scale.

Early Palaeozoic biodiversifications: Plus ça change

David A.T. HARPER[1]*, Durham University (david.harper@durham.ac.uk)
Bertrand LEFEBVRE[2], CNRS, Universite de Lyon1
Thomas SERVAIS[3], CNRS, Universite de Lille

Abstract

Life has diversified on Earth during the past four billion years. 19th Century savants presented models for the gradual increase in diversity and complexity of animals during the Phanerozoic, punctuated by some mass extinctions. More recently views have diverged from those espousing gradual change to those focused on sudden, rapid diversity pulses, based on the interrogation of large databases. The new generation of data capture and evaluation relies on big data and sophisticated analytical techniques. Results, however, are not consistent in all the available big databases; each database is not truly global. The origins and early diversifications of groups of animals are diachronous in both time and space, whereas large hikes in biodiversity in some groups are due to intensive study of a number of key continents, mainly North America and Europe, especially Scandinavia, with large numbers of palaeontologists involved. For example new data from China demonstrate there is no Furongian Gap in the late Cambrian, that artificially separated the Cambrian and Ordovician radiations. Instead increasing diversity segues seamlessly through the Cambrian – Ordovician boundary; high-latitude Early Ordovician biotas contain significant numbers of exceptionally-preserved faunas, some more typical of Cambrian Lagerstätten. We are far from de-colonizing our data: much data especially from the global south may continue to change our perception of biodiversity change and continue to fill in gaps in the fossil record. Interestingly, there is another approach that may be more robust. A recent compilation of the first occurrences of higher taxa such as phyla indicates that most were already present in the late Proterozoic and the early Cambrian, corresponding to the concept of the Cambrian Explosion. The cumulative arrival of orders, families, genera show a gradual and long-term increase during the entire Ordovician. As biases are mitigated and new data added, a vision emerges of a single long-term radiation of Early Paleozoic animal diversity following its initiation in the Proterozoic and earliest Phanerozoic, a view not that different from that of our 19th Century pioneers. Plus ça change.

Foraminiferal biodiversity changes to interpret the paleoenvironmental perturbation across the Late Cretaceous Oceanic Anoxic Event 2 at southern high latitudes (IODP Sites U1513 and U1516, SE Indian Ocean)

Maria Rose PETRIZZO[1]*, University of Milan, Department of Earth Sciences (mrose.petrizzo@unimi.it)
Giulia Amaglio[2], University of Milan, Department of Earth Sciences
Erik Wolfgring[3], University of Vienna, Department of Palaeontology

Abstract

Oceanic Anoxic Event 2 (OAE 2), at the Cenomanian/Turonian boundary (93.9 Ma), was an episode of major perturbation in the global C cycle with a delta13C excursion of 2-3‰ documented worldwide. The boundary interval is also accompanied by warming of the ocean with surface-ocean temperatures that reached 36°C at low latitudes and equator-to-pole sea surface temperature gradients reduced to 5°C.

To investigate the pattern of response of biota to the environmental perturbation at high latitudes, we present microfossils and geochemical data from Integrated Ocean Discovery Program (IODP) Sites U1513 and U1516 drilled in the Mentelle Basin (NE Indian Ocean; paleolatitude 60° S in the Late Cretaceous).

The lithology is composed of alternating sequences of gray and black nannofossil-rich claystone with carbonate content ranging from 0.6 to 70 % gradually increasing from the base to the top except for an interval in the middle part of OAE 2 composed by siliceous and organic matter-rich sediments and lacking carbonate that spans most of the delta13C positive excursion.

The assemblage composition, distribution and variations in abundance of planktonic and benthic foraminifera, radiolaria, and calcipheres are examined in light of their known paleoecological preferences to understand changes in biodiversity related to the OAE 2 perturbations in surface and bottom waters.

Below and in the lower part of OAE 2, planktonic foraminifera are dominated by small-sized (125-38 micronm) opportunistic species of *Microhedbergella*, and *Muricohedbergella*. This interval coincides with a dominantly eutrophic regime in the surface waters. Benthic foraminifera illustrate a depauperate community with the dominance of *Gavelinella*, *Gyroidinoides* and *Stensioeina*. Opportunistic agglutinated *Glomospira* and *Ammodiscus* occur at both sites indicating low oxygen conditions and low organic flux at the seafloor.

The middle part of OAE 2 (plateau phase of the delta13C profile) is masked by absence of carbonate, by the highest TOC values, and dominance of radiolaria indicating this interval corresponded to a time of highly stressed eutrophic conditions with possible shoaling of the Carbonate Compensation Depth. In this interval planktonic foraminifera and calcareous benthic foraminifera are almost absent.

Conditions moderate after this extreme environmental perturbation as reflected by the planktonic

foraminiferal assemblages that show changes in composition. Species occupying relatively deep ecological niches as *Dicarinella* and *Praeglobotruncana* appear, and the overall increase in diversity and abundance indicates a more stable and stratified water column. The higher taxonomic diversity and higher number of low oxygen tolerant benthic foraminifera as *Gavelinella* and *Conorboides* reflects the repopulation of bottom waters, likewise the agglutinated and infaunal foraminifera show an increase in abundance, particularly *Clavulinoides* and *Spiroplectammina*, that was mostly influenced by food supply rather than fluctuations in the oxygen availability.
Overall, this study provides a complete record of the foraminiferal biodiversity across the OAE 2 at high latitudes allowing to understand their evolution that seems to vary among species and proceed at different paces, resulting in the establishment of novel communities that differ from those existing before the environmental change.

Pioneering Data-Driven Discoveries from DeepBone.org

Zhaohui PAN[1]*, Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences (panzhaohui@ivpp.ac.cn)
Haohan Wang[2], Qujing Normal University
Min Zhu[3], Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences

Abstract

DeepBone.org has solidified its role as a crucial resource in vertebrate paleontology, presenting extensive datasets that catalyze data-driven research across several major clades, including Antiarcha, Agnatha, and Proboscidea. Beyond the datasets already published or under review, our efforts to continuously expand and refine data collections across other taxa are unwavering. This initiative is revolutionizing the methodologies employed in studying the paleobiogeographic evolution and biodiversity changes through deep time in vertebrates, shedding light on the dynamics sculpting vertebrate history. By integrating detailed specimen-based datasets with sophisticated quantitative analyses, DeepBone.org facilitates in-depth examinations of vertebrate spatial and temporal distribution patterns, thus elucidating the complex interplay of factors influencing biodiversity and evolutionary patterns.

To demonstrate the significant impact of DeepBone.org, we highlight a series of case studies, including the biogeographic networks and taxonomic revisions of Antiarcha, alongside the investigation into Proboscidea's diversity through different epochs. These instances emphasize the database's essential role in addressing critical questions within vertebrate paleontology, such as resolving contentious taxonomic units, refining character matrices for specific clades, variations in species distributions, paleogeographic dynamics, and the effects of climatic and environmental transformations on vertebrate populations over geological time intervals. New advances augment our comprehension of vertebrate evolution and showcase the importance of adopting deep-time perspectives in conservation biology strategies.

Leveraging DeepBone's exhaustive dataset, we have meticulously compiled and analyzed the last decade of literature in vertebrate paleontology. This bibliometric analysis reveals an increase in vertebrate paleontology research activity and publications. Key contributions stem from resource-rich countries and those with robust research infrastructures. Significantly, the study identifies the rise of new research areas such as Biodiversity Conservation, Biochemistry, and Molecular Biology, marking a shift towards broader and more varied research interests. These areas now emerge as notable trends in vertebrate paleontology, reflecting the expansion of the field into more diverse scientific domains.

In conclusion, DeepBone.org marks a pivotal shift towards a data-centric paradigm in vertebrate paleontology, transforming the study of Earth's vertebrate history. This platform enhances our understanding of vertebrate diversity and its future trends and exemplifies the integration of traditional paleontological methods with advanced data analysis techniques. Our work highlights DeepBone.org's essential role in advancing vertebrate evolution studies, laying a solid

groundwork for future data-driven research. By utilizing its extensive datasets and analytical tools, researchers are empowered to test new hypotheses, refine theories, and engage in interdisciplinary collaborations. DeepBone.org is unlocking unprecedented insights into the complex evolution of vertebrates, fostering research that extends beyond academic curiosity to address vital biodiversity conservation and environmental management challenges.

Latitudinal Shift Patterns of Taxa Through the Phanerozoic

Shuhan Zhang[1]*, Nanjing University (shuhanzhang@smail.nju.edu.cn)
Shuzhong Shen[2], Nanjing University

Abstract

The fossil record documents climate-induced range shifts in taxa, but the nature and scale of these dynamics remain unknown. Numerous genera have shifted their distributions at different scales and magnitudes in response to various environmental changes. In this study, we utilized global fossil data to quantitatively analyze latitudinal shifts (LS) for taxa throughout the Phanerozoic. Employing a variety of indices, we quantified LS, and subjecting the data to rigorous quality control and subsampling techniques to assess the robustness of the results. Furthermore, we employed network analyses to unearth the spatial and temporal intricacies of the LS throughout the Phanerozoic, and the Coverage Cross Mapping method was employed to detect causal relationships between the LS and environmental changes. Our study revealed several intervals characterized by elevated taxon shifts, and the Permian, late Triassic, and late Cenozoic showed most significant signals. These intervals with active biotic shifts were associated with transitions between icehouse and greenhouse climates and large fluctuations in global average sea surface temperature and pCO2. Shifts were concentrated at more southerly latitudes early in the Phanerozoic and more northerly latitudes later in the Phanerozoic. This long-term, northward movement in where shift hotspots occur was likely caused by continental migration northward. We conclude that frequent drastic changes in climate and persistent continental movements are the driving forces behind the magnitude and scale of LS dynamics. These results inform our understanding on how species will respond and move under ongoing rapid anthropogenic change.

Dynamic Linking of Progressive Exhumation to Mendocino Triple Junction Migration

yudan SI[1]*, china university of geoscience (beijing) (sydancugb@gmail.com)
shaofeng liu[2], china university of geoscience (beijing)

Abstract

Deciphering exhumation processes at Earth's surface provide insight into tectonic processes, long-term climate change, and paleoenvironmental conditions. An intriguing study area is the California Coast Ranges and the San Andreas Fault strike-slip system, influenced by the subduction of the Pacific-Farallon Ridge beneath the North American plate around 30 Ma. Understanding the temporal and spatial variations in exhumation rates and their connection to crustal deformation and deep mantle flow remains a challenge. We employ a novel approach that combines age-elevation relationships and multiple thermochronometric systems with different closure temperatures to estimate the exhumation history along the San Andreas Fault since 32 Ma. Our analysis of 731 published thermochronometric ages reveals consistently low and non-uniformly distributed exhumation rates (0.05-0.2 km/Myr) until approximately 4 Ma, coinciding with a period of intensified global glacial erosion. Notably, non-simultaneous rapid exhumation events (0.2 km/Myr) occur in different regions and propagate northwestward, showing consistency with the migration of the Mendocino Triple Junction (MTJ) as indicated by global plate reconstructions. Moreover, we observe hysteresis in the migrating pioneer belts of the rapid exhumation zone compared to the time-dependent position of the MTJ over a considerable distance.

Our findings indicate that climate only significantly influences the erosion process from 4 to 0 Ma, during the period of increased global erosion rates, putatively due to enhanced glacial processes. However, overall progressive rapid exhumation is primarily controlled by tectonic factors rather than climate. The crustal uplift inferred suggests a response to the upwelling of the asthenosphere in the slab gap during the MTJ migration, and the pioneer belts of the rapid exhumation zone can be interpreted as the northern boundary of the slab window. The observed hysteresis in the pioneer belts implies the tearing of the subducting plate towards the north during slab detachment. This model emphasizes the intricate coupling between lithosphere evolution, asthenosphere upwelling, and the constraints on the process of slab tearing, shedding light on the complex interplay of tectonic and climatic forces in shaping the California Coast Ranges and the San Andreas Fault system.

[Invited] Toward a "best-fit" tectonic reconstruction for the Caroline Plate: Oceanic plateau-subduction zone interaction as a driver for plate boundary reorganization?

Samuel MARTIN[1]*, University of British Columbia (smartin@eoas.ubc.ca)
Nicholas Ellis[2], University of Michigan
Jolante van Wijk[3], Los Alamos National Laboratory
Jonny Wu[4], University of Arizona

Abstract

The Caroline Plate is located at the complex junction of the Pacific, Philippine Sea, and Indo-Australian Plates, where there is significant uncertainty regarding how late Eocene to recent Pacific-Philippine Sea Plate convergence was accommodated. At the Caroline Plate's western boundary with the Philippine Sea Plate, arc-affinity rocks suggest late Eocene through early Miocene subduction; however, subsequent seafloor spreading in the Ayu Trough seems to preclude later convergence at this boundary. The plate's poorly-studied eastern boundary with the Pacific Plate could have accommodated the remaining convergence, but seafloor morphology and geophysical observations do not suggest a significant subduction history. Despite this ambiguity, previous plate reconstructions have generally coupled the Caroline Plate to either the Pacific or the Philippine Sea Plate, requiring all convergence to occur at the plate's western or eastern boundary, respectively.

At the northern Caroline Plate-Pacific Plate boundary, a transtensional rift (the Sorol Trough) bisects the Caroline Ridge, an oceanic plateau/large igneous province. Several researchers have suggested an early Miocene collision between the plateau and the Caroline-Philippine Sea Plate boundary jammed the subduction zone and possibly led to the Sorol Trough's development, but implications of this event for the Caroline Plate's other boundaries have not been thoroughly considered. To better constrain the plateau's emplacement age, we used a probabilistic approach to obtain quantitative age estimates from microfossil assemblages cored at four Deep Sea Drilling Program sites on the plateau, three of which reached basaltic substrate. These depositional ages (~25-26 Ma) are generally consistent with radiometric ages of underlying basalts and suggest a ~4-5 Myr time gap between the plateau's emplacement and its collision with the trench.

We present a new tectonic reconstruction for the Caroline Plate, aiming to elucidate the subset of possible models which should contain the best-fit solution to geologic evidence for past relative motions. Considering the Pacific-coupled and Philippine Sea-coupled models as end members, we modified regional reconstructions to test a simple intermediate model in which the Caroline Plate was fully coupled to the Pacific Plate until 20 Ma, the approximate age of plateau-trench collision. Due to subduction zone jamming, the Caroline Plate was then fully coupled to the Philippine Sea Plate from 20 to 0 Ma, requiring active boundaries to develop between the Caroline and Pacific

Plates, including the Sorol Trough. Advantages of this model include its compatibility with both pre-20 Ma arc volcanism and later seafloor spreading at the Caroline Plate's western boundary, and less total convergence required at the plate's eastern boundary compared to the Philippine Sea Plate-coupled model. However, ~700-900 km of post-20 Ma Pacific-Caroline convergence and left-lateral slip along the Sorol Trough are still required, far greater than observation-based estimates. The amount of required convergence would be lower if the Caroline-Philippine Sea Plate coupling was incomplete or of shorter duration. Thus, the best modeling solution likely lies between the Pacific-coupled and intermediate models. Improved understanding of Pacific-Philippine Sea relative motions may also help resolve apparent discrepancies between observational constraints on the Caroline Plate's tectonic evolution.

[Keynote] Topography and deformation of the Polar regions measured with thermochronometry

Matthew College Fox[1]*, University College London (m.fox@ucl.ac.uk)

Abstract

Earth's surface is shaped by tectonic processes and erosion. Knowledge of the evolution of Earth's surface is required across all aspects of the Earth Sciences. In the Polar regions, in particular, the topography hosts ice sheets which control global sea level. In turn, changes in the topography change the potential to support large ice sheets. Furthermore, changes in ice sheet extent may not always be due to climatic variability, but due to evolving topography. Therefore it is crucial to measure topographic evolution across the Polar regions. One method that has been used to measure topographic change is low-temperature thermochronometry. The basis of this approach is that as valleys incise, rocks at the base of the valleys are brought to Earth's surface and cool. It is this cooling that can be measured with thermochronometry. Traditional approaches, where bedrock is accessible, rely on the potential to measure differences in cooling rates, and timings, between valley bottoms compared to surrounding peaks. In the Polar regions, this is not possible because the valley bottoms are covered by ice. Detrital methods exploit the processes of glacial erosion and sediment transport to gain indirect access to samples from below the ice. Using this approach, we can build three dimensional thermal models to constrain likely topographic evolution. I highlight this approach for areas in Antartica and Greenland, and show the unique potential of this method.

Non-cylindrical Slab Subduction and Tearing beneath Southern Iberia

Pengfei MA[1]*, Taiyuan University of Technology (mapengfei@tyut.edu.cn)

Abstract

Oroclines emerge from subduction processes governed by the negative buoyancy of descending slabs. This system becomes particularly complex in the constrained oceanic basins nestled between continental landmasses, where the irregularity at the boundary between continents and oceans exacerbates the intricacies of subduction dynamics. A prime example of such geological complexity is observed in the Betic-Rif orogenic system, which effectively seals off the Western Mediterranean. This system is characterized by an asymmetric orocline, intricately associated with the dynamics of the Gibraltar subduction zone. Despite the critical geological insights it offers, our comprehension of the interactions between the plate and mantle during the Betic-Rif orogeny remains incomplete, especially concerning the mechanisms of trench retreat, the formation of the non-cylindrical Gibraltar slab, and the connection between the deformation of the Iberian lithosphere and slab subduction.

To bridge these knowledge gaps, we have developed advanced four-dimensional thermo-mechanical models grounded in detailed plate reconstructions. These models aim to elucidate the evolution of plate-mantle interactions in the Western Mediterranean region since the Oligocene epoch. Our research findings are strongly supported by seismic tomography and the broader context of regional tectonics, validating the crucial influence exerted by the unique rotational and rollback motions of the Gibraltar slab on its distinctive non-cylindrical shape. Moreover, through meticulously designed control experiments, we have uncovered how changes in the strength of the continental margin can significantly interfere with the tearing of the Gibraltar slab. Such variations also lead to a delayed decoupling between the slab and the Iberian lithosphere, subsequently impacting the migration patterns of the trench. These revelations shine a light on the complex and multifaceted interactions that occur between subduction zones, the mantle, and the lithosphere in the assymetric subduction zone system.

High-elevation Tibetan Plateau before India–Eurasia collision recorded by triple oxygen isotopes

Xiangrui Liu[1]*, China university of geosciences Beijing (lxr_1129@163.com)
Jingen Dai[2], China university of geosciences Beijing

Abstract

The timing and magnitude of the early Cenozoic surface uplift of the Tibetan Plateau pose a challenge due to the limited availability of unaltered terrestrial sediments crucial for paleoaltimetry methods. Nevertheless, this data is pivotal for elucidating the geodynamic and paleoclimatic evolution of the Indian and Eurasian landmasses, as well as for interpreting global climatic patterns, biodiversity trends, and biogeochemical cycles since the Cenozoic era. Our analysis reveals a significant uplift occurring by 63 to 61 million years ago, predating the collision between the Indian and Eurasian continental plates. This inference is drawn from a comparison of triple oxygen isotopes in contemporary meteoric waters with those found in quartz veins containing epithermal Ag–Pb–Zn deposits from the Palaeocene Gangdese Arc in southern Lhasa. The observed low $\delta^{18}O$ and $\delta^{17}O$ values in the quartz indicate precipitation from meteoric waters influenced by substantial topographic rainout effects. Our findings indicate that by 63 to 61 million years ago, the Gangdese Arc had attained an elevation of approximately 3.5 km, suggesting that it had achieved over 60% of its present height prior to the collision between continents. This uplift likely resulted from crustal shortening in response to the shallow-angle subduction of the Neo-Tethyan oceanic lithosphere. This early estimation of high paleoelevation for the Himalaya–Tibetan system challenges previous assumptions suggesting that the uplift of southern Tibet necessitated continent–continent collision for substantial topographic formation.

Tectonic and topographic evolution of the Eastern Himalayan Syntaxis

Zhicheng Yu[1]*, China University of GeosciencesBeijing (yuzhicheng_cugb@163.com)
Jingen Dai[2], China University of GeosciencesBeijing

Abstract

The Eastern Himalayan Syntaxis (EHS), one of the most tectonically active regions on Earth, offers a unique opportunity to explore the intricate relationship between tectonics and surface exhumation processes. Dominated by the imposing Namche Barwa (7782 m) and Gyala Peri (7294 m) mountain groups, separated by the deep Yalung–Tsangpo river gorge, the EHS holds significant implications for understanding the uplift of the Tibetan Plateau and its broader impacts on climate and the interactions among tectonics, erosion, and climate. The tectonic evolution of the Namche Barwa massif is pivotal in unraveling the complex uplift history of the region. Trigger mechanisms for the rapid exhumation of the Namche Barwa massif remain subject to debate, with at least seven models proposed to analyze the geodynamic evolution of the EHS. Central to these debates are the contrasting models of a stationary or localized "tectonic aneurysm" versus a northeasterly "migrating crustal antiform." Given the formidable challenges of sampling at Namche Barwa Peak, researchers often rely on samples from surrounding areas and the foreland basin to infer the exhumation history of the core. Synthesizing data from thermochronology, thermal-kinematic models, seismicity, and structural geology reveals complex temporal and spatial patterns in age distribution and exhumation history. However, discrepancies arising from differences in sampling locations and methodologies continue to fuel controversies surrounding the mechanism and timing of rapid exhumation in the eastern syntaxis. Previous studies have employed multidisciplinary approaches to constrain the exhumation history across various time scales. Initially, it was proposed that coupling between crustal rock advection and surface erosion commenced in the late Miocene (8–10 Ma). However, subsequent research challenges this view, suggesting a Quaternary onset of rapid exhumation primarily driven by tectonic mechanisms. Recent research findings propose a three-stage history that reconciles seemingly contradictory evidence regarding the timing of rapid exhumation since the late Miocene. The rapid exhumation of Namche Barwa is influenced by a myriad of factors, including tectonic uplift, high river power, relief, glacial activity, and megafloods erosion. Quantifying the individual contributions of these factors to rapid exhumation poses a significant and ongoing challenge in the field.

The crustal and uppermost mantle Vs structure of the middle and lower reaches of the Yangtze River Metallogenic Belt: implications for metallogenic process

Yingjie YANG[1]*, Southern University of Science and Technology (yangyj@sustech.edu.cn)
Yongqian Zhang[2], Chinese Academy of Geological Sciences
Qingtian Lü [3], Chinese Academy of Geological Sciences

Abstract

The Middle and Lower Reaches of the Yangtze River metallogenic belt (MLYMB) is one of the most important Fe-Cu polymetallic belts in China. However, the mechanism and deep geodynamical process for the formation of this belt are still controversial. Here, we obtain the crustal and the uppermost mantle structures using ambient noise data from a dense seismic profile. A low velocity zone (LVZ) is revealed beneath the Moho of MLYMB, interpreted as the source of the deep mineralization materials. In addition, a low velocity layer (LVL) and a high velocity layer (HVL) are observed in the crust of the southern segment of the profile. The LVL is interpreted as a tectonic detachment layer between the upper and the lower crust, and the HVL is interpreted as the aggregation zone for mineralizing melts or crystallized magma chambers. Based on the observed velocity features, we propose a three-stage model for the formation of ore deposits in MLYMB. Our model suggests that an upwelling of asthenosphere triggered by the delamination of a previously thickened lithosphere leads to the partial melting of upper mantle rocks, which eventually ponders under the Moho. The magma then infiltrates through the ductile lower crust and reaches a depth of ~7-13 km, forming a minerals-enriched magma chamber. Minerals-rich hot fluids originating from the magma chamber continue to move upward along the pre-existent faults and the minerals finally precipitate in dense veinlets when reaching shallow depths, forming the ore deposits in and around the MLYMB.

Abstract

Earth's continents are underlain by "roots"- 100-250 km thick of depleted mantle rocks, and the properties and history of these roots affect the long-term stability of the continents. Recent studies have demonstrated that Os model-age spectra from mantle xenoliths commonly show age peaks corresponding to the ages of thermal/tectonic events in the overlying crust. These deep-seated events are generally mirrored in the crust suggesting strong linkages between crust and mantle. The Central Asian Orogenic Belt (CAOB) is proposed as the largest area of crustal growth in the Phanerozoic with ca. 50-60 % juvenile crust (Şengör et al., 1993; Jahn, 2004). Processes for deriving juvenile material from the mantle and accreting vertically are expected to have affected the subcontinental lithospheric mantle (SCLM) beneath. Cenozoic alkali basalts occur throughout Central and East Asia encompassing southern Siberia, central and southern Mongolia, NE China and the Russian Far East. Some basalts carry fragments of mantle rocks that provide direct evidence on the nature and composition of the deep lithosphere and contain a record of mantle processes. In this study, we summarize in-situ Os model ages on sulfides in peridotitic xenoliths from off-cratonic settings (in the basalts from Tariat (1.5 Ma), Mongolia; Vitim (14 and 0.65 Ma), Khamar Daban Range (KDR; 17 Ma) and Sviyaginsky volcano (12 Ma), Russia) in the CAOB to examine SCLM formation. Mantle xenoliths collected from these volcanic fields are mainly spinel lherzolites, with garnet- and spinel-garnet lherzolites only found in Vitim. Geochemical evidence suggests these lherzolites represent residual SCLM, some of which is quite refractory and may be ancient. Most of both their Os TMA from the least-disturbed sulfides ($^{187}Re/^{188}Os<0.07$) and

TRD from higher Re/Os sulfides without later introduction/loss of Os, yield model ages ranging from 0.3 to 3.0 Ga, with peaks around 1.7-1.4, 1.2-0.9 and 0.7-0.5 Ga (Wang et al., 2013; 2015). These ages suggest that the certain proportions of the SCLM beneath the CAOB formed at least by the Proterozoic time, and that some domains are Archean. Younger sulfide Os ages (1.2-0.9 and 0.7-0.5 Ga) may mark the commencement of the Central Asia Orogeny since the Neoproterozoic and involvement of the mantle as suggested by Jahn (2004). These sulfide Os ages, recording formation of the SCLM and subsequent metasomatism by juvenile crustal-growth events, are consistent with the thermotectonic events recorded in the overlying crust of the ancient microcontinents where the sampled volcanic fields locate. All geochemical characteristics of these peridotites reveal that ancient, refractory Archean-Proterozoic lithospheric mantle is embedded in the younger, fertile post-Archean lithospheric mantle beneath the CAOB. The ancient Archean-Proterozoic mantle domain has survived but may have been subjected to metasomatic re-enrichment during Central Asia Orogeny since the Neoproterozoic and the Cenozoic extension with intraplate volcanism in this region. Comparing the lithospheric mantle domains from the above regions as revealed by Os model ages, with ancient microcontinents at least Mesoproterozoic in age and predating formation of the CAOB significantly diminishes the volume of new juvenile crust generated during the orogeny (Kroner et al., 2017).

Abstract

The Newfoundland Appalachians preserves one of the most complete and best exposed cross-sections through the Appalachian Mountain's belt.

This study presents the whole-rock Nd isotope mapping of felsic-intermediate igneous rocks from the Newfoundland Appalachians using datasets of 418 Sm-Nd data with ages, including 71 new analyses. The results show that the Humber Belt, the Notre Dame Subzone, the Exploits Subzone, the Gander Belt, and the Avalon Belt have the different Nd Isotopic characteristics. The juvenile crust (εNd(t) value > 0), accounting for 40% of the isotope-mapped area, is mainly distributed on both sides of the suture line (Beothuk Lake Line) between the Notre Dame subzone and the Exploits subzone, as well as in the Avalon Belt. Additionally, although the Exploits subzone and the Gander subzone have different compositions, there is similarity in the central part, and we considered that both of them belong to the same micro-continent (Ganderia). It is also consistent with the geophysical results. The juvenile crustal provinces in the Notre Dame and Exploits subzones control the volcanic-type Cu-Zu deposits. Various types of Au ores are mainly distributed in the old crustal province within the Gander Belt. The distribution of porphyry Cu ores is more inclined towards the juvenile crustal province (Avalon Zone). Our research shows that the isotopic mapping of the deep material composition can provide direct evidence for the delineation of the tectonic units and their control on metallogeny.

Abstract

The continental crust distinguishes Earth from other planets and records its unique evolutionary history characterized by its assembly and growth during orogenesis. Many issues are still not known well, including whether voluminous Phanerozoic growth occurs or not, what are the relationships of the continental crustal growth to orogeny, and how to quantitatively evaluate them.

The study presents the results of our recent research on these issues based on big data of igneous rocks. Nd-isotopic mapping of felsic and intermediate igneous rocks from eight representative and well-studied Phanerozoic orogens characterizes their architecture and crustal growth. The maps illustrate the distribution of isotopic domains that reflect the compositional architecture of the orogens. The results demonstrate that the proportions of juvenile crust decrease from typical accretionary (>59%, e.g., the Central Asian Orogenic Belt or Altaids) to general accretionary (50%–30%, e.g., the Newfoundland Appalachians and the Lachlan Orogen), to accretionary–collisional (30–10%), and to collisional orogens (<10%; e.g., the Tethyan Tibet, Caledonides, Variscides, and the Qinling-Dabie Orogen). This study also confirms voluminous (>50%) Phanerozoic crustal growth. Here, we propose a new method to estimate crustal growth areas or volumes and their percentages of a whole orogen based on isotopic provinces. In this way, we can quantitatively estimate the extent of crustal growth and characterize orogen types as well as their relationships through isotope mapping.

Water Reservoirs and Speciation in the Lithospheric Mantle

Halimulati ANANUER[1]*, Macquarie University (halimulati.ananuer@mq.edu.au)
Olivier Alard[2], Australian National University
Sylvie Demouchy[3], Université Clermont Auvergne
Suzanne Y O'Reilly[4], Macquarie University

Abstract

The distribution and speciation of water in the mantle play a crucial role in mantle geodynamics, including large-scale mineralization. Concepts related to water storage in the mantle have undergone significant evolution over the past two decades.

Indeed, it has been shown that the dominant mantle minerals (olivine and pyroxenes), traditionally known as anhydrous "dry" minerals or NAM (nominally anhydrous minerals), contain a few **µ**g•g-1 of hydrogen locked in point defects. Due to the significance of this discovery, the "water" (detected as H and/or OH-) content in the mantle over the last 20 years has been almost exclusively considered through the NAM's H budget, with little attention given to co-existing hydrous minerals (micas, amphibole) and their role in water storage in the mantle.

Furthermore, most mantle "water" assessments have primarily focused on measuring "water" concentration in mineral crystal lattices, while completely ignoring any Grain Boundary Interstitial Components (GBIC). However, GBIC has been recurrently proposed as a likely major reservoir for incompatible trace elements such as LREE, U, Th, and Ba. Given that H is also an incompatible element, therefore, the contribution of GBIC to the water mantle budget should be considered.

This study has measured the water abundance in the sub-continental lithospheric mantle by studying 22 mantle-derived peridotite xenoliths (spinel facies) hosted in alkali basalts from worldwide occurrences. To ensure a comprehensive perspective on water abundance in the mantle, measurements were made on in-situ analyses using Fourier transform infrared spectroscopy (FTIR) for NAMs and simultaneous thermal analyzer coupled with quadrupole mass spectrometer (STA/QMS) for the whole-rock and mineral fraction (including melt/fluid inclusions).

This unique integrated data set sheds some novel light on the distribution of "water" throughout mantle bulk-rock assemblages and reveals counter-intuitive relationships between NAMs, hydrous phases and GBIC. These include (i) the concentration of hydrogen in NAMs does not depend on the occurrence or the volumetric abundance of hydrous phases; (ii) GBIC is the repository for a significant amount of "water"; (iii) hydrous metasomatic phases compete with GBIC for the storage of volatile elements. In summary, our results indicate that H ("water") abundance in the sub-continental lithospheric mantle has been significantly underestimated and that we need to consider more than NAMs for robust assessment of the budget and behaviour of H and, likely other volatile elements, in the Earth's mantle.

Crustal modification influenced by multiple convergent systems: Insights from Mesozoic magmatism in northeastern China

He HUANG[1]*, Institute of Geology, Chinese Academy of Geological Sciences (huanghecugb@126.com)
Tao Wang[2], Institute of Geology, Chinese Academy of Geological Sciences
Lei Guo[3], Institute of Geology, Chinese Academy of Geological Sciences
Jiyuan Yin[4], Institute of Geology, Chinese Academy of Geological Sciences

Abstract

Convergent continental margins are the major sites for the formation, differentiation, preservation, and destruction of continental crust. This article focuses on the Mesozoic crustal modification history of northeastern China from a magmatic perspective. During Mesozoic times, NE China was influenced by three convergent systems, namely the Paleo-Asian Ocean (PAO) regime to the south, the Mongol-Okhotsk Ocean (MOO) regime to the northwest, and the Paleo-Pacific Ocean (PPO) regime to the east. This study comprehensively synthesizes information on Early Triassic to Early Cretaceous magmatic rocks. We unravel the spatiotemporal effects of the above-mentioned convergent regimes by evaluating the migration of major magmatic belts and other geological and geophysical evidence. The PAO regime is confined to the southernmost part of NE China and exerted influence during pre-late Late Triassic times. The MOO regime-related magmatism lasted until the early Early Cretaceous and occurred throughout the Great Xing'an Range and adjacent regions. The spatial effect of the PPO did not exceed the eastern margin of the Songliao Basin until the Early Jurassic; low-angle to flat subduction of the PPO slab led to the westward migration of continental arc front in the Middle Jurassic and the waning of PPO regime-related magmatism in the Late Jurassic. Since the earliest Cretaceous, the rollback and retreat of the PPO slab became the predominant geodynamic control in NE China, but the superposition of the MOO regime played a role during the early Early Cretaceous. Employing whole-rock Nd and zircon Hf isotope spatial imaging, this study elucidates that, although the pre-Mesozoic lithospheric heterogeneity provides first-order control, the Mesozoic crustal architecture of NE China was further carved by Mesozoic tectonics. Retreating subduction (slab rollback) and post-collisional lithospheric delamination resulted in the prolonged extensional background and crustal growth (rejuvenation); on the contrary, low-angle subduction and syn-collisional compression could cause transient periods of ancient crust reworking. Our results also estimate the high altitude of the Great Xing'an Range and adjacent regions in the Early Cretaceous. This study opens new possibilities to explicitly document crustal modification processes in fossil orogens from a magmatic perspective.

[Invited] Kinematics, Tectonic Events and Orogens

Manuel Pubellier[1]*, CNRS-UMR8538 Paris Sorbonne U. (manupub.pubellier@gmail.com)
Camille François[2], Africa Museum, Tervuren & CGMW

Abstract

Continental growth is mostly made of crustal morphostructures docked at active margins, but also accreted material scrapped off the downgoing plate, as well magmatic material injected in the upper plate. The process of continental plates drifting is nevertheless continuous and only punctuated by relatively short-lived deformation events. Since the early stages in the Proterozoic, plates have moved, agglomerated to each other, and then parted to drift again. This implies that the normal process is oceanic crust formation and subduction which generate moderate deformation if the subducting slab is not too flat. In contrast, orogens are deformation events which jam former oceans but also smaller crustal slivers rifted from the mainland and carrying volcanic arcs. This is spectacular during the Phanerozoic in Eurasia, where large belts have been accreted from the core of Siberia to the present active boundary of the Alpine-Himalayan Belt and associated subduction of relics of oceanic Tethyan crust. The large scale view illustrates how the successive belts were formed at specific orogenies, as large continental slivers were docking to Laurasia at the expense of the shrinking Gondwana. To go deeper in understanding the process of continental growth, detailed dating is necessary in recent and well documented examples, such as opening and closure of marginal basins and Neogene to Present docking of morphostructures. Opening of smaller basins (marginal seas) is almost never cylindrical and display a V-shape geometry implying a diachronism of a migrating breakup. Similarly the closure of these basins also migrates, and results in diachronous unconformities. The paired system of South China Sea and Proto South China Sea coeval opening and closure is a good example to illustrate the discrepancies in the correlation of events. In addition the convergence between two plates is rarely frontal. Late Neogene examples in the Philippines, Indonesia or the Caribbean, illustrate how oblique collision also migrates along the deformation front. These oblique cases allow us to refine the time of shortening and the associate subduction jump. It is shown that the shortening occurs during short lived (<2Myrs) tectonic events. This suggests that the duration of the subduction reversal or jump is extremely fast, and that the whole of the plate convergence has to be accommodated during this time laps by deformation of the crust; faults, folds and metamorphism. In this view, large less understood orogens may actually have integrated several of these short-lived tectonic events.

Geochronology and geochemistry of metamorphic rocks in the Khutag Uul block of the Khatanbulag Massif, South Mongolian Orogenic Belt: Timing of formation and metamorphism and tectonic implications

Narantsetseg TSERENDASH[1]*, Institute of Geology of Mongolian Academy of Sciences (geodyn2018@gmail.com)
Enkhdalai Batkhuyag[2], Institute of Geology of MAS
Lei Guo[3], Institute of Geology of CAGS
Ying Tong[4], Institute of Geology of CAGS

Abstract

Metamorphic complexes, including the Khutag-Uul and Tseel Formations, are scattered in the Khutag Uul Block of SE Mongolia and have long been interpreted to represent the Precambrian basement of the Khatanbulag Massif of the South Mongolian Orogenic Belt; however, reliable evidence is very poor. Here we present new results of petrological, geochemical, and zircon U-Pb age data of schist and gneiss samples from these complexes, with the aim of constraining the depositional and metamorphic ages and the tectonic affinity of the Block.

LA-ICP-MS zircon U-Pb dating results of 5 samples of garnet-bearing quartz-muscovite and chlorite-muscovite schists and quartz-mica orthogneisses suggest the maximum depositional ages of protoliths of the Khutag-Uul and Tseel Formations are 1548 Ma and 1242 Ma, respectively, and strata were subjected to a high-grade metamorphism around 1010–942 Ma. In addition, the zircon U-Pb ages of one quartz-mica orthogneiss sample indicate that the lower and upper intercept ages are 1658±64 Ma and 852±91 Ma, respectively. All of these data indicate that the reasonable Late Paleoproterozoic–Lower Mesoproterozoic and Middle Mesoproterozoic ages for the Khutag-Uul and Tseel Formations, respectively. These new results, in combination with published data, demonstrate that Precambrian basement rocks that were subjected to an early Neoproterozoic magmatic event exist in the so-called Khutag Uul Block of the Khatanbulag Massif, South Mongolian Orogenic Belt.

Whole-rock major and trace element contents of the Paleoproterozoic to Mesoproterozoic paraschists and orthogneisses are representative for the upper continental crust, with Rb, K, Th, U, Pb, Zr, Hf, and LREE enrichment and Nb, Ta, Sr, P, and Ti depletion, and suggest a continental arc setting. In general, the nature and timing of geological events recorded in the metamorphic rocks from Khutag Uul Block support their affinity to the Tarim Block.

Comparative Orotomy of the Archean Superior, North China, and Phanerozoic Altaid orogenic systems

Tim Kusky[1]*, China University of Geosciences, Wuhan (tkusky@gmail.com)
Celal Sengor[2], Istanbul Technical University

Abstract

Geological maps encode vast amounts of data about the rock types, ages, chemistry, and deep-time history or different tectonic units, yet this is often difficult to extract because of the way that different geologists artistically portray their results in maps and cross sections at various scales. Comparative orotomy is the science of dissecting the structure and history of mountain ranges in comparison with one another, against a background of fundamental processes of orogeny, and testing how this structure and inferred processes may have changed through deep time. Currently, this science is just entering the big data Deep-time Digital Earth era, so here we present a preliminary comparative orotomy of a few of the world's best-documented Phanerozoic and Archean accretionary orogens. We compare and contrast the materials and mechanisms of continental crustal growth in the largest preserved regions of Phanerozoic and Archean juvenile additions to the crust, to test for similarities or differences in the formation of continents through time. We accomplish this through a comparison of map patterns, lithological contents, structural and metamorphic evolution, of the Phanerozoic Altaid orogenic system of Asia, with the Archean Superior Province of the North American Craton, and the Archean-Paleoproterozoic North China Block. All three orogenic systems consist of collages of curvilinear belts of eroded arcs, some older continental slivers, vast tracts of former subduction/accretionary complexes, containing numerous shreds of portions of the ophiolite suite, slivers of island and continental arcs, accreted oceanic plateaux, all intruded by multiple magmatic suites during or between multiple deformation events, then sliced by large transcurrent fault systems. The Altaids and parts of the Superior are bent into large oroclinal structures. We make this comparison because the Superior Province, and North China Block, are both typical Archean accretionary orogens that, in the Paleoproterozoic, were incorporated into larger supercontinents (e.g., Kenorland, Nuna, which then formed the core of Columbia, Rodinia, Laurentia, and Pangea). Since the Superior is the largest single fragment of Archean continental cratonic lithosphere preserved on Earth, the Superior Province is widely regarded as a testing ground about how Earth's continental crust was formed. Likewise, the Altaids encompass the largest region of crustal growth for the Phanerozoic. The North China Block is smaller, but preserves similar features. Our comparison of these ancient cratonic fragments with the Altaids is needed, as in recent years many myths about how the planet may have responded to higher heat production and flow in the Archean have emerged, because of trends in the science where the regional geology is ignored in favor of numerical models, isotopic proxies for assumed models of chemical behavior for crust-forming or tectonic processes, or comparisons with other-worldly bodies that bear little resemblance to our hydrous Earth. Thus, we return to the geological record, and here describe the map patterns, lithological associations,

structural patterns, and evolution of the Altaids, Superior Province, and North China, showing how comparative tectonics, orotomy, is useful in the absence of meaningful paleomagnetic or biostratigraphic data. The obvious next stage in this science is making our

[Invited] Dense passive source seismic array reveals detailed shallow lithospheric structures: a case study from Western Australia

Huaiyu YUAN[1]*, Macquarie University (huaiyu.yuan@uwa.edu.au)

Abstract

Dense passive source seismic arrays offer unparalleled insights into the lithospheric structures of cratons, ancient geological entities with rich and complex evolutionary histories. Dating back to the early Archean, the formation of the West Australian Craton (WAC) was initiated by processes such as magma upwelling, crustal material differentiation and gravitational sorting, culminating in the accumulation of the earliest continental crust nuclei. These nuclei have endured through prolonged tectonic activity, preserving invaluable clues about Earth's early geological processes. Over billions of years, the WAC has been subjected to a multitude of tectonic events, including late Archean rifting, Proterozoic orogenies, and Mesozoic rifting during successive supercontinental cycles. These dynamic processes have profoundly influenced the craton's geological architecture, resulting in a mosaic of crustal features and lithospheric structural complexities, which have played a pivotal role in the formation of world-renowned mineral deposits. With the aim of establishing a comprehensive regional background model for the recently initiated 10-year WA Array lithospheric mapping project, we integrate datasets and models from previous dense deployments to unravel the intricate details of the WAC's shallow lithosphere. Our objective is to build a comprehensive understanding of the WAC's evolution, drawing on insights from the 'pre-WA Array' era, and to elucidate the factors governing the distribution of its mineral deposits.

Lithospheric thermochemical structure beneath the southwestern Central Asian Orogenic Belt from joint inversion

Xuewei BAO[1]*, Zhejiang university (xwbao@zju.edu.cn)
Yingkai Wu[2], Zhejiang university

Abstract

Located at the southwestern Central Asian Orogenic Belt, the lithospheric interaction and deformation of the Tarim craton, Tian Shan and Junggar lithosphere are important to understand the complicated tectonic activities in this region. We here obtain the thermal and compositional structure of the upper mantle beneath this unique place by probabilistic joint inversion of the newly processed Rayleigh-wave dispersion data, surface heat flow, geoid anomalies and absolute elevation. The Junggar and Tarim Basins are dominated by a thick lithospheric root of more than 240 km, determined from the 1250 ℃ isotherm. Meanwhile, the spatial variation of the magnesium number shows relatively fertile lithospheric mantle beneath the Junggar and Tarim Basins. Specially, the lower crust and uppermost mantle beneath the Junggar Basin are characterized by high velocities, in agreement with previous models which suggests the existence of fossil oceanic lithosphere. Furthermore, the lithospheric structure beneath the western and eastern Tian Shan show distinct geophysical and geochemical properties, feature by thin lithosphere, high temperature, low density, low velocity and thick lithosphere, low temperature, high density, high velocity, respectively. These observations indicate that while the lithospheric structure beneath the western Tian Shan is significantly affected by mantle upwelling, the lithosphere beneath the eastern Tian Shan is mainly thickened by southward underthrusting of Junggar lithosphere and northward underthrusting of Tarim lithosphere.

Petrogenesis of late Carboniferous garnet-bearing, strongly-peraluminous granites in the West Junggar oceanic arc, NW China: implication for crustal maturation and rapid supracrustal recycling

Jiyuan Yin[1]*, Institute of Geology, Chinese Academy of Geological Sciences (yinjiyuan1983@163.com)
Tao Wang[2], Institute of Geology, Chinese Academy of Geological Sciences
Min Sun[3], University of Hong Kong

Abstract

Subduction and melting of supracrustal materials have been postulated to play an essential role in crustal maturation of oceanic arcs. However, the direct observation and sampling of sediment melt within the base of crust are great challenge so that it has been difficult to constrain the timeframe and magnitude of supracrustal recycling. Here we show geochemical results for the garnet-bearing, strongly-peraluminous and garnet-free peraluminous granitoids in the West Junggar. These rocks are emplaced in a late Carboniferous (~307–301 Ma) intra-oceanic arc setting in southern Central Asian Orogenic Belt (CAOB), and are characterized by high Sr/Y ratio (52 – 100) and strong depletion in heavy rare earth elements (HREE, La/YbN = 32 – 115). Zircon from these rocks have depleted Hf isotopes (+11.1 to +13.5), but elevated δ18O (8.5‰ – 9.8‰), implying subduction and remelting of juvenile greywacke sediments at ~50 – 60 km. In contrast, the youngest inherited zircon cores are dated at ~316 Ma and show low δ18OZrn (4.3‰ – 5.0‰), implying contribution of hydrothermally altered crust to the sedimentary source. Our results reveal that crustal maturation in the West Junggar during the late Paleozoic time most likely involved repeated crustal remelting and rapid (~15 Myr) supracrustal recycling in subduction zones.

Abstract

Genesis and the growth of continental crust are fundamental to maintaining life and supplying resources to our society. It is widely accepted that continental collision zones are favored locations of crustal preservation, yet it remains unclear when and how continental collision generates juvenile crust and maintains net crustal growth. Here we carry out hafnium isotopic mapping of three collisional orogens with distinct maturity in the Tethyan domain, i.e., the Zagros, Himalaya, and Qinling, to reveal the evolution of juvenile crust in collisional zones. Our results indicate that the amount of juvenile crust generated and preserved in collisional orogens far exceeds previous estimates. The pre-collisional juvenile crust generated by arc magmatism was mostly preserved in Zagros, slightly reworked in Himalaya, and partly lost in the Qinling orogen. In growing orogens such as Zagros and Himalaya, the collision produces juvenile crust and leads to net crustal growth by the input of juvenile mafic magmas derived from partial melting of both subduction–modified lithospheric mantle and asthenosphere. In decayed orogen such as Qinling, there is little juvenile crust produced during a collision due to limited mantle melting. The juvenile lower crust is fertilized in ore-forming components, which can be released into hydrous felsic magmas during later remelting, and thus plays a significant role in the genesis of magmatic–hydrothermal ore deposits in collision zones.

Hongwei Zheng[7], Institute of Geology, Chinese Academy of Geological Sciences

Abstract

The nature of the basement in Mesozoic–Cenozoic basins, such as the Junggar Basin in China, is key to understanding the Central Asian Orogenic Belt. In this study, we investigated the geophysical anomalies and identified the structure of the deep crust and upper mantle in the Junggar Basin and its adjacent areas including the West Junggar and Tianshan orogen based on Bouguer gravity, magnetic, and broadband seismic data. The Junggar Basin is characterized by low Bouguer and high magnetic anomalies, and the pattern of the anomalies only changes slightly with increasing depth. The Junggar Basin has deep Curie point depths (~30–42 km) in its centre and shallow depths in its western and eastern parts and northern margin, and it has a crustal thickness of ~40 km. There is a near-vertical area of high shear-wave velocity (Vs > 4.5 km/s) with a horizontal width of nearly 80 km at a depth of 70–75 km in the northwestern margin of the Junggar basin. Low-velocity (Vs < 3.0 km/s) and high-velocity (Vs > 4.5 km/s) areas occur at depths of 15–45 and 60–80 km in the Junggar Basin, respectively. Near-vertical subducted oceanic plates and partially molten lithosphere may coexist in the West Junggar Orogen and western Junggar Basin areas. The basement of the Junggar Basin consists mainly of juvenile oceanic crustal materials based on all observations. Our findings provide important insights into the lithospheric structures of the southwestern Central Asian Orogenic Belt.

Abstract

The Qinling orogen, one of the most important orogens in Asia, belongs to the northeastern part of the Tethyan orogen. The orogenic architecture and processes of the Qinling orogen remain controversial. In this study, we present new zircon U–Pb ages, whole-rock geochemical and Sm-Nd isotopic data, and zircon Lu-Hf isotopic data for early Mesozoic felsic-intermediate igneous rocks in this orogen, combined with data from literature, to delineate the Mesozoic crustal architecture and processes of this orogen. A total of 181 zircon U–Pb ages show three phases (252–230, 230–198, and190–185 Ma) of the igneous rocks. The first-phase igneous rocks occur mainly in the westernmost segment of the orogen and formed in a subduction setting during the closure of the Mianlue Ocean (a northern branch of the Paleo-Tethyan Ocean). The second and third-phase igneous rocks, distributed in the middle to eastern parts of the Qinling orogen, were generated in late syn-collisional and post-collisional tectonic settings, respectively. Whole-rock Nd isotope mapping of these igneous rocks yield six isotope provinces and zircon Hf isotope mapping yield seven isotope provinces. These provinces display that the southern margin of the North China Block and the northern margin of the Yangzi Block are dominated by ancient deep crust, that is, early Paleoproterozoic (2.3–1.8Ga) and late Paleoproterozoic (ca.1.7 Ga) components, respectively. The North Qinling and South Qinling contains different basement, the former basement is younger (TDM(Nd)= 1.4–1.0 Ga) than the latter (TDM(Nd)=1.6–1.2 Ga), suggesting that the North Qinling is an independent terrane different from the North China Block and South Qinling. The isotopic tracing also reveals a deep-seated NNE–SSW-trending zoned architecture that is approximately perpendicular to the WNW–ENE-trending of the orogen. This provides new evidence for the “Spaghetti Junction model” for the Qinling orogen. The old Nd (2.2–1.0 Ga, mostly 2.0–1.2 Ga) and Hf (2.3–0.8 Ga, mostly 2.0–1.2 Ga) model ages indicate that the continental growth in this orogen occurred mainly during the Paleoproterozoic and Mesoproterozoic, with only minor amounts of juvenile (TDM = 0.1 Ga) continental growth (or preservation) along the Shangdan and Mianlue sutures. These characteristics suggest that the Qinling orogen is dominantly formed by the collision of ancient continental blocks, distinct from some typical accretionary orogens, such as the Central Asian Orogenic Belt with voluminous juvenile crust.

Evolution of the Proto-Tethys Ocean in the West Kunlun Orogenic Belt, Northwestern Tibet: Insights from the Sub-Arc Crust and Lithospheric Mantle Modification

Zaili TAO[1]*, Institute of Geology, Chinese Academy of Geological Sciences (Taozaili96@163.com)
Jiyuan Yin[2], Institute of Geology, Chinese Academy of Geological Sciences
Mike Fowler[3], School of the Environment, Geography and Geosciences, University of Portsmouth

Abstract

Radiogenic isotopes serve as a crucial tool for investigating crustal evolution, playing a pivotal role in revealing magma sources and petrogenesis. However, they can be ineffective in distinguishing distinct magmatic sources with similar radiogenic isotopic compositions, a common occurrence in nature. This paper addresses this challenge in the Ordovician igneous rocks from the West Kunlun orogenic belt (WKOB), to distinguish between two potential magmatic sources (i.e., Tarim Craton vs. Tianshuihai terrane) with similar isotopic compositions, by using appropriate thermodynamic and geochemical modeling. Zircon U–Pb dating yields ages of 484 ± 4 Ma, 469 ± 2 Ma, and 461 ± 2 Ma for the Duwa gabbros, Datong monzogranites and syenites, respectively. The Duwa gabbros exhibit low SiO2 (47.4–49.1 wt. %), high MgO (5.45–6.85 wt. %), high large ion lithophile elements (LILEs) and low high field-strength elements (HFSEs), which suggest an origin in subduction-modified mantle. They display high zircon δ18O values (7.6–7.9 ‰) and enriched zircon Hf isotopic compositions (εHf(t)= -5.3 to -7.7), consistent with 1-5% subducted sediments in an enriched mantle source. Trace element models further confirm that the gabbros are most likely derived from low-degree (~8 %) partial melting of subduction-modified Tarim mantle in the spinel-garnet facies, rather than the Tianshuihai mantle. The Datong syenite samples belong to the shoshonitic series and are characterized by medium SiO2 (59.5–61.4 wt.%), relatively low MgO (0.88–1.19 wt.%) and Mg# (37–42), enrichment in LILEs and depletion in HFSEs. They have high whole-rock (87Sr/86Sr)i ratios (0.7103 to 0.7105) and negative whole-rock εNd(t) values (-3.8 to -4.3), plus negative to slightly positive zircon εHf(t) values (–3.8 to +2.6), similar to the coeval mafic rocks. Thermodynamic and geochemical modeling suggests that the Datong shoshonitic rocks likely originated via crystal fractionation of the shoshonitic basaltic magmas in the SW Tarim Craton. The Datong monzogranites have high SiO2 (69.7–72.6 wt.%), low MgO (0.59–0.66 wt.%) and demonstrate a typical enrichment in alkalis, Zr and Nb with depletion in Sr, P and Ti, consistent with A-type granites. They are characterized by high whole-rock (87Sr/86Sr)i ratios (0.7321 to 0.7323), negative whole-rock εNd(t) (-11.3 to -11.8), negative zircon εHf(t) (-11.0 to -16.5) and high zircon δ18O (7.2–8.0 ‰), indicating derivation from the remelting of ancient crustal source. Thermodynamic, major and trace element modeling suggest that their parent magma may have been generated by water-deficient (ca. 2 wt.%) partial melting of ancient crustal material beneath the SW Tarim Craton rather than that of the Tianshuihai terrane, under high temperature (T > ~900 ℃), low-pressure (P= 5–8 kbar) conditions.

Considering the tectonic framework of the WKOB, we propose that the original mantle and crust beneath the southern Kunlun terrane may have been modified by that beneath the SW Tarim Craton during the Ordovician. Since these conclusions all favor Tarim-derived magmatism, they indicate that the Ordovician magmatism in the southern Kunlun terrane is most consistent with episodic northward subduction of the Proto-Tethys Ocean, commencing at ~485 Ma.

Linking the past to the future of tide-domianted estuarine changes under human activities and climate changes, case study at the Pearl River Estuary

Junjie DENG[1]*, School of Marine Sciences, Sun Yat-sen University (dengjj6@mail.sysu.edu.cn)

Abstract

Over the past century, intensive human activities have disrupted the natural dynamic equilibrium of sediment transport and deposition in the coastal region. Under the combined influence of human activities and climate change forcing, the evolution of the coastal zone exhibits complexity and uncertainty. With the aim to study if the tide-dominated estuary will attain an equilibrium state or will be infilled until it became a river, this paper adopts the data-driven and process-based approaches to link the past to the future. Based on the historical data of bathymetric changes, relative sea-level changes, and riverine sediment discharge and so on, this paper utilizes a data-driven model called Bayesian Network to train and verify the estuary filling evolution over the past century. This model is then used to predict future changes based on different scenarios such as sea level rise and riverine sediment supply. The data-driven modeling approach will be compared with a validated long-term process-based morphodynamic model and historical measurements. Both models' results indicate that sediment discharge is the most significant factor influencing volume changes in Lingding Bay, while sea-level rise has minimal impact in the past. Various scenarios will be conducted to evaluate the possible source of uncertainties of future evolution. Process-based modelling will be used to study the equilibrium conditions, which represents the certainty of the future evolution. The Bayes Network modelling can reveal the uncertainties of the future projection, which cannot be reflected by the process-based model. A global comparison with different tide-dominated estuarine evolution will help understand the estuarine responses to external forcings from the prospective of dynamic equilibrium.

[Keynote] Competing Natural and Anthropogenic Influences on Sediment Supply to the Global Ocean

Peter Dominic Clift[1]*, University College London (peter.clift@ucl.ac.uk)

Abstract

Sediment transport in modern river systems is modulated over million-year timescales by tectonic forces and rock uplift during mountain building. On shorter, orbital timescales, source erosion, and the speed of transport are controlled by intensity and seasonality of precipitation that focuses erosion in certain parts of the source mountains, while discharge controls the speed at which different grain sizes are transported to the ocean. In Asian systems this primarily reflects monsoon intensity, but similar patterns are noted in the Mississippi basin linked to deglaciation. While muddy and silty sediments may be transported almost geologically instantaneously to the sea, denser sandy material may take thousands of years to reach the ocean. Sea level variability may then buffer the sediment on the continental shelf during high stands. Sandy sediment may only reach deep-water depo-centres after a complete glacial cycle, especially if the shelf is wide and sediment supply rates are moderate. In general, times of stronger precipitation and warmer temperatures result in faster rate of chemical weathering, but more importantly, greater degrees of sediment recycling out of floodplains and river terraces, resulting in both faster rates of sediment supply, but also deposition of more strongly chemically, weathered sediments. A similar effect can be produced by enhanced erosion of weathered soil by human activities, particularly deforestation and the spread of agriculture. This is seen ~4-5 ka in the Indus River and ~2.5 ka in the Pearl River. Some of the effect of this reworking may not be observed offshore because of preferential sedimentation of sands and also smectite clays in the coastal zone. Resolving the impact of climate change on fluvial systems from that caused by human activities can be problematic and require a number of proxies that uniquely characterize human activities, such as heavy metals related to the smelting of metals by early societies.

THE 4F NUMERICAL MODEL – a solution for past reconstructions of coastal and glacial dynamics and future simulations

Jerzy Jan FRYDEL[1]*, Polish Geological Institute - National Research Institute
(jerzy.frydel@pgi.gov.pl)

Abstract

Climate change, melting glaciers and rising global ocean levels, the development of mass wasting processes (including landslides) on exposed coastal cliffs, and the increasing impact of storms on urbanised areas located in the coastal zone of the seas and oceans should be recognised as key issues whose identification is a challenge for coastal researchers in the 21st century. During the Holocene, the level of the Baltic Sea was subject to major shifts caused by eustatic sea-level changes and glacio-isostasy, resulting in transgression and/or regression of the coastline. The aim of the study was to develop a universal method for reconstructing and projecting future shoreline changes in the southern Baltic Sea using numerical modelling. The postulated approach allows the reconstruction of geological processes including: ice sheet retreat/advance, marine regression/transgression and erosion/accumulation within the coastline. Reconstructions and simulations of the dynamics of the indicated processes, expressed by changes in shoreline position (or glacier extent), were recognised through application of the 4F MODEL developed for this purpose. The model combines time, space and dynamics in its matrix, being the basis for multiscale analyses performed in a homogeneous spatio-temporal environment, enabling both past reconstructions and future scenarios. The 4F (form and function of the Frydel factor) model uses mathematical formulas (functional programming) derived from the equation of coastal and glacial dynamics, by Frydel (2022), which is variable-based, therefore functions can be universally applied in reconstructions and simulations across different regions and spatial and temporal scales (depending on the provided data range). The approach utilises high-level polynomial regression, followed by integral calculus (on the fly) of successive functions using the formulas (Frydel et al., 2017, Frydel, 2022). As a result, the palaeogeographic relationships from the primary matrix become transformed into a nested matrix, in a way expressing palaeodynamics in a function of time. The reconstruction, in the Desmos environment, of the extent of individual glacial phases and coastlines (input data) subject to high-order polynomial regression (or mapping with any other functions) is accurate (coefficient of determination, R^2 ~ 0.9), thus providing reliable data for further application in the process of integral calculus and modelling of development dynamics. The importance of the strategy used lies in its direct applicability both for determining the extent and dynamics of geological processes in the past and for forecasting purposes, including coastal spatial planning requirements, based on hypsometry and sea levels projected from RCP emission scenarios (Oppenheimer et al., 2019; Golledge et al., 2020). The time scales considered in the 4F model include the late Pleistocene, Holocene and Anthropocene (geological, long-term and short-term scales). The 4F model, constructed in the Desmos environment, was validated in the GIS environment achieving <92.6%, 99.9%> compliance for reconstructions and <46.6%, 82.7%> for

prognostic purposes. These results obtained from the palaeogeographic and palaeodynamic analyses and simulations were linked to past changes in the southern Baltic Sea level (Uścinowicz, 1995, 2004, 2006) and palaeogeographic reconstructions (Marks, 2002; Marks et al., 2016), adding a new dimension to palaeoclimatic studies, as described by Frydel (2022).

Regional Relative Sea Level Changes Influenced by Geological Settings: Insights from InSAR Analysis

Zhaoquan Huang[1]*, Xiamen University (hzq@xmu.edu.cn)
Fengling Yu[2], Xiamen University
Yongxiang Huang[3], Xiamen University

Abstract

As the global climate continues to experience ongoing warming, understanding the spatial variation of relative sea level becomes increasingly crucial for studying regional coastal evolution and ensuring local coastal safety. Recognizing vertical land motion at high spatial resolution is now acknowledged as pivotal in analyzing relative sea level changes in regional or local scale. However, obtaining detailed spatial information on regional relative sea level changes from tide gauge stations is challenging due to their sparse distribution. In recent years, high-resolution land motion detected by InSAR have emerged as significant inputs for analyzing relative sea level changes. Yet, most sea level studies tend to overlook the varying influence of geological environments on land motion, potentially leading to an underestimation of the true magnitude of effects on relative sea level in certain areas.

In this study, our focus is on the Xiamen-Kinmen coast, where we employ GPS-calibrated InSAR to extract regional vertical land motion at a high spatial resolution. By incorporating geological background data, we discern the vertical land motion across different geological settings. Subsequently, we examine the correlation between relative sea level changes and geological factors. Our analysis unveils significant fluctuations in relative sea level along the coast, influenced by diverse geological environments, on a spatial scale of several kilometers. It is different from previous conclusions using a single tide gauge station to study sea level changes in this area. This study enhances the spatial resolution of sea level change risk analysis in coastal regions, offering valuable insights into the dynamic interplay between vertical land motion and sea level changes.

A Marine Spatial Data Infrastructure for the Adriatic Sea: Managing Multidisciplinary, Heterogeneous, and Fragmented Geodata with a FAIR Approach to Support Research Life Cycle Management

Federica FOGLINI[1]*, CNR ISMAR (federica.foglini@ismar.cnr.it)
Valentina Grande[2], CNR ISMAR

Abstract

Facilitating wider access and reuse of research data in Earth Sciences has rapidly gained traction because of the need for research integrity, reproducibility, and accountability as well as new opportunities for large-scale data analysis and reanalysis. Adhering to the FAIR principles is crucial for fostering interoperability with European and international marine data management infrastructures, facilitating the handling and exchange of multidisciplinary data.

The Institute of Marine Sciences (ISMAR) and the Institute of Polar Sciences (ISP) of the Italian National Research Council (CNR) have collected diverse geodata from the Adriatic Sea over the years, spanning geological, oceanographic, biological, and anthropogenic aspects, as well as their interactions, using various methodologies and for multiple purposes.

To address the challenges posed by the heterogeneity and fragmentation of these datasets, a Marine Spatial Data Infrastructure (MSDI) has been established. Its purpose is to integrate and preserve geodata, promote their reuse (such as generating scenarios for geological past and future developments using numerical models), and ensure a high level of FAIRness (Findable, Accessible, Interoperable, and Reusable). The MSDI comprises a Spatial Relational Database Management System (RDBMS) built on specific data models partly aligned with the INSPIRE Directive specifications, a WebGIS, a metadata catalogue, and a cloud system. This paper demonstrates the capabilities of the MSDI, discussing its key implementation steps, constituent elements, achieved level of FAIRness, factors enhancing FAIRness, and areas requiring further development.

This study also introduce and demonstrate recent tools and service implemented to manage the entire Earth Science research life cycle through the “Research Object” paradigm. Research Objects are virtual aggregations of resources that bring together data, methods, results and people to document scientific investigations, according to Open Science principles.

This study showcases the importance of integrating and harmonizing these diverse datasets, as it facilitates interoperability with other marine data management infrastructures. This interoperability enables the efficient handling and exchange of a wide range of multidisciplinary data, such as with the European Marine Observation and Data Network (EMODnet) and the Deep-Time Digital Earth (DDE) .

The Adriatic Marine Spatial Data Infrastructure (MSDI) serves as a valuable model or blueprint for other marginal seas worldwide, as it represents the interface between continents and oceans. Marginal seas, such as the Adriatic Sea, play a crucial role in global ocean dynamics and are important for various reasons, including ecological, economic, and strategic considerations. Such

infrastructures facilitates informed decision-making processes related to marine resource management, conservation efforts, maritime transportation, and sustainable development.

Numerical paleogeographic modeling of marginal seas – Holocene evolution of Baltic Sea as a case study

Jakub Miluch[1]*, University of Szczecin (Poland) (jakub.miluch@usz.edu.pl)
Peter Arlinghaus[2], Helmholtz-Zentrum Hereon
Andreas Groh[3], Technical University Dresden
Jan Harff[4], University of Szczecin
Wenyan Zhang[5], Helmholtz-Zentrum Hereon

Abstract

Paleogeographic reconstructions of subpolar and polar marginal seas' evolution require a specified set of input data: Digital Elevation Model (DEM), eustatic climate-controlled sea level change, vertical crust movement (isostatic and tectonic) rate and sediment budget. We applied a conceptual model integrating these parameters for the generation of paleo-DEMs describing the evolution of the Baltic Sea since the beginning of the Holocene (11.7 cal BP). Backstripping of the Holocene sediment cover and adjusting the DEM to the time 11.7 cal BP according to the effect of the Fennoscandian iceshield's load at the beginning of the Holocene (Glacio-Isostatic Adjustment - GIA) and sea level variations allowed to reconstruct the starting condition for the application of the forward modelling procedure to generate a sequence of paleo-Digital Elevation Models (paleo-DEMs) of any time resolution. For our case study the first challenge consisted of the generation of a thickness model of Holocene sediments in the Baltic Sea basin to be backstripped before starting the forward modelling procedure. This generation of regional sediment thickness model of the Baltic Sea required a synthesis of various local-scale datasets. Gathered sub-datasets covered majority of the Baltic Sea basin with the thickness grid. Data were extrapolated to undersampled areas by application of co-kriging as well as Random Forest Machine Learning methods. To model the Glacio-Isostatic Adjustment (GIA) the Sea-Level Equation (SLE) after Peltier using the well accepted regional parameters was applied. The specific geological history of Baltic Sea, involved shifting from sea to lake phases by, either eustatically or istostatically-driven, disconnections of the Baltic Basin from the global ocean. When Baltic was decoupled from the global ocean, the eustatic component corresponded to the level of the Ancylus freshwater lake. In this case, the areas of the "outer coast" of Fennoscandia: North Sea, Norwegian Sea and Barents Sea were modelled separately from the Baltic lake basin. For our case study we selected a time resolution of 500 years, having led to 24 paleogeographic scenarios. We used previous reconstructions of Baltic Sea paleogeography derived from mapping of paleocoastlines based on proxy field-born data for plausibility tests of our numerical model results. These tests validate our method to be generally applicable for the paleogeographic marginal seas reconstruction as parts of glacial, periglacial to postglacial paleo-landscapes in polar to subpolar regions. Further positive validation of obtained paleo-DEMs may support generation of future projections.

Abstract

Marginal seas, as transition areas between continents and oceans, with their highly sensitive ecosystems are particularly threatened by climate change and increasingly human impacts. Their protection requires new holistic strategies that comprehensively describe the management of marginal marine systems, including coasts and catchment areas. We are looking for solutions that abstract from the comprehensive diversity of marginal seas and assign appropriate task-related functional models to classes of these seas. The task, therefore, is to initially develop a marginal sea taxonomy, the systematization of which, in addition to natural parameters and functioning, increasingly considers the interaction with resource users and anthropogenic drivers. The spatial framework is formed by the shelf seas, their coastal zones, and catchment areas. The time frame is determined by the last glacial cycle, but especially by the Holocene and Anthropocene. Influencing factors are determined by the dynamics of climate, geosystems, and ecosystems, as well as from increasingly socio-economic developments. On the one hand, the question of variables and their values (data) is historically determined by developments in measurement and monitoring techniques. On the other hand, the long-term development (trends) of marginal seas' environment requires proxy data – mainly from sedimentary records. In addition to numerical functional models, Artificial Intelligence (AI) and Machine Learning (ML) methods are also available for the complex evaluation and interpretation of these data. To describe our concept, we compare examples of marginal seas based on the dominance of their influencing factors. We compare the glacio-isostatically controlled Baltic Sea and western Greenland shelf with the isostatically stable South African shelf (Agulhas Bank), South Asian marginal seas influenced by the Asian monsoons, and the geo-hazardous threatened Salish Sea on the northwestern American coast. The development of a marginal seas taxonomy requires direct collaboration between scientists (e.g., geological, physical, environmental, ecological, humanities, IT/data), modelers, industrialists, and governments.

Classification of the morphodynamics of the coast - how we can improve projections of the coastline changes

Joanna DUDZINSKA-NOWAK[1]*, University of Szczecin (joanna.dudzinska-nowak@usz.edu.pl)

Abstract

The Morphodynamic of the southern Baltic Sea coasts is determined by a complex interplay of the geological setting, eustatic sea-level change, glacio-isostatic adjustment, wave-driven sediment dynamics, storm surges, and aeolian processes acting in various temporal and spatial scales from millennia to hours and in spatial scale from kilometers to centimeters. In terms of presently occurring climate changes, observed an increased number and intensity of storm events, which pose a threat to the infrastructure, the determination of the future scenario of coastline development is of particular importance for broadly defined coastal safety.

This study presents the method of the classification of the morphodynamics of the coast which can be useful for more accurate prediction of the coastal changes as well as a tool for other marginal seas comparison. To be a complex, the scientific classification of the coast should meet the following conditions: (1) cover all morphological types of the coasts, (2) take into account the processes and factors determining the type of shore development, and reflect the relationships between different types of shore and (3) it should reflect the contemporary dynamics of the shore as fully as possible. The use of high-resolution remote sensing data allows us to indicate precisely the characteristic features of the terrain's morphology, which if repeated, can be treated as indicators of the changes. The presented research shows the methodology and results of the conducted classification of the coastal dynamics of the southern Baltic Sea, focusing not only on the direction of movement and rate of change but also on the dynamic of change in different time scales. The main criterion for this classification is the determination of two numerical indicators for each examined section of the coast, synthesizing the image of registered changes in the dune/cliff base line.

The spatial distribution of individual classes of shore dynamics indicates a great diversity and variability of morphodynamic processes along the entire studied section. Changes with medium and high dynamics of both accumulation and erosion processes dominate. The sections with low dynamics of the processes taking place constitute only less than 20% of the studied area. The coast in dynamic equilibrium covers less than 10%. The spatial distribution of individual classes of shore dynamics proves a large diversity and space and time variability of morphodynamic processes along the entire investigated section of the shore, which may substantially bias future scenarios. The presented classification can be treated as an open classification, making it possible to complete the picture of the contemporary dynamics of the coast of any non-tidal marginal seas and any time intervals. The location of specific dynamic shore classes may change over time depending on the variability of hydro-meteorological conditions.

Characteristics and origin of Quaternary mass transport deposits in the Qiongdongnan basin, northern South China Sea

Tao JIANG[1]*, China University of Geoscieces (taojiang@cug.edu.cn)

Abstract

Mass transport deposits in the northern South China Sea have been extensively studied over the past decade due to their potential as hydrocarbon reservoirs and seals, as well as their role in marine geohazards. Several boreholes have cored the mass transport deposits. The chronological framework is established by Optically Simulated Luminescence dating, AMS 14C dating and 18O date. By integrating core-log-seismic data, this study examines the characteristics, distribution and origins of multiple mass transport deposits in the Qiongdongnan basin. The results reveal the presence of more than ten phases of Quaternary mass transport deposits developed in the Qiongdongnan basin, which have obvious soft deformation structure in the cores and show chaotic reflectors in the seismic date. Those mass transport deposits may have been triggered by factors such as high sedimentation rates, increased slope gradients, fault reactivation, earthquakes, and sea level fluctuations. Among these triggers, earthquakes and rapid sea level fluctuations are considered the most significant. Additionally, the mass transport deposits serve as hydrocarbon seals, facilitating the accumulation of shallow gas reservoirs and gas hydrates within the Quaternary strata. It is important for multidisciplinary scientists to conduct further integrated research to better understand mass transport deposits and related tsunamis, which pose significant marine geohazards.

Yuanzhi Zhang[6], Nanjing University of Information Science and Technology

Abstract

Changes in coastlines and coastal zones reflect human activities and global changes. Using Landsat imagery from 1998 to 2021, the temporal and spatial variation characteristics of coastlines and coastal zone land use/land cover changes in the Pearl River Estuary and Hong Kong (PRE_HK) of northern South China Sea were studied during this period, followed by an analysis of how human activity affects them, in an attempt to provide a basis for decision-making in coastal zone management. Our results show that the PRE_HK coastline expanded outward, demonstrating an obvious trend that featured increasing length. The PRE_HK coastal zone was observed to primarily comprise construction land and cultivated land, of which the construction land displayed significant growth in contrast to the woodland's decreasing trend, indicating that the PRE_HK coastline was changing from natural to artificial in character. Human activity in the PRE_HK coastal zone had a significantly positive impact on the coastline length. While the amount of coastline in all PRE_HK sub-regions has increased overall, the coastline length in Guangzhou-Dongguan, in particular, exhibited the greatest growth. During analysis, a positive correlation emerged between coastline length and fractal dimension, in particular, the correlation between Shenzhen coastline length and fractal dimension demonstrated the highest level among the four sub-regions studied. With the exception of Hong Kong, construction land increased significantly in all PRE_HK coastal zones and encroached on other types of land, such as cultivated land, woodland, and water area. Additionally, except for Hong Kong, human disturbance in the PRE_HK coastal zone increased. Among all study areas, Shenzhen revealed a significant increase in human disturbance over the period of interest, exhibiting the highest level of this factor among the sub-regions in the study. These findings could potentially facilitate effective coastal zone management to achieve sustainable development in coastal zones.

Abstract

The South China Sea is the largest marginal sea between Eurasian continent and Pacific Ocean, with relative wide continental shelf and series of large rivers discharge in the Asian Monsoon realm. Following the global ice volume and sea-level change in the orbital scale, the paleogeography and paleomorphology were shaped frequently in the South China Sea, and overlapping with regional climate change force. To model the sedimentary processes and reconstruction the paleoenvironment is one of important conjunct demands in marine geosciences. Under the time of big data and data driving, a collaboration work is operating to integrate geological survey's data, international joint cruise' results and published data in journals, in order to expose the change of sediments thickness and map the regional depositional history, especially in the Late Pleistocene and Holocene.

Though multi-sources data analysis from hundreds of sedimentary cores in the South China Sea, covering the coast, shelf, slope and deep basin, our study offers the opportunity to describe marine sediments and paleogeography change, particularly in isopachous and isochronic level, following the marine oxygen isotope stage alternation. As a relative sufficient investigation area in the northern of South China Sea, the available single channel seismic data and drilling cores' materials make the regional mapping work more reliable on the shelf and in coast zone. As an on-going work, the geological modelling research is approaching to shelf construction, delta formation, estuary change, making sense to understand the global change impact on this big marginal sea between Eurasian continent and Pacific Ocean, and offering an exemplary for

worldwide marginal seas research as well.

Huatung Basin in West Pacific Marginal Seas: a linkage of West Philippine Sea and South China Sea

Hongfang GAO[1]*, Guangzhou Marine Geological Survey, China Geological Survey/Key Laboratory of Marine Mineral Resources, Ministry of Natural Resources, 1133 Haibin Rd., 511458 Guangzhou, China. (promap@163.com)
Jinpeng Zhang[2], Guangzhou Marine Geological Survey, China Geological Survey/Key Laboratory of Marine Mineral Resources, Ministry of Natural Resources, 1133 Haibin Rd., 511458 Guangzhou, China.

Abstract

The Huatung Basin, east off Taiwan Island, is an intersection of the Pacific Plate and Eurasian Plate, and the convergence point of multiple tectonic movements of subduction, collision and uplift, which records the tectonic activity processes of subduction and collision of geographical units, including the island arc of Ryukyu-Taiwan, marginal sea basins of South China Sea and West Philippine Sea. Based on most recent geophysical data and drilling data in adjacent areas, we found new geological phenomena to benefit the solution of Huatung Basin genesis debate, in term of Mesonic or Cenozoic puzzle.

The results include, (1) Gravity inversion and magnetic anomaly data show that the crustal properties of Huatung Basin, Gagua Ridge and West Philippine Basin are similar; (2) The deep reflection seismic profile shows that the deep crust and upper mantle have folded and deformation, which is consistent with the basement relief of Huatung Basin-Gagua Ridge and West Philippine Basin; (3) Eocene sedimentary strata developed in the upper part of Gagua Ridge; (4) The largest unconformity T7 in Huatung Basin and West Philippine Basin coincides with the Puli movement in Taiwan Island and Ryukyu Islands, during the Late Eocene-Middle Oligocene (35-30 Ma); (5) Huatung Basin and West Philippine Basin on both sides of Gagua Ridge, developed consistent sequences since the Early Miocene, with relatively stable structure and small stratigraphic deformation.

The research conclusions are,

(1) Huatung Basin and Gagua Ridge have similar properties to the West Philippine Basin. Gagua Ridge and its adjacent low uplift are formed by crust- upper mantle folding and deformation. During the folding and deformation process, ridge formed by rock strata bend, anticlinal part arch upward and crust thickens. In the syncline part, basin and trough formed by stretched and thinner rock strata to create a larger accommodating space with number of sediments preservation.

(2) Huatung Basin is not a Mesozoic basin, but like the West Philippine Basin to expand during the Late Paleocene-Early Eocene (60-35 Ma), and then to enter regional uplift and drift period. The regional unconformity T7 records the complete closure and regional uplift and drift of the Huatung and Philippine Basin.

(3) During the northwestward drift of Philippine Sea Plate and Luzon Island Arc, and the eastward subsidence of Manila Trench in South China Sea, Huatung Basin, Gagua Ridge and East Trough of Gagua Ridge were obstructed by the Eurasian Plate with regional flexural folding and

deformation. Large accommodation space was offered in Huatung Basin and East Trough of Gagua Ridge. With the continuous collision between the Philippine Sea Plate and Eurasian Plate in Neogene, Taiwan Island was uplifted, and a large number of matters flooded into the Huatung Basin, and be transported to East Trough of Gagua Ridge through the Ryukyu Trench, forming obvious thick Neogene-Quaternary sedimentary sequence.

Abstract

The South China Sea (SCS) is one of the most active tectonic zones in the world. The massive information on sedimentary infilling in the SCS provided by marine surveys and offshore oil and gas exploration has made the SCS as the best place and natural laboratory for comprehensive research on "climate-tectonics-sedimentation". A large number of seismic and drilling data show that a series of multi-stage progradational wedges have developed along the strike-slip fault zone in the western SCS since the Late Miocene, indicating the characteristics of rapid subsidence and rapid sedimentation. There are developed not only large deltas rapidly propelling progradational wedges, such as the Rajang Delta of the Zengmu basin and the delta of the Wan'an basin, but also rapidly advancing continental clinoforms, such as the seaward migration of the shelf break at the intersection of the Yinggehai and Qiongdongnan basins for nearly 200 km, and similarly the rapid seaward migration of the continental slopes in both the Zhongjiannan and the Wan'an basins.

A plentiful of clastic provenance systems occur in the western continental margins of the SCS, which include multi-directional sediment supply from the Red River, Mekong River, Hainan Island, Indochina Peninsula and eastern Vietnam. Since the Late Miocene, abundant supply of terrigenous detritus and rapid sedimentation occur in the western margins of the SCS. Of them, the uplift of the Tibetan Plateau and the East Asian summer monsoon are likely to be the two key factors controlling the flux of river sediments. Primary reason for abundant supply of terrigenous detritus is due to homochromous regional tectonics, especially rapid uplift in drainage area. According to the study of geological historical records and the uplift history of the Tibetan Plateau, the strong uplift and denudation of the Tibetan Plateau during the Late Miocene and Pliocene provided sufficient clastic materials for the Red River and the Mekong River, and the sediments were further transported to the western continental margins of the SCS through the rivers, resulting in a dramatic increase in the sedimentation rate since the Late Miocene. Second reason is the strengthening of the East Asian monsoon and the strong weathering and denudation in the source area. The strengthening of the monsoon brings about strong rain, while the weathering and erosion of terrestrial materials increases. Therefore, the supply and rapid sedimentation of abundant terrigenous clastics since the Late Miocene in the western margins of the SCS are closely related to regional tectonic events during the same period, such as the rapid uplift of the Tibetan Plateau, and also related to the strengthening of the East Asian monsoon and the strong weathering and denudation in the source area.

Abstract

Land reclamation projects typically alter the natural coastline morphology and submarine topography, affecting the conditions of coastal erosion and deposition, thereby influencing the topography of the seabed. Using the Caofeidian land reclamation project in the Bohai Sea as a case study, this research employs multi-phase nearshore remote sensing data, submarine topography measurements and sub-bottom profiles since 2001. It combines tidal currents, the types of seabed sediments and suspended particle concentration data to discover that there has been a gradual decrease in the rate of coastline change. The land reclamation efforts in Caofeidian have successfully preserved the geomorphic features of the Caofeidian Cape. The strong tidal flow within the deep trough generates shear stress greater than the critical erosional shear stress of the surface sediment, resulting in the removal of surface sediment and the continual erosion in the deep trough. Consequently, new underwater landslides and eroded basins have emerged in the marine area of the deep trough. While this helps to maintain the depth of the deep trough, attention should be given to whether the underwater landslides are advancing towards the front edge of the Caofeidian headland. In order to address this issue, timely measures should be implemented, such as reinforcing submarine slope engineering in Caofeidian and enhancing monitoring and early warning systems for marine geological hazards in the deep trough marine area. The research findings will provide valuable technical support for the management of natural resources and the protection and restoration of coastal areas.

An expansive Ediacaran lagoon: clay mineralogy and geochemistry evidences for the spatiotemporal extent of evaporitic conditions in the Doushantuo Formation

Abstract

The Ediacaran Doushantuo Formation (ca. 635–551 Ma) in South China has yielded a broad array of microfossil and isotope proxy records which underpin much of our understanding of the Earth System and biospheric evolution during a critical time period, while the depositional environment is still debated. Abundant authigenic Mg-rich saponite clay has been reported in the Yangtze Gorges Area as a proxy for local restricted, evaporitic lagoon setting (1), while the spatiotemporal extent of restricted, evaporitic conditions across the Yangtze Block remains largely unexplored. Here we use mineralogical and petrographic approaches to systematically document spatiotemporal variations of clay mineralogy in the Yangtze Block, providing new constraints for depositional environments and further implication on early earth system.

Our results find that the open marine slope and basin settings do not contain Mg-rich clays and are dominated by illite clay, consistent with previous work which suggests that formation of Mg-rich clays require evaporitic, restricted conditions. In contrast, Mg-rich clays persistently occur in all shelf settings studied, including saponite, talc, sepiolite and palygorksite, implying that evaporitic restricted conditions were much more expansive than previous assumed. In addition to this spatial pattern, we identify a clear stratigraphic progression where the basal and uppermost Doushantuo Formation contains illite but Mg-rich clays appear in between, shortly above the cap carbonate. The results suggest an extensive carbonate rimmed, evaporitic lagoon developed on the Yangtze shelf shortly after the deposition of the cap carbonate, consistent with existing paleographic reconstructions (2). Open marine conditions on the shelf only became re-established following erosion of the carbonate rim, most likely during the Gaskiers glaciation, and subsequent marine transgression.

Interestingly, we found the intervals containing authigenic Mg-rich clay show more positive carbonate carbon isotope values and elevated carbonate Sr concentration, which could have been impacted by local restriction and evaporation. Compilation of published carbon isotope data in more sections spreading across the Yangtze Block show that shelfal sections usually show positive carbon isotope values in the middle of the Doushantuo (632.5 ± 0.5 Ma to 579.3 ± 0.8 Ma)

between the global-comparable negative excursion in cap carbonate and the Shuram excursion, while the time-equivalent record of slope to basinal section are mostly negative. The geochemical variations are correlated to our clay mineralogical results, indicating different water chemistry between lagoon and the open ocean. In this case, coupled mineralogical and geochemical proxies can contribute to detailed paleogeographic reconstruction. Moreover, cautions are required when interpreting proxy records derived from shallow, shelfal sections, as these may record local lagoon conditions rather than a ‘global ocean’ signal, and more geochemical proxies can be revisited under the spatiotemperal environment model constrained by clay mineralogy.

Abstract

There are many geological and geochemical proxies used for tracing Earth’s atmospheric O2 level (pO2) evolution, but they always had distinct response dynamics to pO2 fluctuations. This was ascribed to their different sensitivities to changes in O2 fugacity and the lack of their continuous and complete geological records. In this study, a global-scale mineralogical dataset was established, including 30,918 samples of minerals containing manganese (Mn), molybdenum (Mo), chromium (Cr), cerium (Ce), phosphorus (P) and carbon (C) minerals. The tempo and rhythm of valence evolution of Mn, Mo, Cr and Ce can be well fitted a third-order trigonometric Fourier series expansion of a periodic function. Furtherly, we quantified the time lag between variation in pO2 and the corresponding response in these minerals’ evolution through evolutionary dynamic model. According to the results of analysis, it was found that the evolutionary time lag sequence of high-valent Mn, Ce, Mo and Cr minerals after 2.4 Ga followed MnIV>CeIV>MoVI>CrVI, that is, Mn and Ce minerals displaying the most rapid dynamic response, followed by Mo and Cr minerals, which aligns with the thermodynamic sequence of oxidation reactions. All minerals maintained high depositing frequency over the period of orogenic quiescence (1.8-0.8 Ga), while there are two depositional discontinuities or slowdown during the Great Oxidation Event (the GOE) and the Neoproterozoic Oxygenation Event (the NOE) in the evolution of these minerals. Our findings support that Earth's surface environment is actually a dynamic process of continuous oxidation during orogenic quiescence. These two discontinuities of mineral depositional records related to mineral phase conversion or dissolution during the GOE and/or the NOE, which revealed the quick change of the Earth's internal and external environment. The analysis results show that Mn and P minerals have similar evolutionary processes, which may help to explore the origin of Earth oxygenation, for example, whether Mn or P is the limiting element of early atmospheric oxygen level.

George Cody[7], Carnegie Institution for Science

Abstract

Data-driven approaches have been at the center of many recent scientific discoveries and have opened up new frontiers in these areas of inquiry. Most prior efforts on biosignature detection has been focused on the identification of key “smoking gun” biomolecules, such as lipids, hopanoids, and other species that are presumed to be exclusively biotic in origins. Such methods rely on teasing out a few specific analytical peaks from a noisy background.
We adopt a different and powerful new informatics approach in studying early earth and other planetary environments using data-driven methods.

In this presentation, we will go through some of the most recent and exciting discoveries made using machine learning methods we have developed. We look at our work on data-driven biosignature detection from 2 perspectives (1) where we use network science in order to characterize mineralogy of a planet, and to eventually from planetary scale biosignatures and (2) where we combine pyrolysis-gas chromatography-mass spectrometry and machine learning to build a predictive model to detect agnostic molecular biosignatures. We will also take a detailed look at how these descriptive and predictive models can used to characterize early environments through the study of highly degraded biotic samples, even when no single molecular fragment is by itself diagnostic.

[Keynote] Data-Driven Discoveries in Mineralogy

Robert M HAZEN[1]*, Carnegie Institution for Science (rhazen@ciw.edu)

Abstract

The story of Earth is a 4.5-billion-year saga of dramatic transformations, driven by physical, chemical, and biological processes. The co-evolution of life and rocks unfolded in an irreversible sequence of evolutionary stages. Each stage re-sculpted our planet's surface, while introducing new planetary processes and phenomena. This grand and intertwined tale of Earth's living and non-living spheres is coming into ever-sharper focus, thanks to advances in "mineral informatics"—a field that employs large and growing mineral data resources to tell the deep-time stories of our evolving planet. Minerals are remarkably information rich, holding dozens of trace and minor elements, scores of stable isotopes, solid and fluid inclusions, chemical zoning, twinning, exsolution, countless defects, and a host of optical, magnetic, electrical, and other properties. Every mineral specimen is a time capsule waiting to be opened—waiting to tell its story.

This lecture will explore some of the advanced data analytical and visualization methods that are shining new light on the old field of mineralogy by exploiting large and growing mineral data resources. Examples include distribution analysis, cluster analysis, association analysis, and network analysis. These approaches advance our understanding of the changing diversity and distribution of minerals through Earth history, the co-evolution of the geosphere and biosphere, new approaches to predicting critical mineral occurrences, and ways to compare Earth with other planets and moons.

Mineral informatics also points to a new approach to classifying minerals--an approach that complements the current protocols of the International Mineralogical Association. This evolutionary system of mineralogy attempts to use the information-rich attributes of minerals to arrange them according the age a process by which they form.

Abstract

Three natural tourmalines - dravite, elbaite, and schorl - were irradiated by using gamma rays. The results indicate that the far-infrared radiation performance of these tourmalines improved with different irradiation doses. Schorl exhibited the highest far-infrared radiation performance at an irradiation dose of 1500 kGy, with a total emissivity of 94.16% and a maximum emissivity of 99.11%. The structural changes of tourmaline before vs. after irradiation were studied through X-Ray Diffraction (XRD), Fourier Transform Infrared Spectroscopy (FITR), and UV-Vis-Diffuser-Reflectance (UV-Vis-DRS) technologies. The inherent dipole moment and cell volume changes of tourmaline before vs. after irradiation were calculated through X-ray single crystal diffraction refinement results and were studied per the mechanism of the effect of γ-ray irradiation on the far-infrared emission performance of tourmaline. The main factor that improves the far-infrared emission performance of tourmaline is the effect of γ-ray irradiation on the valence state of the Fe element and the consequent decrease in the band gap. However, the spontaneous polarization characteristics of tourmaline can lead to agglomeration, which reduces the specific surface areas and may result in unsatisfactory experimental outcomes.

This study aims to enhance the far-infrared radiation performance of tourmaline by using γ-ray irradiation, and investigate the mechanism behind the influence of γ-ray irradiation on the far-infrared emission performance of various types of tourmaline. Simultaneously, it introduces a promising new method to enhance the efficiency of far-infrared emitting health materials. It investigates how modifications in the composition and structure of tourmaline affect its performance, providing insights for the development of functional mineral materials containing tourmaline.

Abstract

Tourmalines have great application potential because of its natural spontaneous polarization, but there are few researches on its properties at present. In the study, the spontaneous polarization as crucial characteristic of tourmaline was focused on, and common iron-containing tourmaline was selected as the object. The total composition, end element occupancy, crystal microstructure and characteristic properties of tourmalines with different Fe content were analyzing to reveal the effect and control path among composition-microstructure-characteristic property. The results showed that for schorl, the cell volume increased with the increase of magnesium content, and the polyhedron distortion of tourmaline and the intrinsic electric dipole moment increased with the increase of Fe2+ content and iron atom in Z site; for dravite, the cell volume increased with the increase of Fe content, the structural distortion and the intrinsic electric dipole moment decreased with the increase of Fe content, and increased with the increase of Fe2+ content; for elbaite, the cell volume increased with the increase of lithium and iron content, and the polyhedron distortion and intrinsic electric dipole moment increased with the increase of Fe2+ content. By analyzing the variation trend of intrinsic electric dipole moment under the dominance of Y-end element occupancy, the configuration structure-performance relationship of tourmaline with Fe as the main factor was revealed: When the Mg/Fe ratio was less than 1, the performance of tourmaline decreased with the decrease of Fe content; when the Mg/Fe ratio was greater than 1, the performance of tourmaline increased with the decrease of Fe content. According to the results, based on the actual reported composition data of tourmaline, the optimal tourmaline configuration with the best performance were proposed.

Co-evolving N-Fe redox processes controlled iron minerals in banded iron formation

LIUQIN HUANG[1]*, China University of Geosciences, Wuhan (huanglq@cug.edu.cn)

Abstract

The early Precambrian ocean, especially during Archean to Paleoproterozoic, was characterized by low oxygen, rich reductants, and probably warm-hot temperature (>50 ℃, probably higher than 70 ℃) conditions, but irreversibly evolved into oxic and temperate conditions in the late Neoproterozoic. Although many details remain controversial about the evolutionary history of the ocean, there is no doubt that large environmental changes, especially the gradual cooling and stepwise oxygenation of the ocean, fundamentally shaped the physiochemical structure (e.g., ferruginous to stratified euxinic to oxic) of the oceans and the microbial world (e.g., thermophilic anaerobes evolving into mesophilic aerobes). Biogeochemical cycles in the Precambrian ocean responded to the co-evolution of biosphere and the physicochemical structure of the ocean, which closely link to the enigma of banded iron formations (BIFs) that primarily triggered by massive Fe(II) oxidation under anoxic-hypoxic condition for two-billon years (~3.8-1.8 Ga). The current Fe(II) oxidation models, however, rarely consider the effects of the evolution of coupled biogeochemical cycles on secular succession (shifting from magnetite to hematite) of dominant iron minerals in BIFs. Here, we investigated the evolution of coupled Fe-N redox processes under the simulated Precambrian ocean conditions, and propose a dynamic model for the origin of iron mineral succession in BIFs: During the early-mid Archean, NO2- was mainly produced by nitrification in the oceans of warm-hot temperatures (>50-60 oC), which favored the primary precipitation of Fe(II)-Fe(III) oxides (magnetite) and silicates (cronstedtite) in the early BIFs. Subsequently, the cooling and oxygenation of paleo-ocean near the GOE promoted the input of both NO2- and NO3-, resulting in co-precipitation of an increasing amount of Fe(III) minerals (goethite and lepidocrocite as precursors of hematite). This dynamic N-Fe coupling model explains the observed secular transition of iron mineral phases in BIF deposition.

[Invited] New phenomena in high-pressure chemistry, and implications for planetary interiors

Artem R. OGANOV[1]*, Skolkovo Institute of Science and Technology (a.kisil@skoltech.ru)

Abstract

High-pressure chemistry shows many surprising phenomena, such as:
1. The formation of unusual stoichiometries, e.g. Na3Cl and NaCl7 [1]. Many of such compounds possess unusual physical and chemical properties, e.g. high-temperature superconductivity (with Tc up to 253 K in (La,Y)H10 [2]) and may exist in planetary interiors (e.g., novel oxides of Mg and Si and magnesium silicates [e.g., 3,4]).
2. Much more common (compared with normal conditions) formation of electrides [e.g., 5-7], where electrons localized in interstitial voids serve as anions.
3. The destruction of molecular states (e.g., [8]) – with molecules giving way to atomic or polymeric solids or liquids. This has consequences for chemistry of giant planets Uranus and Neptune [8].
4. Stabilization of exotic oxidation states, in particular in anomalously high valence – such as Cs5+ in CsF5 [e.g., 9].
To explain these and many other chemical phenomena, we turn to electronegativities and chemical hardnesses of atoms, which are expected to depend strongly on pressure. We have extended the concept of Mulliken electronegativities to high pressure [10] – which required modification of the definition and gave a new scale. The new electronegativity is defined as minus the chemical potential of the electron in an atom relative to homogeneous electron gas at the same pressure. We have tabulated electronegativities and chemical hardnesses of all elements up to Cm (#96) at pressures up to 500 GPa, and shown that they explain many unusual chemical phenomena known at high pressure [10]. I shall also discuss our recent hypothesis [11] on the origin of oceanic water, which is based on stability of Mg2SiO5H2, probably present in the early Earth.

AI for minerals: Electron transfer rules under pressure informed by machine learning

Yanzhang LI[1]*, Peking University (yzlee@pku.edu.cn)
Hongyu Wang[2], Beihang University
Yuxuan Hu[3], Beihang University
Anhuai Lu[4], Peking University
Xiangzhi Bai[5], Beihang University
Yan Li[6], Peking University

Abstract

Electron transfer, though the most basic process in nature, is infrequently applied to high-pressure environments, such as those found deep within the Earth. In this study, we introduce a deep learning model to determine the electronegativity of 96 elements across various pressures in 0-500 GPa. Additionally, we've developed a unified formula to quantify the relationship between electronegativity, pressure, and electronic configuration. Morevoer, the electronegativity value under high pressure is obtained by our developed AI-based tool named AI4Min-PE, which can further predict work function, bond energy, formation energy, and chemical affinity of compounds with any given chemical formula. AI4Min-PE can serve as a handy AI-based tool in geoscience and help researchers get insight into basic rules about the interaction of materials in the deep Earth before time-consuming calculations and difficult-to-operate experiments. By analyzing the relative work function of minerals, we observe a decreasing trend with increasing pressure due to pressure-induced electron delocalization. Using the work function as a proxy, we find that the force driving directional electron transfer is enhanced by the increasing work function difference between compounds under pressure. This finding provides a plausible explanation for the observed high-conductivity anomalies and sheds light on the redox reactivity between widespread Fe(II)-bearing minerals and water during subduction. Our results offer valuable insights into the fundamental physicochemical properties of elements and their compounds under pressure.

Endolithic microbes catalyze aragonite dolomitization

Geng WU[1]*, China University of Geosciences (wugeng@cug.edu.cn)
Deng LIU[2], China University of Geosciences
Hongchen JIANG[3], China University of Geosciences

Abstract

Dolomite, a calcium-magnesium carbonate mineral, exhibits prevalence in Archean and Proterozoic marine microbialites but has exhibited rarity during the Phanerozoic, perplexing geologists for over a century. Kim et al. (2023) elucidated the crystal growth of dolomite under ambient conditions, drawing upon laboratory experiments and theoretical simulations within a crystal growth framework. Despite extensive study, the mechanisms governing dolomitization in Earth's surface conditions remain inadequately understood, with a dearth of evidence illustrating the evolution of microbially mediated mineral phases into the ordered dolomite observed in the geological record. This investigation focuses on terrestrial geothermal travertine in western Tibet, wherein endolithic microbes have colonized the substrate. Through the application of LA-ICP-MS, SEM-EDS, and FIB-TEM technologies, the presence of ordered dolomite in the endolithic colonization zone of aragonite travertine is confirmed. The outcomes of mineralogical, microbial ecological, and geochemical analyses suggest that endolithic microbes play a catalytic role in aragonite dolomitization within terrestrial geothermal travertine. The involvement of endolithic microbes in the dolomite formation observed in this study signifies a potential biosignature. The identified microbial participation in the formation of ordered dolomite in the current investigation not only contributes substantively to our understanding of terrestrial geothermal areas but also holds implications for recognizing past and present biosignatures, particularly in subsurface regions on Mars. This is particularly relevant within Mars' locales exhibiting geothermal travertine, emphasizing the importance of our findings in advancing the identification of biosignatures on the Martian surface.

Advent of different Iron mineral corresponding to the Eh evolving of Precambrian sea water

Yuanfeng CAI[1]*, Nanjing University (caiyf@nju.edu.cn)
Zhou Fang[2], Nanjing University
Siyi Huang[3], Nanjing University

Abstract

The Eh evolving during the later Archean and Early Paleoproterozoic could be recorded and retrospected by the mineral species. Banded iron formation (BIF) was considered as most typical representatives of changing of Eh of Precambrian sea water which now was thought of a potential example of co-evolving with microbes. Known iron minerals include magnetite, hematite, goethite, lepidocrocite, siderite, ankerite etc. These iron minerals were constituted by different valence of iron, and can be used to indicate different degree of Ehs. With the increase of Ehs, iron minerals might follow in the order of siderite and ankerite, magnetite, glauconite, goethite or lepidocrocite, hematite. Different iron oxide assemblages were found in BIF with different age of formation. For example, Magnetite-martite-specularite assemblages was found in BIF outcropped in Koolyanobbing and Marda greenstone belt with the formation age ca.2.8-2.6 Ga. Martite-microplaty hematite assemblages was found in Mt. Whaleback, Mt. Tom Price and Paraburdoo deposit with the formation age younger than ca.2.2 Ga (Hagemann et al., 2016). In general, magnetite and hematite was the major iron oxide in Archean and Paleoproterozoic BIF, respectively. BIFs present in the Badampahar greenstone belt (3.3–3.1 Ga), East Indian Shield had distinctly negative Ce anomalies which might indicate Fe2+ oxidation in an oxygenated hydrosphere and derivation of free oxygen from microbial photosynthesis (Ghosh and Baidya, 2017). The precipitation of iron formation recorded directly the Eh condition of local seawater and thus useful to restore the paleoenvironmental information. In summary, it is important to explore the first advent of iron minerals one by one and evaluate its forming Eh according to published data in literature.

A preliminary study on the evolution and ecology of arsenic minerals

Minghao TANG[1]*, tianjin university (2021231017@tju.edu.cn)
Xiangyu Zhu[2], tianjin university
Hui henry Teng[3], tianjin university

Abstract

Various information pertaining the evolution of the Earth can be recorded by minerals through their structural characteristics and chemical compositions, such as valence state, isotope composition, and trace element concentration. This recorded information contributes to the discovery of many major geological events. However, the traditional way of leveraging mineral information is low dimensional and always neglects the relevance of multiple data and their dynamic change through deep time, and thus could not be satisfied with the fact that massive and multidimensional mineral data are emerging. Fortunately, not long ago, Hazen introduced the ideal of “mineral evolution and ecology”, which focused on the diversity and distribution of mineral assemblages and stressed their evolutional behavior over time due to a range of physical, chemical, and biological processes. Propped up by such a concept, combined with big data analytics and its relevant technological means, mineral diversity can be used as a carrier to integrate vast and multidimensional mineral information through deep time. Arsenic has a low abundance in the earth system, but approximately 770 arsenic minerals have been recorded to date, indicating that arsenic minerals may be a potential proxy for changing environmental conditions. Moreover, arsenic pollution in essence is the evolution of arsenic minerals that entails the dissolution of primary minerals and formation of secondary As-bearing phases. In the present work, we investigate the evolution of arsenic minerals through deep time, predict the most probable sites for discovering new arsenic minerals, and estimate the number of arsenic mineral species that may currently exist in the Earth’s crust on the basis of existing arsenic mineral locality data. The results reveal that the diversification of geochemical conditions and activation of arsenic associated with supercontinent collisions and the great oxygenation events (GOE) confer the geological environment the ability to innovate arsenic minerals. The arsenic mineral distribution data reveal that most arsenic minerals are rare and are only concentrated in a few mines. This phenomenon can be attributed not only to past hydrothermal events that led to the formation of various arsenic minerals but also to the fact that these mines often contain rare elements or possess unique geochemical conditions. As such, these locales present an abundance of arsenic minerals as well as promising opportunities for discovering new ones.

Abstract

The Paleoproterozoic Era was a critical geological interval involving redox evolution of Earth's oceans and rapid production of banded iron formations (BIF). However, little is still known about the dynamic input and output of Fe in response to oceanic physicochemical evolution. One key variable is the BIF alternating layers that record the fluctuating oceanic physicochemical conditions. Here, we performed analyses of Fe isotopes and Fe-bearing species on samples from the Kuruman BIF ores in South Africa and presented an outline of compositional and textural evolution for BIF alternating layers. The resulting data suggest that these samples feature alternating layers due to varying ratios of goethite to hematite/magnetite. The goethite is interpreted as a secondary phase as a result of weathering of pre-existing Fe oxides. Most yellow goethite-rich layers are characterized by negative δ56Fe values, but grey hematite/magnetite-rich layers by positive δ56Fe values. Such isotopic fractionation is expected to involve the preferential precipitation of heavy Fe isotopes, which would make seawater enriched in light Fe isotopes for precipitation of Fe oxides with negative δ56Fe values. The rhythmic compositional and textural variations within BIF ores might be attributed to pulsed input of Fe into the oceans, but more likely resulted from episodic loss of Fe compositions through oxidation from upper photic zones in closed ocean systems.

Mineralogical phases and redox evolution of manganese in Precambrian manganese deposit: Implications for diagenesis

Huan LIU[1]*, Nanjing University (liuhuan@nju.edu.cn)
Xiangjie Cui[2], Nanjing University
Yuanfeng Cai[3], Nanjing University
Xiancai Lu[4], Nanjing University

Abstract

Precambrian manganese (Mn) deposits that occur in south China are closely related to the environmental change between the Sturtian and Marinoan glaciations. The formation of manganese deposits is generally related to a high concentration of oxygen in Earth's surface environments, revealing the evolution of Mn-bearing mineral phases which may be related to the microbial function. However, to our knowledge, the redox evolution of manganese and the metallogenic mechanism are still in debate. In this study, mineralogical observations were conducted for the Datangpo-type manganese deposit, which is located in Tongren, Guizhou Province. Mineralogical compositions were identified by using X-ray diffraction and Raman analyses. Synchrotron-based μ-XRF and X-ray absorption spectroscopic analyses coupled to electron microscopy were used to investigate the oxidation states and mineral phases, demonstrating that Mn exists in the carbonate phases, including kutnohorite and rhodochrosite. Elemental maps of Mn, Fe, Ca, and Mg indicated an evolution route as dolomite, kutnohorite, and then Fe-bearing rhodochrosite. The increase in Fe contents indicated a late stage of microbial Fe reduction after Mn. The Mn-bearing carbonates could be derived from the reduction of Mn oxides during the diagenesis process. A metallogenesis model was proposed that microbial activities could play key roles in mediating the reduction of oxidized manganese species, coupling with the oxidation of organic matter. These mineralogical observations provide new insights into the redox evolution of manganese oxidation states and Mn-bearing mineral phases in ancient sediments.

Photoinduced ring-opening of native sulfur in driving synthesis of prebiotic building blocks

Huan YE[1]*, Peking university (yehuan1998@126.com)
Yanzhang Li[2], Peking university
Rongzhang Yin[3], Peking university
Zhaoyang Hu[4], Peking university
Yan Li[5], Peking university
Anhuai Lu[6], Peking university

Abstract

Native sulfur (denoted as S0) has been regarded as the crucial species in the biogeochemical cycle of sulfur, and the opening of its eight-membered rings is critical to its activation. By combining optical measurements, theoretical calculations, and photochemical experiments, we investigate the external (incident optical energy) and internal factors (impurity elements) that trigger the opening of S0 ring. Synchrotron radiation in situ X-ray absorption near edge spectra confirms that S0 can undergo ring-opening reactions under light irradiation below ~575 nm, which results from electron transition via indirect bandgap. Density functional theory calculations and ab initio nonadiabatic molecular dynamics reveal that photo-assisted electron transition evokes ring opening in the femtosecond scale, resulting in a new chain-like molecular configuration with changed charge density and electronic structure. Compared with the ring-like structure, the ring cleavage can provide two unpaired electrons on the terminal S atoms as reactive sites, and induce the thermodynamic spontaneous for reducing CO2 to HCOOH.

In the field of impurity elements, we find the room-temperature bandgap of four S0 samples with different substituting concentrations (mainly As and Se, up to 282.0 and 19.3 μg/g, respectively) decreases linearly with the increase of doping amount. It confirms that As and Se can add 4p orbitals into the S 3p-dominated valence and conduction band of S0, thus reducing the energy required for electron transition and promoting the ring-opening reaction. With the increasing of As content, S0 sample with high concentrations of As would produce much less HCOOH from carbonates compared with the few-As sample, attributed to the new three bonds of As with only one active unpaired electron left after ring opening. This research contributes to the excited state of native sulfur under the induction of light energy and can catalyze the efficient synthesis of substances such as inorganic carbon to organic carbon, which provides a new way for the gentle synthesis and accumulation of basic small organic molecules in the abiogenesis.

(Withdrawn) The co-evolution of Earth and life: biosignatures in Earth's mineral networks

Shaunna MORRISON[1]*, Carnegie Institution for Science (smorrison@ciw.edu)
Anirudh Prabhu[2], Carnegie Institution for Science
Robert Hazen[3], Carnegie Institution for Science
Michael Wong[4], Carnegie Institution for Science
Ahmed Eleish[5], Carnegie Institution for Science

Abstract

Determining the habitability of planets remains a fundamental question in science and society. In this study, we harness network theory to explore the unique patterns exhibited by minerals and their mineralizing environments in both biotic and abiotic contexts throughout the evolution of Earth and other terrestrial bodies in our solar system [1-. By examining mineralogical networks across diverse planetary systems, including early solar system bodies, the early Hadean Earth (closely related to modern-day Mars), plate tectonics, and modern Earth, we gain valuable insights into Earth's history and the factors that have shaped the development and sustainability of life. Our investigation reveals distinct characteristics within biotic networks, setting them apart from their abiotic counterparts.

Figure 1. A network representation of the relationships between all known mineral species and their modes of formation in our solar system. Brown nodes represent mineral species. Colored nodes represent paragenetic modes (modes of mineralization). Links demonstrate that a mineral is known to form in the linked paragenetic mode.

This research significantly advances our understanding of the intricate interplay between Earth and life. Network analysis offers deeper insights into the connections between minerals and living systems, providing invaluable perspectives on the emergence and co-evolution of life on our planet. Moreover, our findings contribute to identifying and characterizing planetary biosignatures, essential for the search for extraterrestrial life. Recognizing these unique patterns within biotic networks lays the groundwork for developing targeted exploration strategies for detecting potential biosignatures and interpreting the complexities of planetary environments.

Our innovative network analysis of minerals and mineralizing environments sheds new light on the relationships between Earth and life. By delving into the intricate connections within biotic and abiotic systems, we deepen our understanding of Earth's dynamic history and enhance our knowledge of potential habitats for life beyond our planet.

Phyllosilicates-based nanozymatic microsystems and their significance in geological processes

Shiyong SUN[1]*, Southwest University of Science and Technology (shiysun@163.com)
Ke WANG[2], Southwest University of Science and Technology

Abstract

Enzymes are a group of biological macromolecules, generally referred to as proteins with high catalytic activity, selectivity and specificity. In living organisms, enzymes act as extremely effective catalysts for thousands of specific reactions in the metabolic processes that sustain life. However, the application of enzymes is often hampered owing to their lack of stability in organic solvents and at high temperatures. In addition, the recovery and reuse of enzymes are difficult in a liquid system. Enzyme immobilization is an efficient route to solve these problems, thereby permitting the catalysis under harsh reaction conditions at an industrial scale. The nanobiocatalyst is an emerging innovation that synergistically integrates advanced nanotechnology with biotechnology for improving enzyme activity, stability, capability and engineering performances. Recently, the construction of phyllosilicates-based nanozymatic microsystems by immobilizing enzymes on phyllosilicates has attracted widespread attention, as phyllosilicates have advantages such as natural nanoscale, swelling lamellar nanostructure, exchangeable interlayer cations, high specific surface area, biocompatibility and easy surface functionalization.

In our recent work, phyllosilicates (i.e. montmorillonite, halloysite, nontronite) as enzyme immobilization support, constructing a series of phyllosilicates-based nanozymatic microsystems based on different immobilization strategies. The effects of the nanostructures of phyllosilicates and their interfacial reactivity on the adsorption kinetics, adsorption capacity, enzyme orientation, and conformation of enzymes at the surface and interface were explored. Besides, the methods of mineralogy such as directional structural modification and surface functionalization on the microstructure of phyllosilicates/enzymes complex structure on its catalytic performance was also studied. The results indicates that the phyllosilicates-based nanozymatic microsystems showed enhanced enzymatic activity, better catalytic stability, reusability and storage stability than free enzymes. Our work has provided a promising way for screening, optimizing and rational design of efficient phyllosilicates-based nanozymatic microsystems.

Abstract: Organic minerals are crystalline substaneces with C—C, C—H and/or C—N bonds formed from geological processes in nature, specfically including natural crystalline organic compounds, salts of organic acids and metal-organic complexes. According to the current mineral list of the International Mineral Association (IMA) update to November 2023, there are 83 organic minerals (81 approved) in 407 localities, including 50 organic acid salts in 272 localities, 13 hydrocarbons in 44 localities, and 20 miscellaneous organic minerals in 91 localities. Organic minerals are classified into twenty-two types according to the types of organic groups, among which oxalate (35) arene (12), glycolate (4), uric acid (4) and acetate (3) are the most abundant. The organic minerals may be crystallized in all seven crystal systems with monoclinic (42), orthorhombic (17) and triclinic (9) being the dominant. Depending on the linkage among organic anion groups and metal polyhedra through covalent and ionic bonds, organic minerals can be structurally classified as types of isolated molecules (34 minerals), chain (16 minerals), layer (14 minerals) and framework (18 minerals). Genetically, organic minerals may be formed with relations to guano substance (21), taphonomic and petrified organic materials (6), coal or oilfields (21), or as supergene minerals (27) in various host rocks in metal mines, as well as in caves (4), marine sediments (2) and Antarctic area (2).

Mineralogical Differences of Ooids and Evolution of Water Environment in Xuanlong-type Iron Ore.

Ganyu TANG[1]*, School of Earth and Space Sciences, Peking University
(2101110630@pku.edu.cn)
Yong LAI[2], School of Earth and Space Sciences, Peking University
Ziyi ZHUANG[3], School of Earth and Space Sciences, Peking University
Sai CHEN[4], School of Earth and Space Sciences, Peking University

Abstract

Xuanlong-type iron ore was the most important type of sedimentary iron ore in North China and has played a crucial role in China's mining and industrial development. In order to further explore the mineralogical differences of Fe-ooids in Xuanlong type iron ore and the changes in water environment during the evolutionary processes, this study collected samples of Xuanlong-type hematite from the Chuanlinggou Formation of the North China Block. Through observation and analysis under the optical microscopy and Environmental Scanning Electron Microscopy (ESEM), the oolitic hematite was divided into seven types according to three aspects: main mineral composition, core minerals of ooid formation, and degree of recrystallization. The various types of oolites exhibited differences in the evolutionary process, including environmental phases of oolitic formation, diagenesis and later-stage reworking processes. Through X-ray diffraction (XRD) analysis, it was found that samples from different layers had similar mineral compositions, such as quartz, hematite, siderite, reflecting the stability of the environment during the period of orogenic quiescence. The main valence states of the variable valence elements Fe and Mn in samples at different layers were determined through X-ray absorption spectroscopy (XAS) analysis, where Fe mainly exists in the form of Fe(III), and Mn mainly exists in the form of Mn(II). It suggested that the gradual increase in environmental reducibility during the transgression. The Energy Dispersive Spectroscopy (EDS) and Tescan Integrated Mineral Analyzer (TIMA) data showed the precise distribution pattern of elements up to the ooid layer. Incomplete and thin chamosite layers alternated between fine hematite layers, which demonstrating the oscillatory evolutionary process of the ooid forming water environment in a relative equilibrium system. Based on evidence such as microbial mats, the discovery of primary self-formed apatite in the oolitic hematite deposit for the first time indicated the P-rich environmental phase after microbial involvement in mineralization. The mineral phase coexisting with siderite and apatite limited the composition and state of the ancient water environment. The evolutionary environment of Xuanlong-type iron ore was influenced by the superposition of two opposing factors, namely the transgressive sequence and the increase in oxygen fugacity, which is the result of the interplay between physical and chemical equilibrium and microbial involvement.

Abstract

Building paleogeographic maps that are projected onto different tectonic plate reconstruction models requires team efforts to compile extensive interlinked databases of regional sedimentary and volcanic facies, data sharing standards, and computer projection methods. Two goals of the Deep-Time Digital Earth (DDE) program of the International Union of Geological Sciences (IUGS) Paleogeography Working Group are: (1) to interconnect online national databases for all geologic formations, and to compile these online "lexicons" for countries that currently lack these; (2) to project the combined paleogeographic output of these distributed databases for any time interval onto appropriate plate tectonic reconstructions.

Therefore, we have worked with regional experts to compile and interlink cloud-based lexicons for different regions of the world that are enhanced by graphic user-interfaces. Online lexicons with map-based and stratigraphic-column navigation are currently completed for the Indian Plate (ca. 800 formations), China (ca. 3200), Vietnam-Thailand-Malaysia (ca. 600), and all major basins in Africa (ca. 700) and in the Middle East (ca. 700 formations). These will soon be joined by Japan (ca. 600 formations) and basins in South America (ca. 700 formations). A multi-database search system (age, region, lithology keywords, etc.) enables all returned entries be displayed by-age or in alphabetical order. The genera in the "fossil" field are auto-linked to their entries and images in the online Treatise of Invertebrate Paleontology. With a single click, a user can plot the original extent of the geologic formation (or an array of regional formations of a specified age) onto different plate reconstruction models with the polygon(s) filled with the appropriate lithologic facies pattern(s). Our team collaborated with the Macrostrat team at Univ. Wisconsin (Madison) to interlink with their extensive regional facies-time compilations for North America and the ocean basins to enable a near-global coverage. Following the lead of Macrostrat's ROCKD

app, this project is in partnership with UNESCO's Commission for the Geologic Map of the World and other geological surveys to enable linking online geologic map units for direct access to the lexicon details on that geologic formation and its former paleogeographic setting. Essentially, goal is to create a view of the sediments and volcanics that were accumulating onto the Earth's surface at any time in the past.
The main website (https://geolex.org) has links to the growing array of regional lexicons.

Abstract

The global, public, and geoscience community has a need for easily visualizing and exploring relationships between geological events throughout Earth's history. TimeScale Creator, a free JAVA package, enables you to explore and create charts of any portion of the geologic time scale from an extensive suite of global and regional events in Earth History. The internal database suite encompasses over 20,000 biologic, geomagnetic, sea-level, stable isotope, and other events. Users can append external data packs ranging from British Isles geology to microfossil ranges with images to create charts with regional information that's not provided in the internal dataset. All datasets are calibrated to the age models of Geologic Timescale 2020 (Gradstein et al., 2020, Elsevier)

Some of the functions of the TimeScale Creator Java version include popup windows displaying details on events, adjusting the display format of columns, saving the generated chart in PDF or SVG, map interfaces for regional datasets that also includes a slider to display facies-with-time in that region, search-and-display, depth-age cross-plots and simple data-mining.

In order to increase the public accessibility of TimeScale Creator, TSC Online brings it to the internet via the cloud. TSC Online enables anyone with a browser to use the functionalities of TimeScale Creator. The current TSC Online (Feb, 2024) has all the basic functions and it will be progressively enhanced until it has all the capabilities of the TimeScale Creator.

Anqing CHEN[3], Chengdu University of Technology

Abstract

With the rapid development and increasingly widespread application of machine learning (ML) technologies, their contribution to enhancing the efficiency, accuracy, and automation level of target tasks across various fields are undeniable. However, as we enjoy the conveniences brought by ML, the issue of its internal operating mechanisms being opaque, often referred to as the "black box" problem, has gradually come to the fore. In recent years, an increasing number of researchers have recognized this issue and, as a result, have proposed numerous explainable machine learning (EML) methods. Among these, Shapley Additive Explanations (SHAP), an advanced interpretability tool, visualizes the decision-making process of models by quantifying the contribution of each feature to the target based on the game-theoretic Shapley values. Due to the advantages of SHAP in universality and flexibility, it has been widely applied to the explanation of different tasks (such as regression and classification) and a variety of ML models. Building on this, our research aims to visualize and analyze the decision-making process of Convolutional Neural Networks (CNN) for seismic sedimentary facies classification and the prediction process of Extreme Gradient Boosting Decision Trees (XGBoost) for well-log curve regression through the SHAP tool: (1) For the task of classifying seismic sedimentary facies, we presented the distribution of SHAP values for two-dimensional images, created by stitching together various seismic attributes, in the form of heatmaps. These distributions of SHAP values illustrate the level of contribution of each attribute within the CNN model towards the target sedimentary facies. Based on the importance ranking of these seismic attributes formed by their contribution levels, we trained and obtained an improved CNN model after removing irrelevant attributes. The results indicate that the SHAP-enhanced CNN model has a higher classification accuracy compared to the original CNN model. (2) For the regression task of well-log curve prediction, by calculating the SHAP values of each feature in the XGBoost model, we obtained the importance ranking of various well-log parameters regarding shear-wave velocity (Vs) and the specific contribution of each parameter to a certain predicted value of Vs. The prediction of Vs, provided through the form of addition and subtraction of SHAP values, not only to a certain extent delineates the nonlinear relationships among various geophysical parameters in the actual subsurface but also further reveals the relationships between these parameters and Vs that are distinct from general statistical norms (e.g., Pearson correlation coefficient).

The application of the SHAP tool, based on EML, in sedimentary facies classification and well-log curve prediction has revealed how ML models depend on different features for their respective tasks. This not only increases the transparency of the model decision-making process but also provides valuable insights for further model optimization. In this way, SHAP offers an effective

tool for addressing the "black box" problem in ML, contributing to the advancement and broader application of ML technologies in more fields.

Abstract

The geometric properties of the Earth's magnetic field and its capture in the rock record make possible to track the position of ancestral continents and oceans, and therefore to study the history and the dynamics of plates from the Precambrian to the Present. However, too few well-constrained paleomagnetic data are available for Precambrian rocks, making it difficult to generate a rigorous model for the ancient Earth. In addition, some continental blocks (Kaapvaal, Zimbabwe, West Africa, East Antarctica, South China, Tarim, Amazonia) are almost devoid of any paleomagnetic data, yet they are commonly represented in Nuna (Columbia) reconstructions.
Among the tools available for plate reconstructions, fossils and stratigraphic series are utilized to establish the extent of orogens through time, thereby documenting the zones of deformation related to the collision of crustal blocks. In addition, reconstructions can also use the evolutionary record inherent to oceanic crust, at least during the Phanerozoic. This project is part of IGCP 667 “World Map of Orogens (WMO)”, in which the main objective is to construct a map at a scale of 1:35 000 000 documenting the distribution of ancient to modern orogens and associated markers throughout Earth history. Such a compilation requires careful consideration of both the various types of global-scale compressional tectonic regimes and the best means of portraying the associated tectonic elements or attributes on a map. Consideration of pre-plate tectonic (ca. 2.5 Gyr ago), early Earth crustal deformation processes and features also becomes necessary.
Our objective is to overlay the WMO on established reconstructions (e.g. GPlates, PaleoMap) and document misfits, regardless of whether these are derived from assumptions associated with the reconstruction(s), or due to the lack of geological data. Therefore, we anticipate our map will help

refine reconstructions particularly for the Precambrian or for continental blocks such as those in Africa where paleogeographic data are scarce. The WMO allows us to better visualize misfits between paleogeographic reconstructions and deformation as observed directly in orogens through geological observations. Conversely, paleogeographic reconstructions may also help us to reconsider areas where geological observations could be dated more accurately and/or reassessed.

Abstract

The north Australian part of the McArthur-Yanliao Gulf is a vast frontier exploration province for basin-hosted resources, both hydrocarbons (oil and natural gas) and metals (critical metals [e.g. rare earth elements, Co], Cu, Pb, Zn and Au). This basin system covers much of northern Australia and extends as the Yanliao Basin across much of North China, which lay off northern Australia when the basin formed—ca. 1820–1325 Ma. Hydrocarbon and metal deposits in the basin are largely controlled by host sediment composition and ‘redox traps’ related to ancient water chemistry, which, in-turn, are modulated by biological activity, tectonism and relative sea level change. None of these controls are fully understood or constrained throughout the basin.

In order to better understand the basin evolution we follow a number of approaches, including:

1. Developing new techniques to date shales, rapidly and economically, to assist with intra-basinal correlation, thermal and hydrothermal overprint history, and to help build a basin chronostratigraphic framework.

Innovations in laser mass spectrometry have been used to date shales and carbonates from the

McArthur Basin and triage the resulting data to separate ages interpreted as dating deposition or early diagenesis, from those reflecting later hydrothermal overprints. These are coupled with campaign-style detrital mineral geochronology and targeted high-precision U–Pb thermal ionisation mass spectrometry to build a basin chronostratigraphy.

2. Chracterizing the source areas for the basin system through detrital petrochronology and shale geochemistry.

Detrital minerals (zircon, rutile, muscovite) from the main ‘packages’ in the greater McArthur Basin have been dated and their trace element compositions determined to build a spatial and temporal database of source material that has been interpreted based on the tectonic evolution of the basement terranes around the greater McArthur Basin during the amalgamation of the Australian continents within Nuna/Columbia.

3. Investigating the ancient basin water chemistry through chemical proxies that relate to bio-productivity, salinity/restriction, and redox—temporally and spatially.

Proterozoic basin waters were extremely heterogeneous in dissolved oxygen. We are developing and building basin-wide elemental (e.g. U, V, Cu, Co, Mo, Fe, organic geochemistry) and isotopic (Cr, Cd) proxies for the reconstruction of paleoredox and paleobioproductivity conditions at different sites in the ambient water columns. These will be coupled with elemental and isotopic proxies for restriction/salinity (including coupled 87Sr/86Sr and 88Sr/86Sr datasets from carbonates) and proxies for biological activity (e.g. Cr/Cd, as well as C and N isotopes). These are being interpreted in a sequence stratigraphic framework to understand the dynamics between basin water chemistry, tectonics and basin water level variations.

4. Building a reconstruction of the basin, and of the tectonic geography of the basin and its environs through the ca. 1.8–1.32 Ga history of its existence. This has been facilitated by constructing a full-plate tectonic reconstruction for the Proterozoic.

Here we present a full-plate tectonic reconstruction from 1.8 Ga to present, focussed on the region of the Australian continental lithosphere. The greater McArthur Basin is considered as part of the McArthur-Yanliao Gulf of Nuna/Columbia and the nature of the basin will be addressed at different times/places.

[Keynote] A dynamic evolution of Earth history over the past two billion year

Zheng-Xiang Li[1]*, Curtin University (z.li@curtin.edu.au)
Yebo Liu[2], Earth Dynamics Research Group, Curtin University, Australia

Abstract

Earth's evolution since 2 Ga has been dominated by the cyclic occurrence of three successive supercontinents Nuna (1600–1300 Ma), Rodinia (900–720 Ma), and Pangea (320–170 Ma) and related geodynamic, atmospheric and biological events. This occurred after a billion years of early plate tectonics dominated by continental and cratonic growth, and smaller-scale mantle convection. The start-up of the supercontinent cycle led to the beginning of stable hemisphere-scale (long-wavelength) degree-1 and degree-2 mantle structures. Through the recognition of geodynamicly-defined type-1 and type-2 inertia interchange true polar wander (IITPW) events during the past three supercontinent cycles, together with LLSVP-related global mantle plume events, we are able to hypothesize an evolution history of first-order global mantle structure over the past 2 billion years and establish possible paleolongitudes of continents and supercontinents back to ca. 2 Ga. We argue that Nuna assembled at about the same longitude as the latest supercontinent Pangea over a degree-2 mantle structure that started to exist from ca. 1700 Ma; Rodinia formed through introversion over the legacy Nuna subduction girdle either ca. 90° to the west (a preferred model) or to the east of Nuna's longitude before the migrated subduction girdle surrounding it generated its own degree-2 mantle structure by ca. 800–780 Ma; Pangea assembled through extroversion over the legacy Rodinian mantle structure by closing a long-lived superocean, with the present-day degree-2 mantle structure (including the two antipodal Pacific and African LLSVPs) only started to exist not long before 250 Ma. Recent geodynamic modeling work by the Curtin team further predicts that the future supercontinent (Amasia) could only form through extroversion, i.e., by the closure of the Pacific Ocean — residual of the Panthalassa Superocean.

Abstract

The ‘Cambrian Explosion’ is one of the most important biological events in Earth’s history, and the Ediacaran–Cambrian transition remains one of the most fundamental and enduring research frontiers in Earth science. Plate tectonics has been linked to early animal evolution, though exactly how it may have contributed has remained difficult to establish. Development of a robust tectonic model for the Ediacaran–Cambrian interval (635–485 Ma) is fundamental to resolving how positions and movements of continental plates impacted the first animals and their ecosystems. Global tectonic plate reconstructions are generally underpinned by base models built with palaeomagnetic data. However, Ediacaran–early Cambrian palaeomagnetic data are challenging to interpret, and difficulties reconciling relative plate positions have resulted in a wide variety of differing models for this interval. The Ediacaran and Cambrian both have unratified stage boundaries, hence temporal resolution for this interval also remains relatively poor. For end-users—particularly those interested in scrutinising palaeobiological or palaeobiogeographic patterns—applying these tectonic models becomes a process fraught with uncertainty, with impacts on scientific outcomes that are difficult to quantify.

Comprehensive assessment of other proxies used for plate tectonic reconstructions in the Ediacaran–Cambrian is therefore essential. This is particularly important in the context of leveraging the fossil and sedimentary rock record to compare and evaluate the viability of pre-existing models, mindful of pitfalls associated with circular logic that may confound their application down the line (e.g. testing of fossil distributions with models built with fossil assemblage patterns). Databases such as the Palaeobiology Database (PBDB), and Geobiodiversity Database are essential for generating the statistical power necessary to address fundamental issues both at the model-development and at the model-application stages. How these data are collated, curated, cleaned and distributed is therefore of great importance, and must

follow the FAIR (findable, accessible, interoperable, reusable) and Open Science principles. This work will review the challenges for Ediacaran–Cambrian tectonic models, the mayhem caused by low resolution or difficult to interpret data, and explore pathways toward how best to reconstruct the Ediacaran–Cambrian world.

Abstract

Providing information on the palaeobathymetric evolution of sedimentary basins is essential to propose reliable paleogeographic models of rift systems prior to the onset of oceanic accretion. Constraining palaeobathymetries can however be quite challenging and trigger debates, notably in the case of salt deposition during continental breakup.

Here we investigate the palaeobathymetric evolution of the conjugate Nova Scotian and Moroccan rifted margin during the early stages of the opening of the Central Atlantic Ocean. Breakup of Pangea during the Triassic and Early Jurassic generated a series of rift basins filled by continental deposits passing up-section into evaporites and carbonates. Although first order plate motions are understood, the segmentation of salt basins and tectonic context of salt deposition (pre- or syn-kinematic) prior to the opening of the Central Atlantic remains to be constrained.

We use a flexural backstripping technique, which incorporates decompaction and post-breakup reverse thermal subsidence modelling to predict the palaeobathymetry and palaeostructure through the Jurassic down to the Late Triassic base salt. Quantitative analyses of seismic reflection and gravity anomaly data have also been used to determine crustal thickness variations and along strike variability in breakup related magmatism in the ocean-continent-transition, both controlling the isostatic response.

The palaeobathymetry of base salt determined from reverse post-breakup subsidence modelling exceeds 2 km in the distal parts of the rifted margins where the continental crust is highly thinned (<10km). In contrast in proximal domains where the continental crust was only slightly thinned during rifting, the base salt horizon restores near sea level at breakup time. Our interpretation of this difference is that while the proximal salt underwent post-rift thermal subsidence only, the distal salt was deposited during the latest stage of rifting and underwent tectonic subsidence from crustal thinning in addition to post-rift thermal subsidence. A period of basin isolation most likely occurred during the latest Triassic to Middle Jurassic in the early stage of the Central Atlantic opening, however, this does not seem to be the main parameter controlling the basin bathymetry during salt deposition. Integrating these results into larger scale paleogeographic models enables us to show how the Late Triassic to Early Jurassic salt basins connected and evolved into open

marine conditions in the Middle to Late Jurassic in relation with the opening of the Central Atlantic and Western Tethys.

Abstract

The greater McArthur Basin covers much of the Northern Territory, Australia, and comprises multiple stacked siliciclastic and carbonate sedimentary sequences of Proterozoic age. Despite being labelled as 'the boring billion' due to the perceived stability of Earth systems, this period actually exhibits significant and geochemically traceable fluctuations in water chemistry. These rocks are also of interest for research purposes due to their hosting of economically significant hydrocarbon and mineral resources.

The Batten Fault Zone within the McArthur Basin is a broad structurally complex corridor with structural depocenters and sub-basins. This study uses litho-stratigraphy, geochronology, and sedimentary geochemistry over four of these sub-basins to correlate depositional sequences and highlight post-depositional alteration characteristics. Shale and carbonate geochemical data collected for this project focuses on the middle McArthur Group (ca. 1650-1630 Ma) stratigraphy, aiming to fill gaps in literature surrounding Earth systems and tectonic processes during this time of little preservation of life and productivity.

These rocks in the middle McArthur Group have predominantly been deposited under deep subtidal to slope conditions, and the combination of carbonate and siliciclastic samples sequence has produced Total Organic Carbon (TOC), δ13Corg, and δ13Ccarb profiles for sub-basins in the central and northern Batten Fault Zone. Notable trends observed in these profiles, such as the ~+2.0 ‰ δ13Ccarb excursion transitioning from the Barney Creek Formation into the overlying Reward Dolostone, are valuable tools for local and regional stratigraphic correlation. Major and trace element data further enhance correlations between sub-basins while revealing geochemical changes associated with redox conditions, alteration processes, and paleoenvironmental factors during and after deposition. The combined data set provides a solid framework for the sedimentological, environmental, hydrological, and structural evolution of each sub-basin, which, in the scope of the "mineral systems framework" can then be used to examine models for Pb-Zn-Ag ore mineral formation processes in the McArthur Basin.

Haipeng Li[5], Deep-time Digital Earth Research Center of Excellence (Zhejiang), Hangzhou, China

Abstract

The ability to reconstruct the geologic evolution of the Earth as a system including the geosphere, atmosphere and biosphere interactions, is essential to understand the fate of our environment in the context of the Climate, Life and Energy crises of the new Anthropocene era. Scientists of tomorrow working on environmental changes require ever more detailed databases and maps to access and correlate the overwhelming mass of information stemming from the ongoing surge of environmental data and models. Earth System reconstructions are fundamental assets to assess potential sources and locations of key geo-resources that are now vital for the energy transition (e.g. raw materials, rare earth elements, subsurface storage, geothermal sites). Earth System reconstructions are also the best means to communicate past and future Life and Environmental evolutions, while providing consciousness of our role and situation in the immensity of Time and Nature. They convey these essential lessons in a didactic fashion for teachers and students, museums, or for governments and NGOs to make decisions and promote public awareness. Although Earth System reconstructions have long been recognized as essential, they have yet to deliver their full breakthrough potential combining various booming disciplines. A number of software programs and computer algorithms have been developed in the past three decades to reconstruct either the past positions of continents and oceans or their elevation and depth. The next step is to develop a comprehensive and integrated solution easily accessible on the web that can automate most of the steps involved in reconstructing past plate configurations and topography. We present here a web application that we are developing for the creation of digital paleogeographic maps. As part of a large project over Asia, we review here the case of the intensely studied, yet still extremely controversial India-Asia collision with major implications on regional environmental, depositional and global climate transitions. Ongoing debates argue for radically different end-member models of the collision timing and its configuration, and of associated topographic growth in the collision zone. We present here new Asian paleogeographic reconstructions integrating various end-members models of the India-Asia collision and associated topographic patterns and land-sea masks with implications on the locus, source and generation of resources. Results are provided in various model-relevant formats with associated database and discussion forums to comment an contribute to the amelioration of these maps and databases.

The influence of Earth's thermal cycles on instigating significant geological activities

Chun'an TANG[1]*, Dalian University of Technology (tca@mail.neu.edu.cn)
Bin GONG[2], Brunel University London

Abstract

The Earth's history unfolds in a rhythmic dance of warming and cooling periods, each choreographed with dynamic or tranquil phases of geological activity. When the Earth basks in warmth, expansive geological processes, like the formation of large igneous provinces, come to life. Conversely, during colder spells, geological activity adopts a more subdued tempo. However, amidst this symphony of Earth's thermal cycles and episodic geological phenomena, consensus on their fundamental relationship remains elusive, despite the plethora of models seeking to elucidate their triggers. In this study, we propose a thermodynamic equilibrium equation as a framework to decode the Earth's thermal cycles. We hypothesize that these cycles serve as the driving force behind the planet's evolution, orchestrating the periodicity of geological events such as supercontinental cycles, orogenies, glacial epochs, and biological extinctions. Building upon this premise, we present a comprehensive Wall Chart, synthesizing global data and evidence from geological events spanning Earth's history, to unravel the intricate interplay between these events and the planet's thermal rhythms. Our analysis reveals a compelling nexus between the Earth's thermal fluctuations and the genesis of key geological events, including the formation of evaporites, red beds, and large igneous provinces. Notably, our Wall Chart prompts a thought-provoking inquiry: what links the two Great Oxidation Events to the two Snowball Earth episodes? Through meticulous examination of empirical data, our study unveils the intricate relationship between thermal cycles and pivotal geological milestones throughout Earth's history. This deeper understanding not only enriches our knowledge of Earth's evolutionary journey but also offers insights into the evolution of rocky planets within our Solar System and beyond.

Abstract

It is a challenge to obtain information about the geologic formations and their succession in Africa due to lack of on-line lexicons for most regions. Therefore, we established AfricaLex as a free public online database that includes details on the geologic formations in all major basins of Africa, both onshore and offshore. The entries for each formation contain details on the type sections, lithology, contacts, regional distribution, fossils, age range interpretation and associated images.

AfricaLex (https://africalex.geolex.org/) and NigerLex (https://nigerlex.geolex.org) offer search for geologic formations in the database by standard search criteria (name, partial name, age, region, lithology keywords, or any combination), and a map-based user interface with stratigraphic-column navigation. The returned entries can be displayed by-age or in alphabetical order with the link to each formation shown as color-coded based on its geologic age. Regional extents are also digitized in GeoJSON format to enable plotting of the individual formations or as time-slices of all formations across Africa of a user-selected age onto any of three proposed plate reconstruction models with a single click. The plotted regional extents are filled with appropriate lithologic facies pattern for each formation.

The aim is to make information on Africa geology and its component geologic formations more to accessible to geologists and the general public from the world and for improving paleogeographic maps. Users can obtain a view of the sediments and volcanics that were accumulating at any time across the ancient land of Africa. These lexicon systems will be interlinked to other stratigraphic and paleogeographic databases through the lUGS Deep-Time Digital Earth platform.

Abstract

In a successful collaboration with numerous regional experts on the stratigraphy of China and Southeast Asia, our international team developed cloud-based stratigraphic lexicons with graphical user-interfaces. These databases currently consist of over 4000 onshore and offshore sedimentary and volcanic formations spanning the Proterozoic through Neogene across China, Thailand, Vietnam, Malaysia and Japan regions (chinalex.geolex.org; thailex.geolex.org; vietlex.geolex.org; malaylex.geolex.org; japanlex.geolex.org). The entries for each formation contain details on the type sections, lithology, contacts, regional distribution, fossils, age range interpretation and associated images. APIs enable easy access and integration with other applications. The cloud-based databases and websites can be explored through user-friendly map and stratigraphic-column interfaces generated from the TimeScale Creator software. A comprehensive search system allows users to retrieve information on all geologic formations for a specific date or geologic stage from multiple databases.

Regional extents of each formation are also given in a GeoJSON format that enables visualization as facies-pattern-filled polygons. These can be projected onto three proposed plate reconstructions of its corresponding time interval; or as time slices of regional paleogeography.

These lexicon systems will be interlinked to other stratigraphic and paleogeographic databases through the lUGS Deep-Time Digital Earth platform. This comprehensive approach allows one to explore deep-time dynamics and the evolution of the different regions of our planet Earth.

Abstract

In a successful collaboration with numerous regional experts on the stratigraphy of the Indian Plate and the Middle East, our international team developed cloud-based stratigraphic lexicons with graphical user-interfaces. These databases consist of the Indian Plate (*indplex.geolex.org*) of nearly 1000 onshore and offshore sedimentary and volcanic formations across India, Pakistan, Nepal, Bhutan, Sri Lanka, Bangladesh, and Myanmar and of Middle East regions (*mideastlex.geolex.org*; *qatarlex.geolex.org*). The entries for each formation contain details on the succession of lithology, as well as the fossils present, age range, regional distribution and associated images. APIs enable easy access and integration with other applications. A comprehensive search system allows users to retrieve information on all geologic formations for a specific date or geologic stage from multiple databases. The cloud-based databases and websites can be explored through user-friendly map and stratigraphic-column interfaces generated from the *TimeScale Creator* software.

Regional extents of each formation in a GeoJSON format enables visualization as facies-pattern-filled polygons projected onto three proposed plate reconstructions of its corresponding time interval; or as time slices of regional paleogeography. These lexicon systems will be interlinked to other stratigraphic and paleogeographic databases through the lUGS Deep-Time Digital Earth platform. This comprehensive approach allows one better comprehend deep-time dynamics and gain valuable insights into the evolution of the different regions of our planet Earth.

New Permian Tethyan Paleogeographic Reconstruction and its implication to the collapse of the Late Paleozoic Ice Age

Qiang Ren[1]*, Chengdu University of Technology (renqiang@cdut.edu.cn)
Mingcai Hou[2], Chengdu University of Technology
Anqing Chen[3], Chengdu University of Technology

Abstract

The Late Paleozoic Ice Age (LPIA) is an extreme cold climate event with the longest duration and largest ice sheet area since Phanerozoic. “How the LPIA ended” is an unknown scientific question. Some scientists have studied from the perspective of exhaust of the large igneous provinces and the weakening of chemical weathering of rocks, but they have not been able to explain the sudden reduction of global ice sheet in the early Early Permian and the subsequent multiple glacial-interglacial cycles. It is well known that plate tectonics plays an important role in the evolution of climate and biology, and the existing tectonic features show that the global plate has undergone several variable shifts since the Permian period, represented by the northward convergence of the Tethys tectonic domain. However, whether the plate subduction and volcanic exhaust caused by the convergence played a key role in the extinction of the LPIA has not been answered. This study used a large language model to mine and compile relevant data such as the Permian paleomagnetic and arc magmatic rocks required for full-plate reconstruction, simulated and calculated the subduction flux of global converging plates, determined the causal relationship between subduction flux and arc magmatic rocks through in-depth analysis, and further explored its impact on global climate change (atmospheric CO2 concentration is a climate substitute index). It is revealed that the change of global plate subduction is an important factor driving the final disappearance of the LPIA.

Leveraging Large Language Models for Sedimentary Environmental Interpretation: A New Approach To Addressing The Non-Uniqueness Problem In Paleogeography

Haipeng LI[1]*, Deep-time Digital Earth Research Center of Excellence (haipeng.geo@gmail.com)
Luoqi Wang[2], Zhejiang University
Linshu Hu[3], Zhejiang University
Mingcai Hou[4], Chengdu University of Technology

Abstract

The interpretation of the sedimentary rock record is fundamental for reconstructing paleogeography. However, the inherent non-uniqueness in such interpretations often poses significant challenges, which are further amplified by the exponential increase in scholarly publications. Traditional expert systems, while providing a potential solution, demand substantial contributions from specialists across various sub-disciplines, making them labor-intensive and less adaptive to the incorporation of newly published studies.

In light of these challenges, we propose a novel approach that leverages the advancements in Large Language Models (LLMs), such as GPT-4 and retrieval augmented generation, to process and interpret the vast corpus of publications. By integrating these technologies and fine-tuning them with domain-specific text, we have developed a system capable of providing multiple, probabilistically weighted paleoenvironmental interpretations, each substantiated with specific references.

Our preliminary results suggest that this integrative approach holds significant potential in aiding the interpretation of sedimentary environments and addressing the non-uniqueness problem by harnessing the wealth of knowledge embedded in published literature. This innovative methodology could pave the way for more accurate, comprehensive, and holistic interpretations of the rock record, thereby enhancing our ability to reconstruct paleogeography. We extend an invitation to the broader paleoenvironmental research community to collaborate in refining and applying this promising approach.

Plate Tectonics & Paleogeography during the Last 1.5 Billion Years

Christopher Robert SCOTESE[1]*, Northwestern University (cscotese@gmail.com)

Abstract

Paleogeography is the study of the changing surface of the Earth through time. Driven by plate tectonics, the configuration of the continents and ocean basins has been in constant flux. Plate tectonics pushes the land surface upwards or pulls it apart causing its collapse. All the while, the unrelenting forces of climate and weather slowly reduce mountains to sand and mud and redistribute these sediments to the sea. The following presentation reviews the changing paleogeography of the last 1.5 billion years. It describes with maps and animations the broad patterns of Neoproterozoic and Phanerozoic paleogeography and as well as many of the specific paleogeographic events that have shaped the modern continents and ocean basins. The focus of this discussion is on the changing latitudinal distribution of the continents, changes in sea level, the opening and closing of oceanic seaways, mountain building, and how these paleogeographic changes have affected global climate, ocean circulation, and the evolution of life.

In this review, we present an atlas of 110 paleogeographic maps and a series of animations that illustrates how the surface of the Earth has evolved during the last 1.5 billion years. During that time interval, the Earth has witnessed the formation and breakup of three supercontinents: Rodinia, Pannotia, and Pangea. The continents have been transformed from low-lying flooded platforms to high-standing land areas crisscrossed by the scars of past continental collisions. Oceans have opened and closed, and then opened again in a seemingly never-ending cycle.

Yanxin Wang[6], School of Environmental Studies, China University of Geosciences, Wuhan, 430074, China

Abstract

Older groundwater is generally more susceptible to overdraft and also more difficult to recover once contaminated. To understand the prevalence and vulnerability of fossil groundwater that infiltrated before the Holocene, a global assessment has been conducted recently, but the analysis results for China have been limited by the collection of data. In this study, we combined the groundwater isotope data from the literature databases of CNKI (China National Knowledge Infrastructure) and SCIE (Science citation expanded) and established the groundwater age dataset of China by virtue of the water samples from 1441 wells. By reconstructing the historical precipitation 3H records of China and using the late-Quaternary atmospheric 14C, the fractions of the modern groundwater that infiltrated after the year 1953 and the fossil groundwater that infiltrated before 12,000 years ago in the groundwater samples have been calculated based on the straight-forward mixing models. Then we evaluated the extent and depths of the modern and fossil groundwater in the major 16 groundwater-supply areas of China. The results show that the exploitation of deep groundwater mainly occurs in northern China, such as in the Ordos Basin, the North China Plain, the Hexi corridor, etc. The average critical depth of the vertical transition zone between modern infiltration water and fossil groundwater in China is about 300 m, beneath which more than half of the water samples are dominated by fossil groundwater. Meanwhile, when deeper than 600 m, the groundwater barely can be recharged by the modern precipitation. It is also found that for the uppermost 600 m of the crust in China, the modern and fossil groundwater, respectively, dominates the total groundwater storage at 32% and 51%. Besides, 3H can be detected in half of the water samples containing fossil groundwater. It indicates that the construction of deep wells might have already made the fossil groundwater polluted by modern contaminants.

Abstract

Groundwater is the most important freshwater resource on Earth, playing a critical role in agricultural irrigation and industrial production. As overexploitation-induced groundwater depletion is a common issue in many areas around the world, the spatial-temporal evolution characteristics of groundwater storage (GWS) and its underlying mechanisms are widely studied for the effective conduction of groundwater management. However, the spatiotemporal evolution mechanism of the GWS is still entirely unrevealed, for which objective division of GWS evolution periods and the statistical description of GWS's spatial heterogeneity is a key issue. This study aims to establish a new framework to analyze the spatiotemporal evolution of GWS in the North China Plain (NCP) and its heterogeneity. The Mann-Kendall mutation test and sliding t-test are applied to objectively split the evolution periods of GWS and used the BIRCH clustering algorithm to statistically describe GWS's spatial heterogeneity. The GWS in the NCP during 2002-2021 is estimated based on the Gravity Recovery and Climate Experiment (GRACE) datasets and Global Land Data Assimilation System (GLDAS) models and verified by in-situ groundwater. Results show that reduction rates of GWS in the three stages are -5.87 m/yr (Stage I, April 2002 to December 2009), -12.95 mm/yr (Stage II, January 2010 to December 2013), and -29.11 mm/yr (Stage III, January 2014 to December 2021), respectively. This means that groundwater depletion in the NCP is still worsening. Due to the hydrogeological settings, the most serious reduction of GWS has been shifted from the shallow aquifers in the piedmont alluvial plain to the deep aquifers in the east-central alluvial plain. The significantly different evolution of groundwater storage between the northern and southern regions is highly related to precipitation. Besides, the water diversion projects and the modernization of irrigated areas promote the recovery of shallow GWS in the NCP and even mitigate the reduction rates of deep GWS in certain regions.

Sabin Zahirovic[3], The University of Sydney, Sydney, NSW, Australia
Yisa Wang[4], Deep-time Digital Earth Research Center of Excellence (Suzhou)

Abstract

Paleogeographic reconstruction studies Earth's surface evolution, including tectonic processes, terrestrial and marine patterns, climate, and biological diversity through geological time. This complex field requires analyzing data across geology, geophysics, and geochemistry. Traditional paleogeographic maps, despite their abundance, often suffer from limitations due to their static nature, inconsistent map projections, varied time intervals, and differing plate tectonic models. These constraints challenge the dynamic update and effective management of paleogeographic data. To address these challenges, we introduce Web GPlates (https://dplanet.deep-time.org/DPlanet/), a cloud-based research platform specifically designed for paleogeographic reconstruction. Built upon the Web Assembly and Unity framework to ensure exceptional performance in web browsers, Web GPlates leverages a C# reconstruction of GPlates' plate rotation algorithms, which enables deep-time visualization of plate reconstruction models and data attached to plate models. The platform's user-friendly interface facilitates the management of paleogeographic reconstruction data, allowing for database searches, uploading, visualization, and interpretive analysis of such data. Moreover, by adopting a project-based approach to work, not only can the process of paleogeographic reconstruction be documented, but users can also create dynamic and interactive paleogeographic maps. These maps generated by Web GPlates can illustrate the intricate relationships between paleogeographic reconstruction outcomes and their underlying data, enhancing the depth, dissemination paleogeographic research.

Abstract

The ca. 1.82 to 1.32 Ga north Australian Proterozoic greater McArthur Basin is a part of the larger McArthur-Yanliao Gulf that flooded a large part of Nuna and included much of North China and, at times, may have included the Laurentian Belt Basin. Rocks within the greater McArthur Basin were deposited/erupted in five first-order sequences that have been subdivided as 'packages'. These broadly match up with the 'superbasins' of the Mount Isa region of Queensland. The greater McArthur Basin packages are (from oldest to youngest) the: Redback, Goyder, Glyde, Favenc and Wilton Packages. These rocks preserve some of the eukaryote cell fossils and include chemical biomarkers thought to be produced by eukaryote stem-groups. The basin system also contains the oldest commercial hydrocarbons and extensive sedimentary-hosted metal mineralisation.

Here we present spatially and temporally extensive detrital zircon data (UPb, Hf) and selected additional detrital phases (e.g. rutile, muscovite) from the Redbank Package, Glybe Package, Favenc Package and Wilton Package from five constituent parts of the greater McArthur Basin (McArthur Basin sensu stricto, Beetaloo Sub-basin, Birrindudu Basin, Tomkinson Province and South Nicholson Basin) spanning the Northern Territory of Australia. (The Goyder Package has a limited spatial distribution and is not discussed.) These data constrain the basin evolution, the nature of detritus fluxing into the basin, and reveal the tumultuous plate-tectonic events occurring around all margins of the basin over this half-billion-year time range.

Together the data tell the story of initial Palaeoproterozoic accretionary orogens to the south and east (present directions relative to modern north Australia) that ended in the east by the collision of the North Australian Craton (NAC: the continent in which the greater McArthur Basin overlies) with Laurentia, forming the Isan Orogeny. This major continent-continent orogeny was the last major Nuna-forming collision and the supercontinent reached a maximum size by ca. 1600 Ma. Subsequent rifting led to oceanic separation of Laurentia and isolated a continent formed by North China, the NAC, the South Australia Craton (SAC) and a large part of East Antarctica before this continent collided with the West Australian Craton (WAC) at ca. 1350 Ma. Extension related to the ca. 1325 to 1310 Ma Derim-Derim Large Igneous Province led to ocean-crust formation north of the NAC/NChina and related uplift of northern Australia terminated the half-billion-year history of the greater McArthur Basin.

The progress and perspective of digital intelligence paleogeographic reconstruction

MINGCAI HOU[1]*, CHENGDU UNIVERSITY OF TECHNOLOGY (houmc@cdut.edu.cn)
ANQING CHEN[2], CHENGDU UNIVERSITY OF TECHNOLOGY
QIANG REN[3], CHENGDU UNIVERSITY OF TECHNOLOGY
HANTING ZHONG[4], CHENGDU UNIVERSITY OF TECHNOLOGY

Abstract

The paleogeographic reconstruction is a comprehensive study of the surface tectonic processes, the sea-land pattern, and geomorphic environmental characteristics in geological history. This field is represented by the creation of maps that depict the ancient contours of oceans and continents, as well as important topographic and surface environment characteristics. It serves as a fundamental process for restoring Earth evolutionary history, predicting the distribution of energy and mineral resources, and understanding life and climate evolution. The advent of the era of big data has facilitated the application of digital methods in updating and presenting paleogeographic maps in a rapid and user-friendly manner. To now, several groups published digital global paleogeographic reconstruction models and related data and methods, including Earthbyte, PaleoMap, UNIL, Deep-Time Maps, and other teams. As the concept of data-knowledge-model-driven paleogeography reconstruction proposed by the Deep-time Digital Earth (DDE) International Science Program, this study summarizes and presents a new process for updating global paleogeography maps via developing digital methods. According to interdisciplinary innovation, several technologies, encompassing knowledge-graph-based and machine-learning-based, for paleo-environmental interpretation from geo-data were developed. Here, the Permian-Middle Triassic paleogeography reconstruction for the East Tethys domain is conducted as a case. Firstly, we reconstructed the plate-motion tectonic framework using GPlates. Then the pre-existing lithofacies paleogeography maps were by employed to generate topographic and geomorphic maps automatically by machine-learning-based method with manual fine adjustment. Ultimately, a digital comprehensive paleogeography reconstruction of the Middle Permian-Middle Triassic East Tethys domain was formed through layer superposition. This case is significantly enhancing mapping efficiency, data abundance, traceability, and model accuracy, which could be more timely offering new constraints and insight for understanding co-evolution among landform, ocean anoxia, biological mass extinction, and so on.

"Paleotopographic Mapping": A Tool for Creating New Paleotopographic Models

Fan SHU[1]*, School of Earth Sciences, Zhejiang University (22338023@zju.edu.cn)
Haipeng LI[2], Deep-time Digital Earth Research Center of ExcellenceZhijiang
Jin QI[3], School of Earth Sciences, Zhejiang University
Linshu HU[4], School of Earth Sciences, Zhejiang University
Sensen WU[5], School of Earth Sciences, Zhejiang University
Zhenhong DU[6], School of Earth Sciences, Zhejiang University

Abstract

Paleotopographic reconstruction is a comprehensive research field that provides fundamental support for understanding Earth's evolutionary history, essential for paleoclimate, landscape evolution, and biodiversity modeling. However, various methods exist for paleotopographic reconstruction, and different approaches may yield varying interpretations of the same geological period. To facilitate interdisciplinary collaboration and enable experts to create new paleotopographic models based on their specialized knowledge, the DDE platform has introduced the "Paleotopographic Mapping" tool. The "Paleotopographic Mapping" tool is an online mapping tool developed to create new paleotopographic models based on existing ones. The tool links existing paleogeographic data, serving as references for subject-matter experts. Using the "Paleotopographic Mapping" tool, experts can create a project, select an existing paleotopographic model as the basis and use their specialized knowledge to edit it and generate a new paleotopographic model. This tool supports bulk edit and annotations so that experts can edit models conveniently and explain the reasons of doing so. Additionally, the "Paleotopographic Mapping" tool supports features such as "edit history", "paleogeographic rotation" and "model comparisons". Further more, with detailed tips and references, even non-experts can experience creating new paleotopographic models. The DDE platform aims to leverage this tool to create more paleotopographic models, offering researchers more choices for related studies.

Construction of a fluvial facies knowledge graph and its application in sedimentary facies identification

Lei ZHANG[1]*, 19980873969 (1054359427@qq.com)
cai ming HOU[2], 15982309825

Abstract

Lithofacies paleogeography is a data-intensive discipline that uses lithofacies analysis to reconstruct depositional environments and sedimentary facies, and studies the distribution, formation, and evolution of sedimentary facies. Traditional sedimentary facies analysis and identification are labor-intensive tasks, unstructured knowledge, unstandardized terminology, and the process of sedimentary facies analysis and interpretation are complex. A standardized, structured, and systematic knowledge base coupled with an efficient, fast, and automatic sedimentary facies identification system is necessary. To this end, this study constructed the knowledge system of fluvial facies and carried out knowledge representation. On this basis, we created the domain knowledge graph of fluvial facies and realized visualization, query, and retrieval on the graph database platform. Based on tree logic hierarchical knowledge structure and data mining clustering algorithm, a novel data mining clustering algorithm model suitable for sedimentary facies reasoning was designed, and developed a new sedimentary facies identification and knowledge reasoning system, which provides effective decision support for sedimentary facies identification based on expert experience knowledge. 17 sets of known sedimentary facies data from classical sedimentological literature were applied to the model, compared, and validated. The reasoning results show that the interpretation accordant rate is up to 90%. The model and algorithm provide an efficient and automated reasoning technology, which provides a new approach and route for the rapid and intelligent identification of sedimentary facies in the geology field. Knowledge collection, summary and induction of expert experience knowledge is an effective method for intelligent systems to automatically acquire knowledge from literature data. Combined with the knowledge of palaeogeography, the methods, techniques and processes used to construct knowledge graph and sedimentary facies identification will be extended to the identification, reasoning, and prediction of other sedimentary facies.

Physics-based Machine Learning Model for Predicting Geothermal Heat Flow in Henan Province, China

Jifu He[1], China University of Geosciences, Beijing
Kewen LI[2]*, China University of Geosciences, Beijing (likewen@cugb.edu.cn)

Abstract

Geothermal heat flow (GHF) emerges as a critical parameter for pinpointing geothermal energy-rich areas and decrypting the Earth's inner thermal dynamics. Remarkably, almost half of the world's measured GHF data clusters within the United States and Europe, leaving vast stretches globally grappling with a scarcity and patchy distribution of GHF measurements. To bridge this knowledge gap and map the GHF distribution accurately across these underrepresented regions, the development of a sophisticated prediction model is imperative. In this arena, machine learning techniques stand out, surpassing traditional interpolation or analytical methods in accuracy. Yet, the exploration of machine learning for GHF prediction remains nascent, predominantly leaning on data-driven paradigms. This study develops a novel approach by introducing a physics-based GHF prediction model, which integrates analytical solutions directly into its framework. We have meticulously selected two analytical solutions for this purpose: one derived from merging the Curie point depth with a one-dimensional heat conduction model, and another hailing from the interplay between the Moho surface depth and elevation, processed through a thermal equilibrium model. This innovative model not only enhances the accuracy but significantly bolsters the interpretability over conventional data-driven models, such as those based on Gradient Boosting Regression Trees (GBRT). Employing this groundbreaking model, we have crafted the most up-to-date GHF map for Henan Province, China, unveiling the intricate distribution of the geothermal fields. This cutting-edge research not only paves the way for a deeper understanding of geothermal resources but also showcases the potential of integrating physics-informed mechanisms with machine learning to revolutionize the GHF prediction at a global scale.

Heat extraction performance and seismic potential estimation of horizontal well doublets in enhanced geothermal systems: insights from coupled thermo-hydro-mechanical modeling

Wei JIANG[1]*, State Key Laboratory of Oil and Gas Reservoir Geology and Exploitation, Chengdu University of Technology, Chengdu, China (472666563@qq.com)
Chuan yin Jiang[2], HydroSciences Montpellier (HSM), University of Montpellier, CNRS, IRD, Montpellier, France
Xiao guang Wang[3], State Key Laboratory of Oil and Gas Reservoir Geology and Exploitation, Chengdu University of Technology, Chengdu, China

Abstract

In the long-term injection and production process of deep fractured geothermal reservoirs, fractures gradually open under combined effects of thermal stress and pore fluid pressure. In an anisotropic stress condition, localized stress disturbances may cause normal closure, shear sliding, and shear dilation of fractures, further impacting the local flow and heat transfer behaviors. Understanding this coupled mechanism is crucial for interpreting the evolution behavior of fracture networks and predicting and controlling the heat extraction performance of thermal reservoirs. In this study, we developed a coupled thermo-hydro-mechanical (THM) model based on the discrete fracture network approach to investigate the joint effects of thermal perturbation and in-situ stress on the development of deep fractured geothermal reservoirs during horizontal well development. This model captures important processes, including normal closure, shear dilation, and shear sliding of fractures, thermal expansion of rocks, fluid flow and heat convection/conduction in both fractures and rocks. We quantitatively analyzed the effects of different in-situ stresses, initial reservoir temperatures, wellbore direction, for both vertical and horizontal wells. We quantitatively compute and compare the evolutional behavior of fracture aperture, fluid flow, and heat transfer for the two well types. The results show that, in addition to reducing the normal closure of fractures, the transient cooling effect of the thermal front may trigger shear dilation under anisotropic in-situ stress conditions. The maximum principal stress in the x direction tends to open 30° fractures while closing 110° fractures. A larger angle between horizontal wells and 30° fractures leads to a faster thermal breakthrough but less and smaller induced seismic events. Under the same injection rate, horizontal wells have a larger heat extraction rate but a faster thermal breakthrough than vertical wells. Our research results provide important implications for optimizing the heat extraction efficiency of geothermal reservoirs and managing seismic hazards during fluid injection and production processes.

[Keynote] A Global Energy Outlook: Implications for Geothermal Energy

Richard J Chuchla[1]*, DDE (Deep-time Digital Earth (rchuchla@aol.com)

Abstract

The world's insatiable appetite for energy and the inescapable consequences of global warming due to fossil fuel combustion create an imperative for rapid deployment of carbon-free energy sources. On an annual basis, we currently consume 175,000 TWh of primary energy. From that, we generate approximately 29,000 TWh/yr of electricity. Decarbonized electricity is a foundational element of the energy transition. Over the past four decades electricity demand has almost tripled and will likely increase by another 50% by 2050. Simultaneously solving the complex equations of technology, finance and policy are absolutely required to enable the transition. Global warming provides a critically important additional parameter, which further challenges solutions. The disparity in energy needs and financial capacity between developed and developing economies make clear the need for solutions tailored to local needs.

In exactly this context, we will explore the unique potential and challenges of geothermal energy. Today this energy source fulfills approximately 0.3% of power demand. The dynamic earth, from plate motion to related subduction, mountain building and rifting is driven by a heat engine. However, the lithosphere creates an insulating blanket which only allows higher heat flow where the blanket is torn (plate boundaries) or stretched (rifts). While power generation is localized where hydrothermal systems develop along the hot active plate margins or internal rifts, district heating draws on a much more widely distributed potential resource and, in places, (China, Europe) can tap existing infrastructure. We are already seeing the potential for repurposing existing oil and gas infrastructure and leveraging basic oil and gas technology and workforce knowledge and skills. Hydrothermal systems that produce energy also produce ore deposits and co-production of elements critical to the energy transition are already in the planning stages. All of these factors will be important to growth-to-scale, wide application and cost reduction of geothermal energy.

A fast approach predicting geothermal play fairways using machine learning to multidisciplinary big data-Case studies in Africa and China

Shu JIANG[1]*, China University of Geosciences (jiangsu@cug.edu.cn)

Abstract

Fast and accurate prediction of geothermal play fairways is crucial for efficient exploration, development and utilization of renewable geothermal energy. This study employs spatial analysis of big data and machine learning to predict potential geothermal plays in Africa and China. The multidisciplinary data include regional geology, geophysics, geochemistry, petrophysics, earthquake, volcano, faults, geothermal heat flow, hot springs, groundwater, terrain, and drilled wells. For the geothermal play fairways in data-scare mega regions, we populate the data using Kriging interpolation and Euclidean distance. fuzzy analytic hierarchy process are random forest are used for feature analysis, prediction, and grading of favorable geothermal play areas. Findings indicate high-grade geothermal resources are mainly in regions like Ethiopia, Kenya, northern and southern Tanzania, Uganda, Rwanda, Burundi and Malawi, mostly distributed along structural belts like the East African Rift. For the potential sedimentary-hosted geothermal reservoirs in the Bohai Bay Basin and South China Sea, typical well logs and seismic attributes were firstly correlated with porosity, permeability, water saturation, and temperature of a facies, neural network and genetic inversion were then employed to predict the geothermal reservoirs with higher porosity, permeability, water saturation, and temperature and quickly build a 3D geothermal reservoir model. These predictions have been validated by the existing geothermal power plants and high temperature reservoirs previously drilled.

Target Optimization for Hot Dry Rock Resources in the Jizhong Depression

XIAOXUE JIANG[1]*, National Key Laboratory of Petroleum Resources and Engineering&China university of petroleumBeijing (jiangxiaoxue135@163.com)
chuanqing zhu[2], National Key Laboratory of Petroleum Resources and Engineering&China university of petroleum (Beijing)
Xie Fang[3], National Key Laboratory of Petroleum Resources and Engineering&China university of petroleum (Beijing)
Jiaqi Zhang[4], National Key Laboratory of Petroleum Resources and Engineering&China university of petroleum (Beijing)

Abstract

The Jizhong Depression in the Bohai Bay Basin has enormous potential for geothermal resource development. Previous studies have systematically researched the hydrothermal geothermal resources in the Jizhong Depression, but research on deep-seated hot dry rock resources remains unclear. Based on the data of geology, geothermal geological conditions, and rock thermal properties, this study analyzes the characteristics and controlling factors of shallow and deep geothermal fields in the research area. It also identifies favorable targets for hot dry rock resources. According to the calculated geothermal gradients from temperature data, significant differences exist in the shallow and deep formation geothermal gradients in the uplifted area of the Jizhong Depression. The shallow layer exhibits a high geothermal gradient of 41.79°C/km, while the deep layer shows a lower gradient of 30.73°C/km. In the depression area, the geothermal gradient remains relatively constant with depth, averaging at 28.9°C/km. Additionally, there are noticeable differences in heat flow distribution between the uplifted and depression areas. The heat flow in the raised area is between 70-110 mW/m2, indicating a higher thermal background, while adjacent depression areas generally exhibit heat flow below 60 mW/m2. The characteristics of the geothermal field are mainly influenced by rock thermal conductivity, basement structural undulations, and groundwater activity. The tectonic morphology in the uplifted and depression areas of the Jizhong Depression leads to differences in rock thermal conductivity in horizontal and vertical directions. That causes thermal flow refraction and redistribution, and makes the surface heat flow distribution characteristics correspond to the relief of the basement. Thermal convection is occurring within highly permeable dolomite layers which are widely distributed at the shallow end of the raised zone, causing rapid upward heat transfer from the deeper formations of the region and increasing temperatures in the shallower strata. In contrast, deep formations in the uplifted area are less influenced by thermal convection, primarily transferring heat through conduction. Under the effect of conduction-convection complex heat transfer, there are large differences in the temperature distribution characteristics of shallow and deep formations between the raised and depressed areas. Under the effect of conduction-convection complex heat transfer, there are large differences in the temperature distribution characteristics of shallow and deep formations between the raised and depressed areas. Using measured data to calculate the temperature of different buried layers in the study area, it is observed that the uplifted area

exhibits high temperatures in the shallow layers but lower temperatures in the deep formations, while the depression area shows lower temperatures in the shallow layers but higher temperatures in the deep layers. Consequently, the Jizhong Depression is characterized by high-temperature geothermal resources mainly distributed in the deep-seated areas within 5000 m, with temperatures reaching 190°C, which is a favorable target for hot dry rock exploration. This study deepens the understanding of the genesis and distribution patterns of deep-seated high-temperature geothermal fields in the Jizhong Depression, providing valuable reference and guidance for the development of hot dry rock geothermal resources.

Characterization of structurally controlled geothermal systems

Gemma Mitjanas[1]*, Sustainable Minerals Institute (Univ of Queensland)
(g.mitjanascolls@uq.edu.au)
John Walsh[2], University College Dublin
Gemma Alías[3], Universitat de Barcelona
Pilar Queralt[4], Universitat de Barcelona
Juanjo Ledo[5], Universidad Complutense de Madrid

Abstract

Faults have long been known to significantly influence the migration of fluids within the crust, often acting as the principal conduits and traps for groundwater, and therefore, also having a key role in fault-controlled geothermal systems. This duality of flow behaviour underneath the importance of the characterization of main structures and the parameters that might affect their role.

Recent studies in the Catalan Coastal Ranges (NE Spain) have evidenced the significance of structural complexity in conditioning the role of faults in the circulation of fluids (1). Details of the geometry and nature of fault intersections, splays, relays, and associated damage-related fractures have been considered together in flow localization. And, the integration of geophysical methods, have been proven to be key in their characterization (2).

The Vallès-Penedès fault in the Catalan Coastal Ranges, host hot springs (60-70°C) along its fault trace, which limits a Palaeozoic metamorphic and granodioritic horst from the Miocene sediments that fill the graben. We have integrated geological and geophysical exploration methods, including fracture characterization, gravity, passive seismic, and magnetotellurics, to characterize the main structures and identify the characteristics that allow the presence of hot springs only in specific parts of the fault.

Results show how the geothermal flow is primarily concentrated in the intersection of the Valles-Penedes fault zone with a Palaeozoic thrust sheet, enhanced by fault-related fracturing. The resulting structural complexities, which include the development of a relay ramp and high fracture density, together with the characteristics of the host rock and the flow direction, have been identified as key factors in the localization of the currently active hot springs.

Project InnerSpace's GeoMapTM: Unlocking Geothermal Potential Worldwide

Jamie BEARD[1]*, Project InnerSpace (jackson@projectinnerspace.org)
Dani MERINO-GARCIA[2], Project InnerSpace
Higinia TORREGROSA[3], Project InnerSpace

Abstract

In the quest for sustainable and clean energy sources, geothermal energy has emerged as a promising contender. The Earth's internal heat can be harnessed to power and heat our homes, industries, and communities. However, realizing this potential requires a deep understanding of the Earth's subsurface and surface characteristics. Project InnerSpace's GeoMapTM: has been designed to provide a free platform where various stakeholders can access this data. The GeoMapTM body of work consists of surface and subsurface modules, a suitability analysis tool, and a Techno-Economic Sensitivity Tool ("TEST"), all of which work together to provide outputs to user inquiries about geothermal resources and development potential.

With funding allocated to nine different research projects, including seven focused on the subsurface and two on the surface, Project InnerSpace has brought together over 85 scientists from around the globe to consolidate fragmented datasets, increase their spatial resolution, improve their metadata, and enhance data quality. Through an exciting partnership with Google, GeoMapTM will leverage vast and powerful datasets from Google's Earth Engine to form the backbone of the project's surface suitability assessment. This high-resolution satellite data and building information will help the tool understand heat and electricity demand, a vital aspect of geothermal energy planning.

GeoMapTM aims to serve a diverse range of stakeholders: large industrial corporations looking to harness geothermal energy, geothermal sector companies, governments seeking to highlight their country's potential, and investors with the resources to fund innovative projects. Moreover, the project has gained attention from networks specializing in critical minerals and natural hydrogen. The data generated isn't just valuable for geothermal energy; it has applications across various fields and disciplines, which will help to expand its reach and impact.

The first rendition of GeoMapTM focused on the African continent, with a surface-level heat demand analysis completed for the city of Lagos, Nigeria, the most populous urban area in Africa. In future renditions of GeoMapTM, we will be expanding east to incorporate the Asian continent and are eager to discover synergies with experts in the field from throughout the region.

In conclusion, Project InnerSpace's GeoMapTM is an endeavor that unites global expertise and cutting-edge technology to unlock the potential of geothermal energy. The goal is clear: to create a comprehensive and accessible resource that empowers stakeholders to make informed decisions

about geothermal potential worldwide

Prediction of heat flow distribution in North China, based on digital geomorphic and multi-geophysical data

Chuanqing ZHU[1]*, China University of Petroleum (Beijing) (zhucq@cup.edu.cn)
Nansheng Qiu[2], China University of Petroleum (Beijing)
Yaorong Shen[3], China University of Petroleum (Beijing)

Abstract

Terrestrial heat flow is a comprehensive geothermal parameter reflecting the regional thermal background. The terrestrial heat flow data are of great significance to understanding the thermal state and activity of the crust, the thermal structure of the lithosphere, and the evaluation of geothermal, oil and gas resources. Due to the limitations of the distribution of boreholes and rock coring, the spatial distribution of measured terrestrial heat flow data in China is uneven, and there is a large blank area of heat flow data outside sedimentary basins. The surface heat flow is closely related to the thickness of the lithosphere, the buried depth of Curie surface, and the geomorphology and the age of geological events. This study takes North China craton as the research area, uses the neural network method and the GEOGPT large language model, and tries to establish the internal logical correlation between multiple types of parameters and heat flow based on the analysis and summary of multiple geological and geophysical parameters such as digital geomorphology, thermal tectonic events, geological units, and buried depth of geological interfaces. The high-density grid was used to fill the blank area of measured heat flow, and the local heat flow prediction was more consistent with the regional structure-thermal background.

Abstract

Taiwan Island located in the Circum-Pacific Volcanic Belt (Ring of Fire), an active orogenic zone with abundant volcanic and tectonic activities, and rich geothermal resources in the earth's crust. However, geological exploration is uncertain and risky in the preliminary survey stage of geothermal resource development, which is often difficult and discouraging. Based on the above concepts, this project has selected the geothermal potential area in Guguan, Taichung City to, with the use of multiple multi-scale geothermal surface exploration methods and subsurface exploration techniques, obtain comprehensive geothermal geological information and further develop a subsurface three-dimensional geological model to rationally assess the size and distribution of geothermal energy reserves. The said data may be used as a reference for the exploitation of geothermal resources and facilitate the development of geothermal potential areas. The work items of project include: (1) geothermal geological survey; (2) geophysical exploration; (3) geochemical analysis; (4) drilling and well testing; (5) 3D geothermal geological modeling; and (6) administrative assistance. First, we will compile geothermal geological data in the study area and select a key exploration area of 30 km2 to, supplemented by a 0.5-meter resolution airborne LiDAR derived DEM, carry out field surveys and the production of a 1:10,000 geothermal geological map production; and then, together with a 0.2-m resolution UAV LiDAR-derived DEM and a 0.1-m resolution GB LiDAR derived DSM, measure the nodal fracture of key outcrops and carry out a stress analysis accordingly. Second, geomagnetic and georesistance profiles are planned to follow in accordance with the regional geological architecture to obtain deep geothermal geological data such as subsurface lithology, geological structures, fracture zones, and hydrothermal fluids. In addition, a geochemical analysis of surface water, hot spring water, and rock samples will be conducted in the key exploration areas; and the results will be used to evaluate the chemical properties, hydrothermal sources, and temperature of thermal fluids in the region to estimate the temperature of deep geothermal reservoirs. Finally, based on the aforesaid geological, physical, and geochemical analysis results, drilling sites will be selected to verify the subsurface geological structure via drilling, probing and well testing; and three-dimensional

geothermal model will also be constructed accordingly to make clear the potential and distribution of geothermal resources. The three-dimensional geothermal model, which also incorporates all technological results, will be verified with field surveys and statistically modified by rolling parameters. In the meanwhile, we will integrate all results into the geothermal exploration database and determinate potential geothermal resources in the study area. It is estimated that the research results of this project will be integrated into CGS' Geothermal Exploration Information Platform, through which the geothermal development industry can facilitate their exploitation of thermal resources and the government can refer to for their renewable energy policy.

[Keynote] Deep-time Digital Earth: an overview of progress since 2019, and a look into the future

Michael H Stephenson[1]*, Stephenson Geoscience Consulting Ltd (mikepalyno@me.com)

Abstract

The Deep-time Digital Earth program was initiated in February 2019 at the Fragrant Hills Hotel in Beijing, China, where seventy international geologists and geoscience data specialists gathered alongside representatives of the International Union of Geological Sciences (IUGS). DDE follows the vision of the IUGS which is to promote development of the Earth sciences through the support of broad-based scientific studies relevant to the entire Earth system. Founding members include the International Commission on Stratigraphy, International Association of Palaeontology, International Association of Sedimentologists, Society for Sedimentary Geology, American Association of Petroleum Geologists, and the International Association for Mathematical Geosciences. Major geological surveys, institutes and commissions are also involved including the China Geological Survey, the Geological Survey of India, the Commission for Geological Map of the World, and the Commission on the Management and Application of Geoscience Information. DDE will operate the full FAIR data concept (Findable, Accessible, Interoperable, and Re-usable), and link to desktop systems for geoscientists all over the world as well as to students and teachers in classrooms and on the internet.

In the past four years progress has been astonishing, despite the interjection of the covid pandemic, with projects on geological mapping, geological lexicons, interoperability and standards, marginal seas, geological timelines and national computing nodes. Highlights include the development of the DDE modelling and data platform now with over 1000 datasets, and the ability to offer an advanced modelling environment through ordinary computing equipment (a simple laptop), and the DDE Outcrop 3D visualisation system which already offers an unprecedented 120 high resolution dm to km images of some of the most spectacular and important geological sites on the Earth.

A challenge into the future will be continuing to develop collaboration in an increasingly fractured world with strong geopolitical divides, but DDE's avowed commitment to non-alignment and to science will maximise its ability to work with scientist throughout the world whatever their origin. Another challenge will be to continue to make DDE science relevant to societal problems, including climate change and resources, and to the UNs sustainable development goals (SDGs), but DDE's structure of Task and Working Groups and roots in the Global South will help to keep DDE's science useful and relevant.

In the future DDE will continue to make geological data more Findable, Accessible, Interoperable, and Re-usable so that geological data will begin to resemble the more open and creative scientific environments of bioscience, astronomy and physics, and so that machine learning and artificial intelligence will be more applicable, ushering in a bright future for the Earth sciences into the 2030s.

Unlocking the Deep-time Earth with Open Keys: Collaboration, Platform and Research projects.

Chao LI[1]*, Deep-time Digital Earth (li.chao@ddeworld.org)
Zheng Tong[2], Deep-time Digital Earth

Abstract

The incompleteness of the evidence for Earth's evolution and the difficulty of integrating existing data are inevitable difficulties for geoscientists who are trying to understand the past and the future. A wealth of deep-time earth data and models exist in archives and publications, which are not readily accessible and reusable to scientists.

The most intuitive solution is to collaborate with all geoscientists to build a geoscience cyberinfrastructure, essentially a dynamically updated data network. A collaborative distributed protocol with time-space frameworks, terminology standards, and even multi-jurisdictional intellectual property rules should be developed to enable secure access to and efficient use of geoscience resources on a global scale. Furthermore, an online work platform website should be developed and serves as a user interface.

Case studies could demonstrate the effectiveness of the mechanism. From life to matter, from climate to geography, scientists are conducting ambitious, integrated studies that carefully put global-scale data and advanced models together. It's time to put these separate studies on a unified platform, and enable more studies by the platform, so that more accumulated data yields more value.

This oral will showcase some of the ideas, practices and experiences in building and using the cyberinfrastructure aiming solve Deep-time issues, as well as the great value of global cooperation for promoting discoveries about the deep-time earth.

Data-driven Hydrogeology Research Hatched by the OneGroundwater Platform

Jianmei Cheng[1]*, School of Environmental Studies, China University of Geosciences, Wuhan, 430074, China (jmcheng@cug.edu.cn)
Kun Zheng[2], School of Geography and Information Engineering, China University of Geosciences, Wuhan, 430074, China
Hong Yao[3], School of Computer Science, China University of Geosciences, Wuhan, 430074, China
Ying Yu[4], School of Environmental Studies, China University of Geosciences, Wuhan, 430074, China
Yanxin Wang[5], School of Environmental Studies, China University of Geosciences, Wuhan, 430074, China

Abstract

Either groundwater's sustainable management or its deep hydrogeological process research, relies on the support of massive multi-source heterogenous data. But presently the accessibility and systematisms of groundwater data are quite insufficient. Large amounts of hydrogeological information are still scattered in numerous documents in different forms, and simultaneously, very limited data on the properties and migration characteristics of deep groundwater can be found. Here we aimed to develop the techniques of knowledge extraction and graph data organization for the automatic acquisition of hydrogeological information in literature databases and the construction of the hydrogeology knowledge graph. Then, by establishing the hydrogeological base service platform, OneGroundwater, we can efficiently store and manage the acquired multi-source heterogeneous groundwater data with the knowledge-based intelligent retrieval function in the real-time service computing framework. So far, our hydrogeological mapping team has preliminarily completed the preparation of the African hydrogeological map and uploaded it to the platform for display. Simultaneously, we have conducted the study of groundwater storage in Africa. In terms of thematic dataset construction, data collection, database design, database construction, and database application promotion have been jointly promoted. A large amount of data has been collected for the databases of global spring water, saline water, high-arsenic and high fluorine groundwater. These data have been uploaded on the OneGroundwater platform. In terms of knowledge system construction, a large number of triples and entities have been obtained through work such as data crawlers, entity recognition and relationship extraction, and manual review. Using these triples and entities, a knowledge graph of water containing fluid inclusions has been successfully constructed and visualized. Moreover, for the OneGroundwater platform, the functionality, knowledge system visualization, database optimization and spatiotemporal data analysis tools, user access, and other aspects have been continuously improved and improved. Next, with the increase of the thematic databases in the platform, the data-driven hydrogeological research will be further promoted.

DDE OneSediment: a comprehensive sedimentological and palaeogeographic database and research platform

Xiumian Hu[1]*, NANJING UNIVERSITY (huxm@nju.edu.cn)
Chengshan Wang[2], China University of Geosciences, Beijing
Jitao Chen[3], Nanjing Institute of Geology and Palaeontology, CAS
Jianghai Yang[4], China University of Geosciences, Wuhan
Jingxin Jiang[5], Nanjing University
Mingcai Hou[6], Chengdu University of Technology
Data Team DDE[7], Hangzhou DDE Centre
Platform Team DDE[8], Hangzhou DDE Centre
Sedimentology Working Group[9], Hangzhou DDE Centre
Palaeogeography Working Group[10], Hangzhou DDE Centre

Abstract

OneSediment is a disciplinary data product planned by the Deep-Time Digital Earth (DDE) international big science program, which aims to integrate sedimentological data scattered all over the world, of different sources (journals, books, reports) and of different categories (analyzing data, text, images, etc.).

The construction of OneSediment is based on the knowledge system of sedimentology and paleogeography, covering the whole sedimentological area; The construction method is shared by using cloud technology, big data and other technologies to meet the globally needs of data building and sharing; The formation of a dynamic database with unified standards and platforms, in line with the principles of FAIR (Findable, Accessible, Interpretable, Reusable), promote the informatization and standardization of sedimentological data, and provide sedimentological information services for the public. By way of thematic database construction to interested scientists, OneSediment will integrate databases of different scales and forms, and realize data interoperability and interconnection, and to provide a one-stop scientific data serves for calculations, statistics, figuring, mapping and simulations.

Up to now, 25 thematic databases have been constructed under the joint efforts of the DDE Sedimentology and the Paleogeography working groups. For example, the ocean sediment database (OSD) is under construction, including eight core data categories related to sediment composition (macroscopic, microscopic, clay minerals), sedimentary geochemistry (organic geochemistry, inorganic geochemistry, pore water chemistry), physical properties (moisture and density, diffuse reflectance color), stratigraphic event data for age-depth models, with 2,247 sedimentary boreholes and a total of more than 1,630,000 data entries. The incoming data were standardized by subject experts, and there are 583 standard fields.

Another example is the global detrital zircon database with approximately 600,000 U-Pb age data mainly from China, Iran, Turkey and Cyprus has been developed, which had been published recently as a special collection in Geoscience Data Journal, together with the global deep-time sandstone detrital component database, modern river sediment composition database, global chert

database. Chinese Sedimentological Microscopic Images database was constructed and published in special issues of Chinese Science Data.

[Keynote] The Deep-time Digital Earth Program in the Evolving Global Research Data Landscape

Kerstin Annette Lehnert[1]*, Columbia University (lehnert@ldeo.columbia.edu)
Lesley Wyborn[2], Australian National University

Abstract

Modern-day Geoscientists increasingly want to and need to use Big Data and data analytics to solve the large-scale and urgent questions that they address in their research for both discovery science and applied science. The Deep-time Digital Earth (DDE) Program therefore is a highly relevant, promising, and welcome effort to pursue the challenging but promising goal of moving the Geosciences into a new era of Big Data. DDE was created with the vision to utilize modern and cutting-edge computational paradigms, internet cloud computing, data mining, machine learning and AI to extract knowledge from the massive volumes of data that have been and are generated world-wide to understand the Earth's evolution and contribute to achieving the sustainable development goals." DDE's mission is to "harmonize global deep-time Earth data and share global geoscience knowledge", setting itself an ambitious goal considering the complexity of the global data ecosystem and its continuing evolution and expansion. Since DDE was inaugurated in 2019, new scientific paradigms and new technologies for data storage, description, identification, interoperability, and analytics have emerged and new principles and policies for data management and open and ethical data sharing have been developed and put in place by funders, publishers in many countries to ensure preservation and FAIRness of data (Findable, Accessible, Interoperable, Reusable).

The development of data standards and their implementation as community best practices face many challenges. The biggest ones are not technical, but legal, political, social, or cultural in nature (Edwards et al. 2007; Wittenberg & Strawn 2018). Over the past decade, new initiatives have been launched through international organizations such as CODATA, Research Data Alliance, the World Data System and the IUGS to advance cross-disciplinary and international communication, coordination, and collaboration, helping to build consensus on best practices and standards for the sharing and re-use of digital research data. DDE's progress and success depend on its ability to leverage and complement those initiatives. DDE's move to connect with CODATA and the WorldFAIR project is an important step to advance collaboration with relevant standard developments such as the OneGeochemistry case study in WorldFAIR. Such collaborations are critical to converge on standards and broaden their adoption, particularly in the Long Tail Geosciences communities that are heterogeneous and fragmented.

DDE has shown itself capable of generating tools that will enable analysis of global datasets, but so far, those tools work on DDE-compiled datasets. They will not necessarily work on datasets generated by other regional or international groups, and require adaptation of the tools to these

datasets, and or the conversion of these existing datasets to DDE standards.

The best option for success and long-term impact of the DDE program is for DDE to work with the IUGS, CODATA, RDA and other international initiatives to jointly develop the global standards required to enable machine readability of geoscience data in compliance with the FAIR, CARE and TRUST principles, respecting diversity and inclusion; incorporating ideas, concepts and knowledges from the Global North, Global South, and indigenous communities; and ensuring consistent and sustained data infrastructure.

Building the Earth System History Machine: A Dynamic Simulation of Plate Tectonics, Paleogeography, Paleoclimate and Paleobiogeography.

Christopher Robert SCOTESE[1]*, Northwestern University (cscotese@gmail.com)

Abstract

Since the time of Nicholas Steno, more than 350 years ago, field geologists, paleontologists, stratigraphers, and geophysicists have fastidiously and painstakingly described and mapped the surficial and buried layers of the Earth's crust, revealing its detailed and exquisite history. This story emerged slowly at first, then accelerated as Earth Historians were able to calibrate their correlations using absolute radiometric age-dating. Using this robust chronometric framework, we now can tell the exciting story of the Earth, in all of its interwoven tectonic, geographic, oceanographic, atmospheric, geochemical, climatic, and biologic complexity. During the last 30 years, Energy companies and national geological surveys have compiled 3D exploration databases and have built 3D stratigraphic models covering the globe. An immense amount of high-resolution, digital stratigraphic data are now in-hand. So what does the future hold? The task before us is two-fold: first, a new Earth System History "Library of Alexandria" must be built from this great volume of digital Earth System History data to preserve it for future generations and, more importantly, to create a comprehensive, coherent and authoritative digital data source for the emerging artificial intelligence systems (e.g., GPT5). The second task, though daunting, is to use this Earth System History database, along with important geophysical data bases, to build an "Earth System History Machine". This Earth System History Machine will dynamically simulate the plate tectonic, paleogeographic, sedimentologic, paleoceanographic, geochemical, paleoclimatic evolution of the Earth since its beginnings, through to the present, and forward into the future Anthropocene. Numerous researchers, who span the globe, are now actively working towards this lofty goal They include researchers and students at the PALEOMAP Project (Northwestern University), EarthByte (University of Sydney), CEED (Norway), University of Geneva, University of Chicago, Leeds University, Chronosphere Project (Erlangen), University of Bristol, Texas A&M University, NMNH, DDE Project, Purdue University, Chinese Academy of Sciences, Peking University, University of Geosciences (Wuhan), Nanjing University, Paleobiology Database, Macrostrat (University of Wisconsin), Utrecht University, University of Western Australia, CNRS, ETH, University of Lisbon, and others.

DDE scholar report: a new open and Ai frontier and innovative reflect for solid earth

Meng WANG[1]*, Xiniang institute of Ecology and Geography, Chinese Academy of Sciences (yeswangmeng@gmail.com)
Yu Zhao[2], School of Earth Sciences and Resources, China University of Geosciences (Beijing)
Li Cheng[3], Journal Center, China University of Geosciences (Beijing)
Chengshan Wang[4], School of Earth Sciences and Resources, China University of Geosciences (Beijing)
Hans Thybo[5], University of Copenhagen
Patricio Guillermo Villafañe[6], Instituto Superior de Correlación Geológica (INSUGEO)

Abstract

The Deep-Time Digital Earth (DDE) program was initiated by the International Union of Geological Sciences (IUGS) and is being developed in cooperation with national geological surveys, professional associations, academic institutions and scientists around the world. Following the FAIR (findable, accessible, interoperable and reusable) and TRUST (Transparency, Responsibility, User focus, Sustainability and Technology) principles, DDE aims to link and harmonize global deep-time Earth data and share global geoscience knowledge with the goal of stimulating data-driven discoveries in the study of Earth's evolution through deep time.

In order to release DDE's expert knowledge bonus, data bonus and platform bonus, and help scientists deal with the challenges of earth science research based on their needs, DDE plans to launch a series of annual thematic, scholarly reports. Through in-depth analysis and interpretation of global research trends, it will help scientists understand major research breakthroughs in the field of solid earth sciences, and understand research methods, solutions to major scientific problems and highlight key topics and themes for future research.

The first DDE report is due to be released in 2023. DDE Report will use the theory and methods from bibliometric and altimetric research and release the “hot” topics and development of earth science research in solid earth science. The report will explore the deep reason behind trends and become the barometer of earth science research publications and outputs. DDE report aims to help scientists on determining the future research focus and innovation, and finally, to guide future earth science research trends.

IMMERSIVE VIRTUAL EXPERIENCE: A NEW “LOOK UP” TO THE GSSPs

Simonetta Monechi[1]*, Dipartimento Scienze della Terra, University of Florence, Italy (simonetta.monechi@unifi.it)
Laia Alegret[2], ept. Ciencias de la Tierra Universidad de Zaragoza, Spain
Aitor Payros[3], Department of Geology, University of the Basque Country, Bilbao, Spain
Claudia Agnini[4], Dipartimento di Geoscienze, Università di Padova, Padova, Italy
Gabriele Scaduto[5], Dipartimento Scienze della Terra, Università degli Studi di Firenze, Italy
Bruno Fanini[6], Institute of Heritage Science of the Italian National Research Council (CNR ISPC), Rome, Italy

Abstract

In recent years, three-dimensional digital models have rapidly developed providing diverse and important data that has great potential for innovative information technologies and scientific research in geoscience. The acquisition and digitization of the geological outcrops and in particular of the GSSPs and geo-heritage sites allowed the International Subcommission on Paleogene Stratigraphy (ISPS) to enhance and give visibility to the scientific community and the general public of the most important Paleogene sections (see the ISPS website https://www.paleogene.org/).

The acquisition of these data utilized photogrammetry and Lidar modeling techniques with mobile phone.

The models have been enhanced to create an immersive virtual experience of the geosites. The utilization of ATON, an open-source framework developed by the Institute of Heritage Science of the Italian National Research Council (CNR ISPC), allows the exploration of large, massive 3D datasets using HMDs (i.e. Oculus Quest) directly through a web brouser, without requiring any installation. Such a modular framework offers advanced functionalities like visual immersive analytics and integration with complex multimedia content. Users virtually immerse in the outcrop enabling rea-time querying of all geometries, annotations and measurement functionalities (e.g. examinining 3D fossils and other material or associated information).

This innovative approach offers an incredible opportunity for saving temporary outcrops, geological features or fossils in virtual environments, and will contribute to research, to promote and disseminate geo-education.

[Invited] Building Stacked Relative Paleointensity Records for Chron C18: Insights into the Geodynamo Characteristics Over Extended Timescales

Yuhji YAMAMOTO[1]*, Kochi University (y.yamamoto@kochi-u.ac.jp)
Hiroto FUKAMI[2], Kochi University; Sanyo Techno Marine Co. Ltd
Peter C. LIPPERT[3], University of Utah

Abstract

Knowledge of variations in intensity of paleomagnetic field (paleointensity) can be inferred from volcanic materials and marine sediments. The former allows for the estimation by absolute values, and related data have been reported as old as 4.2 Ga, though their quality is variable and their temporal coverage is sporadic (Bono et al., 2022). The latter could provide estimates in a more continuous form in relative values, i.e., relative paleointensity (RPI), but the temporal coverage had been limited to ~2-3 Ma in the case of stacked records. Deep-sea drilling, such as the Integrated Ocean Drilling Program (IODP), can recover sediments without disturbance to depths of ~200 meters below the seafloor, thus building up stacked RPI records back in time as longer time series. Records of RPI older than ~2-3 Ma began to be reported from sediments recovered by the IODP, primarily in the 2010s: it is possible to build an RPI stack based on these records if they cover the same period and are from different regions. For the period of ~38.5-41.1 Ma, corresponding to the interval of Chron C18, RPI records were reported from two regions 9000 km apart, the equatorial Pacific (Yamamoto et al., 2014) and the northwest Atlantic (Yamamoto et al., 2022). The stacked RPI record for Chron 18, named PIS-C18, is constructed (visually aligned) from these records and it is the oldest stack record to date (Yamamoto et al., 2022). It exhibits general characteristics such that RPI minima always occur at chron boundaries and RPI fluctuates between highs and lows within each chron. In more detail, RPI is generally high with no prominent lows during Chron C18n.2n, whereas it is not as high and has several prominent lows almost equivalent to the RPI minima at the chron boundaries during Chrons C18n.1n and C18r. It is implied that there is a higher probability for a prominent low intensity event such as a geomagnetic excursion during a longer polarity interval than during a shorter polarity interval. Also, a histogram of PIS-C18 RPI is slightly skewed to the right, and the ratio of the standard deviation to the mean paleointensity is 0.38: these are similar to characteristics observed in the PISO-1500 RPI histogram (Channell et al., 2009). It is suggested that all of these features are characteristic of the geodynamo over timescales of 10^4 – 10^6 years which has been unchanged at least since the Eocene.

The reliability of Cretaceous redbed paleomagnetic datasets from the Tibetan Plateau

Jiahui MA[1]*, China University of Geosciences (Beijing) (3001200098@email.cugb.edu.cn)
Tianshui Yang[2], China University of Geosciences (Beijing)

Abstract

Sedimentary rocks, particularly redbeds, which can record nearly continuous geomagnetic fields and provide definitely paleohorizontal relative to volcanic rocks, have always been the most extensively collected material for paleomagnetic studies in the Tibetan Plateau and its adjacent areas. However, Cretaceous paleomagnetic datasets obtained from the coeval redbeds and volcanic rocks of the Lhasa terrane have significantly different inclinations. Considering that the factors that caused the inclination discrepancies in redbeds are controversial, it is extremely urgent to clarify the reliability of the characteristic remanent magnetization (ChRM) of redbeds in the Tibetan Plateau. Here, we performed a new paleomagnetic study on the Upper Cretaceous Abushan Formation (Fm) redbeds in the Anduo area of the central Tibetan Plateau. A detrital zircon U-Pb dating result from the bottom of the sampled Abushan Fm redbeds yielded the youngest zircon age of 89.1 ± 0.9 Ma, which, combined with Cretaceous Normal Polarity Superchron interval (ca. 121.4−83.6 Ma), dated the sampled redbeds with 89.1−83.6 Ma. The tilt-corrected site mean direction for 37 sites is Ds = 0.9°, Is = +36.4°, k = 43.6 with α95 = 3.6°, corresponding to a paleopole at 78.2°N, 266.8°E with A95=3.6° and a paleolatitude of 20.5 ± 3.6°N for the study area (32.3°N, 91.4°E). This paleomagnetic dataset passes both McElhinny (1964) and McFadden (1990) fold tests at the 99% confidence level and the conglomerate test at 99% and 95% confidence levels. But the mean inclination obtained from the southwest dipping limb (Is = +44.2°) is steeper than that from the north dipping limb (Is = +34.2°). The fold and conglomerate tests, combined with the rock-magnetic results, microscopic observations, and credible demagnetization curves indicate that the ChRM directions are the primary DRMs carried by detrital hematite and do not experience obvious distortional strains. Both the elongation/inclination (E/I) and anisotropy-based correction methods suggest that the inclination shallowing is insignificant in sampling sections. Finally, considering that the site-mean inclination of the southwest dipping strata (Ic1 = +41.2°) is consistent with that of the north dipping strata (Ic2 = +40.9°) after syntectonic-sedimentation-correction, the invalid inclination discrepancy should result from unidentified syntectonic growth strata. Furthermore, the mean inclination acquired from two limbs of folds is basically consistent before and after syntectonic-sedimentation-correction, which indicates that the redbed paleomagnetic datasets obtained from two limbs of folds are still reliable.

The Balanced Billion

Ross N MITCHELL[1]*, Chinese Academy of Sciences (ross.mitchell@mail.iggcas.cn.cn)
David` AD Evans[2], Yale University

Abstract

A mid-Proterozoic stretch of Earth's history (roughly 1.8–0.8 Ga) has been called, non-affectionately, the "boring billion". The moniker was first inspired several decades ago by the apparent absence of any significant carbon isotope anomalies and was linked to the relatively dull interval between Earth's broadly two-step pattern in atmospheric oxygenation. Other datasets from Earth's surficial environment during this time have been shown to be equally peculiar, including: the disappearance of iron formation and notable absences of any large oxygenation events, phosphorites, or glacial and manganese deposits, and a billion-year lag between the oldest known Paleoproterozoic eukaryote fossils versus pronounced mid-Neoproterozoic eukaryotic diversity and ecological importance.

Oddities of this billion years come not only from records of surface evolution and palaeoenvironment, but also the solid Earth, including metamorphic style (a paucity of high-pressure conditions) and either absences (ophiolites) or abundances (anorthosites) of specific igneous rock suites. Recently, the mid-Proterozoic anomaly has even been suggested to be expressed as deep as mantle convection and as far flung as the Earth–Moon system: with the billion years suggested to respectively represent the transition between bottom-up to top-down mantle convection as well as a remarkable flat-lining of Earth's rotational history at a constant ~19 hours per day. Anomalies can be recognized as deep as Earth's core, because measured palaeomagnetic inclinations (which convert to palaeolatitude assuming a geomagnetic field model) deviate significantly from the expectation of a geocentric axial dipole.

However, Earth's mid-Proterozoic tectonic record is anything but stagnant. The Grenvillian super-orogen is globally widespread and anomalously deeply eroded. Regardless of whether individual components of that orogenic system involve collisions between continents as part of Rodinia assembly or are produced by long-lived tectonic accretion, the attractive temporal correlations between silicate rock weathering and paleoclimate variability in Phanerozoic time might predict profound atmospheric CO2 drawdown and glaciation during the Grenvillian interval at ca. 1000 Ma, as well as changes to atmospheric oxygen from pyrite weathering and burial. Instead, climatic stability through the Meso-Neoproterozoic transition highlights the important geochemical flux balances and restorative feedbacks that must have existed around the rock cycle encompassing magmatism, weathering, sedimentation, and metamorphism. Profound and rapid changes in Rodinia's paleolatitude could contribute to repetitive episodic activation of such feedbacks.

In light of (i) the original evidence coming from a relatively stable carbon cycles, (ii) the souring over time of the unflattering term "boring billion" and (iii) more recent additional clues coming from the deep Earth, we suggest a rebranding of the 1.8-0.8 Ga interval to the "Balanced Billion". An important benefit of this renaming is that it may inspire better recognition and quantification of

mid-Proterozoic Earth system feedbacks—in not only the balanced paleoenvironment, but also balanced mantle convection and a constant daylength due to balanced solar and lunar tidal torques. Whether these variegated processes are directly related is a frontier for understanding the interconnectedness of the deep-time Earth system, and may lead to a better understanding of the long-delayed fuse in the rise of animals.

Eben Blake Hodgin[3], Brown University
Anthony Fuentes[4], UC Berkeley
Tadesse Alemu[5], Colby College

Abstract

The continent-continent collision of the Grenvillian orogeny that initiated in the latest Mesoproterozoic was a major event in the formation of the supercontinent Rodinia. Leading up to the onset of collisional orogenesis, there was rapid plate motion of Laurentia associated with the closure of the Unimos Ocean. This rapid motion has come into further clarity with new geochronology and paleomagnetic data from the Southwestern Laurentia large igneous province. These data add to the rich well-calibrated record from volcanics and intrusions of the North American Midcontinent Rift known as the Keweenawan Track. New temporal constraints and paleomagnetic data from sedimentary rocks deposited following rift volcanism show plate motion to have dramatically slowed following ca. 1080 Ma. This slow-down is contemporaneous with the onset of collision recorded in the Grenvillian orogeny. Slow rates of continental motion were then sustained throughout the orogeny. These data support the interpretation that the previous rapid motion recorded in the Keweenawan Track is dominantly the result of differential plate motion. We illustrate how site level data can be assigned ages and associated uncertainties within probabilistic frameworks rather than being assigned single ages. Additionally, we can account for the variability associated with processes such as inclination shallowing, enabling us to both utilize the richness of the available data and accurately reflect its inherent uncertainties. Overall, our new constraints show that the position of Laurentia, and associated land masses within the supercontinent Rodinia, at the start of the Neoproterozoic Era differs from current reconstructions that rely on the ages that are currently assigned to paleomagnetic poles of the Grenville loop. These data highlight continued opportunities for the development of new paleomagnetic and geochronologic data to enable substantive progress in deep time paleogeography.

Abstract

How far back in time plate tectonics has operated is one of the largest questions in Earth sciences. Existing estimates for the onset of plate tectonics range from the Hadean to Cambrian based on diverse constraints from geology, geochemistry, paleomagnetism and numerical models. One of the most robust arguments for plate tectonics is Paleomagnetism, which could tell us if two cratons have experienced relative horizontal motions in the geologic past (Evans and Pisarevsky, 2008). At present, the most reliable paleomagnetic data suggested the relative cratonic motion occurred during 2.7–2.17 Ga. In this study, a new paleomagnetic pole was reported from the ca. 2480 Ma mafic dikes from the Wyoming craton. It will provide constraint on the assembly time of Wyoming and Superior, and constrain the oldest relative motion in earth's history at present.

The ca. 2480 Ma mafic dikes appear to be wide-spread in the Stillwater complex in the the Beartooth mountains of the Wyoming craton. The ca. 2480 Ma mafic dikes intruded into the Stillwater complex and the basement. The dikes are NW-trending or NE-trending diabase or gabbro. In this study, a total of 46 sites were collected including 27 sites from dikes, as well as 19 sites from the host rocks. After stepwise thermal demagnetization, 12 dikes hold a consistent high temperature component (HTC) which directs south-southeast and down with moderate inclination. Two tentatively positive baked-contact tests demonstrate that the HTC can be interpreted as primary in origin. The pole was achieved by averaging 12 VGPs from 12 mafic dikes.

By matching the new pole with the poles from the ca. 2505 Ma Ptarmigan-Mistassini dikes and the ca. 2466-2446 Ma Matachewan dikes (Evans and Halls, 2010), while also matching the ca. 2160 Ma poles from the Rabbit Creek dikes and the Biscotasing dikes (Evans and Halls, 2010; Kilian, 2015), the aggregate dataset demonstrates Wyoming and Superior assembled before ca. 2500 Ma. Our preferred reconstruction is based on broad alignment of paleo-magnetic poles as well as geological similarities such as Huronian and Snowy Pass Supergroup juxtaposition and consideration of mafic dike trends within and between the two cratons (Roscoe and Card, 1993).

the ca. 2.71 Ga poles from the Wyoming craton and the Abitibi subprovince of Superior are substantially separated from each other, suggesting Neoarchean relative lateral motion between cratons.

Abstract

A combined paleomagnetic and geochronological study is carried out on the mafic dykes from Shandong Province in the North China Craton (NCC). CA-ID-TIMS baddeleyite dating results from one dike suggest it emplaced at ca. 1240 Ma. Rock magnetic results show the main magnetic carriers in the samples from the dikes are PSD magnetite. After stepwise thermal demagnetization, most samples from the dikes yielded consistent high-temperature component (HC), which directs east and down with steep inclination. The primary origin of the HC is bolstered by positive baked-contact tests and a reversal test. Combined with previous results, a paleomagnetic pole is obtained from 32 virtual geomagnetic poles and it averaged out the paleo-secular variation. The pole is different from any younger paleomagnetic poles of the NCC and it is considered as a key pole of ca. 1240 Ma for the NCC.

The new ca. 1240 Ma pole places the NCC in a moderate paleolatitudinal region. The ca. 1780–780 Ma apparent polar wander paths from Laurentia and NCC (Zhang et al., 2012; Ding et al., 2021; Evans et al., 2021) suggest Nuna broke up during 1450– 1320 Ma; from ca. 1240 to 1110 Ma the two cratons reassembled to be an integrated landmass and had a long-lived connection until the breakup of Rodinia.

Abstract

Paleosecular variation (PSV) studies in the Precambrian offer unique insights into the average morphology of the geomagnetic field and the operation of the geodynamo in Earth's early history. A relative predominance of paleomagnetic data around 1100 million years ago presents an opportunity to investigate PSV behavior during that period. We collected high-quality paleomagnetic data during 1130–1070 Ma and estimated PSV for the interval with magnetic field reversals (1130–1100 Ma) and the subsequent one of stable polarity (1100–1070 Ma), respectively. The Model G fit for the PSV data in the newly constructed data compilation reveals that the period with geomagnetic field reversals (1130–1100 Ma) was characterized by a mild increase in the angular dispersion of virtual geomagnetic poles with latitude. In contrast, the interval with a stable geomagnetic polarity (1100–1070 Ma) displayed a strong latitudinal dependence. This PSV transition resembles patterns observed in the Paleozoic and Mesozoic eras, suggesting that the relative contribution of the dipole dynamo family to the geomagnetic field is higher during low reversal rates compared to high rates. The analysis predicts similarities in geodynamo evolution 1.1 billion years ago and in the Phanerozoic. The geocentric axial dipole-dominated geomagnetic field around 1100 Ma establishes a robust foundation for paleogeography reconstructions.

Abstract

The size of Greater India continues to be debated. Paleomagnetism is one of the principal approaches used to assess the expanse of Greater India, which is to compare the observed paleolatitude from the TH with the excepted paleolatitude for the same reference point calculated based on the Indian Apparent Polar Wander Path. However, the paleomagnetic data from the Zhongba area of the central Tethyan Himalaya suggest that Greater India with an extent of less than 1000 km (Yuan et al., 2023) or about 2000-3000 km (Meng et al., 2023). This controversy was caused by the disputed fossil age and the polarity of the Sangdanlin Formation. Therefore, the paleomagnetic data with precise geochronology limits from the central Tethyan Himalaya are vital for assessing the size of Greater India.

Here we report a combined paleomagnetic and geochronologic study on the Weimei Formation volcanic rocks, dated in the Early Cretaceous, from Zhongba county of the central Tethyan Himalaya. Stepwise thermal , alternating field, and hybrid demagnetizations successfully isolated reliable characteristic remanent magnetization (ChRM) directions that include antipodal dual polarities and pass positive fold tests at the 99% confidence level and reversal tests at 95% confidence level, indicating prefolding primary magnetizations. The distribution patterns of ChRM directions from the Weimei Formation volcanic rocks are consistent with young lava flows at similar latitudes, suggesting that secular variation has likely been averaged out. The tilt-corrected site-mean directions provide a paleopole and a corresponding high paleolatitude for the Zhongba sampling area. Our new results, together with the Indian APWP, demonstrate a smaller Greater India hypothesis. They are compatible (within errors) with the shortening amount measured by the balanced cross-section construction in the Himalayan fold-thrust belt.

Abstract

The south China block (SCB) was traditionally subdivided into the Yangtze block to the northwest and the Cathaysia block to the southeast, separated by an early Neoproterozoic ocean. The identification of the Grenvillian-age ophiolite suites within the Yangtze block in recent years suggested that the northern Yangtze subblock (NYB) and the southern Yangtze subblock (SYB) were once separated by an ocean in the late Mesoproterozoic. Although some paleogeographic models advocated the Pre-Grenvillian connections between the south China blocks and Laurentia, none has been paleomagnetically tested. Here we report the new paleomagnetic results obtained from the ~1270 Ma purplish-red muddy dolomite beds of the Luanshigou Formation, Shennongjia Group, NYB, providing a new clue for reconstructing the south China blocks in Precambrian supercontinents. A total of 447 samples were subjected to stepwise thermal demagnetization. Two components were identified. The low-temperature component is interpreted as the recent viscous remnant magnetization. The high-temperature component was obtained below 580°C or 690°C from 241 samples, directed northeast-up or southwest-down, antipodally, which position the paleomagnetic pole at 18.5°S, 74.4°E (dm/dp = 2.5/1.6°). Rock magnetic results demonstrate that the magnetic carriers in purplish-red dolomite and pale-pink dolomite are predominated by hematite and magnetite, respectively. The data reliability is supported by an inverse baked contact test and a B-class reversals test. The resulting paleomagnetic pole is distinct from any younger poles of the region, which supports its primary origin interpretation. Based on the new results and the coeval poles available, aided by geological data, we propose a reconstruction in which the NYB was juxtaposed to southwestern Laurentia in the late Mesoproterozoic and suggest that the ~1100 Ma Miaowan-Shimian ophiolite zone in the Yangtze block was likely an extension of the

Grenville belt of Laurentia.

Abstract

The evolutionary history of the Meso-Tethyan Ocean is crucial to understand the formation and evolution of the Tibetan Plateau, but the closure time of the Meso-Tethyan Ocean still remains hotly debated, with estimates ranging from the Middle Jurassic up to the Late Cretaceous. To contribute to the mentioned issues above, a combined paleomagnetic and geochronologic study was performed on the Zenong Group volcanic rocks, dated at ~147 Ma, in the Shiquanhe area of the western Lhasa terrane and the Yeba Formation volcanic rocks, dated at ~170 Ma, in the Dazi area of the eastern Lhasa terrane. Stepwise thermal and alternating field demagnetizations successfully isolated reliable characteristic remanent magnetization (ChRM) directions that pass positive field tests, indicating prefolding primary magnetizations. The distribution patterns of ChRM directions from the Zenong Group and Yeba Formation volcanic rocks suggest that the geomagnetic paleosecular variation has been averaged out. The tilt-corrected site-mean directions for the Zenong Group and Yeba Formation volcanic rocks are D/I=342.0°/23.9° with α95=10.2°and D/I=64.0°/27.2° with α95=6.2°, which provides two paleopoles at 63.9°N, 304.4°E with A95=10.3° and at 29.8°N, 180.7°E with A95 = 5.7°, respectively. Comparing reliable Jurassic and Cretaceous paleomagnetic results from the Lhasa and Qiangtang terrane indicates that the closure of the Meso-Tethyan Ocean should be a scissor-like diachronous process, with its eastern part (29.7°N, 91.3°E) closed at ~168 Ma and its western part (32.4°N, 83.4°E) closed at ~143–139 Ma.

Exploring rock-magnetic parameters for efficient sample preselection on the Tsunakawa–Shaw paleointensity method: a study from data of Cenozoic basalts

Hyeon-Seon AHN[1]*, Korea Institute of Geoscience and Mineral Resources (hs.ahn.86@kigam.re.kr)
Youn Soo Lee[2], Retired, Division of Environmental Science and Engineering, Pohang University of Science and Technology (POSTECH)
Yuhji Yamamoto[3], Marine Core Research Institute (MaCRI), Kochi University

Abstract

Despite being essential in determining absolute paleomagnetic field intensity (API) with high fidelity over research topics of Earth, planetary, and space sciences, API determination still suffers little quantitative success. This is due to common non-ideal magnetic behaviors in experiments using natural rocks caused by physiochemical changes in the magnetic minerals contained. While linking rock-magnetic parameters to API results may be fundamental, negligible effort has been made using the Tsunakawa–Shaw (TS) API method despite its potentially high experimental success rate in overcoming non-ideal magnetic effects. Here, we explore the relationships between rock-magnetic parameters retrieved using relatively rapid and widely pre-conducted measurements and TS API results from late Cenozoic basaltic rocks. We selected rock-magnetic parameters quantified from strong-field high-temperature thermomagnetic curves, magnetic hysteresis loops, and back-field isothermal remanent magnetization demagnetizations. We collected data of similar quality, and then compiled 133 pairs of rock-magnetic and TS API data at the sample level (38 sites). Using this data compilation, the following topics of interest were identified: Magnetic coercivity (Bc) and remanence coercivity (Bcr) among the hysteresis parameters, and the thermomagnetic parameter ITC|m| (an index of thermal change quantifying an average of the differences in saturation magnetization at a full temperature range of during a single heating-cooling run) allows meaningful and efficient discrimination between data subsets divided by ‘success’ or ‘failure’ in the API results. We propose sample preselection criteria for the TS experiment: a minimal set of Bc≥13 mT (or Bcr≥26 mT) and ITC|m|≤0.15. Moreover, we argue that extended consideration based on the preselection criteria may allow the screening of potentially biased specimen/sample-level API estimates in the site-averaged determination of such a site with a large within-site API dispersion.

New Early Permian Paleomagnetic Data from the Northern Margin of the North China Block and its Implications for Regional Climate and Biological Evolution

Qiang Ren[1]*, Chengdu University of Technology (renqiang@cdut.edu.cn)
Shihong Zhang[2], China University of Geosciences (Beijing)
Mingcai Hou[3], Chengdu University of Technology
Anqing Chen[4], Chengdu University of Technology

Abstract

In the early Permian period, North China experienced a change from humid-climate coal-bearing sedimentary facies to arid-climate redbeds and a sudden decrease in regional biodiversity, the main cause of which has been a mystery. In order to explore this scientific question from the perspective of land-sea pattern evolution, we conducted combined paleomagnetic and geochronological studies in the volcano-sedimentary strata of the Lower Permian Dahongshan and Qingfengshan formations in the northern margin of the North China Block (NCB). Zircon U–Pb dating of andesites and tuffs from the Dahongshan and Qingfenshan formations yielded ages of ~290 Ma and ~281 Ma, respectively. A total of 318 paleomagnetic specimens underwent stepwise thermal demagnetization. After removing the viscous remanent magnetizations of the recent geomagnetic field, stable high-temperature components (HTCs), carried by magnetite, were successfully acquired from 267 specimens. The HTCs of the Dahongshan Formation passed a fold test, a conglomerate test, and a paleosecular variation test, and those of the Qingfengshan Formation passed a reversal test and a fold test, suggesting that they represent primary remanence magnetizations. We used the elongation/inclination method to test and correct for all the HTC directions of the clastic rocks of the Qingfenshan Formation. Their corresponding paleomagnetic poles
are 41.5°N/5.4°E (A95 = 5.8°) at ~290 Ma for the Dahongshan Formation and 68.1°N/323.6°E (A95 = 2.5°) at ~281 Ma for the Qingfengshan Formation. The new Early Permian paleomagnetic data show that the NCB was located at 12.8 ± 5.8°N at ~290 Ma and 22.1 ± 2.5°N at ~281 Ma for a reference point at 42.5°N, 119.5°E. We used a Monte Carlo simulation to determine the rate of Permian plate motion and associated uncertainty; these analyses reveal rapid northward latitudinal motion of the NCB at 11.4 cm/yr with a 95% confidence range of 7.1–17.6 cm/yr from 290 to 281 Ma. The rapid northward movement of the NCB from 290 Ma to 281 Ma has shifted most of its land area (e.g., Chifeng, Daqingshan, and Ordos areas) from the Equatorial Rainy Belt (0°-14°N) to the Subtropical Arid Belt (14°-28°N), leading to a sharp decline in biodiversity as organisms fail to adapt to a rapidly changing climate.

Junhua Luo[5], School of Earth Sciences, Lanzhou University
Mark Dekkers[6], Faculty of Geosciences, Utrecht University

Abstract

The southwest Ordos Basin is an ideal place to understand the tectonic evolution and the source rocks formation in the North China Block During the Early Paleozoic. The Ordovician is a very important period for this. Great progress has been made in the tectonic evolution and the prospects of oil and gas of Ordos basin. However, the paleomagnetic and magnetostratigraphic study for the Ordovician of the Ordos is still lack. Here we present paleomagnetic and rock-magnetism studies of two sections (Qishan section and the Pingliang) in the southwestern Ordos, which have continuous stratum and over 2 km thickness of the Ordovician marine carbonate rocks and clastic rocks. The remanence magnetism characteristics and magnetic carrying minerals of Ordovician rocks in the studied sections will be analyzed, systematic thermal demagntization and alternating field demangnetization are applied to seperate different magnetization components. By comparing paleomagnetic poles calculated from different magnetization components in diffferent sedimentary formations, possibility and pathyway of remagnetization will be also discussed.

Rock magnetic studies show magnetic bearing minerals include maghemite, magnetite, goethite and hematite, with sizes of single-domain, multi-domain, and a small amount of superparamagnetic particles. Demagnetizations separated at least three components: low temperature component (NRM-150 °C), medium temperature component (150-350 °C) and high temperature component (350-580/650 °C). Through calculation of the corresponding paleomagnetic pole position and comparison with the paleomagnetic pole position of the North China block obtained by the predecessors, we conclude that the low temperature component is the viscous remanence of the modern geomagnetic field, and the medium temperature component is remagnetization one related to the exhumation of Ordos Basin in the Middle Permian and the collision between the North China plate and the Yangtze plate in Triassic. The high temperature component in a large proportion of samples is the characteristic remanence.

How did the Jurassic True Polar Wander meet plate motion in Asia?

Yangjun GAO[1]*, Shengli Oilfield Branch Company, SINOPEC, Dongying 257001, China (g123y456j@foxmail.com)
Shihong ZHANG[2], School of Earth Sciences and Resources, China University of Geosciences, Beijing 100083, China

Abstract

True Polar Wander (TPW) is a migration of the entire mantle-crust system related to the rotation axis of Earth. The Jurassic TPW event was revealed by a large body of paleomagnetic data from continental and oceanic plates. Synchronously, Asia witnessed multiple oceanic subduction and continental mergence, which were closure of the Mongol–Okhotsk ocean (MOO) between Siberia and the eastern Asian blocks, and closure of the Tethyan oceans between Asia and Gondwana. In the context of TPW and oceanic subductions, paleogeographic changes of Asian blocks is still in discussion.

Recently, two studies reported that the north China block (NCB) was located in remarkable paleolatitude of 76°N and 62°N in Late Triassic and Early Jurassic, respectively (Yi et a., 2019; 2023). Comparing with the APWP of Eurasia, the authors argued that the eastern Asian blocks had welded with Eurasia continent already and experienced nothing but the motion of TPW after then. However, the data and interpretations are highly inconsistent with the paleomagnetic database. We suggest that at least the Triassic data that the authors cited from a previous study were wrongly recalculated for tilt-correction, because the geological evidence may demonstrate that the strata had likely been folded when the mafic dykes intruded them. Currently most reliable paleomagnetic data may suggest that the NCB and its then connected blocks did not undergo any significant paleogeographic shift during late Jurassic (Gao et al., 2021). In addition, the high-quality and well-dated paleomagnetic poles newly obtained from Tibet can also indicate that the Lhasa terrane remained latitudinal stand-still in late Jurassic due to the interaction between its northward plate tectonic motion and the simultaneous southward TPW (Li et al., 2022; Ma et al., 2022).

New paleomagnetic results from the late Ediacaran Dengying Formation in South China

Haiyan LI[1]*, China University of Geosciences (Beijing) (hai2216@cugb.edu.cn)
Shihao Li[2], State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Beijing
Shihong Zhang[3], State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Beijing
Tao Zhong[4], State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Beijing
Tianshui Yang[5], State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Beijing
Huaichun Wu[6], State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Beijing

Abstract

The Ediacaran paleogeographic reconstruction is crucial for deciphering the biological evolution. However, the reconstruction is still not clear due to the lack of high quality paleomagnetic data. Palaeomagnetic studies were thus carried out on the Shibantan Member of the late Ediacaran Dengying Formation (551-538 Ma) in the Yangtze Gorges area, South China.

Oriented samples were drilled from four sections, including the Toudingshi, Qinglinkou, Jiuqunao and Zhengjiatang sections around the Huangling Anticline. The anisotropy of magnetic susceptibility (AMS) and thermal demagnetization were performed on 223 specimens of the four sections. The AMS results of the four sections showed no obvious deformation. All specimens of the four sections exhibited the same demagnetized characteristic. They all unblocked at 470 – 490 °C, indicating that the dominant remanence carrier was magnetite. Most specimens had three components. The low temperature component (LTC) was isolated below 150 °C. The sample-level mean direction before tilt correction of each section was close to the present geomagnetic field (PGF) in the sampling area. Therefore, the LTC was a viscous remanent magnetization (VRM) of the PGF. The intermediate temperature component (ITC) was isolated between 200 – 300 °C. The virtual geomagnetic poles (VGPs) of the site-level ITCs from the four sections clustered in the geographic coordinates, and the average VGP was close to the late Jurassic paleomagnetic pole of the South China, resulting in a late Jurassic remagnetization. The high temperature component (HTC) of the four sections was mainly isolated between 330 – 490 °C. Compiling the published paleomagnetic data of the Shibantan Member from the Sanxiarenjia section (Jing et al., 2018), the site-level HTCs passed a fold test (McElhinny, 1964; McFadden, 1990) at 99% confidence level and yielded a maximum grouping (“k” value) at 97.4% unfolding (Watson and Enkin, 1993). The site-level average of the VGPs of the HTCs from the Toudingshi, Qinglinkou, Jiuqunao, Zhengjiatang and Sanxiarenjia sections yielded a paleomagnetic pole DY of the Shibantan Member. This pole is near the middle-late Silurian palaeomagnetic pole, resulting in a possibility of remagnetization. However, the pole DY is preferred to be reliable based on the following two

factors. One is that the pole DY is also close to the reliable early Cambrian palaeomagnetic pole (Lin et al., 1985). The other is that the paleolatitude of the South China calculated from the pole DY is consistent with its Neoproterozoic - early Paleozoic paleolatitude shifting model, that is from high latitude to equator after ~720 Ma (Zhang et al., 2015). To sum up, the new paleomagnetic pole DY (~545 Ma) of the South China will be helpful for the paleogeographic reconstruction in Ediacaran time.

Exploring sedimentary records of sea level and carbon cycling as independent tests of true polar wander: Case studies from the Paleoproterozoic to Cretaceous

Yu-Shu Liu[1]*, Institute of Geology and Geophysics, Chinese Academy of Sciences (liuyushu23@mails.ucas.ac.cn)
Ross Mitchell[2], Institute of Geology and Geophysics, Chinese Academy of Sciences

Abstract

True polar wander (TPW) is the rotation of solid Earth (mantle and crust) about the liquid outer core in order to realign the principal moment of inertia with the geographic location of the spin axis. TPW can significantly and potentially rapidly change the paleographic locations of continents. Therefore, it carries profound implications for the evolution of relative sea level of a continent, and can cause relocation of carbon depocenters which can reorganize the global carbon cycle. In this study, we consider two case studies where sedimentary records can provide tests of TPW independent of paleomagentism: (i) sea level changes of the North China craton in the Paleoproterozoic are compared with shifts in paleolatitude, and (ii) shifts in the carbon isotopes (δ13C) of the Indian Himalaya terrane in the late Cretaceous are compared with paleolatitude changes predicted by TPW. Our preliminary results suggest that shifts in paleolatitude are coincident and consistent with expected changes in relative sea level of North China craton in the Paleoproterozoic, and the paleolatitude predicted by TPW and the shifts in δ13C of Indian Himalaya in the late Cretaceous also exhibit consistency—as well as noted contrasts with the coeval δ13C record in England that was positioned in a different paleogeographic TPW quandrant. These results initially indicate that the response of sedimentary records of sea level and carbon cycling can also be used as stratigraphic tests of putative ancient TPW events independent of paleomagnetism.

Paleomagnetic studies of the Neoproterozoic Jinchuan Ultramafic rock Unit and Paleozoic dykes inside it, revealing its affinity to North China Block since Cambrian

Ronghua Wang[1]*, Lanzhou University (wangronghua@lzu.edu.cn)
Mingjie Zhang[2], Lanzhou University
Wenbo Xu[3], Lanzhou University

Abstract

Paleogeographic location of the Neoproterozoic Jinchuan Ultramafic Rock Unit is key to understand the geodynamic background of Rodinia breaking-up and its contribution to the extraordinary enrichment of Platinum Group Elements and cobalt metals in Jinchuan. Previous studies have discussed the changes of source material in Alxa block and corresponding tectonic movements by analyzing the zircon U-Pb age distributions and geochemical features in both sedimentary and metamorphic rocks, suggesting different timing of amalgamation between Alxa block and Ordos block. Here we will present a direct approach to obtain the paleogeographic location of Jinchuan Ultramafic Rock Unit by paleomagnetic studies. Oriented core samples from 23 sites were collected from both the outcrops and underground mines of Jinchuan Ultramafic Rock Unit, bedrocks and dykes in it. Rock magnetic studies suggest Pseudo single domain magnetite is the main magnetic mineral with few contribution of pyrrhotite and titanomagnetite. Stepwise thermal demagnetization show at least two components, with one component within 300℃ and 580℃ as the characteristic remanent magnetization (ChRM). Part of the samples reveal a different component above 540℃ (JC-H2). Except one site (JC5), all the other sites from Jinchuan Ultramafic Rock Unit present ChRM similar present geomagnetic field. Paleomagnetic poles calculated from JC5-ChRM is 61.2N14.2Edp/dm=3.6/-5.2, similar to the pole position of North China Block in Triassic Periods. Paleomagnetic poles calculated from JC-H2 of six sites in the Jinchuan Ultramafic Rock Unit is located at 20.8S, 125.6E,dp/dm=8.9/-14.08, which is consistent to reported poles (930 Ma) of North China Block, and also close to the reported pole position of North China Block in Cambrian/Ordovician periods. Since this component was carried by magnetic minerals with blocking temperature above 540℃ rather than the primary magnetite, we speculate this component as secondary component, and thus Cambrian/Ordovician remagnetization.

Four sites of the Paleozoic dykes423 Ma) exhibit different demagnetization behavior. Besides the low temperature component similar to present field, the ChRM is quite scattered while the demagnetization trajectory is within a confined great circle. Applying the poles of North China block (420 Ma and 220 Ma), the primary Ordovician magnetization and secondary Triassic remagnetization may all be recorded and fall on this great circle. We thus infer the dykes might also be remagnetized in Triassic Period.

To sum up, the remanent magnetization of Jinchuan ultramafic Rock Unit suffered two-three times of remagnetization. Although the primary magnetization component is not retrieved, the oldest

remagnetization in Cambrian/Ordovician periods suggests the affinity of the Alxa block to the North China block since Cambrian.

A Review of True Polar Wander in the Tonian (~850-750 Ma)

Joseph MEERT[1]*, University of Florida (jmeert@ufl.edu)
Manoj K Pandit[2], University of Rajasthan
N.V. Chalapathi-Rao[3], National Center for Earth Science Studies

Abstract

Paleomagnetic data from the Yangtze craton and Laurentia form the casus belli for an episode of true polar wander in the Tonian (~(850-750 Ma). The total angular shift implied by some of these data exceeds 90 degrees and the rates of TPW (depending on the choice of poles) is over 100 cm/yr. Recent paleomagnetic data either confirm or refute TPW with the most conservative estimates for rates of apparent polar wander less than 10 cm/yr. A new U-Pb titanite age of 820 ± 15 Ma is recorded from a lamprophyric dyke in the Harohalli alkaline province (India). Rb-Sr and K-Ar ages are similar to the U-Pb age, but Pradhan et al. (2012) obtained a much older U-Pb (1192 Ma) age from one of the dykes. Because the dated dyke in that study did not yield paleomagnetic data, caution was urged in using the Harohalli dykes paleomagnetic pole. We have reviewed the paleomagnetic data from previous studies and calculated an updated pole for the alkaline dykes (HD) at 36.1° N, 84.0° E (A95=11.3°, K=30). The Malani Igneous Suite (MIS; India) is used as the younger tie point at ~770 Ma. Coeval data from South China at 824 Ma (Yanbian Dykes-A=YA pole) and 770 Ma (Yangtze dykes=YD) can be used to reconstruct India and Yangtze. Poles from Yangtze craton are rotated into Indian coordinates using an Euler pole at 46° N, 106.1° E, -174.5°. The fit between the two pairs of similar age poles from both cratons is excellent (HD-YA Bayes error=.482 and MIS-YD Bayes error=.384) and supports conjectures about the contiguity of these two regions in the Tonian. If we assume that the Yangtze craton and India were fellow travelers during the 825-770 Ma interval, then we can use other poles from the Yangtze craton to evaluate plate/non-plate motions. Depending on the choice of poles used from the Yangtze craton, extreme rates of TPW are possible. While true polar wander is anticipated to produce a roughly synchronous global signal in paleomagnetic data, this poses a challenge to the extant database, particularly regarding data from Svalbard. Our presentation will focus on this time interval and the implications for both TPW and the breakup of the Rodinia supercontinent.

Progress and challenge in geoscience standards of the IUGS Deep-time Digital Earth program

Minghua ZHANG[1]*, CGI/China Geological Survey (zminghua@mail.cgs.gov.cn)
Harvey Thorleifson[2], CGI/University of Minnesota
Simon Hodson[3], CODATA
Francois Robida[4], CGI
Mark Rattenbury[5], CGI/GNS Science
Jianhui LI[6], CODATA/China Academy of Science

Abstract

Standards for global multiple disciplinary geoscience data Open and FAIR (findable, accessible, interoperable and reusable) are essential and critical for the IUGS Deep-time Digital Earth program (DDE) to achieve its goal of harmonizing global deep-time digital earth data for enhanced data and knowledge-driven discoveries. The DDE Standards Task Group (DDE-STG) was jointly established by CGI-IUGS and CODATA to work with DDE Working and Task Groups (DDE-WTGs) scientists. Aiming at facilitating DDE with implementable international geoscience standards, expertise and relevant supports on demand, big progress has been made in the past 4 years by the DDE-STG with timely and targeted products deliveries and conduction of R&D project Geosciences Data Standards for DDE. Six main achievements including work strands have been made and completed or are underway. (1) A formal DDE Knowledge System review procedure was issued and released in August 2020 and updated in May 2021 with recommendations and guides provided to the DDE-WTGs to enable the rapid development of DDE knowledge system. (2) DDE Geoscience Information Metadata Standard (DDE S01-2023) enabling DDE data and resources to be machine Findable online was formally released in November 2023 at CGI-DDE Global Geoscience Standards Workshop and Forum at Suzhou. The metadata schema has been utilized by DDE-WTGs since its first interim version in 2021 and has now been implemented by DDE and other organizations. (3) In-depth training and consultation to DDE-WTGs on existing geoscience standards and implementation methodologies have included formal training workshops (26-28 October 2021, 7-8 November 2023), informal daily consultations and technical documentation. These have assisted the DDE-WTGs with existing CGI/OGC standards like GeoSciML, EarthResourceML, GroundWaterML, geoscience terminology, and expertise from CGI, OneGeology, OGC, USGIN and CODATA. (4) A practical DDE Accessible Data Evaluation Guide was also drafted in 2022 with considerations of data authority, data quality, data volume, data openness, data service capability and data user scale. (5) A general guide for DDE geoscience standard framework is also being drafted based on the coordination of standards necessary to implement DDE. (6) Activities on international cooperation conducted by the DDE-STG has also significantly contributed to DDE including solid links with CGI, CODATA, national nodes and several regional and national geological survey organizations and the Global Open Science Cloud.

However, for DDE to fully achieve FAIR principles compliance and meet expectations around

Open data and knowledge transfer, further work is needed. In-depth training and consultation on existing CGI/OGC/ISO, CODATA and other related standards, FAIR principles application for DDE Knowledge System, DDE geoscience resource FAIR implementation profiles identified and achieved through partnership with the WorldFAIR+ initiative and global communities starting in 2024 are main works to be carried out by DDE-STG together with support from the R&D project FAIR Principles implementation for DDE. Upcoming challenges include (1)developing practical FAIR compliant standards for DDE multi-disciplinary databases and knowledge graph system, (2)finding skilled people, particularly early career scientists, with geoscience background, IT knowledge and understanding of information standards, and (3)building international cooperation, especially the network development among data/knowledge-rich geological surveys, institutes and international standards organizations.

Abstract

In the era of big data, rich geoscientific datasets on the internet lay a solid foundation for scientific research. However, the lack of unified semantic markups makes accurate data webpage retrieval a significant challenge. To address this problem, we developed a one-stop dataset service called DataExpo (https://dataexpo.deep-time.org/) in the context of the Deep-time Digital Earth Program (DDE). It introduces deep-learning-based methods for multi-source geoscientific metadata aggregation, data webpage classification, and structured information extraction.

DataExpo provides geoscientists with data discovery, search, and recommendation services for open scientific research. Considering the characteristics of Earth science data, DataExpo has also developed a spatiotemporal map retrieval service, which allows users to further refine search results based on geographic location and time scale. Taking the "Global Ocean Dissolved Oxygen Spatiotemporal Database" as an example, we have accumulated websites that not only include multidisciplinary databases such as GBIF and Zenodo, but also specialized geoscientific databases such as PANGAEA and NOAA, and even long-tail data that is difficult to find on the internet. We collect dissolved oxygen data from 1900 to 2023, and establish uniform quality standards for multi-source data to construct a global spatiotemporal ocean dissolved oxygen database.

In the future, we will continuously improve the services of DataExpo and facilitate data-driven scientific discovery for open science research.

Abstract

Deep-time Earth research is of great significance for understanding the rate, law and mechanism of Earth evolution in geological history that can support mankind better predict climate change, explore natural resources and protect our planet in the future. In order to promote Deep-time Earth research in the era of big data and artificial intelligence, the International Union of Geological Sciences (IUGS) launched the "Deep-time Digital Earth International Big Science Program" (DDE) in 2019. One of the core objectives of DDE is to build multidisciplinary geoscience knowledge graph which support the integration and sharing, mining and analysis of heterogeneous geoscience big data, and promote geoscience knowledge discovery, and finally make the transformation of geoscience research paradigm driven by "data-model-knowledge". In order to push the construction of geoscience knowledge graph, DDE has adopted two ways which are top-down domain experts manual collaborative construction and bottom-up machine intelligent mining, updating and completing. And so far, DDE has developed a series of related software and tools, and formed three levels of basic, discipline and application geoscience knowledge graphs which cover about 20 geoscience disciplines.

This paper first introduces the organizational model and technical methods of the construction of DDE knowledge graph, and then systematically summarizes the progress of DDE geoscience knowledge graph construction, software system development and specifications in the past three years. Finally, it analyzes the shortcomings and challenges of DDE knowledge graph, and discusses the direction and key issues of DDE knowledge graph in the future. We hope that geoscientists around the world will understand the philosophy, methods and achievements of DDE knowledge graph, so as to promote the "" of DDE knowledge graph worldwide and finally drive the research and application of geoscience knowledge graph.

Abstract

Metadata is critical for making resources Findable. FAIR (findable, accessible, interoperable and reusable) multi-disciplinary geoscience data, knowledge, and relevant services are required to achieve the IUGS Deep-time Digital Earth program (DDE) goal of data- and knowledge-driven scientific research. This requirement demands granular specific metadata standards based on generic standards like ISO19115, OGC CSW and Dublin Core. Thus the geoscience information metadata standard was built by CGI/CODATA/DDE scientists worldwide and the Edition1.0-2023 was formally released in Nov 2023 (https://cgi-iugs.org/publication/dde-metadata-standardv1). The DDE program is now developing a metadata aggregation and search application for its open data platform using the GeoNetwork-opensource software and this metadata schema to make DDE metadata interoperable with the global geoscience data ecosystem.

This metadata standard meets the demands from DDE for simplicity, efficiency, domain coverage, machine readability, consistency with existing standards and with geological history. It consists of 13 entities (MD_Metadata, MD_Identification, SV_ServiceIdentification, MD_Imagery, MD_SpatialRepresentation, MD_Distribution, CI_Date, EX_GeographicExtent, MD_Identifier, CI_OnlineResource, CI_Responsibility, EX_TemporalExtent, MD_Constraint) and 86 elements (22 Mandatory), 14 code lists (AcquisitionCode, CharacterSetCode, CountryCode, DateTypeCode, FunctionCode, LanguageCode, ProcessingLevelCode, ReferenceSystemCode, ResourceTypeCode, RestrictionCode, RoleTypeCode, SpatialRepresentationTypeCode,

ServiceTypeCode, TopicCategoryCode). The scheme is implemented in XML with transforms to and from ISO19115-3. It extends the one topicCategory code for geoscientificInformation in ISO 19115 to 41 secondary topicCategories existing currently and one more first category dataScience. Temporal extents can be specified using calendar Date and Time, geological time intervals from the International Commission of Stratigraphy, or numeric positions. Data, knowledge and various services are all defined as resources (both spatial and non-spatial) within MD_Identification. MD_Imagery covers key information from remote sensing and laboratory imaging of specimens, samples and analytical results. Typical and specific methods for geological data acquisition and observation are specified using a new codelist AcquisitionCode based on CGI's Observation Method Vocabulary. A code list for service types is defined in ServiceTypeCode to populate the serviceType property for common services and DDE provided specific services.

A Geoscience Temporal Ontology Incorporating ISO Standards and Allen Temporal Relations

Shu WANG[1]*, Institute of Geographic Sciences and Natural Resources Research, CAS (wangshu@igsnrr.ac.cn)
Yunqiang Zhu[2], Institute of geographic sciences and natural resources research, CAS

Abstract

Time serves as a crucial reference system for documenting entities, events, and processes in the field of Geosciences. A unified and semantically clear expression of geoscience time serves as the semantic foundation for addressing ultimate geoscience questions such as climate change, the origins of life, societal behavior, and Earth's evolution. The field of Geosciences encompasses diverse expressions of time dependent on various reference frameworks, including the Julian calendar, Coordinated Universal Time, geological time, Hebrew time, and the Chinese lunar calendar, among others. These expressions share common elements such as time descriptions, reference systems, and units, but also possess diverse unique elements such as time zones, time uncertainties, epoch origins, and leap month records. Achieving a unified and accurate recording of geoscience time is of significant importance for the coordination of geoscience data, understanding geoscience phenomena, and resolving geoscience issues.

International organizations and scholars have made continuous efforts to standardize the expression of geoscience time, yet compatibility in terms of time expression elements and temporal relationship expression remains elusive. Efforts include ISO 8601:2004 standardizing the representation of calendars and Coordinated Universal Time, the International Chronostratigraphic Chart (ICS) unifying geological time representations after 2004, the Open Geospatial Consortium (OGC) Time Ontology detailing the construction of a standardized sequential expression of calendars and timing systems based on Allen's temporal relations, and Unified Temporal Framework (UTF) laying the groundwork for the unified expression of geological and modern time.

Building upon the foundation of the geoscience Unified Time Framework, this study expands upon temporal expression elements such as point time, interval time, and time references to conform to the standardized representations of time descriptions outlined in ISO 8601:2004 and ICS. Furthermore, the study inherits and incorporates various temporal relationships expressed in the OGC Time Ontology. It proposes a novel unified ontology for geoscience time and presents it through an open ontology website. The study discusses in detail the design motivations and background of the time ontology, the symbols, and namespaces used, the basic principles of time ontology expression, an overview of the overall vocabulary, detailed specifications of classes, properties, and relationships, and a series of time expression examples including calendars, Coordinated Universal Time, geological time, and historical periods. This research aims to establish the semantic foundation for the coordination of various types of geological time, thereby advancing the integration of Geoscience big data and large models.

Construction and Sharing of CGS National Geological Database

Shoutao JIAO[1]*, Natural Resources Survey of China Geological Survey
(jshoutao@mail.cgs.gov.cn)
Rongmei LIU[2], Natural Resources Survey of China Geological Survey
Xiaohong WU[3], Natural Resources Survey of China Geological Survey
Yan YANG[4], Natural Resources Survey of China Geological Survey
Hailong YU[5], Natural Resources Survey of China Geological Survey
Hanrui SUN[6], Natural Resources Survey of China Geological Survey
Mingming ZHAO[7], Natural Resources Survey of China Geological Survey
Min WEN[8], Natural Resources Survey of China Geological Survey
Yi YUE[9], Natural Resources Survey of China Geological Survey

Abstract

The China Geological Survey(CGS) is committed to the construction, update and maintenance, sharing and application of public welfare and basic geological databases and the development of related database standards, led by scientific and technological innovation and information technology, through more than 20 years of efforts, together with relevant units, to take the lead in the construction of 98 influential geological databases, with a data volume of about 6.6PB, which has laid a solid and valuable first-hand data resource foundation for the development of China's geological survey. GeoCloud adopts distributed technology architecture, based on distributed database, and adopts spatial data hybrid processing technology to realize the integrated management and sharing services of multiple heterogeneous spatial data, and based on service interface management, it constructs a rapid invocation mechanism of cloud service resources and realizes unified management and monitoring based on services, and constructs a unified cloud resource monitoring system to realize a map of cloud resource application services. GeoCloud 3.0 has realized the sharing services of 98 national core geological databases, initially built a geoscience big data system, released more than 3,700 data services, realized the data sharing and interconnection of 56 nodes, and released more than 20,000 new products, built an open cloud ecology and geological cloud platform. In 2023, CGS has released 12 national geological databases, including the spatial database of China's geological map. CGS has completed the update and maintenance of more than 30 databases, including the national work degree database, the global scale geochemical survey database, the national land quality geochemical data, and the global petrogeochemical database. CGS has organized and updated a number of dynamic observation and monitoring data, accessed the data monitoring data of 20 natural resource monitoring stations for the first time to share on the geocloud, and completed the update of domestic resource satellite image data, 10171 groundwater monitoring stations of the National Groundwater Monitoring Project, and 272,000 potential geological disaster sites across the country. As the main participating member, the China Geological Survey, together with DDE and IUGS-CGI, jointly released the international standard "DDE-DS01 2023: Geoscience Information Metadata". The general data model of 16 specialties such as regional geology have been

continuously studied. The China Geological Survey has built the DDE-CHINA national node and compiled the overall plan for the construction of the DDE national node. For international users, DDE-CHINA adopts GEOSCIML standard and conforms to the FAIR principle. CGS has realized the sharing of some data from 30 national geological databases, including 1/500,000 China Geological Map, 1/1,000,000 China Geological Map, 1/2.5M series of tectonic maps, 1/10M series of tectonic maps, 1/4M series of geochemical maps, etc., and has completed 5 DDE-CHINA promotion training sessions in the "One Belt and One Road" Advanced Workshop on Earth Observation Data Policy and Data Application, Slovenian GIC Conference, Armenia, CCOP-IGDP Training Course, and Moroccan Geoscience Information Training Course.

Construction and application of an ontology-based domain-specific knowledge graph for petroliferous basin evaluation

Xianming TANG[1]*, SINOPEC (xianmingtang@qq.com)
Zhiqiang Feng[2], SINOPEC
Xinghua Wang[3], SINOPEC

Abstract

How to realize intelligent analysis and inference, and support exploration and development decision-making through the connectivity and correlation of the required data, models, methods, and knowledge in petroleum geological evaluations. The lack of unified semantic standard and is built in a fragmented manner in the petroleum geological knowledge impose great challenge on data integration and smart application for petroliferous basin. Knowledge graph, as an emerging technology, can potentially provide a way to tackle the challenges associated with petroliferous basin evaluation. This paper describes the knowledge system of petroleum basin evaluation in detail from the aspects of knowledge classification, attributes and relationships. On this basis, an engineering based method is proposed, which improves the traditional natural language processing method, and constructs the domain knowledge map based on the evaluation ontology of petroliferous basin. Through the integration of Sinopec multi-source heterogeneous database and millions of nodes, a unified knowledge map in the field of oil and gas basin evaluation is constructed, which supports the machine reading of massive literature and intelligent analysis of massive data, and promotes the transformation of Petroleum Geoscience Research Paradigm. The applications based on the constructed knowledge graph are developed and validated for effectiveness and advantages in providing better knowledge services for petroliferous basin evaluation.

[Keynote] Standards: a challenge for the future of geosciences

Francois Robida[1]*, CGI (f.robida@outlook.fr)

Abstract

Sharing data and knowledge has always been at the heart of the scientific process and the production of new knowledge.

Earth sciences are first and foremost observational sciences, based on data collected on the planet over generations. It is from data that interpretations, concepts and models are produced. The description of data by those who produced it, and its preservation, has always been a duty of scientists, to enable its reuse and reproducibility.

This sharing has long taken place between researchers, often from the same discipline. These exchanges have always been based on the development of a common language based on shared vocabularies and common standards, such as for indicating the geographical coordinates of an observation or the units of the measurements taken.

Today's scientific challenges, first and foremost the climate challenge, call for the mobilization of different scientific disciplines, often with different languages and practices.

At the same time, the development of data infrastructures on an international scale is giving researchers access, via computer protocols, to considerable sources of data from their own and other disciplines. Digital tools such as AI make it possible to make machines "reason" about data to produce new knowledge.

This ambition lies at the heart of DDE.

All these elements make it critical for both humans and machines to be able to "understand" the data they use. This understanding necessarily requires the adoption of common frames of reference on an international scale and across all disciplines. These frames of reference are based on a common "vision" produced by the scientific community (and updated as knowledge evolves), which translates into multilingual vocabularies and ontologies shared by this community.

In the past, this formulation has sometimes been seen as a low priority, outside the remit of the most advanced researchers, and to be delegated to specialists in knowledge management or information systems.

On the contrary, explicating a domain of knowledge in the formalism of ontologies reflects the state of knowledge and concepts at a given point in time, and therefore implies mobilizing the best experts in the scientific field.

It is therefore of the utmost importance that scientists are fully committed to this international approach, and that their contribution in these fields is recognized by their peers.

Chengshan Wang[6], State Key Laboratory of Biogeology and Environmental Geology and School of Earth Sciences and Resources, China University of Geosciences, Beijing

Abstract

Geologic time scale (GTS) stands as the unified standard for referencing Earth's temporal history. It is composed of time intervals which anchored with standard stratigraphic divisions based on rock sequences. The understanding of geological intervals mentioned in literature has been in alignment with the prevailing versions of the GTS at their respective times. However, GTS versions undergo dynamic updates in relative and absolute ages with the advent of new technology and data, leading to shifts in our comprehension and interpretation of historical data. In the current landscape of continuous data accumulation in various earth science domains, it is imperative to consider the temporal context of data during critical stages like data collection, cleansing, and storage. To quantitatively depict the evolution of the GTS, this study compiled GTS data spanning from 1893 to 2023 and harnessed a knowledge graph to represent this geological temporal knowledge. The outputting Geologic Time Scale Knowledge Graph (GTSKG) is an innovative knowledge base that encompasses all published versions of geological time scales, transformed into a machine-readable format. This compilation features data from 98 versions of global and regional geologic time scales of the Phanerozoic Eon. It involves encoding the geological time intervals across different versions and deriving semantic relationships between intervals of the same version through computational operations. The GTSKG aims to enhance data utilization by supporting improved data reusability, shareability, and scalability, thereby facilitating a more dynamic and integrated approach to analyze the Earth's complex systems.

Paleobiogeographic Knowledge Graph: An Ongoing Work with Fundamental Support for Future Research

Linna ZHANG[1]*, Nanjing Institute of Geology and Palaeontology, CAS (lnzhang@nigpas.ac.cn)
Zhangshuai HOU[2], Nanjing University
Boheng SHEN[3], Nanjing University
Qing CHEN[4], Nanjing Institute of Geology and Palaeontology, CAS
Shaochun DONG[5], Nanjing University
Junxuan FAN[6], Nanjing University

Abstract

Paleobiogeography investigates the geographical distributions of fossil organisms and controlling factors that affect their distributions in geological history, to reveal the macro-evolution and coordinated development of life and the environment. It is a crucial window for understanding the biosphere and the geographical environment. After two centuries of development, paleobiogeographic studies have led to the accumulation of significant amounts of knowledge and data; however, the voluminous outputs present the characteristics of an “isolated island” with a scattered, limited number of authoritative definitions of terminologies and semantic heterogeneity among them. This makes data queries cumbersome, the rate of data reuse low, and data sharing more difficult. A knowledge graph (KG) has the advantage of expressing concepts and their semantic relations, which is an important tool for achieving data organization and fusion, and data mining; further, it is also a key technology for realizing the unrestricted sharing of paleobiogeographic information. Through our efforts over the past two years, a paleobiogeographic KG was developed based on the established construction procedure of the KG, which contains 273 concepts, 172 properties, and 47 rules. Meanwhile, the completion of this KG and the construction of a paleobiogeographic platform for display and analysis are now being carried out.

Abstract

Around the globe, geochemical datasets have been collected for nearly 180 years by thousands of researchers and research groups on an incredible diversity of samples (rocks, minerals, meteorites, fluids, gases, etc) using hundreds of analytical techniques across many disciplines. These geochemical datasets are notoriously heterogeneous and integration and comparison of datasets from multiple repositories is difficult because there has rarely been consensus on the definition of the minimum variables required for interchanging data from different analytical methods, combined with inconsistencies used in the vocabularies that describe each variable.

Next-generation analytical machines are producing data in exponentially increasing volumes, and there is a growing tendency for analytical results to be presented as 2D/3D imagery. Simultaneously, new data-driven research questions are emerging that require global aggregation of geochemical datasets for data analytics to enhance our understanding of earth and planetary system processes. Combined, these factors are accelerating the need to make geochemical data around the world Findable, Accessible, Interoperable and Reusable (FAIR), which in turn is driving an increasing demand for standardization of geochemical variables and vocabularies.

To accelerate the development of the much needed standards, the OneGeochemistry initiative (http://onegeochemistry.org/), formed in 2018, has been working towards enabling an Open Global Network of all types of geochemical data from multiple countries, repositories and researchers. To achieve a balance between meeting increasing demands for FAIR vocabularies versus time required to reach international agreement, OneGeochemistry has developed a four-tiered approach (local, regional, international, global):

1) Data providers with locally defined vocabularies are encouraged to make these available online and that ensure each term has a persistent identifier;

2) Groups with similar topics begin working together to harmonize multiple locally-derived concepts/definitions and publish these as regional resources;

3) Raising awareness of communities acting at a regional level and motivate them to come

together and decide on building crosswalks and mappings or coalescing regional resources into international resources;
4) Taking the best and most appropriate vocabularies from either local, regional, international resources and have them endorsed, maintained and extended as global vocabularies and resources by international authoritative groups (e.g. Scientific Unions/Societies).
As convergence takes place towards internationally-agreed terms, the size of the community that is able to share both metadata and data in machine to machine environments grows. As better defined vocabularies become available online they should be easy to translate into multiple languages.
The OneGeochemistry initiative is part of the CODATA/RDA-led WorldFAIR Project on Global Cooperation on FAIR Data Policy and Practice (https://worldfair-project.eu/). Geochemistry is one of 11 disciplinary and cross-disciplinary case studies, which together seek to advance implementation of the FAIR principles and to create a Common Data Interoperability Framework (CDIF) that improves the reusability of digital research data across multiple domains. The WorldFAIR project is providing valuable insights into the available vocabularies and other currently much used FAIR Enabling Resources, and is showing where standards are urgently required to advance a global network of geochemical data repositories within a multidisciplinary framework.

DDE OnePetrology Database and Standard (Igneous Rocks)

Ying TONG[1]*, MNR Laboratory of Deep Earth Sciences and Technology(SinoProbe Laboratory) (yingtong@bjshrimp.cn)
Tao Wang[2], MNR Laboratory of Deep Earth Sciences and Technology(SinoProbe Laboratory)
Yi Ding[3], Institute of Geology, Chinese Academy of Geological Sciences

Abstract

The OnePetrology database, built on the knowledge system of petrology with the idea of 'data+mapping+research', represents a significant advancement in the field of petrology and geoscience research by harnessing the power of big data and digital technologies. This initiative, supported by the Deep-time Digital Earth (DDE), an international Big Science Program of IUGS, aligns with the 21st-century scientific research paradigm that leverages data and models to drive new discoveries and insights. The database's mission is multifaceted, aiming to: (1)Integrate and Network Global Databases: By identifying, augmenting, and networking globally distributed petrological and geochemical databases for igneous rocks, OnePetrology seeks to create a comprehensive, service-oriented platform accessible via DDE. This platform is designed to facilitate in-depth data mining and comprehensive analysis, with the ultimate goal of addressing major geological challenges through big data analysis. (2) Elucidate Deep-Earth Material Evolution: Through the analysis of magmatic rock evolution, the database aims to understand the 3D architecture and 4D evolution of deep-earth materials across regional, orogenic, and global scales. (3) Provide Evidence for Deep-Time Processes: The database serves as a resource for understanding deep-time plate reconstruction, continental assembly processes, and paleogeographic reconstruction. It also aids in revealing the growth and evolution of the Earth's crust and mantle. (4) Reveal Deep-Earth Dynamics: By studying the movement of fluids and magma, material exchange from the core to the crust, and the mechanisms of tectonic plate movement and supercontinent cycles, OnePetrology contributes to the understanding of the Earth's Deep-engine workings. The database encompasses a wide range of data types, including rock types, occurrences, spatial information, geological background, geochronology, geochemistry, isotopes (including Sr-Nd-Hf-Pb-O), and non-traditional isotopes. These data come from published literature, our team's data, laboratory analyses, and interconnected international databases. OnePetrology also supports various software and tools that enhance its utility., including PDF data extractor, mapping services, and diagram plotting tools, all of which can be downloaded from the website. Adhering to principles of FAIR (Findable, Accessible, Interoperable, Reusable), TRUST (Transparent, Robust, Usable, Shareable, Transparent), and CARE (Consistency, Accuracy, Richness, Efficiency), etc., the database follows the concepts, semantics, and ontologies of the CGI (Commission for the Management and Application of Geoscience Information), API (Application Programming Interface), IUGS (International Union of Geological Sciences), textbooks, and online databases. The OnePetrology standard (Version 2.0) complies with relevant technical specifications for information technology and discipline

research, and efforts are underway to further refine this standard with the vision of becoming the benchmark for the IGC (International Geological Congress) and CODATA (Committee on Data for Science and Technology). In summary, OnePetrology is a groundbreaking resource that not only supports petrology education and research but also serves as a model for how big data can be utilized to advance our understanding of the Earth's complex geological history and processes.

Research on the standard of building database of Geophysical-Geochemical-Remote Sensing data based on data model

wei REN[1]*, Command Center for Integrated Natural Resources Survey (renwei@mail.cgs.gov.cn)
Xiaohong Wu[2], Command Center for Integrated Natural Resources Survey
Rongmei Liu[3], Command Center for Integrated Natural Resources Survey
Sheng Zhang[4], Command Center for Integrated Natural Resources Survey

Abstract

Geophysical, geochemical, remote sensing data is an important basis for resource exploration and development, resource evaluation and utilization and related decision-making, with the increasing development of materialized remote exploration technology, the amount of data shows explosive growth, geophysical, geochemical, remote sensing data exploration data into the big data era. This paper will refer to the concept of data model, constructed the physical remote data storage model and library building standards, to realize the construction of Geophysical-Geochemical-Remote Sensing data management system of cloud architecture.

Over 60 years of China's mineral geological survey , detailed survey and exploration work in key areas have accumulated a large number of Geophysical-Geochemical-Remote Sensing data resources. However, in terms of the way of data storage, the data are mainly scattered and stored in each exploration unit, maintained and operated in the form of projects, the data convergence mechanism has not yet been established, and the problem of "information silo" is still relatively prominent. In terms of database construction standards, due to the complexity of the professional direction of Geophysical-Geochemical-Remote Sensing, most of the geological exploration units have not established a unified physical and chemical remote survey database construction standards, which is not conducive to data sharing and comprehensive utilization. There is an urgent need to build a unified database construction standard and data management system for Geophysical-Geochemical-Remote Sensing data, so as to standardize the database, classify and manage the data, share the service and make comprehensive use of the data.

The standard for building Geophysical-Geochemical-Remote Sensing data libraries stipulates that the database is logically divided into three libraries, including the basic library, the core library and the auxiliary library. The basic library mainly stores the unstructured document data of each specialty of physical and chemical remote data, and with reference to the relevant technical standards and specifications and combined with the actual exploration and construction situation, it has formed the basic library model of 22 different specialty data types according to the combing of original data and result data categories. The core library mainly stores structured data of various specialties, and 35 core library models are formed by standardized extraction and quality checking of structured data files in the base library. The auxiliary library consists of data supporting system operation and management and front-end data sharing services. The data storage of the Geophysical-Geochemical-Remote Sensing data Management System is based on the hybrid architecture of PostgreSQL+MongoDB+distributed file system, and the independently researched

and developed cloud native raster map service RMapServer geographic information service engine is constructed to guarantee the consistency and completeness of the standardized and integrated library building requirements and data services for the Geophysical-Geochemical-Remote Sensing original data and the result data.

Study on the Crowdsourcing and Sharing System Model for Lithogeochemical and Geochronological Data

Rui YU[1]*, Development Research Center, China Geological Survey (yurui@mail.cgs.gov.cn)
Yanggang Wang[2], Development Research Center, China Geological Survey
Lirong Hao[3], Development Research Center, China Geological Survey
Yi Ding[4], Institute of Geology, Chinese Academy of Geological Sciences

Abstract

Lithogeochemical data and geochronological data are essential for understanding Earth's evolution, unraveling geological process, and mineral resources exploration. Scientists have established relevant geochemical databases such as EarthChem, GEoReM, GEOROC, and DataView separately for these purposes. But huge lithogeochemical data and geochronological data currently are still been stored many disparate flat files. It’s critical to accumulate those data scattered among research institutions and individuals and create a system for data uploading and sharing through a crowed-sourced database along with a data acquisition App.

A multi-terminal open system model for lithogeochemical data management has been developed, which integrates the collection of online/offline field data, laboratory analyzing data, description and literature data. While, users could also manage their data and share them independently with high efficiency. The database operates through an automated process for data compilation, quality control, uploading, and releasing, which helps consistent, standardized, and long-term data storage and management. The App designed to guarantee the traceability and accessibility of samples with their lithogeochemical and geochronological attribute data has also been created. It can be installed on a mobile terminal for use in laboratory and geological field. The sample origin and sample location information will be recorded by the mobile App in the field. The lithogeochemical and geochronological data will be recorded by lab App in the laboratory consistently.

The system model adheres to the FAIR principles (Findable, Accessible, Interoperable, and Reusable) and Open Science principles and practices which contribute to promoting earth science research from traditional theory-driven to data-driven. The system model has been adopted in the igneous database of the IUGS Deep-time Digital Earth Program. And its data are utilized in the Map of Mesozoic Granitoids and Related Rocks of Asia already.

Knowledge Graph Schema of Mineral Deposit: The Design, Application, and Significance

Chengbin WANG[1]*, China University of Geosciences(Wuhan) (wangchb@cug.edu.cn)
Mingguo Wang[2], China University of Geosciences
Jianguo Chen[3], China University of Geosciences

Abstract

The knowledge graph has become a hot topic for mining geoscience big data. The program of Deep-Time Digital Earth accelerates the development and application of a geoscience knowledge graph. However, the extraction of information from unstructured literature still remains a challenge, in which a fundamental issue is the categories and the type of discipline-specific information. This paper presents an effective workflow for designing a schema including geological entities and their semantic relations for mineral deposits. This paper includes the following aspects: (1) a use case-driven method for building an ontology of mineral deposits. The geological entity and semantic relation classes are derived from the ontology of mineral deposits based on background knowledge. (2) According to the schema of mineral deposits, relational data mapping, deep learning, and natural language processing are employed to build the knowledge graph of mineral deposits. (3) we will show several application cases of question-answering systems based on a mineral deposit knowledge graph and knowledge discoveries for mineral deposits. In the last parts, we will conclude the further challenges and opportunities of the knowledge graph in the domain of mineral deposits. Our studies will provide some experiences for construction of a knowledge graph and application for improving geoscience research.

Joint inversion of gravity and magnetic 2-3D for the structure of hidden phosphorus deposit

xingting WANG[1]*, 18309669725 (2429400825@qq.com)

Abstract

Northeast Yunnan is one of the important mineral resource gathering areas in China, with superior metallogenic geological conditions and good prospecting prospects.The regional stratigraphy has a well-defined double-layer structure, with a metamorphic basement in the lower part and an unspoiled caprock in the upper part.

At present, only Yangchang phosphate ore has been found in the Zhenxiong area of the region, and there are more than 20 boreholes with phosphorus in the early stage, and the phosphate rock body in the area is not encircled in the direction, and the degree of exploration in the middle and deep of the area is low , and the prospecting potential is huge.In this study, the gravity-magnetic joint inversion method was used to explore the study area and found out the occurrence of underground ore bodies.

According to the abnormal response of physical properties in the study area, combined with the profile information of the previous electrical exploration method, the joint inversion method between different physical property parameters is applied to achieve the following three main links:

(1)parameterization of the model; (2) the construction of the objective function; (3) Selection of inversion algorithms.Among them, the first two links are the basis for the realization of joint inversion.According to the current research status, in most of the existing joint inversion algorithms, it is necessary to clarify the correlation between the physical parameters used in advance, which makes the method more dependent on prior information.In this study, the stratigraphic mineral information obtained from geological drilling in the early stage will be used as the prior information of the joint inversion of gravity and magnetism, and then the underground structural morphology of the target geological body will be obtained based on the reliable information in the joint inversion of gravity and magnetism.

YU FAN MENG[1]*, 1403999876@qq.com (1403999876@qq.com)

Abstract

Research on cloud geophysical data visualization technolog

In 2006, the concept of "cloud computing" was introduced. The development of cloud computing technology has promoted the transformation of the working model of the geophysical industry. The data visualization work after data discovery based on the network is to realize the geophysical data visualization operation of the original workstation (stand-alone) on the cloud platform, and further expand the online application of geophysical data processing and interpretation business. The overall work content of the project is huge, using web front-end technology to store and manage multi-source and large amounts of geophysical data on the cloud efficiently and reasonably, realize the storage, processing, display, interaction, analysis and output of geophysical data on the web, and solve the actual problems of users.In this study, we analyzed the various needs of geophysical data visualization and determined the necessary visualization functions. Based on the use and refactoring of existing code, a number of comparisons choose methods with strong adaptability to integrate, extensibility, and write code. Build a front-end framework, select an appropriate visualization library, form a complete geophysical data visualization interface, and determine each functional module. Practical application of successful geophysical visualization methods to ensure the feasibility of the study. Finally, the rapid analysis of geophysical data in the cloud is completed to form high-quality visualization images.

An One-Stop Application for DDE Metadata

Yuhao Dong[1], Institute of Integrated Information Mineral Resources Prediction, Jilin University, China
Wei YAN[2]*, School of Geophysics and Information Technology, China University of Geosciences (Beijing) (yanwei_2021@126.com)
Yongzhi Wang[3], Institute of Integrated Information Mineral Resources Prediction, Jilin University, China
Xizhu Wang[4], College of Geo-Exploration Science and Technology, Jilin University, China
Minghua Zhang[5], Development Research Center China Geological Survey

Abstract

Metadata focus on describing basic information about various types of data. It also plays an important role in geosciences data in DDE big science program for resource Findable. DDE aims to provide a loosely one-stop data center that meets FAIR principles and serve global geoscientists by manipulating, integrating, sharing, applying all kinds of data such as geology, marine, tectonic, geophysics, geochemistry, remote sensing, borehole, planetary, etc. The variety of complicated geosciences data is a big challenge for search, accessing, management, integration, share, discovery, application, mining. In order to pave the way to utilize big data in DDE platform, DDE standard group has issued DDE geoscience information metadata standard, it offers core metadata requirements for all data participated in DDE. To managing DDE metadata efficiently , an application (APP) fits the standard was developed based on service-oriented architecture in DDE cloud computing environment. The APP performs registration, search, update, import, export, harvesting, cataloguing, publishing, visualization, statistics for DDE metadata. It is useful at both handling input metadata manually and dealing with local XML metadata and online metadata URIs. Same or similar values retrieved from local files or online URIs can be set to match corresponding elements/columns automatically. as a result the metadata center can be act as ALL in ONE for metadatabases in and outside DDE program. The metadata saved in DDE metadata center will be published as Web services when they were registered. Five format metadata so far can be reused for the core information from different specifications of metadata including OneGeology, CSW, DDE, ISO 19115 respectively. And this metadata App can interact with other geosciences application for metadata harvest with further imporvement . The APP has been integrated with DDE big data website for metadata collection in the past few years. It will contribute more for further interdisciplinary matadata applications in open science in the future.

Abstract

Knowledge graph (KG) a tool for graphically presenting knowledge, consists of nodes and edges that represent the relationship between entities and nodes, respectively. KGs can effectively organize and manage massive amounts of data and mine for deeper knowledge and rules through associations between entities. In particular, the Deep-Time Digital Earth program (DDE), aims to build comprehensive KG to facilitate the creation of standard terminology and knowledge integration in geoscience.

Antarctica is important for global warming, resource sustainability, and the preservation of biodiversity as the last clean land on Earth that has not been exploited on a large scale. Advances in geophysical technologies have led to an exponential growth in scientific data from Antarctica, thereby presenting an unprecedented opportunity to delve deeper into the mysteries surrounding this enigmatic continent. To better exploit this data and derive valuable information from it, the construction of KG becomes essential. The KG in geophysics facilitates the integration of data scattered across diverse literature and reports, enabling the application of correlation analysis to elucidate the interrelations among a broad spectrum of geophysical data within the Antarctic region.

In this study, literature and textual information on geophysical research in Antarctica between 1982 and 2022 was systematically collected using the Web of Science database. An in-depth analysis of these materials was used to construct KG in Geophysics of the Antarctic. Six popular research topics were identified: Antarctic ice sheet instability and sea level change, Southern Ocean and sea ice, tectonic activity in the West Antarctic Rift System, paleo-continental rift and reorganization, magmatism and volcanism, and subglacial lakes and subglacial hydrology. These topics not only cover several important areas of geophysical research in Antarctica but also reflect research hot spots and research trends. In a drive to reveal further research directions, development trends, and challenges this study also analyzes in-depth the evolution of research themes of these popular topics within three consecutive subperiods (1990-1995,1996-2005, and 2006-2022) in geophysical research in Antarctica. By comparing the intensity, citation frequency per article(>10), main research content, and method of each topic during the different periods, it is possible to predict its likely future direction.

The construction of the Geophysical KG as a tool has provided researchers with new research perspectives, as well as strong support for scientific research in Antarctica. The results of this study will serve as a powerful reference and guide for future scientific research in the Antarctic.

Geospatial-aware representation learning model for point of interest(POI) matching

Xiaoliang DAI[1]*, Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences (daixiaoliang079x@igsnrr.ac.cn)
Yunqiang Zhu[2], Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences

Abstract

Point of interest (POI) data serves as a digital representation of real-world locations that may pique the interest of specific demographic groups. POI datasets from different sources often vary in spatial coverage, attribute emphasis, and data quality. To accurately portray locations within a research area, the integration of multiple POI datasets becomes crucial. POI matching stands out as a pivotal step in this amalgamation, discerning POIs from disparate datasets representing identical real-world locations.

Despite the multitude of POI matching methods developed, they typically cater to specific research domains, limiting their efficiency and generalizability. This paper introduces a geospatial-aware POI matching method. The approach initially transforms diverse POI attributes into vectors through POI name embeddings, POI type embeddings, and spatial location embeddings. Subsequently, vector similarity is computed, and the final POI matching is executed employing a deep neural network.

Experimental evaluations conducted on datasets from various regions in China conclusively demonstrate the superior performance of the proposed POI matching method over existing alternatives. It excels in terms of accuracy, recall, F1 score, and precision. Additionally, it showcases enhanced spatial generalization capabilities, making it a robust solution applicable across diverse geographical contexts. This method contributes to advancing POI matching techniques, providing a comprehensive and adaptable approach for spatial data integration.

Abstract

Earth science knowledge empowers us to adopt a global perspective and take local actions, contributing to the achievement of the Sustainable Development Goals (SDGs). This study aims to qualify the contribution of Earth Sciences towards realizing of the SDGs through a comprehensive bibliometric analysis.

We employed category filters induced by Dimensions AI to collect and analyze more than 282,000 articles and 36,000 datasets related to Earth Sciences and the SDGs spanning from 2015 to 2022. This extensive dataset pertains to the nexus between Earth Sciences and the SDGs. Our analysis encompassed an evaluation of indicators such as publication quantity, citation patterns, international collaboration networks and topic trends, elucidating the contribution and impact of Earth Sciences in achieving the SDGs.

Preliminary findings indicate that Earth Sciences play a significant role in multiple SDGs. For instance, Earth Sciences can offer scientific knowledge and technological support in some specific SDGs such as 13 Climate Actions(114,314 articles), 15 Life on Land(56,365 articles), 14 Life Below Water(47,836 articles), and 7 Affordable and Clean Energy(26,033 articles). Additionally, Earth Sciences facilitate cross-disciplinary collaboration(e.g.'Earth Sciences' and 'Environmental Sciences' 48,213 articles) and cross-field collaboration(e.g.'Geology' and 'Physical Geography and Environmental Geoscience' 21,837 articles), enabling cross-cutting solutions for sustainable development goals.

The insights derived from this study offer a nuanced understanding of the instrumental role played by Earth Sciences in sustainable development practices. They provide guidance and recommendations for policymakers, scholars, and practitioners regarding the role of Earth Sciences in achieving the SDGs. Further research can broaden the scope of data and employ more analytical methods to further delineate the impact of Earth Sciences on the SDGs.

Abstract

Airborne gamma spectrometry is an important method of uranium exploration. It contains rich prospecting information in the data, but complex noise caused by various reasons will seriously reduce the signal-to-noise ratio of the data, especially affect the screening of anomalies, the extraction of weak information, and the analysis of uranium migration laws. It directly affects the effect of measurement and geological interpretation. Therefore, how to quickly achieve the signal-to-noise separation of a large amount of airborne gamma spectrometry data is one of the important issues to improve data quality and exploration results.

First, the basic principle of curvelet transform is studied. Compared with wavelet transform or other eigenvalue methods, this method not only inherits multi-scale, but also has multi-directionality, which can better represent two-dimensional or high-dimensional data. At the same time, in the process of signal-to-noise separation, curvelet transform generally only makes local changes to some detail scales and angles of the data, which is not easy to cause data distortion and try to retain real information. These features are suitable for denoising airborne gamma ray data, especially for full-spectrum data processing, which will achieve better results. Secondly, about 30,000 km of measured data in a certain basin in 2023 are processed using this method. Before processing, there are obvious white noise and northwest-southward strip noise in the original data. These two kinds of noise overlap in the anomaly area, which has a great impact on the identification of the true shape of the anomaly. After processing, the strip noise basically disappears, the white noise is significantly suppressed, the anomaly characteristics and other detailed geological information are preserved, and no data boundary distortion occurs. Good practical processing results are achieved.

Therefore, a curvelet transform-based technique for signal-noise separation in airborne

radiometric data is proposed, which is characterized by fast processing, high fidelity, and applicability to large amounts of data. It is also an effective technique for solving the problem of denoising data before weak signal extraction in basins.

This research was supported by the National Natural Science Foundation of China (U2067204).

Underground spatial distribution of uranium and radium elements in Barun uranium deposit, Erlian Basin, Inner Mongolia

Nan Gan[1]*, Beijing research institute of chemical engineering and metallurgy
(152067094@qq.com)
Tingting Xie[2], Beijing research institute of chemical engineering and metallurgy
Nanping Wang[3], China university of geosciences beijing

Abstract

The characteristics of sandstone type uranium deposit in China is known as low ore grade and small ore body size, and the cost and technical difficulty of uranium exploration are getting higher and higher. The relationship between radon anomalies observed in soil gas and deep uranium deposits has always been an attractive subject. Therefore, a study on the distribution of uranium, radium and radon above the uranium deposits in the Barun Uranium Mine in Erlian Basin, Inner Mongolia.

Based on the borehole geological and geophysical logging data of the proposed mining area, a three-dimensional mixed geological model of heterogeneous layer and lithology of Barun uranium deposit was constructed by using smooth indicating kriging method in EVS software. By using the depth-quantitative gamma-ray logging and borehole uranium-radium equilibrium data, the spatial distribution of uranium and lithology interactively modeled are to show the spatial distributions of uranium elements in oxidizing and reducing sand layers. It is found that the specific activity of uranium and radium in sandstone in the group of Yierdinmanhe Formation above the ore bodys is higher than it in Saihan Formation, the ore-bearing layer, as well as in the surface soil. In addition, small local concentrations of uranium and radium were observed. The distributions of uranium element in ore-bearing layer, sand body and mudstone layer provide an important basis for the division of ore-bearing layer and the layout of boreholes in the leaching mining. The spatial distributions of uranium and radium elements from the uranium body roof to the near surface of the mine for the first time also provides important valuable data for understanding radon migration above the uranium deposits.

This research was supported by the National Natural Science Foundation of China (U2067204).

Abstract

A knowledge graph (KG) is a knowledge base that integrates and represents data based on a graph-structured data model or topology. Geoscientists have made efforts to construct geoscience-related KGs to overcome semantic heterogeneity and facilitate knowledge representation, data integration, and text analysis. Paleontology is the study of the history of life on Earth based on fossils. An enormous number of fossil taxa have been recorded and published with their described information, such as diagnostic features, age, distribution, etc. Assembling and analyzing the information is the first essential step in reconstructing geological history. However, there is currently no comprehensive paleontology KG or data-driven discovery based on it. In this study, we constructed a two-layer model (the ontology layer and fact layer) to represent the ordinal hierarchical structure of the paleontology KG following a top-down construction process. An ontology containing over 19000 concepts has been defined up to 2023. It consists of six TopConcepts: Fossil, Taxonomy, Paleoecology, Evolutionary paleontology, Biostratigraphy, and Paleobiogeography. The construction of the paleontology KG ontology layer also marks the completion of the main framework of the paleontology knowledge system. Considering the increasing digitizing tendency in paleontology research, the paleontology KG would become a fundamental part of any paleontological database. On this basis, we derived the synonymy list based on the paleontology KG and designed corresponding online functions in the OneStratigraphy database to showcase the use of the KG in paleontological research.

Modelling Phanerozoic Climates and Biogeochemistry

Paul VALDES[1]*, University of Bristol (p.j.valdes@bristol.ac.uk)
Alex Farnsworth[2], Bristol Univesity
Daniel Lunt[3], Bristol University
Chris Scotese[4], Northwestern University

Abstract

The Phanerozoic period offers a unique insight into variability of the Earth System. Geological data provides a huge wealth of information about climate and biogeochemistry change during this period but it is difficult to attribute the mechanisms of change from data alone. Computer models of the Earth System provide an additional valuable tool to help us understand the causes of past changes and to quantify different processes. The talk will present results from a unique series of 109 simulations covering the whole of the Phanerozoic. We use the model (HadCM3) to quantify the contrasting roles of paleogeographic change, carbon dioxide variability, and solar constant changes on both the temperature and hydrological cycle. We show that a modified version of our model is able to reproduce the warmth of high latitudes during the Mesozoic and early Cenozoic, thus offering a solution to one of the long standing paleoclimate model-data challenges. Recently, the model has been extended to include a simple ocean carbon cycle model. We will use this model to show the changes in marine and terrestrial carbon cycle for a number of selected periods. The results show that the terrestrial (vegetation) carbon pools can vary significantly through the Phanerozoic due to the changes in climates.

Phanerozoic Paleotemperatures and CO2 Levels

Christopher Robert SCOTESE[1]*, Northwestern University (cscotese@gmail.com)

Abstract

This presentation provides the first comprehensive and quantitative estimate of how global temperatures have changed during the last 540 million years. It combines paleotemperatures measurements determined from oxygen isotopes with broader insights obtained from the changing distribution of lithologic indicators of climate, such as of coals, evaporites, calcretes, reefs, and bauxite deposits. The waxing and waning of the Earth's great polar icecaps have been mapped using the past distribution of tillites, dropstones, and glendonites. The global temperature model presented here includes estimates of average global temperate (GAT), changing tropical temperatures (ΔT˚ tropical), deep ocean temperatures, and polar temperatures. The history of global changes in temperature during the Phanerozoic has been summarized in a "paleotemperature timescale" that subdivides the many past climatic events into 8 major climate modes; each climate mode is made up of 3-4 pairs of warming and cooling episodes (chronotemps). The paleotemperature model presented here allows for a deeper understanding of the interconnected geologic, tectonic, paleoclimatic, paleoceanographic, and evolutionary events that have shaped our planet. The quantitative paleotemperature model presented here makes explicit predictions about the Earth's past temperature that can be tested and evaluated.

By quantitatively describing the pattern of paleotemperature change through time, we may be able to gain important insights into the history of the Earth System and the fundamental causes of climate change on geological timescales. These insights can help us better understand the problems and challenges that we face as a result of Future Global Warming.

CO2 is a greenhouse gas that has played an important, if not the predominant role, in regulating the Earth's temperature through time. Global Climate Models, such as CESMX and the HadleyCM3 require estimates of atmospheric CO2 to modulate the temperatures produced by these simulations. Therefore, an accurate estimate of the ancient concentration of atmospheric CO2 is essential if we are to successfully model past climates. In order to improve the estimates of CO2, we have used our growing understanding of the temperature history of the Phanerozoic (Scotese et al., 2021) to refine and update the Foster CO2 curve. By considering an independent estimate of temperature, we can now "fill in the gaps" and reject contradictory CO2 data. At first this may seem like circular reasoning. However, no CO2 proxy data was used to determine the cool and warm intervals (Scotese et al., 2021). We are simply redrawing the CO2 curve so that it conforms with what we independently know about global temperature change. The goodness of fit between the revised CO2 curve and the CO2 proxy data actually improves as a result of the rejection of questionable CO2 values.

This is not a final answer. There are still large gaps in the CO2 proxy record, and the estimation of some of the CO2 peaks, where there is no data (i.e., Cambrian, early Triassic,Cenomanian-Turonian), is speculative. This curve, however, represents a testable hypothesis that awaits conformation or rejection with additional data.

Abstract

The rise of the Tibet Plateau played a significant role in Asian climate evolution, especially the Southeastern (SE) Tibet which forms the transitional area where the South Asian Monsoon and East Asian Monsoon systems interact. The rise of SE Tibet potentially makes it one of the global biodiversity hotspots. However, the impact of the topographic evolution of SE Tibet on the development from the orbital climate to the Asian monsoon system is still unclear.

We reconstruct the uplift history of the SE Tibet in three Cenozoic basins, including Gonjo, Relu and Markam Basin. These basins are NW- SE trend and narrow, with an elevation of ~4000 m at present. Today the climate in these basins is semi-humid monsoonal with a mean annual air temperature (MAAT) of 5 ℃ and annual precipitation of 600 mm/yr. We found eolian deposits are popularly developed at the bottom of the SE Tibet Cenozoic basins before early Eocene (>50 Ma), especially in the Gonjo and Relu basins. Fluvial and lacustrine strata were deposited in the middle part of Gonjo Basin and the lower part of Relu Basin (50-45 Ma). A large number of lacustrine sediments (45-34 Ma) exists in the middle of the Relu Basin and the top of the Markam Basin. Oxygen and clumped isotopes from the Gonjo Basin suggested an earlier uplift from 0.7 km to 3.8 km during the middle Eocene (Xiong et al., 2020). The CLAMP and clumped isotope results for the Relu Basin in the Yidun Arc indicated a rise in elevation from 0.6 km to 3.7 km between 45 to 34 Ma (He et al., 2022). The Markam Basin remained at a moderate elevation of 2.6 km between 42 to 39 Ma, then rose rapidly to 3.8 km by 36 Ma as indicated by oxygen isotope paleoaltimetry (Zhao et al., 2023). Combined with published paleoelevation results from the Nangqian, Songpan and northwestern Yunnan Basins, the SE Tibet remained lowland until the

early Eocene, and then underwent quickly rise in the middle Eocene, so that all basins had reached or approached their present-day elevations by the latest Eocene of ~35 Ma, forming the high-landform of SE Tibet.
Numerical climate modelling with realistic paleo-landscapes shows that with the raising SE Tibet, a Mediterranean climate developed in SE Tibet and the adjacent southeastern China region characterized by bi-modal precipitation with two peaks during the spring (MAM) and autumn (SON) seasons, and a lower precipitation in the summer (JJA) seasons (He et al., 2022; Chen et al., 2023). Another line of evidence that supports the Mediterranean-like climate comes from the plant fossils. A typical semi-arid or arid flora that includes Palm, Eucalyptus, Palibinia and Quercus shows some similarity to Mediterranean vegetation. This flora co-evolved with the rise of SE Tibet in the Relu and Markam basins, and even dispersed to the southeastern China. The high topographic relief of SE Tibet, coupled with this distinctive Mediterranean climate system, significantly contributes to the development of the high biodiversity of the Hengduan Mountains.

Steep oceanic DIC δ13C depth gradient during the Hirnantian Glaciation

Shengchao Yang[1]*, Nanjing University (scyang@smail.nju.edu.cn)
Junxuan Fan[2], Nanjing University
Thomas Algeo[3], University of Cincinnati
Chao Li[4], Chengdu University of Technology

Abstract

The Hirnantian carbon isotopic excursion (HICE) was characterized by a global positive δ13C excursion (up to ~+7‰ in excursion magnitude) during the Ordovician-Silurian (O/S) transition, while its mechanism remains controversial, impeding our understanding of this global event and its environmental significance. Since local and regional δ13Ccarb signatures can be decoupled from global seawater δ13CDIC and cause a bias in carbon cycle reconstructions, basin-scale investigations to fully assess local variations in carbon isotopic signatures are essential to elucidate the mechanism of the HICE, but few such studies have been conducted for the O/S transition.

In this study, we performed a comprehensive analysis of global carbon isotope records, based on 65 paleogeographically widely distributed sections (4,612 carbon isotope data in total), documenting a steep oceanic δ13C water-depth gradient (e.g., a 4.6‰ offset in the HICE excursion in Laurentia and 3.3‰ in South China) during the Hirnantian Stage. We propose a hybrid hypothesis that the HICE records a shift toward more positive values owing to a large glacio-eustatic fall (>100 m) under the herein-identified steep oceanic δ13C water-depth gradient, with potential contributions from global-ocean δ13CDIC changes and authigenic carbonates. This study provides the first large-data evidence for a steep oceanic DIC δ13C water-depth gradient and widely density-stratified ocean during the Hirnantian Glaciation, which has implications for reconstructions of the carbon cycle and ocean circulation during the Early Paleozoic.

Domenico C.G. Ravidà[7], Georg-August-Universität Göttingen
Paul J. Valdes[8], University of Bristol

Abstract

The largest mass extinction in Earth history occurred at the end of the Permian (~252 Ma), and coincided with rapid global warming1, extraordinarily high sea surface temperatures and a perplexing homogenization of low-latitude climates. Voluminous CO2 emissions from Siberian Traps volcanism are widely regarded as the driver of the warming. Over 20 such volcanism-driven hyperthermals punctuate Phanerozoic history, yet only a few coincide with extinctions, and none of which approach the ~90% global species loss of the end-Permian. This raises the question of why the end-Permian world was so sensitive to CO2-degassing and challenges our understanding of climate modulation and Earth system tipping points. In order to understand the enigma of the Phanerozoic's hottest climate, we couple a new temperature proxy dataset with state-of-the-art Earth system model simulations. This reveals major changes in the ocean-climate system: El Niño-Southern Oscillation intensity became much higher than today in both amplitude and duration, and reorganization of atmosphere-ocean circulation caused ocean stagnation and contraction of Hadley cells. We postulate that the elevated climate variability caused extreme warmth and drought severe enough to cause the collapse of terrestrial ecosystems tens of thousands of years before that of marine ecosystems. Initially, plankton changes and the demise of reefs heralded the marine crisis before major extinction losses began. In conclusion, we show that short-term climate fluctuations, which are inter-annual today, can be amplified by extreme greenhouse gas forcing, leading to a cascade of catastrophic terrestrial and marine losses.

Abstract

How and why has the East Asian summer monsoon evolved through time has been a topic of controversy for many decades. Once believed to be a Miocene phenomenon, recent work has been pushing this boundary further back in time. With the increase in computational resources, the use of paleoclimate models is now highly widespread. However, the computational cost of running these models has meant a tradeoff between running long integrations of simulations to ensure an equilibrium climate state versus running many time periods/boundary condition sensitivity studies (e.g. variable carbon dioxide) to assess temporal evolution through geologic time versus running different paleogeographic reconstructions. Here, we investigate the evolution of the East Asian monsoon system using three different paleogeographic reconstructions (Getech Plc, Roberstons Plc and Scotese) through the Cretaceous to the Modern (145 Ma – 0 Ma) where the mean climate state has reached equilibrium and compare with a compilation of proxy data. Further, a problem with many legacy as well as contemporary paleoclimate models is the inability to capture higher latitude warmth as reconstructed by various paleo-proxies. Using an improved version of HadCM3/L we analyse the impact of improved model physics that better captures higher latitude warmth and its impact on the East Asian Monsoon evolution.

Abstract

The main dinosaur fauna of the Cretaceous period in China include the Early Cretaceous Psittacosaurus Fauna and the Late Cretaceous Hadrosaurus Fauna, primarily distributed in the northern and eastern regions. Cretaceous dinosaur fossils distribution in the southwest is extremely limited, which sharply contrasts with the abundant discoveries of Jurassic dinosaur fossils in the southwestern region of China. In recent years, a dinosaur fossil assemblage has been discovered in Zhengyang, Qianjiang, Chongqing. Through surveys conducted from 2022 to 2023, it has been confirmed that the distribution range of this fossil assemblage is 6.2 square kilometers, and the fossils are mainly found in the upper section of the Upper Cretaceous Zhengyang Formation. This is the only newly discovered Cretaceous dinosaur fossil assemblage in southwest China.The fossil group has a wide distribution range, abundant fossil quantities, and diverse species. The dinosaur groups mainly include sauropods, hadrosaurs, tyrannosaurs, and ceratopsians, with sauropods and hadrosaurs comprising the vast majority. Preliminary studies of skeletal morphology indicate that both sauropods and hadrosaurs in the Zhengyang area belong to new taxa. The rich dinosaur fossil resources in Qianjiang can fill the research gap in Cretaceous dinosaur fossils in southwest China and are of great significance for exploring the evolution of Cretaceous dinosaurs and the changes in the Earth's environment.

Dinosaur distribution under long-term climate changes

Qi Cui[1]*, Peking University (cyu@amnh.org)
Qi Cui[2], Peking University
Yihui Chen[3], Peking University

Abstract

Climate plays a pivotal role in shaping organism geographic distribution. Dinosaurs were the major terrestrial animals in the Mesozoic terrestrial ecosystems, which had achieved global distribution, both gigantic and miniaturized body sizes, and acquired a suite of ecological niches. Previous studies posited temperature as a principal factor controlling the distribution of dinosaurs, especially sauropods, but this hypothesis incompletely explains the variance at finer taxonomic resolutions. The role of other factors, such as the monsoon system, has been insufficiently considered. Here, based on a state-of-the-art earth system simulation model and global dinosaur fossil occurrences, we analyse long-term climatic influences on dinosaur distribution through the Mesozoic. Our results corroborate previous hypothesis that different lineages had distinct temperature preferences and tolerances. However, strong overlapping has been observed in the climate-space, which features temperature and precipitation. The monsoon systems emerged as critical in delineating dinosaur geographic distributions. Sauropodomorpha and Ornithischia had a strong preference for monsoon zones in the tropics, while this tendency is less pronounced outside the tropics. Our results show the complicated role of climate in shaping dinosaur distribution and the previously hidden climatic adaptabilities across different subgroups. The integration of large-scale sampled data with earth system models provides a robust tool for data-driven paleontological studies.

[Invited] Mass extinctions make way for metabolic makeovers: the rise of dinosaurs and the avian metabolism

Jasmina WIEMANN[1]*, Earth & Planetary Science, Johns Hopkins University
(jwiemann@fieldmuseum.org)

Abstract

Birds have the highest metabolic rates in the animal kingdom and are thus capable of physiological thermoregulation (endothermy). They generate heat as a by-product of mitochondrial respiration. The closest living relatives of modern birds are represented by the crocodile lineage which is characterized by reduced metabolic capacities, resulting in ectothermy. Due to the lack of a metabolic proxy integrable across extant and extinct taxa, it has been speculated that birds are the only clade of dinosaurs surviving into the present because of their uniquely high metabolic performance. Metabolic endothermy is thought to represent a major selective advantage in surviving the environmental and ecological perturbations associated with the Cretaceous-Paleogene (K/Pg) mass extinction event.

Here, I present a novel molecular metabolic marker detectable in modern and fossil skeletal tissues via non-destructive vibrational spectroscopy: systematic analysis (500-3000 cm-1, 10 replicates) of >80 modern and fossil amniote long bones, demonstrated that the quantity of metabolic lipoxidation markers, byproducts of aerobic respiration, correlates (r=0.87) directly to the metabolic rate. The effect of fossilization is empirically captured, modelled in vitro and in silico, and corrected, allowing for the integration of metabolic signals in extant and extinct taxa: tracing the evolution of the avian metabolism across a time-scaled consensus phylogeny allowed for the comparison of trends in the emergence of endothermy and its downstream manifestation in bone-microstructure and morphology. We constrained the evolutionary onset of avian-style metabolic endothermy to their ornithodiran (possibly archosauromorph) ancestor, refuting exceptional metabolic rates as a selective advantage of the avian clade during the K/Pg mass extinction event. Rather than representing a trait of resistance, metabolic endothermy appears to embody a trait of resilience, as it independently evolved along avian, mammalian, and marine reptile stem groups immediately after the Permo-Triassic (P/T) mass extinction event.

We find a significant positive correlation between the observed independent evolutionary origins of metabolic endothermy and niche space availability after the P/T mass extinction, and discuss the impact of ecological versus environmental variables on the selection toward increased metabolic fitness.

The Digital Transformation of Geological Data in Cambodia

KEAT LENARITH[1]*, Ministry of Mines and Energy (keatlenarith@gmail.com)
MEAS PANHA[2], Ministry of Mines and Energy

Abstract

The digitization of geological and mineral data, coupled with research papers, brings about a major change in Cambodia's scientific scene, shifting from paper records to electronic databases. This transformation also demonstrates the commitment of Cambodia to developing digital infrastructure by lending important digital data to international scientific platforms, including AMDIS, GSi Portal, GSi WebGIS, and the GeoSample Data Repository project supported by KIGAM. Cambodia is bringing about a digital ecology and scientific robustness through programs such as streamlining the mining registrar system platform and the Khmer lexicon of geosciences in support of AMTG. Led by the Department of Geology and Minerals, Cambodia is promoting open science for geoscience that brings positive changes on a global scale.

In this digital revolution, Cambodia has proven to be a farsighted country by joining international platforms and establishing its own independent sharing platform. The conceptual center of geology functions as a merging scientific database to share comprehensive Cambodian geology and mineral data that provide an economic and propagating global knowledge bank. Utilizing advanced digital data management tools can significantly enhance Cambodia's earth sciences field, leading to tangible benefits and professional advancements. Embracing technology plays a pivotal role in progressing in this area and enjoying its advantages.

Investing in technology goes beyond just making changes; it's a strategic move towards sustainability for Cambodia. The country values cooperation and sees working with the international community as crucial. Overcoming challenges like data sharing and integrating new technology will follow the standards set by the DDE initiative. By collaborating with experts from around the world, Cambodia aims for success, speeding up scientific progress and working towards sustainable development.

Mingcai Hou[11], Chengdu University of Technology

Abstract

Paleogeography, pivotal for research from paleoclimate modeling to resource exploration, faces challenges in data availability and accessibility due to the fragmented nature and long-tail distribution of deep-time data. Additionally, complex workflows and the decoupling between reconstructions and their underlying data impede the efficient quality assessment and the updating of paleogeographic maps.

This study aims to address these issues through global collaboration within the framework of the IUGS Deep-time Digital Earth program. By implementing a mediated schema, we have successfully interlinked key stratigraphic and paleobiology databases, such as Macrostrat, PBDB, GeoLexicon, and Boucot's climate-sensitive lithology database. This linkage has greatly improved the accessibility of paleogeographic data, facilitating seamless cross-database queries.

Furthermore, we have integrated GPlates into the Unity engine to facilitate web-based visualization of deep-time geological data. This advancement allows for the dynamic rotation and rendering of extensive data points directly in a web browser. Moreover, by leveraging large language models with retrieval augmented generation and prompt engineering, we have achieved preliminary automated interpretations of sedimentary environments that are verifiable and less prone to interpretive bias.

Our research then extends into data-driven paleogeographic reconstruction, where we have successfully refined global paleo-coastlines using fossil evidence, and delineated climatic zones with climate-sensitive sediment data. These efforts significantly enhance the efficiency of paleogeographic reconstructions and establish a solid foundation for quality assessments and automated updates of paleogeographic maps, paving the way for future advancements in deep-time geological research.

Abstract

Data-intensive scientific discovery is a new paradigm in the era of big data, and databases are an essential tool for accumulating data and conducting quantitative research in scientific work. However, researchers often lack the professional skills to build databases, failing to leverage the advantages of rapidly advancing IT technologies. The core issues are concentrated in: 1) Data structures need to change frequently as research progresses, which poses a significant challenge to traditional relational databases; 2) Researchers' deep understanding of domain knowledge cannot be effectively communicated to IT personnel, and IT personnel are unclear about how to apply new IT technologies in domain research, leading to communication gaps and difficulties in collaboration; 3) Earth science databases require spatial concepts and spatial analysis capabilities, which are further enhanced features of traditional relational databases. The DDE OnePetrology team, based on the concept of "data-graph-text" integration, has developed a one-stop database construction software system with the knowledge system at its core. Through this software system, researchers can easily edit their own knowledge trees, flexibly express domain knowledge, and the system converts the knowledge tree into Excel templates. By collecting and organizing data through the Excel templates and importing them into the system, the database construction is completed. As scientific research progresses, the knowledge tree can be adjusted flexibly, fully meeting the needs of scientific work to keep pace with the times. At the same time, researchers can fully utilize the big data filtering (spatial/attribute filtering), map analysis, and other functions provided by the software system, which perfectly solving the aforementioned problems encountered in library construction by researchers.

Digital geological maps on the Global Layer platform

YANG SONG[1]*, Chinese Academy of Geological Sciences (sheep7878@163.com)
Yan Yang[2], Chinese Academy of Geological Sciences
Zhenhan Wu[3], Chinese Academy of Geological Sciences
Manuel Pubellier[4], Ecole Normale Supérieure

Abstract

On the DDE-Global Layer platform, we showcase a globally significant geological map that has been imbued with a renewed purpose. The world geological map at scale 1:5 MThe World 5M, available on this platform, presents an abundance of geological attributes, ranging from chronostratigraphic polygons and fault lines to seafloor ages and structures. Members of the public can easily engage in functions such as retrieval, browsing, viewing, and image generation at different scales, thereby effectively encompassing the entire workflow within the platform. During the project's implementation phase, to ensure the smooth presentation of this work compilation by international Earth Science experts, we conducted a comprehensive data exploration on the DDE platform. This entailed tracing the origins of global geographic data and acquiring additional geological maps and databases to supplement and enhance the geological and geophysical datasets, particularly for islands, located in the oceanic domains. This not only reduced a significant amount of vectorization work but also ensured data integrity and accuracy.

Notably, the Global Layer platform offers diverse options for visual presentation, including providing visual solutions for both raster and vector tiles. Real-time online rendering of geological maps was achieved through accurate symbology definition. As a result, DDE users can swiftly export unique geological maps using template-based operations and conduct online attribute information queries. This not only helps Earth science researchers with more precise data support to comprehensively comprehend Earth's dynamic processes but also catalyzes advancements in scientific research and outreach to the younger generations and various stakeholders. Concurrently, as the DDE platform propagates the dissemination of digital geological maps, it is poised to augment the geographic and geological knowledge of the general public and raise environmental awareness. This contribution holds significant implications for driving societal progress. Through the visual dissemination of the World 5M, it empowers the entire DDE community and its users to readily embrace the future of geographic spatial analysis, unlocking the concealed treasures embedded within the world's geological heritage.

The need for Open Multidisciplinary Geodatabases in Earth Sciences: from the World 5M to Basement Geology and Water Circulation

Benjamin SAUTTER[1]*, UBS (benjamin.sautter@univ-ubs.fr)
Yang Song[2], Chinese Academy of Geological Sciences, 26 Baiwanzhuang Road, Beijing, 100037, China
Manuel Pubellier[3], CNRS-UMR8538, ENS – PSL University, Paris – France
David Menier[4], Geo-Ocean UMR CNRS 6538, Université Bretagne Sud, 56017 Vannes Cedex, France

Abstract

The International Union of Geological Sciences (IUGS) initiated the Digital Data Exchange (DDE) program with the objective of disseminating geoscience knowledge and data openly to the global community. One of the initial projects within this initiative was the development of the World 5M, the Geological Map of the World at scale 1:5M. While such maps have been created at various scales in the past, achieving global harmonization has historically presented challenges. Utilizing advancements in computing capabilities and communication technologies, the collaboration between the DDE, the Commission for the Geological Map of the World (CGMW), and the Chinese Academy of Geological Sciences (CAGS) culminated in a significant breakthrough with the production of the World 5M. Notable features of this map include seamless layers, standardized attributes, rectified continental boundaries, and a comprehensive digitization of mid-oceanic ridges.

The World 5M geological map now serves as the fundamental framework for global geological studies, marking a critical milestone in the field. As the need for comprehensive geological data intensifies, there arises a demand for the incorporation of additional datasets into this compilation. Geological maps traditionally focus on surface rock formations, posing challenges in extrapolating subsurface information without access to depth profiles and well data, which are often not available.

In prevailing economic and environmental concerns, there exists an urgent need for a synthesis of basement structures and associated resources. The scarcity and degradation of potable water highlight the importance of exploring basement aquifers, requiring innovative techniques to characterize the complex geometries and properties of these heterogeneous reservoirs, along with their associated environmental and anthropogenic stresses.

In Brittany, where redundant studies have been conducted over time at local scale, without proper follow-up by changing elected governments and water management professionals, such kind of synthesis is crucial. In this French coastal region, where groundwater is essentially stored in fractured basement aquifers, a collaboration on the perturbations of the water cycle is bringing together the local government, professionals of water management and the university, sharing knowledge and data. The creation of a multidisciplinary database encompassing diverse datasets such as geoscience maps, field data, water properties monitoring data, natural vs man-made conduits for water flow, among others, allow for a better understanding of the stresses acting on

water quality and resources in the region. Similarly to geological maps being created from local scale field observations, and being synthetized at regional, national and international scale, the datasets of the collaboration mentioned above are being compiled at local scale, and the synthesis shall be integrated in multi-scale synthesis to promote and correlate similar initiatives in a DPSIR framework.

By providing such kind of synthesis to all, DDE contributes to centralizing access to data, thereby mitigating the heavy carbon footprint associated with duplicated data. Facilitating joint access to these datasets through widely used internet browsers will progressively enhance this effect. It is imperative to enhance collaboration and expand datasets and models collectively to avoid redundant work and datasets. Let’s unite efforts and embrace the DDE initiative.

Global Layer and Geological Map of the World at a scale 1/5M

Xingchen YANG[1]*, Institute of Geomechanics, Chinese Academy of Geological Sciences
(530884521@qq.com)

Abstract

In the current stage of scientific research, it is necessary to break the barriers between traditional disciplines and promote the cross integration of various related disciplines. As one of the important carriers of research achievements of various disciplines, maps can be superimposed and integrated to more intuitively display the results of multidisciplinary integration, promote the integration of disciplines and discover new scientific problems. Traditional geological mapping is often based on different scales for single scale mapping, aiming at the mapping mode of paper printing results. It is difficult to read maps between different scales at the same time. To solve this probleman integrated platform named Global Layer is being built under the support of Deep-time Digital Earth (DDE). Global Layer is embedded with several core databases such as Geological Map of the World at a scale 1/5M, Global Geothermal Database etc. These databases presented in form of electronic map which enables the results of different scales to be displayed and browsed through one-stop hierarchical promotion. In addition, Users can also upload data in four ways: local file, database connection, cloud file and arcgis data service, and data or maping results can be shared to Facebook, Twitter and other platforms in the form of links, widgets, etc. Construction of Global Layer could provide experience and foundation for integrating global databases related to geological map and constructing data platforms.

Georjuridicality: law, forensics and the Anthropocene

Alexander DAMIANOS[1]*, University of Kent, Kent Law School (a.damianos@kent.ac.uk)

Abstract

The Anthropocene presents a paradox: it suggests that human activity is so intense as to have fundamentally changed the material constitution of the planet; a geological event on par with the extinction of dinosaurs, or the end of the last ice age. Yet it also confirms human finitude. It implies that humanity is simply a passing event, and that one day the planet will go on without us, albeit substantially altered by our lapsed presence. In this paper, I provide an outline of how a political assertion of this kind is uttered in the register of a hypothesized geo-scientific fact. I argue that the effort to formalise the Anthropocene as a geological unit unfolds as a techno-juridical exercise. Geologists generate new categories of artefacts, such as the technofossil, which furnish new species of 'geo-witnesses', in order to illicit accounts of human finitude and planetary dynamics from mundane artefacts of every-day life (the plastic bottle, the bones of genetically engineered chickens, the concrete foundations of buildings and transportation networks). They draw on the formalisation strategy of previous geological units as precedent, according to which they structure their account of the Anthropocene, so as to encourage consensus within the geoscientific community (the jury). They engage a formal decision making procedure, submitting their proposal for an Anthropocene unit to the judgement of their peers. What can law learn from an account of geo-science as a techno-juridical exercise? How can attempts to reassure ourselves that law has something to contribute in response to ongoing ecological devastation be expanded by an account of geo-science as juridical technique? Although I may not fully answer these questions, my ethnographic account of the Anthropocene Working Group's ongoing formalisation effort seeks to open a dialogue between disciplines in the face of earthly finitude. Ultimately, I ask whether the Anthropocene unfolds as a geo-judicial review of the administration of geological time and space itself.

Soils and Sciences in the Anthropocene: Historiographic Considerations

Robert M. BRAIN[1]*, University of British Columbia (rbrain@mail.ubc.ca)

Abstract

Soils and Sciences in the Anthropocene: Historiographic Considerations

Soil exists at the centre of what geologists have called “the critical zone”: the porous living layer that bridges rock and sky, and underpins all terrestrial life. Because of its unique position in the biosphere, soil is a key variable of the Anthropocene crisis of threatened planetary boundaries. The recognized existential cornerstones for the sustainable development of human societies (Food Security, Water Security, Energy Security, Climate Change Abatement, Biodiversity Protection, Ecosystems Service Delivery) have threatened status. Soil is related to each of them and, despite two centuries of scientific research, remains probably the least understood of nature’s eco-systems and increasingly the most degraded. This paper explores how the history of soils and soil science might address this crisis. From the late 18th century, when soil was first conceived as a natural body worthy of its own scientific investigation, pedology explored soil as a system developed from a complex of natural processes. Classics by Dokuchev (1883), Darwin (1881), and Hilgard (1906) identified the five so-called “soil forming factors” (parent material, time, climate, topography, and organisms) as long-term processes that made soils. Yet in recent decades soil scientists have come to recognize that in the contemporary world each of these factors are significantly altered by anthropogenic impacts. Soils do not preexist the mundane practices in which humans interact with them, but are formed within these very practices. This entails an ontological approach to soils as human-made rather than found as an object of scientific practice. An Anthropocene historiography of soil science thus moves beyond disciplinary history to consider soils as a relational materiality formed in tandem with the histories of human-built infrastructures, waste production systems, agricultural practices, land use, and population patterns.

Anthropocene scepticism?

Michael WAGREICH[1]*, University of Vienna (michael.wagreich@univie.ac.at)
Diana Hatzenbühler[2], University of Vienna
Eva Horn[3], University of Vienna
Robert Braun[4], Institute for Advanced Studies, Vienna
Colin N. Waters[5], University of Leicester

Abstract

The Anthropocene Working Group (AWG) of the Subcommission on Quaternary Stratigraphy (SQS) of the International Commission on Stratigraphy (ICS) was founded in 2009 to investigate the potential of the Anthropocene as a chronostratigraphic unit of the Geological Time Scale. After more than 14 years of work, many key publications and fierce discussions both within and outside the AWG, and several rounds of voting, the AWG concluded by great majority that the Anthropocene concept of Crutzen (2002) has stratigraphic reality and that a formal GSSP definition is pragmatic and suitable at the mid-twentieth century, coincident with the Great Acceleration of Earth System Sciences. The resulting GSSP proposal is located in Crawford Lake (Canada) sediment core with the base of the Anthropocene marked by an upturn in plutonium coincident with autumn 1952. However, during the years of AWG investigations, criticisms from outside and a minority group within the AWG opposed to the majority consensus and published results of the AWG (see Zalasiewicz et al., in press) have undermined the significance, importance and usefulness of the Anthropocene as a (chrono)stratigraphic unit. Nevertheless, beyond its debated geological implications and in its wider interdisciplinary and popular context, the term has evolved into a symbol emblematic of global change, and the current climate and ecological crises. An argument of prominent critics is that the AWG is politically and not scientifically motivated when dealing with the Anthropocene. Despite the AWG following established ICS protocols and procedures for stratigraphic working groups and founding their conclusions transparently on a wealth of published geological data (e.g. Waters et al., 2016, 2023; Zalasiewicz et al., 2017), a political dimension is implicitly imposed on both, the Anthropocene supporters but also at the Anthropocene sceptics. Anthropocene scepticism maybe conceptualised as a form of agnotology (Proctor 2008) akin to the use and misuse of science to support climate scepticism (Oreskes 2019). To what extent would rejection of the Anthropocene proposal by the geological community be interpreted outside of the geosciences as a rejection of the scale of the current global crises and a step towards "business as usual"? AWG research into the Anthropocene has resulted in transparency, awareness and engagement of involved scientists in a crisis for which geology has some liability, resulting in a wider interest of the humanities, media and arts on the stratigraphic work of the AWG. Hence, one may interpret geological research in the Anthropocene as a great and timely societal and interdisciplinary mission for the geosciences, leading to a sustainable geological discipline emerging out of its historical linkage with the fossil energy sector.

Why the concept of the Great Acceleration is crucial to defining the Anthropocene

Francine M.G. McCarthy[1]*, Brock University (fmccarthy@brocku.ca)
Julia Adeney Thomas[2], University of Notre Dame
Jan A. Zalasiewicz[3], University of Leicester
Colin N. Waters[4], University of Leicester
Martin J. Head[5], Brock University
Mark Williams[6], University of Leicester
Simon D. Turner[7], University College London

Abstract

The conception of Earth as an evolving system in which humans have become a critical component is central to Paul Crutzen's assertion that we are no longer living in a Holocene world. The new world of the Anthropocene is marked by the precipitous rise of human domination and alteration of the Earth System, pushing it beyond Holocene norms. The Anthropocene Working Group, charged with the mission of discovering whether there was 'stratigraphic reality' to this concept, identified a clear, globally synchronous signature of humans "overwhelming the great forces of nature" in the mid-20th century. The proposed GSSP, at the base of the organic lamina that accumulated on the lakebed during fall turnover in Crawford Lake in 1952 CE, clearly illustrates this point. Indigenous agriculture from the late 13th through 15th centuries altered the lake chemistry sufficiently to allow varved sediments to accumulate in the deep basin of this meromictic lake, and the lumber mill that operated on its shore for several decades in the late 19th century further altered the lake's biogeochemical cycles – but these are inherently local signals. It is the sudden appearance of markers of the Great Acceleration that records the planetary-scale impact of the rapid increase in human population now reliant on fossil fuels for everything from chemical fertilizers to plastic, not only in the varved sediments of Crawford Lake but also at proposed auxiliary sections and in numerous other geologic archives around the world. It is important to engage the humanities and social science in understanding what it means in social, economic, political, and cultural terms that the well-intentioned goal of reducing hunger and disease through 20th century innovations was at a cost to future inhabitants of this planet: human and non-human. Erecting an epoch of the Cenozoic Era with ἄνθρωπος (Anthropos) as a prefix may help formulate the policies needed to minimize the hardships projected to result from the irreversible changes to the atmosphere that are quickly impacting on the hydrosphere, cryosphere, and biosphere, and are being recorded in the geosphere.

Climate change revealed by the sedimentary record of the Pearl River Estuary and its implications for the Anthropocene

Jianfang HU[1]*, Guangzhou Institute of Geochemistry (hujf@gig.ac.cn)
Lihui Wang[2], Guangzhou Institute of Geochemistry
Bingyan Zhao[3], Guangzhou Institute of Geochemistry

Abstract

The annual and winter sea surface temperatures (SST) in sediment Core S26 taken from the Pearl River Estuary were reconstructed using long-chain alkyl diols and GDGT-TEX86 proxy. The reconstructed results reveal that in the study area, the winter SST experienced a more pronounced increase compared to the annual average SST after 1900. This phenomenon is attributed to the joint impact of anthropogenic aerosol pollution and El Niño phases, which have contributed to the amplification of winter SST since 1900. The Pearl River Estuary has experienced a substantial rise in annual average SST since around 1950, primarily as a consequence of the significant increase in greenhouse gas emissions resulting from human activities, thereby exacerbating global warming. Hence, the disparities in the precise timing of the rise in annual average SST and winter SST might potentially indicate the gradual influence of human activities on climate change in the Pearl River Estuary.

After 1950s, the TOC (Total Organic Carbon) content in Core S26 also exhibited an increasing trend, accompanied by a corresponding negative deviation in δ13Corg. This indicates that the increase in sedimentary TOC during this period was primarily due to an enhanced input of terrestrial organic matter. Meanwhile, the Pearl River Estuary area experienced an increase in fossil fuel consumption and/or intensified soil erosion due to human activities after the1950s. Therefore, the intensified soil erosion caused by anthropogenic activities after the 1950s, has led to the increased input of terrestrial organic matter into the Pearl River Estuary.

Therefore, since 1950, human activities have become the primary factor influencing the climate/environment in the Pearl River Estuary. As a result, sediment records in the Pearl River Estuary indicate that the year 1950 is more suitable as a boundary for the Anthropocene - the epoch defined by significant human impact on the Earth’s ecosystems.

The Historiography of the Earth and 'Anthropocene': Regional Geo-history and Possible Worlds in the Steno-Leibniz Process

Toshihiro YAMADA[1]*, Taisho University (tosmak-yamada@muf.biglobe.ne.jp)

Abstract

While the 'Anthropocene' issue is going to be solved in a way of stratigraphy proper, we now seem to be facing with a 'historiographical' problem on the other hand. When we consult Steno's illustration of the six-stage procedure of regional geography developed from the sedimentological or crystallographic analysis and synthesis in his Prodromus (1669), we certainly recognize a description of regional geo-history in the Earth history, which then represented the universal history including Bible history. Leibniz adopted Steno's principles of 'solids within solids' to construct his whole Earth history in Prototogaea (c.1691/ 1749), in which three epochs were segmented: 'incunabula', the world of 'solids within solids', and human history. In the age of incunabular Earth, melting glass made an enormous round planet and gradually cooled down to the primitive Cartesian 'terra'. Secondary, Leibniz followed Steno's method of fossil analysis to reconstruct regional geo-history, which summary may be called geological times. And lastly, natural geo-history is complimented with human history. Namely, as a historian, Leibniz distinguished three dimensions of history in the Earth history. In this process from Steno to Leibniz, histories of sacred, secular, and nature were shaken and being reorganized. For example, Steno's friend and Leibniz's acquaintance Spinoza apparently introduced a concept of 'history of nature' by his Bible text critique while Steno introduced it by his principle of 'solids within solids'. Steno, at the same time, consider the sacred history compensated with natural history. Moreover, Leibniz philosophically and theologically mediated plurality of the world in a Cartesian sense in his Essais de Théodicée of 1710. If we redefine the third epoch of Leibniz's as 'Anthropocene', what kind of historiographical problem should we solve?

EARLY-MODERN VISIONS OF THE « EARTH SYSTEM » LEIBNIZ, TELLIAMED, HUTTON

Claudine COHEN[1]*, EHESS (cohen@ehess.fr)
Claudine Cohen[2], EHESS

Abstract

The vision of the Earth as a wandering planet, subject to the sole determination of its physical causes, emerged in whole Europe during the XVIIth Century among post-Galilean naturalists and physicists. Starting with Descartes's Principia books III and IV (1644) , and well into the 18th Century, a number of "Earth Theories" cultivated a new way of looking at the formation of the Earth, its transformations and its present aspect. Beyond their claimed attachment to the literacy of the Biblical narrative, these attempts aimed at finding keys to a self sufficient system. Descartes' physics of whorls, Leibniz's alternance of water and fire, Telliamed's "system" of the diminishing sea, or Huttons' vision of the Earth as a heat engine animating cyclic transformations through the action of an inner fire, were attempts at pointing out the definite causes of the Earth's history. These elaborations have often been neglected as constituting an inconsistent "prehistory" to more recent scientific elaborations.

Indeed in contrast with XIXth century scientific geology definitely focused on exploring and theorizing singular process such as volcanoes, glaciers, sedimentation, erosion, etc, the forgotten "genre" of Early-Modern Earth Theories can still be of interest for us today. Taking examples from some of these treatises, I will show how their various attempts at viewing the Earth as a totality, opened new question on life and its origin, on environnemental changes and on the relationships of Man with Nature. I will argue that these texts can be reread today with interest, in the light of the notion of the "Earth System" which conceptualizes the interactions of geosphere, biosphere, cryosphere, hydrosphere, and atmosphere, and constitutes a basis for thinking about the Anthropocene.

The Anthropocene, Crawford Lake and Human-Geological Interactions

Ernst HAMM[1]*, York University (ehamm@yorku.ca)

Abstract

The history of geology can be conceived of as geohistory, the idea that knowledge of the earth's crust is a fundamentally historical science concerned with temporal processes on a scale that bursts the limits of human history, or as geodynamics, the consideration of the causes that forged earth's crust to form mountains and continents, operating on a scale that dwarfs human action (Taylor 2016). Whatever shortcomings befall such grand narratives, it is remarkable how much of the history of geoscience they do encompass. It is also striking how awkwardly the Anthropocene epoch fits such schemes. The varves or sediments of Crawford Lake, the proposed "golden spike" marking the onset of the Anthropocene, are unquestionably historical depositions, just as nuclear weapons testing is the cause of plutonium-239 traces in the varves. However, that cause is not based on a reconstruction of the geological record, it is a confirmation of what is already known from the historical record; likewise, the record in the varves is not needed to know when humans began nuclear testing. That said, pollen analysis of the varves has yielded profoundly important evidence for reconstructing fifteenth-century Iroquaian agriculture and longhouse villages at Crawford Lake, though this considerably predates the proposed Anthropocene epoch (McCarthy 2022). Even small changes in the varves can be a trace of human activity of great consequence. They are an indicator that human activity is changing the Earth system, but they do not show that we are controlling that change. In that sense, at least, the Anthropocene epoch and its record preserved in Crawford Lake is enormously important, a geological symbol of largely unchecked human ambition. It is also noteworthy that there is a very distinguished pedigree for interactions between the human and geological record. Of these, the most well-known must be the columns of the so-called Serapis Temple, marked by a band of boreholes of marine lithophaga mussels, that adorn the frontispiece of Charles Lyell's Principles of Geology (1830-1833). These columns were a beautiful and powerful illustration of the principles Lyell claimed to be founding. Lyell was also keenly aware of the symbolic appeal that a reference to classical antiquity would have for his campaign to make geology a prestigious science. The Anthropocene epoch is not about establishing the prestige of the geosciences, but it is very much about demonstrating their relevance in a time of precarious, global environmental change. The simple and jewel-like beauty of Crawford Lake is a powerful symbol of the need for change in the way humans interact with the environment, and the record of the varves is a sobering reminder of the need for humility after so much hubris.

[Keynote] The decision in favor of the Anthropocene

Juergen RENN[1]*, Max Planck Institute of Geoanthropology (renn@gea.mpg.de)

Abstract

Although the Subcommission on Quaternary Stratigraphy of the International Union of Geological Sciences recently voted against the Anthropocene becoming an official geological epoch, it is clear that we live at a point in history when the Earth system cannot be understood without reference to human social, economic, and political systems and behaviors. But what exactly depends on the decision for the Anthropocene, and what does it concern us outside of geology? In my talk, I will argue that a decision for the Anthropocene concerns all of humanity and that it matters on how this decision is understood and what conclusions are drawn from it. The talk emphasizes the co-evolutionary dimension of the underlying Earth System processes that have led to an intensification of our species' involvement in planetary dynamics. The Anthropocene as humanity’s self-reflection on its position in nature is nothing new in itself. Such positionings have accompanied human history since its beginnings and are part of a self-analytical process that we refer to here as species reflection. A further aim of the talk is therefore to use the history of species reflection as a resource for the current discussion and to motivate the decision for the Anthropocene from this history.

Tae Soo Chang[6], Faculty of Earth and Environmental Sciences, Chonnam National University, Gwangju, Republic of Korea

Abstract

Plastic litter and particles have become pervasive in terrestrial and marine environments worldwide, as a consequence of a surge in global production and mismanagement practices since the mid-20th century. The widespread presence of microplastics across the Earth's surface not only signifies a critical environmental pollutant, but also serves as a distinct marker of the Anthropocene epoch. As plastics become a ubiquitous component of natural environments, it is imperative to recognize them as integral components of sedimentary systems. This study describes the characterization of plastic particles as sediment constituents and examines numerically their influence on geological processes. The trajectory of plastics, from disposal, disintegration to deposition, mirrors the source-to-sink dynamics observed in natural sedimentary systems. Microplastic particles, ranging from 1 μm to 5 mm in size, align with sediments spanning clay to gravel sizes. The diverse size, shapes, and polymer types affect sediment grain architecture, pore geometry, and physical properties of deposition. Notably, microplastics possess a distinct grain density averaging 1.3 g/cm3 when derived from polymer types in the ocean subsurface, which is approximately half that of typical sediments (~2.65 g/cm3). The lower grain density results in a deceleration of sediment settling velocity. As the volume of microplastic particles in sediments increases, a consequential decrease in the bulk density of sediments is observed during deposition and burial with depth. Our study suggests that microplastics alter fundamental sediment properties, including density, porosity, frictional properties, bonding dynamics, water content, wettability, as well as microbial communities. The alteration of physical properties and other characteristics in plastic-enriched sediments necessitates further research to comprehensively understand the intricate effects of microplastics on geological processes and ecosystems.

Introduction to UNESCO IGCP 732 LANGUAGE of the Anthropocene and the International Geoscience Program

Veronika Koukal[1]*, Natural History Museum Vienna (Veronika.Koukal@nhm-wien.ac.at)
Michael Wagreich[2], University of Vienna

Abstract

IGCP 732: LANGUAGE of the Anthropocene (Lessons in anthropogenic impact: a knowledge network of geological signals to unite and assess global evidence of the Anthropocene). Present and future Geology – the global scale evidence of the Anthropocene was granted as an UNESCO IUGS IGCP project in spring 2021 and will run for 5 years. The former International Geological Correlation Project, now International Geoscience Program started in 1972 as a knowledge hub of UNESCO to facilitate international scientific cooperation in the geosciences. IGCP Projects bring together scientists for workshops and field trips and support especially participation from developing countries.

Because the Anthropocene establishes a powerful concept associated with unprecedented global change, the aims of IGCP 732 are to involve a global community in geoscientific research into this topic and the anthropogenic predominance on the Earth System. Both recognizing and managing this novel situation in a sustainable way requires a planetary network and accompanying knowledge framework. IGCP 732 aims to engage new ideas and networks in the development of the Anthropocene concept by cooperating globally with scientists, especially those in developing and less developed countries. The core aims are to unite and assess global evidence of the Anthropocene and to establish the Anthropocene as a fertile framework for future geosciences. This will be achieved by developing a network of expertise and project partners globally; and designing and running workshops in developing countries. Close collaboration also takes place with the IUGS ICS-SQS Anthropocene Working Goup (AWG), especially related to the definition and the correlation of a GSSP (Global Stratotype Section and Point) and the base of the stratigraphic Anthropocene. So far, 138 scientists from 30 countries joined our network and participated in the annual meetings, that were held in Vienna (Austria, 2021: online kick-off meeting), Nairobi (Kenya, 2022: Nairobi's Anthropocene 2022 – past, present and future archives) and Xi'an (China, 2023: The Anthropocene 2023 – Impacts and Sustainability of Earth System Development). The annual meeting 2024 will be organized during the IGC at Busan (Republic of Korea: Session Session T38.2 - UNESCO IGCP 732 and the Stratigraphy of the Anthropocene). Ongoing projects within the IGCP 732 framework include the Austrian Academy of Science funded project on recent lake sediments from Pakistan, Austria and Kenya (PI Mehwish Bibi), a Brazilian project on correlating urban anthropogenic sediments of Vienna and Brazilian cities (PI Érika Cristina Nesta Silva), and a cooperation project of the Republic of Korea and Austria on the Holocene-Anthropocene transformation on the west coast of Korea and the Japan Trench (Eun Young Lee & Tae Soo Chang). Cooperation was also established with geoparks in Austria, China and the Republic of Korea, and potential geopark areas in Kenya.

Radioactive fallout defining the base of the proposed Anthropocene Series in the varved sediments of Crawford Lake

Francine M.G. McCarthy[1]*, Brock University (fmccarthy@brocku.ca)
Andrew B. Cundy[2], University of Southampton
Karin Hain[3], University of Vienna
Pawel Gaca[4], University of Southampton
Brian F. Cumming[5], Queen's University
Krysten M. Lafond[6], Queen's University
R. Timothy Patterson[7], Carleton University
Michael F.J. Pisaric[8], Brock University
Martin J. Head[9], Brock University
Paul B. Hamilton[10], Canadian Museum of Nature

Abstract

Individual varves from the meromictic basin of Crawford Lake (Milton, Ontario, Canada) provide an annually resolved record of radionuclides (239Pu, 240Pu, and 137Cs) deposited following nuclear weapons testing, here demonstrated from 1946 – 1971 CE. A well-defined increase in 239+240Pu activities (calculated from atom concentrations of 239Pu and 240Pu measured using Accelerated Mass Spectrometry) from 0.0007 Bq/g in 1951 to 0.0048 Bq/g in 1952 is consistent with the onset of thermonuclear weapons testing. The detonation of the first H-bomb, 'Ivy Mike' at Enewetak Atoll at 7:15 AM, Nov. 1, 1952 (7:15PM Oct. 31, GMT/ 2:15 PM at Crawford Lake), coincides with fall 1952 turnover, when most of the organic matter accumulates on the lakebed, with the base of the dark lamina marking the base of the proposed Anthropocene series/epoch in the varved succession. Activities of both Pu-239+240 and Cs-137 peaked in 1963 (0.0299 and 0.2652 Bq/g, respectively) before declining sharply after ratification of the Partial Nuclear Test Ban Treaty to nuclear era background by 1970 CE. Pu-240/ Pu-239 ratios provide an additional chronostratigraphic marker of the base of the proposed Anthropocene, showing a defined increase from the early 1950s to values typical of average global stratospheric fallout in the 1960s. The well-oxygenated monimolimnion where brackish bottom water conditions prevent macroscopic benthos from disturbing the lakebed may also play a role in preventing mobilization of plutonium in the varved succession, allowing the nuclear moratorium that lasted from November 1958 to September 1961 to be represented by a distinct shoulder, with lower activities of Pu-239+240 and Cs-137 in 1960 (0.0104 and 0.0025 Bq/g, respectively). This radionuclide signature, coinciding with the Great Acceleration, should be a globally synchronous marker of the associated permanent shift in the Earth system postulated by atmospheric chemist and Nobel laureate Paul Crutzen in 2000 CE.

Does anthropogenic interference disturb sedimentation in closed lakes? Evidence from the Kalar Kahar Lake, Potwar Plateau, Pakistan

MEHWISH BIBI[1]*, University of Vienna, Austria (bibimehwish15@gmail.com)
SHAHID IQBAL[2], Department of Earth Sciences, Quaid-i-Azam University, Islamabad, Pakistan
MICHAEL WAGREICH[3], Department of Geology, University of Vienna, Austria

Abstract

Lacustrine sediments are considered key archives for tracing anthropogenic signals in the Earth's system and thus have remained the major focus for research into the Anthropocene. The present work focuses on the sediment geochemistry of the Kalar Kahar Lake located in the Potwar Plateau of Pakistan, to unravel the impact of decreasing siliciclastic flux over historical time due to anthropogenic controls. The Kalar Kahar Lake is an old (2 ka documented history) saline lake and the area gained fame during the 16th century CE when the Mughal king Zaheer ud Din Babar established an army camp on a hill near the lake. Since then the population around the lake has gradually increased and the lake area has shrunk. A core section of 180 cm was collected from the lake and continuous high-resolution samples were collected from this core for bulk sediment geochemical analysis. Preliminary results indicate a progressive upward decrease in SiO2 (54.6% to 16.4%) coupled with a decrease in Al2O3 (9.8% to 3.5%). Similarly, Fe2O3, K2O, and Na2O reflect considerable drops of 4.5% to 1.7%, 1.6% to 0.6%, and 1.5% to 0.3% respectively. Sc also reveals a significant drop from 10 ppm to 4 ppm. On the contrary, CaO displays a progressive upward increase from 11% to around 30% coupled with an increase in the Loss On Ignition (LOI) from 14% to 44%. Further, the Total Organic Carbon (TOC) and the Total Organic Sulphur (TOS) show the lowest values of around 3% and 0.3% respectively in the lower part (zone of high siliciclastic input) that reach higher values of around 15% and 0.9% in the upper part (zone of high carbonates precipitation). Thus the upward increase in TOC and TOS content supports "cultural eutrophication" like that observed in many European lakes due to anthropogenic polluting inputs including fertilizer runoff, sewage, and wastewater flows into the lake. The overall major elements geochemistry results indicate that the siliciclastic flux has reduced to around one-third during the time of the sampled interval. The decrease in siliciclastic input allowed carbonate precipitation to dominate and an overall three-fold increase in carbonate sedimentation has been observed in sampled interval. Thus the present results reveal that the establishment of human settlements around the Kalar Kahar Lake gradually blocked the natural drainage system around the lake. Urbanization during the last two centuries closed both natural water inflow into and outflow from the lake, therefore, inhibiting the siliciclastic flux into the lake. The lake has slowly transformed into a closed water body where carbonate precipitation is the major sedimentation process. Numerical age dating of the sampled interval will allow a more precise linkage between the siliciclastic flux fluctuation and various historical events in the area including both anthropogenic contribution and climate fluctuations.

[Keynote]Evolution of stratigraphy in the Anthropocene Across Africa

Lydia A. OLAKA[1]*, Technical University of Kenya (lydiaolaka@tukenya.ac.ke)
Christine A. Omuombo[2], Technical University of Kenya
George OKOKO[3], Lamont-Doherty Earth Observatory, Columbia University
Daniel O. OLAGO[4], University of Nairobi

Abstract

The widespread alteration of earth conditions and processes has brought humans to the fore as a formidable force of nature. Whilst the Anthropocene working group is working to determine the stratigraphic marker of the proposed new geological Epoch from Lake Crawford. Questions on the resolution and magnitude of change recorded in the environmental archives and markers in Africa where no candidate site was selected can be answered by comparing multiple records. This will help to understand the impact of global, regional and local drivers of change. The aim of this study is to present an Africa wide synthesis of the chronology and stratigraphy of different geological material derived from different archives from coasts, lakes and peat. Africa is the cradle of mankind and human occupation extends back thousands of years, but until about 300 years ago, their impact on the environment was localized and transitory. The impacts intensified during the 19th century due to rapid population growth and extension and intensification of agriculture, that was largely driven by colonists; during this period, the overprinting of natural environmental changes by humans is clear, marked by increased erosion, sedimentation, and changes in lake water quality and sediment geochemistry as a consequence of land and water degradation, expansion of urban environment and overexploitation of terrestrial, aquatic and marine ecosystems. As a result the geochemistry of soils and water resources have changed, major losses in biodiversity have occurred. Exhibiting spatial and temporal lags of the changes, depending on locality, but there is a widespread agreement of these effects from the mid-1900s, supporting the Anthropocene Working Group's proposed date of 1950 as the start of the Anthropocene.

Progress on the Anthropocene study in China

Luyuan ZHANG[1]*, Institute of Earth Environment Chinese Academy of Sciences
(zhangly@ieecas.cn)

Abstract

Human activities had caused very profound impact on the Earth's environment, such as rapid increases in CO2, Methane, temperature since the mid-20th century. In 2000, Paul Crutzen proposed the Earth had entered a new geological epoch - the Anthropocene, following the Holocene. And other scientist suggests that the trajectory of the Earth System shifts away from the glacial–interglacial limit cycle toward new, hotter climatic conditions and a profoundly different biosphere.

Once being proposed, the concept of the Anthropocene have fast become a hot topic and been paid wide attention. It is the same case in China. Early in 2004, Prof. Dongsheng Liu has suggested that China has have a good foundation to study the Anthropocene on the basis of Holocene research. China has a long history, large population and intense human activities, rich records of human activity, historical documents and archaeological remains. In this presentation, we present some examples on the Anthropocene records including heavy metals, polycyclic aromatic hydrocarbons (PAHs), black carbon (BC), char, and soot, SCPs, radioactive proxies (14C, 137Cs, 129I and Pu), as well as paleo-environmental DNA, mainly in the archives of lacstrine sediments, tree rings and stalagmites. In Chine, we have proposed a Chinese Candidate GSSP of the Anthropocene, the Sihailongwan maar lake. There are twelve sites from the global, and the Sihailongwan is the only maar lake with no fluvial inlets or outlets, only receives the atmospheric input.

For in-depth study of the Anthropocene, the National Natural Science Foundation of China has approved a Major research project, entitle "Geological New Era—the Anthropocene: Timing, Characteristics and Impact", which include four subprojects: historical background of the Anthropocene, Markers and proxies, GSSP of the Anthropocene, as well as impacts and adaptation of human activities in the Anthropocene.

In terms of academic exchange, The Anthropocene Research Branch of the Geological Society of China was established in December 2021, which is affiliated to the Institute of Earth Environment of the Chinese Academy of Sciences. The aim of the branch is to promote the development of international and domestic Anthropocene research. The first Conference of the Anthropocene Science was successfully held in Xi ‘an on 17-18th June, 2023. This conference had 7 sessions and over 140 oral presentations. About 400 people on site, and nearly 7,000 people online have participant this conference. Other conference/sessions on the Anthropocene Science have been held, such as sessions on the 2023 Annual Meeting of Geological Society of China, The 8th Youth Geoscience Forum. On the aspects of international cooperation and exchange, Chinese scholars act as the members of the Anthropocene Working Group, proposed the Anthropocene research theme to the IGCP Council, and are involved into the IGCP project.

In summary, the Anthropocene study has been studied more and more by Chinese scholars, and

has also gradually been accepted and used by the general public. International cooperation is encouraged by the Chinese funding agencies to achieve a global view of the Anthropocene.

Anthropocene 129I record in the Yellow Sea sediments and its indication for river-delivered radioactive pollution to marginal seas

Yanyun WANG[1]*, Institute of Earth Environment, Chinese Academy of Sciences
(wangyy@ieecas.cn)
Xiaolin HOU[2], Institute of Earth Environment, Chinese Academy of Sciences

Abstract

As the number of coastal nuclear facilities rapidly increases and the wastewater from the Fukushima Nuclear Plant has been discharged into the Pacific Ocean, the nuclear safety of China's marginal seas is gaining increased attention along with the heightened potential risk of nuclear accidents. However, insufficient work limits our understanding of the impact of human nuclear activities on the Yellow Sea (YS) and the assessment of their environmental process. This study first reported the 129I and 127I records of post-human nuclear activities in the two YS sediments. Source identification of anthropogenic 129I reveals that, in addition to the gaseous 129I release and re-emission of oceanic 129I from the European Nuclear Fuel Reprocessing Plants (NFRPs), the Chinese nuclear weapon testing fallout is an additional 129I input for the continental shelf of YS. The 129I/127I atomic ratios in the North YS (NYS) sediment are significantly higher than those in the other adjacent coastal areas, attributed to the significant riverine input of particulate 129I by the Yellow River. Furthermore, we found a higher 129I latitudinal disparity in the sediments than those in the seawaters in the various China seas, revealing that sediments in China's marginal seas already received a huge anthropogenic 129I from terrigenous sources via rivers and thus became a significant sink of anthropogenic 129I. This study will broaden the insight into the potential impacts of terrigenous anthropogenic pollution on the Chinese coastal marine radioactive ecosystem.

A Marine Geological Park Concept for volcano-tectonic and Hydrothermally Induced Submarine Groundwater Discharge Features and Their Implications to Coral Reefs in Mabini, Batangas

Caroline Marie Brinas Jaraula[1]*, Marine Science Institute (cjaraula@msi.upd.edu.ph)
Iris Mabanta[2], Marine Science Institute

Abstract

A coordinated network of Marine Geological Parks are not yet established in the Philippines although there are diverse coastal scapes that can be incorporated into tourism activities while highlighting information on their formation, implications on coastal processes, (paleo)climate and (paleo)environment. So far, only one UNESCO Geopark has been established and this includes three marine geosites that are concretely linked to geological processes of formation. Only one paper about Marine Geological Park has been published in the literature and this is by Hartoko et al (2018) that emphasize Indonesia's endemic coastal ecosystems, maritime anthropology, ancient tribes, flora and fauna, as well as sunken ships and their Chinese and European ceramics. There are many more ways to diversify and enhance the current list of marine geosites. Similar to Indonesia, the Philippines is ripe in developing Marine Geological Parks with stronger emphasis on the links to influences of volcanic and tectonic processes or indicators, and oceanographic features. As part of the Verde Island Passage Marine Corridor, the "center of the center " for marine biodiversity, marine geological park can be used as an educational tool for tourists, researchers, and scientists alike, for a more informed tourism venture into the geological events in the area. A concept note for Mabini Marine Geological Park is being developed and focuses on an area where Hydrothermally Induced Submarine Groundwater Discharge in various coastal areas are emanating warm to hot mixture of recirculated seawater and fresh groundwater with or without bubbles, composed mainly of >95% Carbon Dioxide. Hot submarine springs even in intertidal areas or accessed through SCUBA diving are already part of tourism activities. With temperatures of the emitting waters as warm as 84 deg C, this hosts extremophiles, such as thermophiles, hyperthermophiles, and capnophiles providing a wide latitude of educational topics including natural analogues to warming seas and ocean acidification where the projected global warming scenarios are naturally in effect in these areas already.

Abstract

Some Anthropocene activities include biogeochemical alteration in the sediment deposits from landscape conversion. Mangrove tree planting since 1990 was encouraged at the mouth of Aklan River, which helped to trap the sediments and extended the forest area by at least a kilometer flourishing to around 121 hectares today. The mangrove area increased by an average of 52.42% every five years. The spatial evolution of enlarging sand bars combined with the biological transformation by maturing mangrove forests is also reflected in the evolution of soil deposits to which average total organic Carbon content at present increased to 4% and as much as 6.46% comprising mostly of labile carbon (3.92%). Belowground carbon was estimated at 31,011.69 Mg. The C:N ratio of planted mixed-species zones and sandbar were consistent with a mixture of riverine- and mangrove-derived organic matter. δ13C and δ15N values of sediment samples ranged from -28.75‰ to -26.11‰, and -1.09‰ to 1.37‰ respectively. For biomass samples, δ13C and δ15N values ranged from -30.82% to -27.85%, and -10.70% to 1.83%, respectively. Integration of landscape and forest cover and maturation of organic-rich soil have implications on the Carbon stock. A comprehensive evaluation on a larger perspective is necessary to check on impedance of sediment transport to coastal areas in the longshore current direction and stability of the accreted landforms against massive release of Carbon Dioxide from destabilization after extreme storm events.

Anthropogenic stratigraphic signals downstream a metropolis: Extracting Vienna's signature from Danube river plain archives (Austria)

Andreas Lang[6], Paris Lodron University of Salzburg, Faculty of Geography & Geology, Salzburg, Austria
Michael Wagreich[7], University of Vienna, Department of Geology, Vienna, Austria

Abstract

The Anthropocene describes a potential new unit of the Geological Time Scale of rising anthropogenic influence on environmental and geological processes and how their traces are stored in geological archives. Even though this human impact can be seen on a global scale across multiple depositional environments, regional studies characterizing the onset and scope of anthropogenic influence, are still scarce, especially for urban or peri-urban fluvial environments. In this study, we investigate the anthropogenic impact of the European metropolis Vienna on its peri-urban environment and the potential base of the Anthropocene epoch in the 1950s CE by applying sedimentological, geochronological and geochemical methods.

The study area is set downstream of Vienna, in the Austrian National Park Donau-Auen, where direct human intervention into the archived Danube river sediments is currently nil. These river sediments represent an 'Urban Anthropocene Field Lab' to trace and quantify the human stratigraphic fingerprint and to search for potential markers and correlations to the proposed GSSP Golden Spikes of the Anthropocene. Within the proximal flood plain sediments of the Danube, i.e. erosional profiles and sediment cores, sedimentological, geochronological and chemostratigraphic markers are applied to characterize and date the anthropogenic strata in this area. First observations indicate three periods of distinct sedimentation patterns, potentially corresponding to the natural state prior to significant human intervention, the river system's reaction to the first extensive river channelization in the 1870s CE, and it's following response to the construction of hydropower stations (1956-1998 CE) and second river regulation (1990s). The lowermost section is characterised by clay and organic rich thin layers (few cm to mm) being suddenly replaced by alternating silt and sand packages of 5 to 20 cm beds. The uppermost silt to fine-sand dominated section is massive and shows almost not sediment structures, unlike the other sections, and exhibits a uniform light grey colour distinct from the light beige and dark brown colour of the underlying deposits.

The archive of natural Danube deposits is further analysed for natural and artificial radiogenic isotopes (210Pb, 239Pu, 137Cs), trace metals, and (micro-)plastics with the aim (i) to disentangle

the anthropogenic fingerprint of Vienna from the natural sedimentation and characterise the interplay between upstream human interventions and local river dynamics, (ii) to identify and evaluate the proposed Holocene-Anthropocene geological boundary around 1950 CE, and (iii) to evaluate markers for the Anthropocene and a potential correlative stratigraphic reference section downstream of Vienna.

The geological usefulness of a defined chronostratigraphic Anthropocene for urban deposits of Karlsplatz, Vienna (Austria)

Michael WAGREICH[1]*, University of Vienna (michael.wagreich@univie.ac.at)
Maria Meszar[2], University of Vienna

Abstract

Anthropogenic strata form the primary geological legacy in the underground of large cities, the urban Anthropocene. We looked for geological markers for the Anthropocene using mainly artificial isotopes in the city of Vienna, the capital of Austria. The tested archaeological site Karlsplatz - Wien Museum is situated in a park area at the city center. Archaeology and historical data set age constraints in the 19th century, at 1922 (sales hall), 1936 (demolition of the sales hall), 1945 (WW2 rubble), and at 1959, with the opening of the Wien Museum at this place. A layer on top of the fundaments and rubble of the sales hall post-dates 1922/1936, and pre-dates the levelling of the artificial park ground in front of the Wien Museum of an inferred 1959 age. Archaeological stratigraphy and lateral correlation of layers specifies the dating of this uppermost soil layer with a mixture of historical artefacts including brick fragements, glass, slag and plastics to the interval of 1945 to 1959.

Using the primary marker suggested for the base of the geological Anthropocene, the artificial radionuclides of atmospheric atomic bomb testing fallout material (the "bomb-spike"), this soil layer could be more precisely dated than based on the archaeological record so far. The presence of Pu-239 and Pu-240, among others, and their typical isotope ratio clearly indicate an age of 1952 (first H-bomb testing with global fallout) to 1959 for this layer. Thus, the "bomb-spike" can be identified and used as a primary stratigraphic marker even in coarse urban anthropogenic sediments exemplifying the correlation potential of these radionuclides and demarking a reference section for the base of the proposed chronostratigraphic Anthropocene epoch. The stratigraphic markers and technofossils in the coarse urban sediments contain signals that have potential correlations with findings from other Anthropocene sites, namely the fallout radionuclides like plutonium, which can be correlated to the lake warves like the one from Crawford Lake, Canada.

Abstract

Deposits in an urban environment like the city of Vienna (Austria) pose many challenges compared to natural archives. They often have only limited lateral continuity, highly variable deposition rates, they are prone to (anthropogenic) erosion, resedimentation and show many omission surfaces. As part of a transdisciplinary project involving geosciences, isotope physics and urban archaeology, we investigated sediments from an archaeological excavation site near the city centre of Vienna at Karlsplatz. The study area records the changing land use of the expanding city, from the anthropogenic fill of the Wien River before 1900 to the latest levelling period of the park area in the 1950s. Archaeological stratigraphy and historic data sets provide age constraints for the multiple deposition phases, with the oldest road structures dating from the 18th century and the youngest deposits dating around 1922, post-1945 and the park opening in 1959. Anthropogenic materials found in the samples include bricks, ceramics, concrete, glass, plastics, metal slags and tiles. Sediment reworking is evidenced by a mix of artefacts from different time periods. The fine-grained matrix (< 2 mm grain size) of the deposits was used for X-Ray fluorescence (XRF) analysis of trace elements such as lead, copper and zinc, as well as for analysis of actinides by Accelerator Mass Spectrometry (AMS). Several artificial radionuclides, including 239Pu, 240Pu and 236U which are associated with atmospheric atomic bomb fallout material of the 1950s and beginning of the 1960s, were found in the post-1945 layer. These radionuclides and their ratios were successfully used to identify the signal from nuclear weapons testing and provide a primary stratigraphic marker for the Anthropocene, even in these urban anthropogenic sediments. Concerning trace metals, XRF analysis revealed the highest levels (Cu 330 ppm, Pb 633 ppm, Zn 852 ppm) in sediments of a 19th century deposit rich in charcoal and metal slags associated with nearby metal-working industry. The second highest peak occurs in a layer of WW2 rubble rich in technofossils of that era (Cu 71 ppm, Pb 208 ppm, 296 ppm). Higher depositional levels of the 1950s show again much lower values (Cu 24 ppm, Pb 28 ppm, Zn 61 ppm) similar to the range of low contamination background and infill materials, although the

uppermost topsoil layer shows a slight recent enrichment (Cu 35 ppm, Pb 56 ppm, Zn 99 ppm) compared to the 1950s. These XRF results indicate a local control on trace metal contamination and a correlation with technofossil findings. In addition, spheroidal carbonaceous fly-ash particles (SCPs), the product of industrial coal and oil combustion, were found in elevated concentrations in the post-1945 levels. In conclusion, stratigraphic markers for the Anthropocene were identified and quantified in the urban anthropogenic sediments of the Karlsplatz site. Therefore, the site could be used as a correlative reference section for the Anthropocene series.

Michael Wagreich[5], University of Vienna/Department of Geology, Vienna, Austria

Abstract

Anthropogenic signals in sediments can be assessed through various methodologies and techniques, e.g. geochemical proxies. The present study presents geochemical data of four points located within the Córrego da Piscina basin, in the city of Rondonópolis, Mato Grosso, Brazil, being one natural soil and three anthropogenic deposits. The first profile, situated near the former location of the watercourse spring, was classified as an Arenosol, with presence of pedological structures such as subangular blocky (weak to moderate), and one anthropogenic deposit at the top layer. The second one was related to layers originating from a paving street, with layers exhibiting laterite, brick fragments and charcoal. The third profile presented layers composed of predominantly sandy sediments and anthropogenic materials, for example debris, fragments of bricks and plastics. The fourth profile was composed of natural sediments alongside anthropogenic materials, exhibiting interesting features related to pedogenesis. Geochemical analysis of sediments and various sizes of anthropogenic materials ground altogether – from some layers at these locations - was focused on the concentration of As, Ba, Cd, Cr, Cu, Ni, Pb, Sb, and Zn, obtained through ICP-OES analysis, and Al obtained through XRF analysis (used for the calculations). We compared the results with the values specified in RESOLUÇÃO CONAMA Nº 420, DE 28 DE DEZEMBRO DE 2009 (a resolution providing criteria and reference values for soil quality in Brazil in terms of chemical substance presence). Subsequently, calculations were performed for the Enrichment Factor (EF), Degree of Contamination (Cdeg), and Pollution Load Index (PLI), using the Upper Continental Crust values as background. The results for the first profile revealed EF <1.5 for all the elements and layers analysed, as well as PLI and Cdeg <1; for the second profile, the highest EF values were Zn (2.7) and As (2.6) for the layer 5, PLI <1 for all this profile layers and the highest Cdeg value was 6.7. Relative to Brazilian resolution, the first profile present low concentrations values, and the second one, in the layer 8, Ba considered as “Investigation Value” (478ppm), and in the layer 5, Ni (42ppm) considered as “Prevention Value”. The third profile garnered the most attention. For instance, in layer 5, the EF for As was 9.4, the PLI for this layer was 1.6, and Cdeg was 16.1. Furthermore, according to the Brazilian resolution, As (37ppm) and Cr (353ppm) presented values considered as "Investigation Values". And in the last profile, just the Cr present value considered as “Prevention Value” in the layer 3C1

(94ppm), and the EF for the same layer and element was the highest in this profile (3.1), PLI <0.4 and Cdeg <2.4 for all this profile. This way, the highest values were related the third profile, the one in which the layers present a significant amount of anthropogenic materials.

Introduction and first results from FT-IR microplastics identification in natural sediments

Veronika Koukal[1]*, Natural History Museum Vienna (Veronika.Koukal@nhm-wien.ac.at)
Eun Young Lee[2], University of Vienna
Mehwish Bibi[3], University of Vienna
Michael Wagreich[4], University of Vienna

Abstract

Plastics became a very abundant novel material since the late 19th century, with an increase in production and variations starting from the 1950s onwards. Nowadays, polymers are found almost everywhere around us, in remote places like the deep sea or isolated lakes and even within the human body. Microplastics (MP), either manufactured as small polymer particles (primary MP) or fragmented by degradation of larger plastic litter pieces (secondary MP), are noticed as an environmental pollutant, studied by a broad range of disciplines worldwide. MP has been also proposed as a secondary marker for the stratigraphic Anthropocene by the ISC Anthropocene Working Group. Nevertheless, a standardised definition of the size classification of microplastic particles is still missing, despite the existence of several established size classification schemes, commonly determining size class boundaries in geosciences between 1 µm to 5 mm.

In contrast to the first attempts of MP identification in natural sediments, where particles were identified and counted by visual criteria using a stereo-microscope, the identification of polymer types has become indispensable. This is often accomplished by destructive thermoanalytical methods, such as pyrolysis gas chromatography-mass spectrometry or thermal desorption gas chromatography-mass spectrometry. To avoid loss of the sample material, non-destructive vibrational spectroscopic identification techniques, like Fourier transform infrared spectroscopy (FT-IR) or Raman spectroscopy can be used.

For this study, core samples of the coastal sediments of Jeungdo and Ganghwado islands (Republic of Korea) and riverbed sediments of the Kabul River in Nowshera (Pakistan) were prepared for MP identification using FT-IR (Bruker Lumos II, nitrogen-cooled MCT detector). No established workflow existed for this technique at the labs of the Department of Geology, University of Vienna so far. Furthermore, existing methods described in the literature lack standardization regarding sampling, removal of natural organic material, sample density separation, and measurement mode (transmission, ATR, kind of detector). Therefore, the main focus shifted towards implementing a best practice method suitable not only for artificially with new polymers spiked sediment samples, but for natural sediment samples yielding altered MP particles and fibers. These particles might have undergone various environmental and depositional processes, including sediment sorting, (re)deposition, burial, compaction, cementation, leaching, degradation, UV and/or biofilms exposure. Another challenge is given by the fact that most

polymers contain producer-specific additives or auxiliary materials, depending on the intended use, which can be substituted in the recipe quickly and without declaration. This might cause problems for the interpretation of the FT-IR spectra, particularly for older samples, because limited information exists regarding the alteration and degradation effects of the additives in combination with changes of the primary polymer component.

Anthropogenic activities tamper with Laguna Lake's (Philippines) 20th century record of the Pacific Decadal Oscillation

Chris Carl Agustin Vargas TOYADO[1], Marine Science Institute, University of the Philippines
Caroline Marie Briñas Jaraula[2]*, Marine Science Institute, University of the Philippines
(cjaraula@msi.upd.edu.ph)

Abstract

Increased land use changes in the suburbs of Manila during the 1960s to the 1980s [1], presently the constituent cities of Philippines' Capital Region, could have contributed to the contemporaneous increase in and sustained high input of terrigenous Al, Ti, and Fe to the east-bordering Laguna Lake [2]. These changes could also have elicited changes in the grain sizes of sediments coming into the lake, and so a sediment core from the lake's western lobe was analyzed for its grain size and bulk elemental profiles. Seven major chemo- and litho-stratigraphic zones for the 20th century were delineated by Constrained Incremental Sum of Squares hierarchical clustering: Clusters pre-1912, 1912-1932, 1932-1953, and 1953-1957, with a 7-year lag, coincide with the phases of the Pacific Decadal Oscillation (PDO) whereas clusters 1957-late 1960s, late 1960s-1981, and post-1981 are identified as the first three phases of the Anthropocene [2]. Wavelet analysis also reveals common cyclicities in %sand, %silt, mean grain size, standard deviation, and 95th percentile grain size from 1916 to 1956 with periods of 17 to 18 and 20 to 23 years ($p<5\%$) which could correspond, respectively, to the 16.7-year [3], 20- and 23-year [4] modes of PDO. Since the 1950s, however, these cyclicities lost statistical significance ($p>5\%$), suggesting anthropogenic structures/processes which (1) generated more silt- and clay-sized sediments, (2) retained the sand-sized sediments on land, or (3) reduced the sand-sized sediments into finer particles. Studies pinpointing these anthropogenic structures or processes and their effects on the grain size profiles of nearby sedimentary archives are recommended for future study.

Anthropogenic large-scale dune remobilization in medieval–early modern Central Europe, evidenced by multi-proxy data and radiocarbon dating

Krzysztof Ninard[1]*, Faculty of Geography and Geology, Jagiellonian University, Kraków, Poland (krzysztof.ninard@uj.edu.pl)
Alfred Uchman[2], Faculty of Geography and Geology, Jagiellonian University, Kraków, Poland
Piotr Łapcik[3], Faculty of Geography and Geology, Jagiellonian University, Kraków, Poland

Abstract

The chronology and determinants of Late Pleistocene–Early Holocene dune development in Central Europe were studied for several decades, but research on analogous Late Holocene processes remains less advanced. While Late Glacial–Early Holocene dune formation was climatically controlled, remobilization of inland dunes during the Middle and Late Holocene is attributed exclusively to anthropogenic factors: deforestation and land cultivation. In the case of coastal dunes, numerous coasts worldwide admittedly experienced extensive dune activity during early modern period, but only rarely human impact is strongly evidenced to be a trigger of large-scale coastal dune buildup.

The present contribution reveals the scale of anthropogenic dune remobilization based on 27 new AMS 14C dates from 17 Polish inland and coastal dune sites, complemented with ichnological and palynological records. All calibrated 14C dates from paleosols buried in dune deposits fall within the range of 5th to 19th centuries. The widespread occurrence of such young paleosols under cover of aeolian sand reflects the scale of dune remobilization during the medieval and early modern periods. Even though the volume of anthropogenically-remobilized sand was limited compared to the Late Glacial–Early Holocene period, the impact of human activities on dune mobility seems to be far more widespread than it was known before.

The highest dune ridge of the Vistula Spit, a sandy coastal barrier on the Polish Baltic coast, extends to a height of over 25 m and reaches 500 m landwards. This transgressive dune ridge was hitherto reported to have been formed between 4k and 2k years BP. In contrast, recent excavation of Vistula Spit ship canal allowed to reveal that the highest dune ridge overlies small dune hillocks that were stabilized for several thousand years. They are covered by paleosol and peat lenses that were developing up to the 15th century and were buried afterwards. The nearby Curonian spit (Lithuanian Baltic coast), which was subjected to more intense settlement, experienced large-scale dune advances during the early modern period, which led to the burial of several villages reported in the historical sources.

Either in the case of Polish inland and coastal dunes, pasture and farming is directly recorded in the paleosols and their sandy overburden as trample grounds containing human and livestock footprints, as well as grazing-indicator pollens and spores. In addition to deforestation,

overgrazing could promote desertification and soil erosion, leading to dune remobilization and land-use abandonment.

Examining the spatio-temporal frames and mechanisms of human-related dune environment change during the last two millennia, the study contributes to the present discussion on the proposed Anthropocene epoch.

This research was financed by the National Science Centre, Poland, from the programme Daina 1, grant agreement No 2017/27/L/ST10/03370 and by Jagiellonian University from Initiative of Excellence programme, Research Support Module.

Anthropogenic landscape changes with planting pines on coastal dune fields

Kwang Hee CHOI[1]*, Catholic Kwandong University (geoist@cku.ac.kr)
Jun Ho Lee[2], Catholic Kwandong University
Jae Hyun Hwang[3], Catholic Kwandong University

Abstract

Planted sand dunes covered with pine trees are common along the coasts of East Asia including Korea and Japan. Black pine (*Pinus thunberggii*) was planted since the early 20th century to protect the hinterland of coastal area from salt spray, blown sand, and strong winds. Although the tree-covered dunes may seem to stabilize the natural landscape, they actually weaken the coastal barrier as the wind field shifts and the landforms become more fixed. This study aims to discuss the effects of coastal afforestation on the landscape changes, focusing on wind environment and topography of coastal dunes on an island in the Yellow Sea. The coastal dunes in this area were formed about 5.6 ka and were active dunes until a few decades ago due to abundant sand supply. The average sand size in these dunes is approximately 220-230 μm, which makes them susceptible to wind blowing. However, since the large-scale planting of black pine in the early 1980s and late 1990s, trees between the fore and hinter dunes have acted as a barrier to sand exchange between the two dunes. To investigate the wind changes caused by the trees, four Automated Weather Stations (AWS) were set up at the front and back of the forest, and topographic changes were measured using drone-based photographs, LiDAR, and Network RTK-GPS surveys. As a result, severe changes in wind field and topography were found. According to the data collected from three AWSs in the front area, it appears that strong winds are blowing towards the landward side. However, the AWS located at the base of the dune behind the forest indicates a noteworthy shift in wind direction. Furthermore, the dune volume has decreased significantly compared to the topographic survey data from about 15 years ago, and the elevation of dune crest has become lower and flatter. The reason for this phenomenon is that the sands from the beach have not moved towards the hinterland dunes, while the sands of the hinterland dunes have been washed away by rainfall and carried towards the sea. This has caused the neighboring port to fill with sand, and a new sand bar is gradually forming in front of the coastline. In order to restore the natural resilience of the coastal dunes in the study area, the planted trees need to be removed to allow the sand to move dynamically.

Geomorphic Succession of an Abandoned Paddy Field in Mountain Area

Junho LEE[1]*, Catholic Kwandong University (juno9705@cku.ac.kr)
Kwang Hee CHOI[2], Catholic Kwandong University

Abstract

As paddy fields are left unused for extended periods, they tend to transform into wetlands through ecological succession. Many of the mountain wetlands in South Korea are a result of abandoned paddy fields that were previously used to cultivate grains such as rice. These fields usually have the necessary environmental conditions to develop into wetlands even before cultivation. However, previous studies have overlooked meteorological and hydrological conditions and the processes of landscape change, instead emphasizing morphological factors such as reliefs and slopes. In this study, we aimed to examine the physical environment of a mountainous abandoned paddy wetland in Gyeonbuk-do, South Korea, and explore its successional process over the last millennium. The wetland was formerly a rice field until 1996 but has now transformed into a wetland. We conducted topographic analysis, local meteorological observations, and sediment analysis. We analyzed its morphological characteristics like slope, curvature, and topographic position index using a digital elevation model of its drainage basin and soil characteristics such as grain size, moisture, and electrical conductivity. We also analyzed local climatic and hydrological conditions using an automated weather system and water level gauges in the wetland. The geomorphological succession history was identified using radiocarbon dating on the organic matter from a 1.5-meter-long core. The results showed that the topography of the study area is gently sloping and concave, making it conducive for moisture collection. The inflow between late spring and summer predominantly contributes to the total water content of the wetland. The soil core was divided into three units based on their grain size characteristics. The lower unit, mainly composed of organic matter and silt, was dated to approximately 1.6 ka, indicating that the wetland was a peat wetland before cultivation. All three samples from different depths in the middle unit, composed of very poorly sorted soils, were dated to about 0.35 ka, indicating the period of human cultivation. In conclusion, the wetland in this study formed over a thousand years ago in a place with favorable topographical conditions, and cultivation has been carried out for at least 350 years. Since the land has been left unused for several decades, it is gradually returning to a mountain wetland.

Interplay of climate forcing and human impact during the Holocene: a case study from an inner marine basin in the Mediterranean region

Gabriele NICCOLINI[1]*, Dipartimento di Scienze della Terra, Università degli Studi di Firenze (gabriele.niccolini@unifi.it)
Adele Bertini[2], Dipartimento di Scienze della Terra, Università degli Studi di Firenze
Niccolò Degl'Innocenti[3], Dipartimento di Scienze della Terra, Università degli Studi di Firenze
Massimo Moretti[4], Dipartimento di Scienze della Terra e Geoambientali, Università degli Studi di Bari Aldo Moro
Giuseppe Mastronuzzi[5], Dipartimento di Scienze della Terra e Geoambientali, Università degli Studi di Bari Aldo Moro

Abstract

During the Holocene the Mediterranean Region underwent significant environmental transformations, due to rapid climatic changes and increasing human activity. High-resolution palynological analyses focusing on pollen, dinocysts, and Non-Pollen Palynomorphs (NPPs) were carried out on a well-preserved sedimentary core retrieved from the Mar Piccolo, a small inner marine basin of the Taranto Sea system (Southern Italy). The selected core interval, 30-meter thick, provides invaluable insights into climate dynamics and environmental responses, spanning from the latest Pleistocene to recent times. At the onset of Holocene, increased freshwater input into the basins favoured the expansion of freshwater marshes (e.g., Cyperaceae) over saltmarshes (e.g., Amaranthaceae) and steppe (e.g., *Artemisia*) which characterized the end of the Pleistocene under a dominant arid climate (H0). Evidence of some precursor marine spillovers is also indicated by organic foraminiferal linings and halophythes. The clearest evidence of marine ingression is found from 10.30 ka BP with the consistent presence of dinocysts (e.g., *Impagidinium patulum*) providing insights into sea level fluctuations in the Mediterranean. Concurrently, an increase in mixed semi-deciduous oak forests suggests a climatic improvement, likely resulting from global circulation reorganization following the retreat of the ice sheet in the Northern Hemisphere (e.g., Laurentide Ice Sheet). The palynological record reveals 22 rapid climate changes including the 8.2 ka BP, 4.2 ka BP and 2.8 ka BP events, all characterized by an increase in aridity as evidenced by the expansion of steppe vegetation and the contraction of thermophilic forests. Between 11.8–7.2 ka BP, such aridity events in the Mediterranean region (and cooling in the North Atlantic) are significant and concomitant with the melting of ice sheet leading to a slowdown in the Atlantic Meridional Overturning Circulation (AMOC). After the complete melting of the ice sheets, around 6.8 ka BP, rapid climate changes driven by variations in solar insolation led to the expansion of steppes, albeit more limited than the previous ones, with the exception of the 4.2 ka BP event. For the last 2700 ka Mar Piccolo emerges as a pivotal site to illuminate the intricate interplay between natural climate factors and the most recent human influence, given its historical significance as a cultural crossroads dating back at least the Bronze Age. Starting from the Greek Period (Taras foundation at 706 BC) human impact on Mar Piccolo became evident by several shifts in flora and vegetation. Pollen records indicate a notable increase

in Olea cultivation (olive trees) accompanied by biodiversity loss, likely related to deforestation. Major historical events, including agrarian reforms, famines, and wars, are discernible by fluctuations in *Olea* and Cerealia-group. During the Roman Period and the Middle Ages, intriguingly, pandemics manifest as an abundance of resting eggs of human parasites such as *Trichuris* and *Ascaris lumbricoides*. Today, the Taranto Sea system stands out as one of the most polluted marine areas in Europe; understanding paleoclimatic changes and human adaptations could provide invaluable insight for anticipating future scenarios amidst contemporary Global Warming and escalating environmental degradation.

Stratigraphic signals of human-environment interactions on the Meghalaya Plateau: Implications for defining the Anthropocene boundary

Pawel PROKOP[1]*, Institute of Geography and Spatial Organization Polish Academy of Sciences (pawel@zg.pan.krakow.pl)

Abstract

The Meghalaya Plateau in northeastern India serves as a unique site for the study of human-environment interactions and their stratigraphic signatures. This study examines the stratigraphic record of human-induced change on the plateau, focusing on the Meghalayan and Anthropocene within the context of the broader Holocene. Through a comprehensive review of lithostratigraphic, biostratigraphic and chemostratigraphic markers, this study elucidates the complex interplay between natural processes and anthropogenic activities.

The Meghalayan age, ratified by the International Union of Geological Sciences (IUGS), provides a crucial temporal framework for understanding environmental changes in the region. Speleothems, particularly stalagmites, are proving to be valuable archives for reconstructing past climatic conditions and human impact. These stalagmites, found in caves such as Mawmluh Cave, provide insights into variations in monsoon intensity and vegetation cover over millennia. In addition, dendrochronological data from *Pinus kesiya* trees indicate localised climate responses, albeit limited in extent.

Sedimentary records further underline the dynamic nature of the Meghalaya Plateau landscape. Radiocarbon dating reveals the dominance of Holocene sediments, possibly accelerated by high rainfall and human interventions such as deforestation and agriculture. Pollen and grain size analyses corroborate these findings, indicating a shift from subtropical forests to open grasslands and subsequent deforestation episodes associated with agricultural expansion and iron ore mining. The onset of Neolithic activity, marked by the production of pottery and iron smelting, further accentuates the human impact on the geomorphology of the region.

Stratigraphic signals also extend into the post-industrial era, characterised by radionuclide fallout from nuclear weapons testing. Studies of caesium (137Cs) and lead (210Pb) concentrations in soil profiles near Shillong and Cherrapunji provide insights into the dynamics of soil erosion and the pervasive nature of anthropogenic impacts. In addition, the emergence of a distinct anthropogenic layer characterised by concrete, brick and plastic debris underscores the contemporary human alteration of the landscape.

In summary, the Meghalaya Plateau offers a rich tapestry of stratigraphic signals reflecting millennia of human-environment interactions. From prehistoric deforestation to modern industrialisation, these records provide invaluable insights into the environmental history of the region. Moreover, the implications of these findings extend beyond regional boundaries, shedding light on broader debates about the boundaries of the Anthropocene. By integrating multidisciplinary approaches, this study contributes to a nuanced understanding of humanity's imprint on the Earth's geological record.

Lithostratigraphic Study on Human-made strata in Kirishima City, Kagoshima Prefecture, Japan

Hiroshi TAKASHIMA[1]*, Daiichi institute of technology (h-takashima@daiichi-koudai.ac.jp)

Abstract

Human-made strata are defined as geological formations formed through human activitiesNirei H. et al., 2012These formations are created through human activities and constitute the primary geological structure in urban areas. They are typically categorized into two associations: dumped associations formed through embankment construction on terrestrial land, and landfill associations formed through water area reclamation (Kazaoka O. et al., 1994). Despite their widespread use, detailed analysis of the lithology and stratigraphy of human-made strata is often lacking. This deficiency can be attributed to the diverse nature of human-made strata compositions across different land parcels, time, and the lack of continuity in strata deposition (Ford, T., et al. 2014). However, the sourcing of embankment materials from nearby construction sites often leads to the development of human-made strata with compositions resembling natural strata in general, particularly in regions where the same geological strata extend over large areas. In these areas, lithologic differences are likely to be dominated solely by sedimentary structures and heterogeneous material contamination, making it easier to characterize the human-made strata.

This research explores the lithostratigraphy formation and characteristics of human-made strata in Kirishima City, located within the Kagoshima Graben, Japan. The city's central district, Kokubu, sits on the Kokubu Plain, characterized by river lowlands and terraced surfaces. Surrounding the plain are extensive deposits of the Ito and Iwato Pyroclastic Flow deposits originating from the Aira Caldera, forming elevated plateaus (Aramaki S., 1969). These pyroclastic flow deposits serve as essential materials for embankments and are extensively utilized in the region.

Excavation investigations in three locations within the Kokubu district revealed the stratigraphy of human-made strata, identifying rice paddy paleo-soils beneath and several formation s of human-made strata above. The mineralogical analysis showed that the human-made strata were composed of the same types of mineral particles found in natural strata—plagioclase, quartz, orthopyroxene, amphibole, and magnetite, with the addition of four varieties of volcanic glass. However, specific differences were noted, such as the presence of ilmenite and biotite in human-made strata, which is rare in neighborhood natural strata, and the surface of minerals is coated with artifacts, such as Ca-carbonate, making it impossible to identify the original mineral. Additionally, human-made strata subjected to surface ground improvement exhibited particles with radial coverage by volcanic glass, indicating specific construction practices. Related to this, the results of grain size analysis showed that the coarse-grained fraction of the human-made strata were enriched compared to that of the natural strata.

As a result of the investigation, special constituent materials of the human-made strata were identified, and the characteristics of the human-made strata in the Kirishima area were clarified. This could be used to distinguish between natural and human-made strata and to identify the Jin-ji

unconformity Nirei H. et al., 2012 boundary between natural and human-made strata.

Mayank Shekhar[4], Birbal Sahni Institute of Palaeosciences, Lucknow, India
Pankaj Kumar[5], Inter-University Accelerator Centre, New Delhi, India

Abstract

Climate change coupled with the increasing anthropogenic activities is modifying the vegetation distribution and land-cover of the Himalayan region. Here we compared the modern pollen dispersal along the valley gradient of 2700-3500m amsl with the sub-surface pollen assemblage from a 60 cm deep peat deposit collected at ~3400m amsl altitude in the, Baspa valley, Kinnaur, Western Himalayas. Baspa valley is presently characterized by the temperate to sub-alpine vegetation type, occupied by conifers, broadleaf trees and non-arboreal taxa. The pollen assemblages from surface and sub-surface sediments represented the extant flora growing in the valley, and also captured the land-use signatures during last two millennia. In the modern pollen assemblage along the valley gradient, high pollen percentages of conifers (*Pinus*, *Cedrus*, *Picea*, *Abies*) and broadleaf taxa (*Alnus*, Rosaceae and *Quercus*) are consistent with the present dominant growth of arboreal vegetation in the valley. Moreover, abundance of *Picea* and *Cedrus* pollen is reported within the vicinity of their respective forest patch. Significant frequency of micro-charcoal content and cultivated (Cerealia) Poaceae pollen (>35µm) reported at 3000-3500m amsl altitudes represent the ongoing burning and land-use activities at higher elevations.

Sub-surface pollen assemblage showed marked changes in the vegetation and land-use in the valley during last two millennia. We recorded decline in the pollen percentage of subalpine tree-line taxa (*Juniperus*, *Rhododendron*, *Betula* and *Abies*) and temperate tree taxa (*Cedrus*, *Picea* and Rosaceae), and gradual rise in wild and Cerealia Poaceae pollen since 6th century till recent. This indicated the timber extraction from temperate forest and land clearance activities at the higher elevations for cultivation. Significant increase in micro-charcoal percentage during last millennium reflects the intensifying wood burning activities, thus supporting the exploitation of forest for fire-wood in the valley. Declining trend of aquatic pollen taxa (*Potamogeton* and *Typha*) and increase in the pollen percentage of Cyperaceae, steppe and other non-arboreal ground vegetation represents the soil moisture decline till recent. However, increase of Asteraceae elements since last millennia possibly indicates the grazing activities at the site. During last millennia, anthropogenic pressure has become a significant factor in controlling the vegetation and land-use pattern of the area. Results illustrated a close intertwinement of climate and local human

activities during past two millennia. Generation of such datasets from the Himalayan region is highly crucial for demystifying the role of climate and human factors responsible for alteration of the natural vegetation at a finer spatial and temporal scale.

Deciphering Social-Ecological Transitions in the Anthropocene: An Evolutionary Framework Reveals Dynamics and Decoupling in China's Yangtze River Delta

KE ZHANG[1]*, Chinese Academy of Science (kzhang@niglas.ac.cn)

Abstract

Understanding the transient dynamics of interlinked social-ecological systems (SES) is imperative for assessing sustainability in the Anthropocene. However, how to identify critical transitions in real-world SES remains a formidable challenge. In this study, we present an evolutionary framework to characterize these dynamics over an extended historical timeline. Our approach leverages multidecadal Rates of Change (RoCs) in socioeconomic data, paleoenvironmental, and cutting-edge sedimentary ancient DNA records from China's Yangtze River Delta, one of the most densely populated and intensively modified landscapes on Earth.

Our analysis reveals two significant social-ecological transitions characterized by contrasting interactions and feedbacks spanning several centuries. Initially, the regional SES exhibited a loosely connected and ecologically sustainable regime. Nevertheless, starting in the 1950s, an increasingly interconnected regime emerged, ultimately resulting in the crossing of tipping points and an unprecedented acceleration in soil erosion, water eutrophication, and ecosystem degradation. Remarkably, the second transition occurring around the 2000s, featured a notable decoupling of socioeconomic development from eco-environmental degradation. This decoupling phenomenon signifies a more desirable reconfiguration of the regional SES, furnishing essential insights not only for the Yangtze River Basin but also for regions worldwide grappling with similar sustainability challenges. Our extensive multidecadal empirical investigation underscores the value of co-evolutionary approaches in understanding and addressing social-ecological system dynamics.

Anthropogenic beachrock analogues and their significance for the Anthropocene stratigraphy

Agnieszka GAŁUSZKA[1]*, Jan Kochanowski University (Agnieszka.Galuszka@ujk.edu.pl)
Zdzisław M. Migaszewski[2], Jan Kochanowski University

Abstract

Current coastal sedimentary formations including human artifacts were reported as rock analogues by many researchers. Most of these rock analogues consist of plastic waste as a major constituent mixed with a variety of mineral grains and rock pieces. In many cases, the plastic component is thermally-altered. The examples of such rock-like materials are termed plastiglomerates, anthropogenic beachrocks, anthropoquinas, plasticrusts, pyroplastics or plastistones (Wang and Hou, 2023). Here, we report a material composed of a fragment of brass gun bullet which is attached to a ferruginous micritic light brown limestone pebble and a dark brown ferruginous conglomeratic quartz-limestone sandstone resembling a natural conglomerate. It was found in northwestern Poland, on the Kołobrzeg beach of the Baltic Sea. This military artifact dates back to the World War II. It can be linked to a battle between Polish-Soviet armed forces and German troops that defended the strategic fortified town of Kołobrzeg on March 4 through 18 of 1945.

Rapid cementation of coastal sediments favors the formation of beachrocks containing recent human artifacts. It has been estimated that lithification of such sediments may occur within a few years (Vousdoukas et al., 2007). These artifacts may be a proxy for the Anthropocene strata. In our presentation, we show different types of beachrock analogues and discuss their relationship to a rock definition commonly used by geologists. We also point to their preservation potential in the present and future geologic record as evidence for the Anthropocene epoch.

Anthropocenic significance of waste strata

Wook-Hyun NAHM[1]*, Korea Institute of Geoscience and Mineral Resources
(nahmwh@empal.com)
Min HAN[2], Korea Institute of Geoscience and Mineral Resources
So-Jeong KIM[3], Korea Institute of Geoscience and Mineral Resources

Abstract

The most stark measure of our daily lives is 'waste.' Various types of waste have already been produced in enormous quantities, threatening the right to survival and health of humans and the ecosystem for a long time. The waste problem is being addressed from a variety of perspectives, not only in the engineering field but also in the humanities, economics, and arts fields. Recently, the field of geology has also begun to think of waste as sediment and landfills as artificial strata. A landfill is considered a sedimentary basin where artificially generated sediments (waste) are moved and deposited artificially.

Debate is currently underway as to whether the Anthropocene is a 'period' that can be recognized by sedimentological strata division or an 'idea' that reflects various perspectives on the relationship between humans and nature. Whatever it is, the waste produced by humans tells the story of many of the issues we are struggling with, namely, how we can understand the Anthropocene, including the Capitalocene, Carbocene, Chthulucene, Manthropocene, Phagocene, and Plantationocene.

In particular, plastic waste has become a symbol of the Anthropocene, creating several new types of plastic rocks such as plastiglomerate, plasticrust, anthropoquinas, and plastitar. Additionally, e-wastes such as computers, monitors, cell phones, batteries, and televisions contain harmful substances such as lead, mercury, and cadmium, but can also be a source of urban mining containing gold, nickel, lithium, and manganese. In the field of geology, there is a need to look at the waste problem from a geological perspective, actively discover research topics, and seek appropriate response measures.

This work is supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (NRF-2018R1A5A7025409, NP2018-026), and the Basic Research Project (GP2022-006) of the KIGAM funded by the Ministry of Science and ICT, South Korea.

[Keynote] Time to explore more of the Anthropocene

Buhm Soon PARK[1]*, KAIST (parkb@kaist.edu)

Abstract

In March 2024, the International Union of Geological Sciences (IUGS), in conjunction with the International Commission on Stratigraphy (ICS), approved the vote to reject the proposal for an Anthropocene Epoch as a formal unit of Geological Time Scale. They then added a forward-looking statement that “the Anthropocene will nevertheless continue to be used not only by Earth and environmental scientists, but also by social scientists, politicians and economists, as well as by the public at large” (IUGS official website). This decision prompts an important question on how the future multi-disciplinary exploration of the Anthropocene will or should differ from previous efforts that have focused on establishing stratigraphic evidence for its status as a geochronological epoch. Interpreting the Anthropocene as a general descriptor of anthropogenic impact on the Earth system is one thing; viewing it as a specific signifier for the existential crises of humans and nonhumans is another. This paper aims to revisit the implications of two sets of graphs depicting the Great Acceleration, i.e., Earth System trends and socioeconomic trends, by updating and revising some of them. Additionally, the paper argues for a more robust study of the Anthropocene by geological scientists, not only within their disciplinary boundary but also in cross-disciplinary spaces for broad scholarly and public engagement.

Anthropogenic changes in river landforms and application of nature-based solutions in South Korea

Dahae GO[1]*, Catholic Kwandong University (ekgo3232@cku.ac.kr)
Kwang Hee Choi[2], Catholic Kwandong University

Abstract

Rivers have historically been a reliable source of water for humans and have acted as natural infrastructure. People have traditionally settled around rivers and managed them. Gray infrastructure, which is a traditional method of river management, mainly involves using materials from civil engineering, such as dams, embankments, and weirs and straightening the river to make it easier to manage. However, these artificial rivers are now more vulnerable to flood risks, as heavy rains and tropical cyclones have increased due to climate change. Recently, Nature-based Solutions (NbS) are emerging as a new river management method. NbS is a river management plan that sustainably manages and utilizes nature to solve social and environmental problems using ecosystem functions. It is implemented in various ways, such as floodplain acquisition, levee relocation, and small dam removal. Similar concepts such as close-to-nature river techniques (CRT), green infrastructure (GI), and low-impact development (LID) have been proposed. The study attempts to categorize the NbS types of river management in South Korea and examines three case sites. In the case of Gapcheon River in Daejeon, a barrage was removed in 2023 to improve the water ecosystem connectivity. The study compared the DTMs before and after the removal of the barrage to check the landform changes. In Yeongwol-gun, a reservoir for the Seogang River was created in 2012 using the abandoned channel. The study aims to check the flood reduction effect after the reservoir was built. In the Jangdong region of Geumgang River, a project to remove part of the existing embankments will be implemented soon. Through drone-based photogrammetry, cross-sectional surveys, and sediment surveys, the study aims to gather the basic data on the future landscape changes.

Abstract

Increasing human interactions with the biosphere over tens of millennia have left a fossil record that shows the growing geographical spread and technological sophistication of humans evident in patterns of extinction and domestication of the landscape and its plants and animals. Here, we focus on the “Great Acceleration” of the mid-20th century (e.g. Steffen et al. 2015) which provides the causal mechanism of the proposed Anthropocene epoch (Waters et al., 2023) in which rapid increases in human and domesticated animal populations, energy consumption and technological innovation coincide with globalization of industry and commerce. Key parameters and their diagnostic palaeontological signals of the Anthropocene include: 1) the rapid breakdown of discrete biogeographical ranges for marine and terrestrial species with successions in North America, South America, Africa, Oceania, Europe and Asia correlatable using palaeontological signatures of highly invasive species and changes to ecologies that demonstrate the growing interconnectivity of human systems through expansion of global shipping, road networks, physical connection of water masses and recent development of aquaculture; 2) rapid changes to ecologies resulting from climate change, e.g. loss of coral reefs and poleward shifts of species through thermal stress, and ecological degradation, e.g. nutrient enrichment in lakes and coastal zones causing eutrophication and hypoxia, and extensive damming of rivers inhibiting movement of species and causing local extirpation; 3) an ‘acme biozone’ of human and domesticated animal

skeletons co-occurring with a domesticated plant pollen record and coincident with greatly reduced populations, ecological ranges and extinctions of ‘wild’ species; 4) the rising volume and unique depositional settings of landfills containing large quantities of organic wastes recording the spread of exotic foodstuffs far beyond their geographical range of environmental tolerance, notably of seeds of internationally traded fruits, e.g. avocados, coconuts, mangos and peaches; and 5) the accumulation of reconfigured forest materials including paper, paperboard and engineered wood products such as medium density fibreboard (MDF). The presentation addresses how a range of depositional settings may preserve a long-lived, unique palaeontological record for post-mid-20th century deposits that is distinct from all past records of deep-time biotic change, including those of the Holocene, and is consistent with the proposal of the Anthropocene as an epoch of geological time.

Mapping of submerged landforms by dam construction using historical aerial photos

Jae Hyun HWANG[1]*, Department of Sustainable Environment, Catholic Kwandong University (hjh3962@cku.ac.kr)
Kwang Hee CHOI[2], Department of Geography Education, Catholic Kwandong University

Abstract

A dam is an artificial reservoir created to control the water in a river. Dams supply water for living or industry to surrounding areas, control floods, and produce electricity. However, large-scale dams significantly impact the climate and landscape of their neighboring areas. The construction of such dams can lead to the submergence of important geomorphic features, causing the loss of historical information and local communities that once lived there. Current digital maps based on aerial surveys only display the topography above water level, omitting submerged areas. However, it is possible to use past data, such as historical aerial photographs and topographic maps, to identify the old landforms beneath the lake's surface. Using the data, we can create a Digital Elevation Model (DEM) of the lake bed to reveal its topography.

This study focuses on the Daecheong dam, which was constructed in the central area of South Korea between 1975 and 1980. During the dam's construction, 50.3 of rice fields, villages, and other areas were submerged, displacing 4,075 households. The lake created by the dam makes it difficult for researchers to access the past landforms, including river terraces that are not well-known in this region. To overcome this challenge, this study created a past DEM of the submerged area by merging the interior and exterior of the lake, using historical aerial photos. The past DEM shows the submerged landforms such as old channels, bars, floodplains, river terraces, and small tributaries. The river terrace identified for the first time in this study appears to have at least three thread surfaces along the old channels. This study concludes that the hidden landforms can be recognized in submerged areas through the DEM generated using the combination of historical aerial photographs and current maps. This approach can help researchers identify past landforms, including those not well-known in the region.

The lagoon of Venice (Italy) in antiquity: insights into settlement dynamics, adaptive behaviours, and palaeoenvironmental reconstructions

Carlo Beltrame[1], Dipartimento di Studi Umanistici - Università Ca' Foscari Venezia
Adele BERTINI[2]*, Dipartimento di Scienze della Terra - Università degli Studi di Firenze (adele.bertini@unifi.it)
Paolo Mozzi[3], Dipartimento di Geoscienze - Università degli studi di Padova

Sandra Donnici[7], CNR-IGG

Abstract

This interdisciplinary research project (PRIN 2022), funded by the Italian Ministry for University and Research encompasses historical, archaeological, geomorphological, palaeoecological, and palaeoclimatic investigations, with the focus on the intricate relationship between environmental changes and cultural responses during the latest Holocene in the Lagoon of Venice (Italy). Central to the research is the interaction between human activity, water, and coastal wetlands in Roman times. The lagoon of Venice and similar environments likely served as pivotal economic resources and strategic seaport locations. This is evidenced by the analysis of Roman construction techniques, such as the utilization of wood and reused amphoras, which offer valuable insights into their adaptive strategies tailored to the unique environmental conditions. Geophysical surveys, coring, and targeted excavations are currently underway at key sites within the northern Venice Lagoon and in the harbour area of Altinum. Palynological (pollen, dinoflagellate cysts, and other Non-Pollen Palynomorphs-NPPs) and carpological analyses from archaeological deposits and nearby natural sedimentary archives provide valuable insights into both cultural practices and environmental changes. The tracing of floristic, vegetational, and climatic changes including those with decadal resolution offers snapshots of vegetation responses during key periods (e.g. Roman Periods, Medieval Climate Anomaly and Bond events). Previous proxies together with foraminifers provide insights into aquatic environments, furnishing evidence on lagoon palaeohydrology and connections with the sea. This contributes to the detection of sea-level fluctuations and changes in coastal ecosystems, including modifications in the extent of fresh to salt marshes. Collectively, these diverse observations enrich our comprehension on the palaeogeography of the lagoon and coastline in antiquity, offering perspectives into how lagoon systems responded to relative sea-level rise. They also help to better understand settlement dynamics in the Venice lagoon and similar environments in antiquity, shedding light on human adaptation and resource exploitation. As part of public outreach, this historical, geoarchaeological and anthropological approach may augment local awareness of origins and environment, potentially fostering community cohesion and mitigating depopulation. The collection of data from imperilled archaeological sites, aimed at preserving their significance, is crucial when considering the growing risks associated with erosive phenomena caused by environmental

factors, exacerbated by the construction of the MOSE flood barriers, in use since October 2020, which pose a threat to some sites, such as the Roman villa of Lio Piccolo. An integrative aspect of this research involves active collaborations with several institutions such as the Museo di Storia Naturale di Venezia and the Museo Archeologico Nazionale di Altino, facilitating educational initiatives addressing past and future sea-level and environmental changes. Valorisation of archaeological sites in the Venice lagoon could bolster cultural tourism offerings, and support museums like the future Museo Nazionale della Laguna di Venezia. The findings will be shared with a wider audience also through the creation of a digital storytelling platform.

Radiogenic Isotopes, Geochemistry, Petrography of Raw Materials: A Case of Archaeological Ceramic Circulation in the Atacama Desert (Iluga Túmulos, Tarapacá, Northern Chile)

Camila RIERA-SOTO[1]*, University of Cape Town (cami.riera.soto@gmail.com)
Petrus le Roux[2], University of Cape Town
Osvaldo González-Maurel[3], Universidad de Concepción
Mauricio Uribe[4], Universidad de Chile

Abstract

Sands and clays can make an ideal mixture with precise colour and granulometry, which can be used to define the primary petrography determined by ancestral pottery knowledge with agency and social meanings. From the archaeometric point of view, the petrographic or textural differences that can be determined with the help of hand lenses or microscopes give a closer approximation of the detail of the components of the raw materials.

These groupings are created through a visual petrography classification closely related to the geochemical data. These data can reveal the geological environments from which the raw materials originated, such as volcanic, fluvial or coastal. These environments can be familiar and repeated within human circulation circuits, especially in the Andes, where the central part of the landscape is volcanic. So, what is its relationship with social-geological landscapes and local or foreign pottery traditions?

This research focuses on the ceramic fragments recovered from the site of Iluga Túmulos (900 BC - 1600 AD), an archaeological area located in the Tarapacá Region (northern Chile), with abandoned agricultural and public structures partially buried by desertification processes in the Pampa del Tamarugal, the hyperarid core of the Atacama Desert. Within the material recovered at the site, ceramic fragments abound in quantity, types or styles and periods; identified specimens correspond to the Formative, Late Intermediate of the Western Valleys and Altiplano periods, along with Imperial, Provincial and Local specimens from the Inca period, as well as Hispanic colonial pieces.

In this work, we present detailed microscopic petrography (optical and automated SEM mineralogy), together with new trace elements and REE, and strontium and lead isotope data, for ceramic fragments from Iluga Túmulos. We have identified three distinctly different groups of ceramic fragments: Arica, Tarapacá, and Altiplano-Inca. These groups, differentiated in terms of macroscopic attributes (such as surface finish and fresh paste) and microscopic petrography, have been classified among the most representative pottery traditions in northern Chile. In addition, the radiogenic isotope and geochemical data have shown that some petrographically different pastes share a similar isotopic/geochemistry signature, which is interpreted as different sources of raw

materials within a given geological context.

With this archaeometric review of the ceramic materials from Iluga Túmulos, we hope to rethink the supply of raw materials, ceramic production and the circulation of vessels that keep the different experiences and pottery traditions of these pre-Hispanic populations that inhabited the South Central Andes.

Tracing Anthropocene signatures: Sediment core analysis along the west coast of Korea, Yellow Sea

Eun Young LEE[1], University of Vienna
Tae Soo CHANG[2]*, Chonnam National University (taesoo20@jnu.ac.kr)
Michael WAGREICH[3], University of Vienna
Veronika KOUKAL[4], University of Vienna
Serin LIM[5], Chonnam National University
Maria MESZAR[6], University of Vienna
Chaon KIM[7], Chonnam National University

Abstract

In recent years, the concept of the Anthropocene has emerged as a prominent topic of discussion, symbolizing humanity's profound impact on geological processes. Human activities have reshaped the Earth's systems to such an extent that contemporary geological deposits now bear unmistakable anthropogenic signatures. Since the 1950s, fundamental shifts have occurred in the structure and functioning of the Earth's system, manifesting in increased concentrations of long-lived greenhouse gases, rising surface temperatures, and ocean acidification. These transformations are closely linked to socio-economic trends like population growth, industrialization, and intensified use of minerals and energy. Notably, the widespread proliferation of manufactured materials like aluminium, concrete, and plastics has become a marker of Anthropocene sediments.

The Yellow Sea region stands out for boasting one of the world's most developed coastlines, situated between mainland China and the Korean peninsula. Since the mid-20th century, rapid population growth along the coastline has led to widespread loss and degradation of natural intertidal zones and basin areas. Annually, more than 1.6 billion tons of sediments and anthropogenic materials are transported from metropolitan areas into the Yellow Sea by river systems including the Yellow River, Changjiang River in China, and Han River in South Korea. Consequently, the coastal area has received significant international attention as a focal point for studying the impacts of human activities on natural systems. To investigate anthropogenic signatures in coastal sediments of South Korea, core sections were collected from two islands, Ganghwado and Jeungdo, on the west coast of South Korea. Comprehensive core descriptions, including analyses of macroscopic components and sedimentary features, were conducted. Select core samples underwent thorough processing to determine characteristics of geochemical and mineralogical composition, microplastic contents, and variations in Anthropocene deposits. This study presents our findings regarding anthropogenic signatures in coastal sediments on the west coast of Korea. The distinctive markers can be correlated with diverse environments and socio-economic trends in Korea and globally. Through this international research collaboration, our aim is to deepen our understanding of local and regional anthropogenic signatures, thereby contributing to broader insights into the Anthropocene.

Abstract

Applying the basic principles of carbon chemistry and physics, along with a comprehensive understanding of past climate change, Steffen and colleagues confirmed in the Proceedings of the National Academy of Sciences 115, in 2018, that fossil fuel usage and resulting carbon emissions will cause substantial global warming into future millennia. The climate shift caused by increasing greenhouse gases is provoking a major perturbation to the Earth System likely to last for hundreds of thousands of years according to Talento & Ganopolski in Earth System Dynamics 12, in 2021, because of (i) the long residence time of CO2 in the atmosphere; (ii) the reduced ability of the global ocean to serve as a carbon sink as warming continues; (iii) the release to the atmosphere of CO2 currently stored in the ocean to maintain chemical equilibrium between the ocean and atmosphere as emissions of CO2 begin to decline; (iv) the decrease in albedo through continuing ice melt; and (v) a transgression forced by sea level rises of 10-15m or more supplying organic rich sediments to coastal seas and thus increasing the ocean's carbon content. These drastic changes and associated largely irreversible changes to the biosphere justify the creation of a new epoch – the Anthropocene.

Intensification of the greenhouse effect results from the growth in emissions of the CO2 equivalent (CO2-eq), calculated as the sum of the effects of CO2+CH4+N2O+CFCs and other trace gases. According to NOAA's Annual Greenhouse Gas Index, in spring 2022 the CO2-eq had reached 523 ppm. Such high concentrations of greenhouse gases in the atmosphere are above those identified in the early Late Pliocene, around 3.5 Ma ago, and are close to those identified for the mid-Miocene (16.9–14.7 Ma ago), which were known intervals of uncommon warmth during Neogene times. According to the IPCC's 6th assessment report (of 2023) projections based on

intermediate emissions scenarios place us on track by 2100 to experience CO2 concentrations of 600 ppm that would raise mean global temperature by 2.7°C, a level higher than experienced during Quaternary time. That same report considered that global mean sea-level rise approaching 2m by 2100 and over 15 m by 2300 cannot be ruled out due to deep uncertainty in ice sheet processes, with severe impacts on coastal populations. The ensuing prevention of the glacial maxima typical of the past 1 Ma is expected to last at least 500,000 years, assuaging concerns that the Anthropocene it too short in duration to qualify as a new epoch.

Towards Integrating Indigeneity and Geoethical Practice – Case Studies from Aotearoa New Zealand

Matthew W. HUGHES[1]*, University of Canterbury (matthew.hughes@canterbury.ac.nz)
Norm Kereikeepa[2], Te Rūnanga o Kaikōura
Clint McConchie[3], Te Rūnanga o Kaikōura
Alexander R.L. Nichols[4], University of Canterbury

Abstract

When they arrived in Aotearoa New Zealand (ANZ), the Polynesian peoples who would become Māori rapidly explored the landmass to identify Earth resources. Development of settlements entailed local terraforming – the sculpting of landforms for defensive purposes and food production – leading to empirical knowledge of rock and soil properties encoded in language and traditional practice. Land was intrinsic to identity, and narrative traditions developed in which landscape features were considered ancestors. In Māori philosophy, humans were a dependent component of wider dynamic geo-ecosystems. Māori therefore have a rich legacy of anthropogenic landforms, and deep spiritual ties to geomorphic and geological features across diverse landscapes. British colonisation in the 19th century brought different philosophical approaches to landscapes, and land alienated from Māori through military conquest and purchases was developed for agriculture and municipal infrastructure systems, resulting in significant alteration of traditional landscapes by forest clearance and earthworks. These tensions between Indigenous Māori and European settler approaches to landscape values and management persist today. Māori philosophical views have evolved from being solely dependent on the natural world to acknowledging their role as stewards and guardians of it – the concept of kaitiakitanga – and in recent years natural systems such as rivers have been awarded legal personhood to acknowledge their geo-ecological integrity and tribal importance. While greater emphasis is placed on sustainable infrastructure development and resource extraction, current and future landscape disturbance without regard to Indigenous values and concerns is still problematic. Here we present case studies of past and future potential conflict between Indigenous landscape values, national prioritisation of post-disaster infrastructure recovery, and potential mineral extraction to support climate mitigation technologies. The aim is to encourage geoethical thinking and practice among relevant professional geoscience and engineering communities.

The first case study concerns re-instatement of coastal transportation infrastructure following the 2016 Hurunui/Kaikōura Earthquake in Te Wai Pounamu (South Island) of ANZ. This coastline has a rich and dense Indigenous history evidenced by archaeological sites and terraformed landscapes. Due to the government wanting to expedite recovery of infrastructure deemed of national economic importance, legislation requiring environmental safeguards and community engagement was suspended, with subsequent negative impacts on sacred sites and heritage landscapes by construction works. Although eventual community input led to preservation of culturally significant coastal landforms, there remains a need for increased awareness within the

engineering profession of Indigenous landscape values, and to proactively address concerns. The second case study concerns the potential extraction of olivine-rich lithologies such as serpentinites (hydrated exhumed mantle peridotites) for geo-engineered carbon dioxide sequestration. In ANZ potentially exploitable serpentinite deposits are concentrated in Te Wai Pounamu along an ophiolite belt, comprising distinct landscapes with recognised conservation and heritage values and lying within traditional Māori domains. In the event that technological constraints are overcome for serpentinite-mediated carbon dioxide sequestration, cultural and environmental factors may preclude resource extraction. A geoethical framework informed by Māori conceptual approaches is presented to facilitate discourse among communities, geoscientists and engineers, and to inform decision making in the context of competing landscape values.

Operational ethics for researching geohazards

ILAN KELMAN[1]*, University College London / University of Agder (ilan_kelman@hotmail.com)

Abstract

Researching geohazards can, in itself, be hazardous to researchers and to others. Hazards to researchers are often known, identified, and accepted, with an example being institutional risk assessment processes. Geohazards research might also require formal ethics approval. Hazards to others, even when documented in any risk assessment or ethics approval processes, can be harder to fully account for.

This investigation examines three main questions regarding the ethics of the hazardousness of geohazards research:
1. How might conducting geohazards research produce problems for risk reduction and risk management?
2. How might publishing geohazards research produce problems for risk reduction and risk management?
3. How much responsibility should geohazards researchers take for any detrimental operational outcomes of their research?

Science diplomacy is used as an example, drawing on disaster diplomacy research, in order to demonstrate how these questions and the answers might be addressed to improve operational ethics for researching geohazards. Key areas for exploration and discussion include:
1. How useful are codes of conduct for improving ethical behaviour?
2. How much is risk reduction a preference compared to risk management?
3. How effective are monitoring, enforcement, and accountability mechanisms?
Some geohazards researchers might suggest that no further governance of operational ethics would be needed, indicating the importance of open and respectful discussion.

Geoscience Across Borders: Leveraging Geoscience Diplomacy for International Cooperation.

Munira Raji[1]*, University of Plymouth, United Kingdom (munira.raji@plymouth.ac.uk)

Abstract

Geoscience diplomacy involves international collaboration among geoscientists from different countries to address pressing global challenges. Global challenges such as climate change, energy poverty, environmental degradation, geological hazards, and resource scarcity have complex, interconnected causes that span national and geographic boundaries. Cooperation between geoscience experts from different countries and backgrounds is necessary to develop comprehensive solutions. Geoscience diplomacy facilitates this by encouraging the exchange of geoscientific knowledge and best practices. It brings together geoscientists, policymakers, interdisciplinary researchers, and other stakeholders to leverage their expertise in finding real-world solutions to global problems. Even if they don't label it as such, geoscientists can practice geoscience diplomacy through international research projects. The core goals of geoscience diplomacy are to strengthen cooperation between geoscientists worldwide and enhance relationships between nations. It is an important approach that allows geoscientists to work together globally to address global challenges.

For example, the Group on Earth Observations (GEO) is an intergovernmental organisation that aims to make environmental data more accessible for informed policymaking. Through initiatives like the Global Earth Observation System of Systems (GEOSS), GEO connects thousands of scientists across disciplines and nations to collaborate on gathering environmental data and information from the large array of observing systems contributed by members from 115 countries and organisations within GEO. This information informs disaster management and climate change adaptation strategies. The Integrated Research on Disaster Risk (IRDR) program, co-designed by the International Council for Science and the United Nations Office for Disaster Risk Reduction (UNDRR), also exemplifies geoscience diplomacy. IRDR brings together researchers worldwide across fields like volcanology, environmental science, seismology, climate science, ecology, health, engineering, social science, economics, etc. Their interdisciplinary collaboration aims to develop solutions for managing all types of natural disasters, including flooding and erosion, landslides, earthquakes, tsunamis, and those associated with active volcanoes, increasing resilience, mitigating their impacts, and improving policy-making mechanisms. International collaborative initiatives, such as UNESCO's International Geoscience Programme (IGCP), facilitate joint research collaborations between geoscientists from different countries. The IGCP projects promote North-South and South-South cooperation and prioritise societal benefits, skill development, knowledge advancement, and sharing. By fostering collaboration and exchange among geoscientists worldwide, such initiatives address global challenges and contribute to sustainable development through geoscience research and innovation. On a smaller scale,

partnerships between specific universities and institutions across borders on joint geoscience research projects represent geoscience diplomacy.

An infrastructure designed for the research and global promotion of geoethics

Giuseppe Di Capua[1]*, Istituto Nazionale di Geofisica e Vulcanologia (giuseppe.dicapua@ingv.it)
Silvia Peppoloni[2], Istituto Nazionale di Geofisica e Vulcanologia (Rome, Italy), International Association for Promoting Geoethics (IAPG), IUGS Commission on Geoethics, CIPSH Chair on Geoethics

Abstract

In recent years, there has been a notable surge in the refinement of the theoretical foundations of geoethics and its practical applications. A growing number of scholars from diverse disciplines are actively engaging in this progressive development. This has increasingly underscored the need for establishing platforms where reflections, discussions, findings, and study materials can be readily exchanged and disseminated. The network of scholarly relationships has evolved to create both physical and conceptual spaces for meaningful discussions. The aim has been to maintain conceptual coherence in geoethical thinking by grounding reflections in the discipline's historical evolution and encouraging further advancements through open analysis, inviting contributions from a diverse array of disciplinary backgrounds. Today, the research infrastructure dedicated to geoethics and the promotion of its content is characterized by a complex structure, acting as a focal point for diverse cultural and scientific experiences. At the heart of this infrastructure is the International Association for Promoting Geoethics - IAPG (https://www.geoethics.org), founded in 2012. It comprises an Executive Committee, national sections, and Task Groups dedicated to specific topics within geoethics. More recently, two additional entities have complemented this structure: i) the Commission on Geoethics of the International Union of Geological Sciences (IUGS), established in February 2023, serving as the supporting branch of the IAPG to the IUGS and officially handling geoethics and social geosciences for the Union; ii) the Chair on Geoethics of the International Council for Philosophy and Human Sciences (CIPSH, an organization operating under the umbrella of UNESCO), established in January 2024, with the aim of expanding and strengthening an international research network involving institutions, non-governmental organizations, and individual scholars to promote interdisciplinary initiatives bridging geosciences, humanities, and social sciences through geoethics. The research infrastructure on geoethics has evolved and expanded with the addition of two editorial initiatives: a) The SpringerBriefs in Geoethics series by Springer Nature (https://www.springer.com/series/16482), established in 2020 and endorsed by the IAPG. This series aims to provide concise publications discussing the ethical, social, and cultural implications of geosciences knowledge, education, research, practice, and communication; b) The Journal of Geoethics and Social Geosciences (https://www.journalofgeoethics.eu/), a diamond open-access publication of the National Institute of Geophysics and Volcanology (Rome, Italy), supported by the IAPG, and founded in 2021. Lastly, the research infrastructure on geoethics is complemented by the School on Geoethics and Natural Issues (the "Schola"), established in 2019 (https://www.geoethics.org/geoethics-school). The “Schola” serves as a dedicated space for the

teaching and learning of the principles and values of geoethics within the context of the philosophy and history of Earth sciences. Its purpose is to furnish foundational knowledge and critical evaluation skills needed to comprehend the intricate relationship between human actions on ecosystems and the decisions made by geoscientists in the discipline that have societal and environmental implications. This includes enhancing the awareness of professionals, students, decision-makers, media operators, and the public regarding accountable and ecologically sustainable development.

Responsible Earth/Geosciences and Planetary-Scale Anthropogenic Change

Martin Bohle[1], International Association for Promoting Geoethics (IAPG), Ronin Institute Research Scholar
Giuseppe Di Capua[2]*, Istituto Nazionale di Geofisica e Vulcanologia (giuseppe.dicapua@ingv.it)

Abstract

In an age marked by planetary-scale anthropogenic change (PSAC), the Earth sciences, including Geology, face a pivotal transformation. They gain the status of providing vital knowledge for the stewardship of planetary commons. Considering this context, this talk presents a book project that explores intersections between science and society from a geoscience perspective.

The proposed book project critically examines the dynamic interface between Earth/Geosciences and the profound concept of PSAC, particularly accentuated by the proposed Anthropocene. Recognizing the Anthropocene's unsettled formal status, this work delves into the ethical, philosophical, and cultural implications surrounding PSAC, reflecting its inevitable impact on communities, individuals, and societies globally. Against this background, the book project delves into the interdisciplinary debates and geo-philosophical considerations that emerge from PSAC. These discussions encompass geological perspectives and extend to the humanities and political sciences, highlighting the multifaceted impact of PSAC.

The geoethical perspective, a leitmotif of the book, emphasizes responsible conduct in Earth/Geosciences, especially considering experiences and challenges posed by unfolding PSAC. The epochal transformation of Earth's systems through PSAC calls for an appraisal of Earth/Geosciences' societal responsibilities. This book project, backed by the International Association for Promoting Geoethics, dissects PSAC's societal, cultural, and ethical ramifications. Central to the book's narrative is a geoethical perspective, underpinning a responsible approach to Earth/Geosciences. This perspective critically engages with human practices and behaviours in the face of PSAC. The geological community's forthcoming decisions regarding a possible geological notion of Anthropocene add urgency and significance.

Structured in three parts, the book initially situates Earth/Geosciences at the intersection of STEM disciplines and PSAC, emphasizing its multifaceted impact on research, engineering, and commercial sectors. The second part interweaves concepts of 'responsible science', 'citizen science', and 'stewardship' within Earth/Geosciences, showcasing their integral role in societal and environmental stewardship. The final part champions geoscience literacy as a cultural and educational imperative in navigating PSAC. The conclusion reflects on the emerging research questions and the necessity of developing geoethical perspectives for responsible Earth/Geosciences. The book aims to deepen societal understanding of PSAC, advocating for informed decision-making and collective action. It is a clarion call for embedding geoethical perspectives, responsible practices, and geoscience literacy in the discourse of Earth/Geosciences amidst the challenges of PSAC.

In summary, the book aims to foster a deeper understanding of the PSAC implications for

Earth/Geosciences and emphasize the critical role of geoethics in guiding responsible scientific inquiry and public discourse in an age of planetary-scale human impact.

Bridging Continents: Building Environmental Awareness and Sustainability with geoscience communication through EuroGeoSurveys' PanAfGeo and GSEU projects

Julie Alison HOLLIS[1], EuroGeoSurveys
Krishnan Subramani Ramakrishnan[2], EuroGeoSurveys
Céline Andrien[3], EuroGeoSurveys
Francesco Pizzocolo[4], TNO - Geological Survey of the Netherlands
Nicolas Charles[5], BRGM - French Geological Survey
Josephine Uushona[6], GSN - Geological Survey of Namibia
Tracey Dancy[7], EuroGeoSurveys
Jean-Claude Guillaneau[8], BRGM - French Geological Survey
Rokhaya Samba Diene[9], CGS - Council for Geoscience
Mosa Mabuza[10], CGS - Council for Geoscience
Patrick Wall[11]*, EuroGeoSurveys (Patrick.wall@eurogeosurveys.org)

Abstract

Environmental awareness and sustainable use and management of the Earth are at the heart of the mission of EuroGeoSurveys – the collaborative association of the Geological Surveys of Europe. EuroGeoSurveys is involved in two major projects which are PanAfGeo and the Geological Service for Europe (GSEU). PanAfGeo aims to increase African-owned geological knowledge and skills for sustainable natural resources management through geoscientific on-the-job training, including geoscience communication and dialogue training, for geoscientists of the African geological surveys. GSEU aims to deliver a permanent collaborative network of European geological surveys to provide up-to-date, high-quality harmonised information on the European subsurface. While these projects are distinct in many ways, both address training or data and knowledge services across a wide range of geoscientific thematic areas, and both are united by a shared vision of subsurface management and sustainability practices supported by a wide-reaching commitment to geoscience communication and dialogue with diverse stakeholders.

To ensure maximum outreach and engagement, the communication activities of PanAfGeo and GSEU use methods and language tailored to specific target audiences, including industry, academia, government, civil society, and the broader public. Communication channels cater to diverse audiences through the use of social media platforms for online interactions, face-to-face workshops, conferences, and training sessions, stakeholder interviews, surveys, reports, and explanatory videos.

In PanAfGeo, science communication plays a pivotal role in empowering African geoscientists to effectively explain the significance of Earth sciences to non-specialists, to support environmental management, and to promote sustainable practices. Through a combination of social media engagement, reports, public speaking, and training, PanAfGeo fosters collaboration and knowledge exchange among participants, transcending geographical boundaries, and fostering a

deep understanding of Earth's interconnectedness.

Through GSEU, EuroGeoSurveys promotes awareness of the many crucial roles of the European subsurface in achieving net zero and promotes its sustainable use. GSEU engages diverse stakeholders, including governmental agencies, industry partners, and civil society organisations, to ensure that the harmonised geoscientific data, information and knowledge that fits their needs can reach them through the European Geological Data Infrastructure (EGDI) and associated expert services. GSEU focuses on result-driven stakeholder analysis and implementing diverse engagement methods to drive dialogue, build partnerships, and promote evidence-based decision-making for sustainable subsurface use and resource management practices across the continent.

Through both projects, EuroGeoSurveys delivers comprehensive information and communication campaigns. By tailoring messages to specific stakeholder groups and using diverse communication channels, EuroGeoSurveys aims to cultivate a geoscience-informed society committed to preserving the planet for future generations. These concerted efforts not only focus on geoscience education as a foundation for promoting environmental awareness, but also contribute to the development of a new generation of geoscientists deeply invested in sustainability practices.

EuroGeoSurveys' collaborative efforts through PanAfGeo and GSEU represent a holistic approach to advancing environmental awareness and sustainable practices globally. By empowering geoscientists with effective communication skills and engaging diverse stakeholders in meaningful dialogue, these initiatives contribute to building a more sustainable and resilient future for all.

Ethical Solutions: Climate Intervention Research, Experimentation, and Potential Deployment

Lisa Graumlich[1], American Geophysical Union
Janice Lachance[2]*, American Geophysical Union (AGU) (jlachance@agu.org)
Mark SHIMAMOTO[3], American Geophysical Union (AGU)
Billy Williams[4], American Geophysical Union

Abstract

Climate change requires urgent action. Aggressive actions toward carbon emissions reduction must remain the primary strategy for reversing and addressing climate change. However, increasingly the world is considering technology-based climate intervention approaches—often called climate engineering. There are major practical and ethical questions about the significant risks and potential trade-offs some of these approaches would bring and how they would be measured against the risks of our warming world. Recognizing the need for guiding principles in this fast-moving, dynamic space and building on AGU's longstanding history of advancing and advocating for strong scientific ethics, AGU is facilitating the development of a draft Ethical Framework for Climate Intervention Research, Experimentation, and Deployment. The ethical framework will be released in 2024 and will serve as a resource to help governments, researchers, NGOs, and the private sector make responsible decisions when engaging in climate intervention research or policy. In 2023, the draft framework completed a rigorous three-month public comment period and consultation process to include more holistic input from other scientists and ethicists, as well as community voices, youth advocates, and many more. This presentation will highlight the ethical principles and how the science community can incorporate and advocate for ethics in climate intervention research.

Ethical Frontiers and Legal Landscapes: The ethics of geoengineering the Moon, Mars and other celestial bodies

Dov GREENBAUM[1]*, Reichman University/Yale University (dov.greenbaum@yale.edu)

Abstract

As humanity eyes the colonization of celestial bodies like the Moon and Mars, the endeavor to geoengineer these environments for human habitation presents a unique constellation of ethical, legal, and social challenges. These challenges, while echoing the concerns associated with terrestrial geoengineering methods such as solar radiation management (SRM) and carbon dioxide removal (CDR), also diverge significantly in context and complexity. Terrestrial methods, which address the pressing issue of climate change, involve moral, governance, and societal dilemmas around the potential alteration of Earth's climate. In contrast, the concept of terraforming celestial bodies like Mars necessitates a thorough examination of our ethical responsibilities and the possible ramifications of such profound interventions. The ethical questions surrounding the geoengineering of planets like Mars are particularly poignant. There is a critical moral consideration regarding the potential disruption of undiscovered ecosystems or the destruction of nascent astrobiological life. This underscores the imperative to approach our cosmic ventures with utmost caution, to prevent irreversible harm to these alien environments. The legal considerations are equally complex, rooted in the Outer Space Treaty's directives against harmful contamination and the unilateral annexation of celestial territories. Proposals by visionaries like Elon Musk to geoengineer Mars for human habitation prompt a reevaluation of these legal frameworks, suggesting the need for updated or supplementary guidelines that reconcile the ambition to colonize Mars and other celestial bodies with the imperatives of international space law. Moreover, the social implications of geoengineering Mars introduce a further layer of complexity. There is a valid concern that in our rush to colonize other planets, we might replicate the environmental mistakes made on Earth, exacerbating planetary degradation on a galactic scale. In light of these considerations, it becomes clear that the journey towards making Mars habitable demands a holistic integration of ethical foresight, legal precision, and social justice, some of which we can extrapolate from efforts here on Earth. Such a multidimensional approach is essential not only for the responsible stewardship of extraterrestrial environments but also to ensure that our endeavors in space are aligned with the highest ethical standards and contribute to the collective good. This strategy promises not only to safeguard the integrity of celestial ecosystems but also to inspire a framework for interplanetary exploration that honors our shared values and responsibilities as stewards of the cosmos.

Geotourism and geoethics as support for rural development in the Sundarbans Wetlands - a Ramsar site of West Bengal, India

Amit Mandal[1], Geological Survey of India
Sayani KHAN[2]*, Geological Survey of India (sayanikhan@gmail.com)

Abstract

The study aimed to emphasise geotourism potential and geoethics in rural development of Sundarbans Wetlands, one of the richest areas in India, specifically in West Bengal in terms of Geoheritage and Geoconservation.

Sundarbans, world's largest delta system is formed by Ganges-Brahmaputra-Meghna River confluence with innumerable channels-tidal creeks in Bay of Bengal. Sundarbans are also badged as world's largest contiguous mangrove belt, covering ~1,44,000 hectares. The system acts as a barrier against cyclones-tidal surges-saltwater intrusion, where mangroves play the most important role. Sundarbans are a hotspot of rich flora-fauna, habitat of unique and endangered biodiversity including trees like Sundari (Heritiera spp.), Gewa (Excoecaria agallocha), and animals like Royal Bengal Tiger (Panthera tigris tigris), Gangetic (Platanista gangetica) and Irrawady (Orcaella brevirostris) Dolphins, Greater Adjutant Stork (Leptoptilos dubius), Masked Fin Foot (Heliopais personata), River Terrapin (Batagur baska), Shark (Glyphis gangeticus), Estuarine Crocodile (Crocodylus porosus), 315-avian species, etc. Four-protected areas have been enlisted as UNESCO World Heritage Sites in Sundarbans.

Apart from scenic beauty and rich biodiversity, making it a popular international tourist destination, Sundarbans is also a paradise for Geoscience researchers. Being a classic example of a tide-dominated delta, active geomorphic processes can be studied and compared here with similar other systems in world. Wave-dominated sedimentary regimes in Matla-Saptamukhi riverfronts, text-book-like asymmetrical ripples near Bakkhali-Henry islands, aeolian dunes, cross-beddings at Sitarampur beach, accretionary tidal landforms in Hatania-Doania channel, mid-channel-bars in Thakuran river, sand-bars at MuriGanga riverfront, mudflats in Saptamukhi river are well-preserved. River bank erosion is pronounced by high-energy current flow and wave activity, banks of Sagar-Gorumara-Ghoramara islands in Hugli-MuriGanga rivers being highly susceptible. Bank erosion vulnerability, cyclonic-supercyclonic storms, loss of riverine islands over last-hundred-years, mangrove forests destruction thereby removing topsoil, changing landuse-landcover, global climate change affecting sea-level, natural geomorphic processes, etc. are the alarming issues for Sundarbans research. Mangrove ecosystem morphodynamics and diverse geomorphic features of creeks-channels-rivers of Sundarbans enriched with magnificent biodiversity, thus has vast possibilities for developing geo-heritage as well as geo-tourism site, which in turn help in increasing awareness about nature and its conservation.

Despite being a biodiverse reserve and an important Ramsar Site, Sundarbans are under severe threats due to anthropogenic stress imparted by ~4-millions inhabitants, vulnerability to climate change, alteration of natural habitats because of shrimp-crab-molluscs-fish farming, dredging-

oil/gas drilling-logging-wood harvesting-hunting-fishing-aquatic resource exploitation etc. However, its potential for geotourism development has been ignored, and geoheritage has not been sufficiently explored.

This study makes an inventory of geosites in Sundarbans. Selected sites are evaluated by applying Geosite Assessment Model to discover the most suitable geosites for future geotourism development, to support rural development as well. Results uncover information about areas of improvement for each evaluated geosite. Moreover, areas demanding more attention and better management in upcoming period to become recognisable geotourism destinations are identified. In present scenario of fast disappearing Wetlands, it is high time to take preservation steps on a serious note on geoethical point of view. Sundarbans require better management and precautionary conservation measures. Geoethical implications in geosite management can contribute to sustainable geoconservation in Sundarbans Wetlands.

Synthetic Seas: Ethical, Legal, and Social Dimensions of Genetically Engineered Phytoplankton for Climate Mitigation Contrast with Ocean Iron Fertilization

Dov GREENBAUM[1]*, Reichman University/Yale University (dov.greenbaum@yale.edu)

Abstract

The burgeoning field of synthetic biology offers transformative approaches for mitigating climate change, notably through the genetic engineering of marine microorganisms to enhance their carbon sequestration capabilities. Specifically, we will examine the ethical, legal, and social implications of deploying genetically engineered phytoplankton as a novel strategy. This strategy will be juxtaposed and contrasted with established geoengineering methods such as ocean iron fertilization, a well-discussed CDR method that involves the addition of iron to ocean waters to stimulate phytoplankton blooms.

Genetically modified phytoplankton potentially represent a scalable and efficient solution for reducing atmospheric CO2 levels, offering additional enhancements such as increased growth rates and improved resilience to changing ocean conditions. We further introduce yet another novel dimension by examining the potential role of artificial intelligence (AI) in refining these genetic modifications. Leveraging AI researchers may be able to predict optimal genetic alterations that enhance phytoplankton's carbon sequestration capabilities, potentially revolutionizing our approach to mitigating climate change.

However, this approach raises significant ethical concerns regarding the manipulation of natural ecosystems, potential ecological risks, including biodiversity impacts and unforeseen ecological consequences, and the moral considerations of intervening in oceanic biospheres. Moreover, legally, the deployment of genetically modified microorganisms in international waters presents complex jurisdictional challenges, necessitating a global governance framework to ensure responsible research, development, and monitoring of such efforts. Social implications revolve around public acceptance, the equitable distribution of technology and its benefits, and the engagement of indigenous and local communities in decision-making processes. The potential integration of synthetic biology with AI further poses unique ethical and regulatory challenges, particularly in terms of algorithm transparency and data usage.

In contrast to our proposal, ocean iron fertilization, while seemingly less invasive than genetic modification, has also been criticized for its unpredictable ecological impacts, potential for toxic algal blooms, and uncertain long-term carbon storage outcomes.

Ultimately, we argue for a cautious, ethically grounded approach to the use of synthetic biology in CDR, emphasizing the need for comprehensive risk assessment, transparent stakeholder

engagement, and international cooperation to navigate the complex interplay of ecological benefits, risks, and ethical considerations inherent in these innovative yet contentious methods of climate intervention.

Geological and Natural Inheritance of Uzbekistan: Research and Conservation of Wealth

Ziyoda Kamunalovna AKHMEDOVA[1]*, Ministry of Mining Industry and Geology (ziyoda06-28@mail.ru)

Abstract

Geoethics and Earth studies are of great social relevance as they aim to explore different aspects of our planet and its interaction with society. This field of study is important to all of us as it allows us to better understand our Earth, predict change and address the world's challenges related to climate change, biodiversity conservation, resource management and building a sustainable future.

Geoethics serves as an aide in the study and management of our planet's natural resources such as water, minerals, oil, gas, energy and others. It allows us to better understand how to utilize and conserve these resources, taking into account environmental, economic, and social factors.

At the same time, the earth sciences, including geoethics, study the state of ecosystems, climate, the Earth's surface, the atmosphere, and other components of the environment. This allows us to assess the impact of human activities on nature, identify the causes of global climate change and develop strategies for more environmentally sustainable development. Geoethics and Earth studies also play an important role in planning urban environments and regulating land use. They help to determine the optimal location of buildings, efficient use of resources and population, natural disaster risk management and the creation of sustainable cities.

It is also worth mentioning that geological and geographical studies play an important role in studying earthquakes, volcanic eruptions, floods and other natural disasters. Through these studies, warning and monitoring systems are created to protect life and reduce losses in the event of disasters.

Uzbekistan, which occupies a significant area in the centre of Central Asia, is becoming an indispensable part of our planet Earth.

The nature of Uzbekistan amazes with its diversity and beauty. The majestic Tien Shan Mountains, the breathtaking Kyzylkum Desert, the picturesque Aidarkul Lake and the Ugam-Chatkal Mountains - all these natural wonders are only a small part of the uniqueness of Uzbek nature.

Uzbekistan is located in the northern part of the Pamir-Alai and Gissar mountains, part of the majestic Tien Shan range. Uzbekistan's mountain systems present stunning landscapes with high mountain lakes, mountain passes and unique climatic conditions.

In the west of Uzbekistan stretches the vast Kyzylkum Desert, one of the most extensive deserts in the world. Here majestic sand dunes, oases and unique flora and fauna create unique landscapes and leave a deep impression.

Rivers such as the Amu Darya, Syrdarya and Zarafshan, which flow through the territory of Uzbekistan, play a significant role in farming and water supply for the country. In addition,

Uzbekistan has beautiful lakes such as Aidarkul and Charvak, which are becoming places of recreation and natural reserves of amazing beauty.
Uzbekistan is truly an amazing country with a wealth of nature and the living creatures that inhabit it. All this beauty inspires us to care for and preserve this unique natural world for future generations.

Regulating Geoscience in a Diverse Federation of Independent Regulators – The Canadian Example

MARK PRIDDLE[1]*, Egis Group (priddlemw@gmail.com)
Andrea Waldie[2], Geoscientists Canada

Abstract

Professional Geoscience is regulated in eleven of the thirteen provinces and territories in Canada. These jurisdictions vary significantly in size, demand for geoscience services, mineral resources and population. The numbers of professional geoscientists varies widely (~100 to 5000) between these jurisdictions, and most are co-regulated with engineers.

Geoscientists Canada is the national organization for ten of the geoscience regulated jurisdictions and provides a forum for cooperation and information sharing. The licensure requirements are consistent across Canada; however, the practice of geoscience is regulated independently by each province and territory. Because of this independent regulation and the need for mobility of geoscientists, cooperation between associations, and consistent practice across Canada, a national body such as Geoscientists Canada plays an important role. One key item developed and maintained by Geoscientists Canada is the Geoscience Knowledge and Experience Requirements for Professional Registration in Canada utilized by Canadian geoscience regulators in the assessment of applicants for professional licensure.

Geoscientists Canada does not license or regulate geoscience in Canada, but provides a forum for the independent regulators to work together on common goals. Several recent examples of cooperation will be presented:

• Development of an admissions support tools
• Review of all professional practice guidelines related to geoscience in Canada
• Preparation of a “qualified persons” short course (for students and practitioners
• Spearheading competency-based assessment for licensing practitioners

These activities all promote and enhance the regulation of professional geoscience and geo-ethics in Canada.

Bias in accepting diversity of interpretation in Earth Sciences – historical perspectives and modern challenges

Rob BUTLER[1]*, University of Aberdeen (rob.butler@abdn.ac.uk)
Clare Bond[2], University of Aberdeen
Mark Cooper[3], University of Aberdeen

Abstract

As in all areas of human investigation, as Earth Scientists we need diverse explanations if we are to evaluate uncertainty in geological interpretations. But do we practice what we preach?

Famously, in November 1926, a group of leading American Earth Scientists met in a symposium in New York to debate Alfred Wegener's proposal of continental drift. They rejected not just of Wegener's hypothesis but also the general notion of significant horizontal tectonics, globally or in orogenic belts. The aggressive, mocking tone of his opponents closed down debate. Deep irony lies at the heart of this. Much of the hostility towards continental drift, and the assertion of a fixist Earth disregarding empirical evidence to the contrary, can be traced to Thomas Chrowder Chamberlin (1843-1928), and his son Rollin Thomas Chamberlin (1881-1948). As well as being a geologist with wide-ranging interests, Chamberlin senior is credited with promoting the approach for establishing knowledge in science through the method of multiple working hypotheses. Continental drift was evidently a hypothesis too far for the Chamberlins. Earth Science had to wait until the 1960s before fixism was broadly abandoned in favour of plate tectonics. Today scientific debates are generally more respectful, and we may believe that we are now less prone to such biases. But are we really?

Modern Earth Scientists may consider themselves as above the polemical debates of the 1920s. Scientific conferences of course regularly pit opposing views. This however does not mean that diverse geological interpretations are given appropriate consideration. Our concern is the role of Earth Science in characterising and forecasting behaviour of the subsurface for engineering projects, in sedimentary basins. Much existing understanding has come from the extraction of earth resources – especially hydrocarbons. Uncertainties in geological interpretation can be met iteratively, perhaps by drilling another well when the initial hypothesis fails. But for subsurface geo-storage there is far less tolerance of failure.
These engineering challenges demand different approaches – and the recognition of uncertainties. How well are alternative interpretations and approaches valued? It is very rare for scientific journals to publish multiple interpretations. And the problem is exacerbated by literature search engines – that return literature on the basis of citation. This is an inherent bias that is self-reinforcing, reducing visibility of less cited texts, and therefore consideration of alternative approaches and opinions by the community. These approaches to seeking literature can have a similar effect to the infamous echo-chambers of social media – where a narrow range of opinions

and information are selectively reinforced to the exclusion of others.

While we are becoming better at accepting, promoting and valuing diversity in our community of scientists, the IT tools we use may engender exclusive and biased appreciation of science. Studies have recognised this for paper citation metrics of scientists in different communities and with different characteristics but to date, not about the literature itself. We draw examples from studies of the geological interpretation of complex subsurface structures, examining biases and impacts on uncertainty assessments .

Geological Surveys, Mining Industry Cycle and Government management! Sustainable development or conflict in national interests!

shirin safavi[1]*, UNESCO Chair on Coastal Geo-Hazard Analysis, Research Institute for Earth Sciences, Geological survey of Iran, Tehran-Iran (Shirin.safavi50@gmail.com)

Abstract

In the path of sustainable development, the mining economy chain lies in the harmonious link of exploration, extraction and processing, which, due to the breadth of the cycle in the case of continuity and production of final added value, in addition to entrepreneurship, can also play a role in the regeneration of gross national product. The Geological Surveys, with the twin key missions of generating capital and safeguarding national wealth in the field of geosciences, are among the most notable government institutions in terms of utilization of internationally expert.

In countries such as Iran with an oil-based economy, the share of mines and mineral industries without considering its downstream industries and uses, although at an increasing rate, still seems to be small, in order to make the national cost in the financial compensation of natural damages, the role Constructive and key governing organizations and basic knowledge such as Geological Survey doubles the economic cycle of developing countries!

Due to the increase in population and the increasing need of humans to know and use as much as possible from the few minerals and available biological resources in the earth's crust, as the only currently known habitat, exploration and search for mineral resources as the foundation and the first link. In the chain of mining industries, in addition to the unquestionable need for risky investment, it is dependent on having modern knowledge, using modern tools and equipment along with risk capital coverage mechanisms. In the meantime, based on the global experience, governments enter in the form of devices such as Geological Surveys, only in the two initial and final parts of the production cycle, in providing basic information for national exploration or entering specific cases targeted for the future, which the possibility can be defined due to the lack of investors or the lack of knowledge and technology in a period of time beyond the ability, or the interest of the private sector.

Fossils, museums and ethics – from site based conservation to institutional acquisition

Kevin Neil Page[1]*, ProGEO (kevinnpage@gmail.com)

Abstract

Considerations of geological heritage conservation and related legal issues are fundamental to both the initial collection and the subsequent acquisition of geological specimens by an institution as a resource for future generations - not least as there can be legal consequences for all involved if they are ignored… Ideally, the conservation measures in place should be beneficial to science and heritage custodianship by ensuring that key localities remain available for study as well as ensuring that key specimens of scientific and heritage importance are deposited in appropriate institutions for safeguard for future generations. This is not always the case, however, as highly restrictive measures can virtually prevent continued scientific study, as well as making it almost impossible for all but a very small number of local or national institutions to legally hold material from such sites.. In many cases, such restrictions represent either a confusion with the very restrictive regimes needed for rare species or archaeological conservation or attempts by national and regional agencies to safeguard a national heritage which had historically been plundered or otherwise damaged though misuse.. More insidiously, however, they can also reflect attempts by individual, politically influential scientists or institutions, to ‘control’ a resource for their own ’exclusive’ use – and this can take place at all levels from regional to national. In a few cases, however, the motivations are altogether darker, and it is an unfortunate fact that the palaeontological resource can be economically controlled by oppressive regimes or criminal activity, leading to a concept of ‘Blood Fossils’. But whatever the on-site, regional or national legal framework is, there are four key themes to consider, both in the field and as a manager of palaeontological collections: 1. Who does the fossil belong to? (e.g. landowner, collector, commercial company, governmental body, etc?); 2. Do any local, regional and/or national legal regulations apply to the source locality, and can or have the specimens been collected in accordance with such regulations?; 3) Can or has the specimen be legally removed from a region or country, according to regional to international level legislation?; and crucially, 4) Are there any ethical considerations, such as supporting damage to protected sites and loss of palaeontological heritage (i.e. irrespective of any legal consideration), supporting oppressive regimes and organised criminal activity, ‘neo-colonisation’ of heritage and science of low to middle income countries by high-income countries, and the contravention of established regional, national and international guidelines, agreements and conventions. Against this background, a concept of ‘Palaeontoethics’ has been developed, but as in so many of the broader themes relevant to modern geosciences, the issues represent an interface between several different disciplines, in this case geological heritage, field geology, palaeontology, institutional collection and ethical professional practice. As such there is a very strong need that international guidance is developed and approved by organisations such as IUGS, IUCN and UNESCO to ensure that all geoscientists are fully aware of not just the

legal considerations behind any field sampling or specimen acquisition, but also the ethical context.

Science of Geoethics: Challenges and Opportunities

Devesh WALIA[1]*, North-Eastern Hill University (deveshwalia.17@gmail.com)

Abstract

Geoethics combines a complex of ethical relation to the components of the Earth, and to the diverse socio-economic objects, by preserving the geo-diversity and geo-heritage with knowledge expansion and is the crucial pillars for maintaining scientific integrity and credibility. Ethical conduct involves responsibilities toward society and Earth System. Self-monitoring and self-regulating behaviors promote knowledge, truth, trust, respect, and objectivity while avoiding conflicts and make geoscientists accountable for the quality and outcome of the earth system study following the ethical norms to unravel the geo-resources.

Geoethical principles aimed at implementing geological projects provide realistic and efficient support to not only apply economic criteria, such as profitability, commercial viability and profit margins because of continuous technological evolution and requirements, for which more and more earth resources are needed, but also consider ethical and transparent practice of management, improving the effectiveness, regeneration of mineral reserve base, and making sure the mineral resources are being used taking into account their exhaustibility, scarcity and resource ownership by future generations. Hence, promoting deep moral essence with spiritual development of personality to avoid social conflicts with deep time.

The challenges are plenty, but we need this opportunity to inculcate the science of geoethics to protect the mother earth for sustainable future generations.

Martha Cornelius-Furlani (1886-1974) and Adelheid Kofler (1889-1985) - the First Female Geoscientis at the University of Vienna

Margret HAMILTON[1]*, University of Vienna (margrethamilton@hotmail.com)

Abstract

Martha Cornelius-Furlani (1886-1974) and Adelheid Kofler (1889-1985) – The First Female Geoscientists at the University of Vienna

Margret Hamilton
Geological Archive, Department of Geology
University of Vienna
margret.hamilton@univie.ac.at

Abstract
In the late 19th and early 20th centuries, social and political life in the Habsburg monarchy was male-dominated, despite some women's activities in 1848 and 1866. In 1897 women were admitted to the faculty of Philosophy for the first time. All candidates needed to have high school diplomas. The final certificate from the secondary schools intended for girls was not recognized for university studies due to the shorter school duration. Therefore, the candidates had to take an additional exam in order to be recognized as regular university students.
The first female doctors (PhD) were Adelheid Kofler at the mineralogical-petrographic institute and Martha Cornelius-Furlani at the geological institute.
Adelheid Kofler (Schaschek) was born 1889 in Haugsdorf, Lower Austria. In 1907 she passed the school leaving examination and enrolled at the philosophical faculty of the University of Vienna as an extraordinary student. In 1911 she passed the Matura examination “Maturitätsprüfung” so that she could continue studying as a regular student and passed her rigorous exams in mineralogy with the well-known Professor Friedrich Becke (1855-1927). Four years later she received her doctorate in medicine. In 1922 she got married with the medical doctor Ludwig Kofler (1891-1951). In 1926 the family moved to Innsbruck. Here Adelheid Kofler supported her husband in setting up the pharmacological institute at the University of Innsbruck. She worked on the micro-thermoanalysis of two- and three-substance systems and thereby created a way to qualitatively record the themodynamic behavior of two substances without serial experiments on a single microscopic preparation. After her husband's death in 1951, she continued to work successfully at the institute in the microscopic field. For her scientific work she received the Fritz-Pregl-Prize from the Academy of Sciences and the Austrian Cross of Honor for Science and Art.
Martha Cornelius-Furlani was born 1886 in Triest. After graduating from the teacher training college) in Triest in 1905, she enrolled as an extraordinary lecturer in geology at the University of Vienna. In 1907 she passed the Matura examination, which made her a regular student and in 1910 she got her PhD for Geology under the professor Viktor Uhlig (1857-1911). And in 1911 she

passed the examination for becoming a teacher in the subjects Natural History. In 1921 she got married with the geologist Peter Cornelius (1888-1950). She joined him on numerous excursions in the Alps, which resulted in a number of joint publications. After her husband's sudden death in 1950, she published the textbook "Geschichte der Geologie” (Principles of Geology), which she wrote with her husband. After her retirement she worked at the Natural History Museum in the paleontology department.

The two female scientists were able to successfully improve their knowledge and skills in the scientific subjects of mineralogy and geology after finishing their studies.

Etheldred Benett (1776-1845) and the Unacknowledged Contributions of an Early English Woman Geologist

Renee M CLARY[1]*, Mississippi State University (rclary@geosci.msstate.edu)

Abstract

Etheldred Benett (1776-1845) is largely unknown as an early woman participant in geology, although she preceded Mary Anning (1799-1847) in her fossil interests and paleontological contributions. As a woman of independent means, Benett could pursue her investigations in paleontology. She amassed large numbers of fossils, through both self-collection and purchase, and she generously donated or loaned many of her specimens to other paleontologists and museums. Some of the local collectors who provided fossils to Benett were also women. Benett's paleontological interests were not fleeting; she regularly investigated fossil taxa in her area and networked with important geologists, including George Bellas Greenough (1778-1855) and Gideon Mantell (1790-1852), the latter with whom she had a three-decade long correspondence. Although barred from participation in the Geological Society of London because of her gender, Benett named fossil taxa, constructed and revised a stratigraphic column, published a fossil monograph, and may have been the first person to sieve for microfossils. Benett's letters document her thorough understanding of fossils and taphonomy. She felt confident enough to challenge Mantell's interpretations as early as 1815; he included some of her interpretations in his book, The Fossils of the South Downs. While Mantell emerged as a celebrated English paleontologist, Benett remained in the shadows. Other gentlemen geologists used her fossils and knowledge, but they did not always acknowledge her contributions. James Sowerby (1757-1822) even published her stratigraphic column without citing her authorship, and without her consent. Benett, however, seemed to accept her secondary role as a woman in geology, and even apologized for naming new fossil sponges, noting that after three scientific gentlemen did not describe and name these new genera, "I have done the best I could." Two centuries later, we should recognize and acknowledge Benett's contributions to geology.

Marie Stopes (1880-1958) and Kono Yasui (1880-1971)- the beginning of paleobotany in Japan

Michiko dvan Yajima[1]*, Tokyo Metropolitan University (pxi02070@nifty.com)

Abstract

Abstract
Marie Stopes was born in UK and presented her dissertation in German and received a PhD in botany in 1904. She came to Japan in 1907 and explored coal mines on Hokkaido for fossilized plants. She came back to UK and published the paper (Stopes and Fujii, 1910). It gave a great shock to Japanese scientific world that there is a woman paleontologist who had doctorate, made research even in coal mine .

Kono Yasui, who was born in 1880, came to Tokyo to enter the Women's Higher Normal School. After graduation, she worked as a teacher for 3 years at a middle school for girls. In 1905, in order to study biology more, she joined the graduate course first established at the Women's Higher Normal School as its only one science student. She published the first paper, "Weber’s organ of carp fish" in 1905 and changed the research to botany, particularly in cytology. She completed the graduate course at Women’s Higher Normal School, became assistant professor in 1907.
Japanese universities could give the doctorate students who studied at the foreign universities after graduation of universities in Japan. Yasui also had to go abroad to study more in order to get doctorate. Yasui applied for going abroad many times and at last in 1913, she was ordered by Japanese Government to go to USA and Germany to study more on biology. In 1914 she studied abroad in the US, at first conducted cytological research at the University of Chicago and began research on coal under the professor Edward Charles Jeffrey (1866-1952) at Harvard University. Jeffery might know that a good paper on Japanese coalStopes and Fujii, 1910.
Upon returning to Japan, she found it difficult to secure research funds at the Women's Higher Normal School in order to continue her study of coal. However, through the efforts of Professor Kenjiro Fujii (1866-1952) at the Botany Course of Tokyo Imperial University, she was able to continue this research for 10 years at Tokyo Imperial University. Yasui collected coal samples from various places around Japan by entering the deep shafts of coal mines using a basket. This was regarded as outstanding research that could not be surpassed by others, and thus bore fruit as the doctorate thesis "Botanical Study on Coals Produced in Japan"(Yasui, 1928). In this way, in 1927 the first female doctor of science among universities in Japan was born.

Geological Scenes from Two Marriages – Mary Elizabeth Lyell and Emma Darwin Compared

Martina KÖLBL-EBERT[1]*, Ludwig-Maximilian Universität Munich (m.koelbl@lmu.de)

Abstract

When Charles Lyell married Mary Elizabeth Horner in 1832, he had found himself a well-educated wife who took interest in his geological endeavours. She acted as his geological and secretarial amanuensis. She accompanying him on his travels, went in the field together with her husband as well as alone. As Charles Lyell had trouble with his eyesight, Mary Elizabeth did a considerable part of his correspondence. She was fluent in German and French, which allowed her to act as interpreter. However, she was also greatly interested in palaeontology and over the years became an accomplished taxonomist of fossil shells in her own right.

Seven years after Lyell, Charles Darwin married his cousin Emma Wedgwood. When she expressed her plans to read up on geology after people of their acquaintance had commented on her ignorance, her husband told her not to bother. Charles apparently was favouring a wife that took care of his household, played the piano and pampered him during his long phases of illness. As to his friend Charles Lyell, Darwin commented rather negatively about his marriage, believing that Lyell ill-treated his wife, when she sat by when the two men talked science.

The paper explores the respective gender roles of the two women, the views of their husbands and how these were shaped by their upbringing.

Women and diamonds

Leonid R. KOLBANTSEV[1]*, Russian Geological Research Institute (VSEGEI)
(Lkolb57@Gmail.com)

Abstract

Everyone knows that women love diamonds. However, in the history of geology, the topic of "women and diamonds" has a completely different meaning. In the discovery of Yakut diamonds in 1954-1955, 4 woman geologists played an important role: N.Sarsadskikh, L.Popugaeva, N.Kind and E.Elagina. In the extremely difficult climatic and living conditions of Yakutia, they became the discoverers of kimberlite bodies.

The search for diamond deposits in the USSR began in the late 1930s. Then the main search area was the Urals, where individual diamonds had been found since 1829. After World War II, intensive searches for diamonds began throughout the country: in the Urals and Kazakhstan, Karelia, Siberia, the Far East, etc. Intensive searches led to the discovery in 1954 of the first kimberlite pipe "Zarnitsa" (L.A.Popugaeva, based on materials from N.N.Sarsadskikh), and in 1955 - one of the richest diamond pipe "Mir" (discovered by E.N.Elagina and Yu.I.Khabardin, according to the forecast of N.V.Kind).

Natalia Sarsadskikh (1916-2013), mineralogist and petrographer, began searching for diamonds during WWII, when she was evacuated to the Urals from besieged Leningrad together with her husband, mineralogist A.A. Kukharenko. In the late 1940s, she ended up in Siberia, where she participated in prospecting for diamonds. The main merit of N.Sarsadskikh is the identification of minerals - genetic satellites of diamond, the proposal of the "pyrope" method for searching for kimberlites and the localization of the most promising area for the discovery of kimberlite bodies: the valley of the Daldyn River. In 1954, due to the birth of her daughter, she was unable to go to fieldwork, sending L. Popugaeva there.

Larisa Popugaeva (1923-1977) has been participating in the search for diamonds since 1950. In 1954, she went on an expedition alone and, using the "pyrope" method, discovered the first kimberlite pipe, "Zarnitsa". Later she searched for colored stones and discovered several deposits.

Natalya Kind (1917-1992). Geologist and geomorphologist, specialist in the geology of Quaternary deposits. She began searching for diamonds in 1939 in the Urals. Since 1950 she worked in Siberia, found the first diamond on the Malaya Botuobia River, compiled a forecast map of the location of primary sources of diamonds in this area, sent her employees there. Subsequently, she worked in Moscow, was engaged in human rights activities, together with dissidents: A.Solzhenitsyn, I. Brodsky, etc.).

Ekaterina Elagina (1926-2011). In 1941, she was evacuated from Moscow to the Urals, where she began searching for diamonds. In 1951, she went in Siberia, where she worked together with N.V.Kind, on whose instructions in 1955, having gone to field work with geologist Yu.I.Khabarnin, discovered the "Mir" pipe at the very beginning of the season. The famous radiogram was sent: "We lit a "Mir" pipe, good tobacco."

Despite the important discoveries made by woman geologists, the state was extremely stingy in gratitude and rewards. Their merits were hushed up and consigned to oblivion, and they themselves were often persecuted. However, justice gradually finds its way and memory returns.

Mrs A. H. Foord and G. M. Woodward: 19th century translators and illustrators of cephalopod studies

Catherine (Kathleen) HISTON[1]*, IUGS INHIGEO (hiscat@interfree.it)

Abstract

British palaeontologist Arthur Humphreys Foord (1844-1933) and the Austrian palaeontologist Johann August Georg Edmund Mojsisovics von Mojsvar (1839-1907) are well known for their contributions to cephalopod studies in the late 19th century. However, the contribution of two women to their most famous works has remained very much hidden in the background where one is mentioned in a title page as translator and the other in the authors' introduction as illustrator. Reference to both women was discovered during biographical research on A. H. Foord.

Foord worked as a volunteer in the collections at the Natural History Museum (London) and was highly regarded by Henry Woodward (1832-1921), Keeper of the Geological Department, for his diligent study of the collections. He was assigned the task of compiling detailed systematic descriptions of the cephalopod faunas for the 'Catalogue of the fossil Cephalopoda in the British Museum (Natural History)'. Two volumes were published in 1888 and 1891, however, on transferring to Ireland to take up a position as librarian and scientific editor at the Royal Dublin Society in 1891 he completed the third volume of the catalogue from there through correspondence with co-author G. C. Crick and this was published in 1897.

Foord had been renowned as a scientific illustrator, had held the position of artist in the Geological Survey of Canada up until 1883 and had been praised by Henry Woodward in the preface by the museum keeper in Vols I and II. No mention is made in Woodward's preface in part III regarding the illustrations. However, Foord in the introduction to Vol. III with co-author G. C. Crick acknowledges G. M. Woodward for her careful preparation of the illustrations. Gertrude Mary Woodward (1861-1939) was the daughter of the museum keeper.

Foord obtained a doctorate from the University of Munich in 1896 by submitting a thesis to the distinguished palaeontologist Karl Alfred von Zittel (1839-1904). This thesis was in German and presumably had been translated from English.

On the 2nd of April 1896 Foord married Ida Franziska Adelheid Kuhlmeyer (1842–1916) of German origin in Dublin. Both Dr A. H. Foord and Mrs A. H. Foord are cited as translators of the Monograph by E. Mojsisovics (1902) Upper Triassic Cephalopod Fauna of the Himalaya.

The aim of this presentation is to shed light on the identity and role of both these women in the shadows who contributed by their work as illustrator and translator to cephalopod studies in the 19th century.

Anna Hietanen (1909–1994) – from Finland to the world

Elina LEHTONEN[1]*, University of Helsinki (elina.lehtonen@helsinki.fi)

Abstract

Anna Hietanen (1909–1994) was a Finnish-born geologist who defended her doctoral thesis in 1938 (Hietanen 1938). Hietanen was the first woman to have a doctorate in the field of geology in Finland.

In the fall of 1938 Hietanen moved to the United States for two years on a researcher exchange. She spent her first year at Brywn Mawr College and the second year at the Johns Hopkins University. During her time in the United States Hietanen worked for example with Ernst Cloos (1898–1974). Their joint study published in 1941 (Cloos & Hietanen 1941) has been described as an outstanding publication (Waters & Stanley 1980).

Hietanen returned to Finland later in 1940 and made, for example, extensive fieldwork during the Continuation War. Hietanen applied for an assistant position in geology and mineralogy that was open in the 1940s at the University of Helsinki, but was not selected to the position. In 1946, Hietanen moved to the United States, where she continued her career as a geologist. For most of her career, Hietanen worked at the United States Geological Survey, and progressed all the way to the chief of the petrology unit (see e.g. Isakson n.d.). Many of Hietanen's research articles were concentrated on the metamorphic rocks, and in the USA her research areas were, for example, Idaho and California. Hietanen was also a pioneer in terms of research, as she was the first researcher to present a plate tectonic model to explain the development of the Finnish bedrock (Hietanen 1975). Hietanen's career has been recognized both in the United States and in Finland, but, to my knowledge, no extensive research or biography has been done on her before. She is shortly featured in the Woman of Learning project (Isakson n.d).

In my research on Anna Hietanen, I have focused especially on the first half of the 20th century, when she mainly lived in Finland. In addition to the external stages, I have been interested, for example, in thinking about how the wartime and social structures possibly affected Hietanen and her career as a geologist. The research is still partially in progress, and I am also working on a non-fiction book based on the research.

[Keynote] Mexican Women in the Paleontology and Oil Industries

Lucero MORELOS-RODRIGUEZ[1]*, UNAM (lunalucerom@yahoo.com.mx)

Abstract

In history, the forgeting and invisibilization of women who stood out in fields such as science is commonplace. In an exercise of memory and in order to rescue them from oblivion and value the lives of intelligent women, who studied, held positions and great responsibilities, traveled, led communities, laboratories, museums, imposed themselves and built their scientific-technical practice. And they opened a gap, is that we propose to offer a glimpse of the history of Paleontology developed for more than 90 years at the Institute of Geology of Mexico. Among the pioneers in the study of Micropaleontology in Mexico we place María Luisa Robles Ramos and Clara Flores Covarrubias, who carried out their work since the 1930s. Both were part of the academic team of the Institute of Geology and simultaneously worked in the Paleontology Laboratory of the Exploration Management of Petróleos Mexicanos (PEMEX) a state company created to contribute to economic development through the exploration, exploitation and marketing of oil. It was not a research laboratory per se, but was aimed at solving problems related to oil exploration through the study of fossils and microfossils, such as foraminifera from the various basins of oil interest in the Mexican Republic. The laboratory team was made up of 35 people, among whom were 12 women who formed a group of geas that experienced serious labor challenges after the expropriation of the oil industry in 1938, since with the departure of foreign companies from the country, experts , archives, collections and machinery, forced Mexican specialists to start from scratch and launch Petróleos Mexicanos (PEMEX). The legacy of these geas is overwhelming since Micropaleontology is one of the most cultivated disciplines in the highest house of studies in Mexico: the National Autonomous University of Mexico (UNAM).

[Keynote] Takla Makan, Pamirs, Karakorams, Indogangetic Plain, Singhala and Java: The Buddhist topography of Faxian (Fa-Hien), at the beginning of the 5th Century CE.

Sharad MASTER[1]*, School of Geosciences, University of the Witwatersrand
(sharadmaster@yahoo.co.uk)

Abstract

Faxian or Fa-Hien Kung (c. 337-422 CE) was a Buddhist monk from Shaanxi Province of central China. While in Chang'an (near modern Xi'an), Faxian bemoaned the degraded state of the copy of the Buddhist scriptures in their possession, and resolved to make a journey to India to obtain new copies of these and other texts. He departed Chang'an in 399 CE, accompanied by several fellow monks. His wanderings on foot would take him across deserts, mountains, great rivers, and many towns through 30 kingdoms (in the present day countries of China, Afghanistan, Pakistan, India, Nepal, Sri Lanka and Indonesia) over a period of sixteen years. He ultimately returned to China in about 415 CE, and brought back many Buddhist manuscripts to Nanjing, where he spent several years translating them from Sanskrit into Han Chinese. He died in Jingzhou in Hubei, aged 88 years.

Faxian recorded a detailed account of his journey, giving incidental information about the distances travelled, the length of his stays, and the landscapes and natural topographic features he encountered, such as deserts, rivers, mountains, caves, rocks, minerals, as well as the climate, vegetation, peoples and animals. His main interest was to record the people, their temples, their lives and their habits in the Buddhist countries he had visited, and to collect scriptures. His journey took him to Lanzhou, Zhangye, Dunhuang, then into the Takla Makan Desert along the northern foothills of the Kunlun Mountains, Shan-shan south of Lop Nor, then NW to Woo-e (Karashahr), then SW across the desert, to Khotan, where he spent three months. He then went into the mountain kingdom of Tsze-hoh (Karghalik), then crossing the Tsung-ling (Onion) mountains (Bolor Tagh range) to Taxkurgan in the Pamir Mountains, then to the city of Kashgar, in the crook of the Tien Shan and Pamir ranges. Thence they crossed the Snowy Mountains (Karakorams) and emerged at a steep gorge of the Indus, which they crossed on a rope bridge, to emerge into Udyana and Gandhara (northern India), and on to Takshasila (Taxila). They proceeded across the Indus, to Purushpur (Peshawar), and further west into the Hindu Kush. From here they crossed the Safed Khirs, re-crossed the Indus across a flat plain, and entered northern India in the Indogangetic Plain. Many years were spent travelling back and forth along the Ganga basin, visiting the Buddha's birthplace at Lumbini, Varanasi, Pataliputra (Patna) and the nearby gneissic Vulture Peak (Gridhra-kuta Hill), and layered rocks resembling the Vindhyan sandstones. From Tamalipti on a western distributary channel of the Ganga-Brahmaputra delta, Faxian boarded a boat for Singhala (Sri Lanka), where he visited caves and Anuradhapura (and mentioned Buddha's footprint on Adam's Peak), After two years he sailed east to a large island

abounding with pirates (Great Nicobar), and then travelled through phosphorescent waves across unfathomable depths (over the deep Sumatra-Java Trench) to Java. From here he headed back to China, arriving on the Shandong Peninsula, before making his way to Nanjing.

The first geophysical studies, and descriptions of mineral deposits, in Thailand: The French Jesuits under Guy Tachard, and Simon de la Lubère, at the Siamese Court in 1687 and 1689.

Sharad MASTER[1]*, School of Geosciences, University of the Witwatersrand
(sharadmaster@yahoo.co.uk)

Abstract

In 1685 and 1689 the Jesuit savant Père Guy Tachard (1651-1712) led two expeditions of astronomers and mathematicians to the court of the Kingdom of Siam (Thailand), on behalf of the French King Louis XIV. On the first voyage, which arrived in Siam on 23 September 1685, at the invitation of King Narai, Tachard was accompanied by five other astronomers. They came with a large consignment of scientific instruments (including telescopes, compasses, magnets, equinoctial quadrants, thermometers, barometers, microscopes, burning mirrors and repeating pendulums), as well as books. When Tachard was sent back to France to recruit another, larger group of savants (who came on his second expedition), his remaining men continued with their astronomical studies in Siam. Two of them (the Fathers Visdelon and Bouvet) were sent to visit magnetite mines near Bansoun in the Chainat district (about 100 km north of Ayutthaya on the Chao Phraya River) in January 1687. The purpose of their visit to the magnetite mines was to determine whether the variation of the compass needle is caused by the unequal attraction of magnetic parts of the terrestrial globe. In the first geophysical study in Siam, they took measurements of magnetic declination and found huge variations in the magnetic field as given by the needle as they approached the magnetite mines. They concluded that the local concentrations of magnetite were responsible for the magnetic anomalies, and cautioned against the use of magnetic compasses when constructing maps of the region. On Tachard's Second Expedition in 1689, he was accompanied by Special Envoy Simon de la Lubère (1642-1729), who gave the following description of Siam's mineral riches: "…the greatest riches of Siam lies in the Bowels of the Earth, there being no country in greater reputation for mines than this. The great quantity of Gold which appears in their temples,… show that they have had large mines, from whence it was extracted, though the King that now reigns [Mahaburut] hath not been able to find any, though he employed several Europeans to search them out. They, after much pains, found some mean Copper-Mines, mixed with small quantities of gold and silver". La Lubère further stated that they have plentiful profitable mines of lead, and tin, which they mix with Cadmia to render it harder and whiter (but more brittle), to produce a White Tin called Tontinaque. He noted the Lodestone mines near Louvo, the iron mines near Campeng-pet, as well as occurrences of curious Agates and Sapphires, and the recent discovery of diamonds. A French physician, M. Vincent Francois, was given 1000 ecus by the King of Siam, to inspect the work on his mines, and he shortly discovered many mines, including of iron, crystal, antimony, emeralds, white marble, and one of gold, which, so far as he could judge without assays, was "very rich" but which he would not show to the Natives (according to La Lubère).

Crossing the Urals: A Glimpse into Asia in 1841

John DIEMER[1]*, UNC Charlotte (jadiemer@charlotte.edu)

Abstract

In 1840 and 1841, Roderick Murchison and his collaborators, Edouard de Verneuil and Alexander von Keyserling, engaged in two extensive field campaigns to explore the geology of Russia in Europe and the Ural Mountains. The results of their research were published in The Geology of Russia (1845), a two volume book accompanied by numerous plates containing geological sections and maps as well as fossil illustrations. Their campaigns were undertaken at a time of important developments of the geologic time scale and a growing awareness of the practical utility of applying 'system' terminology to lithostratigraphy. During the 1841 campaign, Murchison and his team crisscrossed the Urals as many as seven times. They had been charged by the Czar and his ministers to assess the state of mineral production in the Urals and their routes were governed in part by the locations of mining establishments. Plates 2 through 7 of The Geology of Russia (1845) provide a record of the routes they took, and the geology they observed along those routes is explained in the text of the book. Those records are supplemented by Murchison's field notebooks, his journal, and detailed letters written to his wife, Charlotte. The discoveries they made, the people they met, and the new cultures they experienced are reported on here. Murchison's experiences inspired him to make plans to travel farther east to the Altai Mountains in subsequent years. Murchison's glimpse to the east of the Ural Mountains, while tantilizing, did not in the end lead to him making additional expeditions to Asia.

Drainage work at the Clausthal mine in the Harz region in the 17th century: Achievements of the Japanese Peter Hartzing1637-1680

Takeshi Ozawa[1]*, NAA Retailing Corporation (bzp17623@nifty.com)

Abstract

The Harz region in the eastern part of north-central Germany covers parts of the states of Lower Saxony, Saxony-Anhalt and Thuringia and is located approximately 100 km south-east of Hannover, the capital of Lower Saxony. The Harz region was originally developed as a mining area with many underground resources including lead, silver, copper, zinc and iron ore. Mining took place as early as the 13th century, stagnated in the 14th century and was revived in the first half of the 16th century. At the Clausthal Mine in the Duchy of Hanover, miners faced the problem of dealing with waste water - finding a way to pump the groundwater that was constantly seeping into the mine to the surface. However, as the mine became deeper, human and animal labour could no longer cope with the problem. Developing a countermeasure was a major challenge. The solution was to use a water wheel to pump out the seeping water. A mining engineer, Peter Hartzing (1637-1680), was sent to Clausthal to find a way of making the water wheel run stably. He was born in Japan and moved to Germany as a child. His idea was to create a recirculating system by returning the river water used to power the water wheel to a reservoir. This ensured a stable supply of water to power the water wheel. This idea of using recirculating water to ensure a stable source of water was also proposed by Gottfried Wilhelm Leibniz (1646-1716), who was later involved in the project. However, it was Hartzing who first proposed the idea. This study presents the drainage project at Clausthal Colliery, focusing on the water wheel plan document in the Clausthal Colliery archives that Hartzing submitted to the local mining authority.

Charles Gould: Travels in Asia

Carol Anne Bacon[1]*, INHIGEO (gclota@trump.net.au)

Abstract

Charles Gould (1834–1893) BA FGS was the first government-appointed geological surveyor of Tasmania. He was a son of the famous ornithologist, John Gould and his wife, Elizabeth (Coxen) and was educated at Kings College London and the Royal School of Mines. He worked for a time for the British Geological Survey before taking up a contract with the Tasmanian Government in 1859. During the next ten years he produced numerous reports on and carefully drawn maps of the geology of Tasmania. His employment ceased in 1869 when the government was unable to continue financing his position.

In the years after he left Tasmania, Gould travelled extensively through Asia and South America, taking work if offered, but for the most part living on an allowance from his father while indulging his curiosity about the origins of mythological creatures. Gould spent the years from 1879 to 1889 largely in China, Hong Kong and Japan, interspersed with trips to Singapore, Myanmar, Korea and Thailand.

In China he visited Peking (Beijing), Canton (Guangzhou), Shanghai and numerous smaller towns; at one time travelling on the Hai (Peiho) River when it was choked by ice, with workmen cutting a passage for the steamer. In Japan he had lengthy stays at many places including Nagasaki and Tokyo, visited Hakodate and Yokohama, went shooting at Kobe, salmon fishing on Hokkaido and travelled the Nakasendo between Tokyo and Kyoto in a rickshaw. Gould immersed himself in cultural traditions, visiting hot springs and a ceremony at a Shinto shrine.

Gould wondered if mythological creatures described in legends were based on animals that had once existed, with the descriptions of them distorted through time. His thoughts on the subject were published in a book, Mythical Monsters, in 1886. To make his arguments, Gould drew upon observations made during his travels, his extensive knowledge of ancient texts and depictions of such creatures in woodcarvings and other art.

Dragons, which Gould noted featured in the legends of many societies, were of particular interest. He noted the similarity between ancient flying reptiles such as the Pterodactyl and dragons, and observed that modern flying lizards (Draco sp.) need only the element of size to render them also sufficiently to be dreaded. He surmised that the dragon in mythology comes from a now extinct terrestrial lizard, which had the ability to glide. Gould devotes chapters in his book to the Chinese dragon and the Japanese dragon, quoting exhaustive references in historic writings to both. He was also interested in the Chinese phoenix, surmising it might be a memory of an extinct bird similar to Semioptera wallacii (standardwing bird-of-paradise) and he thought that depictions in Japanese art of a giant octopus strangling a human could be derived from a type of giant cuttlefish with long tentacles.

Gould spent the last few years of his life in South America. He died in Montevideo, Uruguay, in 1893.

Geological travels and mapping in the Himalayan region between the 19th and the 20th century

Ezio VACCARI[1]*, INHIGEO - IUGS Commission on the History of Geological Sciences / University of Insubria, Italy (ezio.vaccari@uninsubria.it)

Abstract

The history of the geological travels and fieldwork in the Himalayan region, and in particular around Mt. Everest, still needs to be properly investigated. During the years 1848-49 some early geological fieldwork was carried out in India by Richard Strachey (Bengal Engineers) and his brother John Strachey (Bengal Civil Service), which led to the publication of the first printed geological map of a part of western Himalayas (1851). More extended fieldwork was undertaken during the early years of the 20th century by geologist Henry Hayden of the Geological Survey of India, with the help of military engineer Sidney Burrard, Surveyor General of India. Their studies led to another map, which shows a surveyed area in the north-western region of Himalaya, including Kashmir and a portion of southern Tibet, the latter investigated in 1904. Other attempts to explore and describe the mountains of the Himalaya include the first climbs in Karakorum by mountaineers Martin Conway and Charles Granville Bruce in 1892, as well as some photographical reports, like those by the Italian Vittorio Sella during a journey with Douglas Freshfield in 1899, or by Claude White in 1904. Later, the report given in 1919 by British explorer and photographer John Noel, about his journey in Tibet in 1913, where he traveled only about 30 miles east from Everest, contributed to reinforce the idea to climb and to explore this impressive mountain and its region. On January 10, 1921, during a meeting held in London, the Royal Geographical Society and the British Alpine Club established a joint Everest Committee, chaired by Francis Younghusband, in order to organize the first reconnaissance expedition to Mount Everest. The expedition, took place from April to October 1921 and included, among its nine members, also the Scottish geologist Alexander Macmillan Heron, who had the task to study the geology of the region, with particular attention to the age and the structure of the Himalayan range. Heron undertook a series of excursions and fieldwork on high grounds in Nepal, in some valleys around Mt. Everest and in Sikkim. This work, undertaken by Heron with the assistance of cartographers Henry Morshead and Oliver Wheeler, produced a preliminary geological map over about 8000 square miles, which was published in 1922 as the first geological map of the Everest region. The geological research on this area continued with some difficulties in the following years, as in the case of the geological map prepared by Noel Odell after the 1924 expedition to Mt. Everest. Heron's geological map was revised in 1933, within the second edition of the 1908 memoir by Hayden and Burrard, A sketch of the geography and geology of the Himalaya mountains and Tibet. The aim of this paper is to reconstruct the extent of some relevant geological travels, undertaken in the Himalayan region between the mid-19th century and the early decades of the 20th century.

The Early History of Graptolites Discovery in Asia

Muhammad Aqqid Saparin[1]*, Universiti Teknologi PETRONAS (otakuclubrkidz@hotmail.com)

Abstract

The discovery of graptolites in Asia took almost a century after the earliest recognition of graptolites as true fossils in Europe. The first record of these organisms in Asia is credited to F. von Richthofen during his exploratory journey in the Kiangsu Province of China between 1868 and 1871, however, the results were not published until more than 40 years later by Frech in 1911. As such, the earliest reference to graptolite in geological literature of Asia was made by Lydekker in 1883 who attributed the obscure marking found on the rock of Panjal System, Kashmir, to possible graptolite remains. In the latter years of the 19th century, reconnaissance surveys in Upper Myanmar (Burma) recognised widespread graptolite-bearing strata. For over the next 4 decades, more graptolite faunas were collected in the Shan States of Myanmar and the neighbouring Yunnan Province of China. The appointment of A.W. Grabau in 1920 to the post of Chief Palaeontologist in the National Geological Survey of China established the basis for systematic palaeontology research in the country. Numerous graptolite discoveries were made in the following decades and work had been proceeded vigorously even during and after the political changes in 1948-50. Many papers dealing with graptolites appeared in the Journal of the Geological Society of China before 1948 and have since contributed to Acta palaeontologica Sinica after 1952. The early graptolite research in China culminated in the publication of “Chinese Graptolites” by Mu and Hsü in 1962. Meanwhile in Southwest Asia, Blanckenhorn (1914) described graptolites from Arabia, while oil companies in the region managed to report the occurrence of graptolite-bearing strata, including in Turkey, Syria and Iran. In central and northern Asia, geological exploration after the end of the Second World War has also revealed extensive tracts of graptolite-bearing strata in the region. These findings were later published by the Geological Institute of the Soviet Academy of Sciences and other Russian organisations. In other parts of Southeast Asia, graptolite work had been done, such as in Vietnam by Mansuy (1915,1918) and much later by Nguyen Van Phuc from 1978 to 1995. In West Malaysia, graptolites were first discovered from the Langkawi islands in 1955 by C. R. Jones. Subsequently, systematic mapping by other geologists in Peninsular Malaysia in the late 1950s and early 1960s led to the discovery of further graptolite localities and the results were compiled in a two-volume PhD thesis, a summary of which was published in a publication of the Institute of Geological Sciences in 1973. In Thailand, the presence of graptolite was first reported by Kobayashi (1964), and subsequent graptolite finding was made later in southern Thailand. Overall, the discoveries of graptolite fossils in Asia have significantly contribute to our understanding of the rich geological history of the region.

Prussian geographer J. J. Rein travelled to Japan in 1873-76 and introduced Japan to the world

Michiko dvan Yajima[1]*, Tokyo Metropolitan University (pxi02070@nifty.com)
Naotoshi Yamada[2], ex-AIST

Abstract

Prussian geographer Johannes Justus Rein (1853 - 1918) made various scientific journeys in Europe, Asia, and America. Under Prussian government orders Rein came to Japan in 1873. He spent the first five months in Japan, residing in the German Legation in Tokio [Tokyo] and studying lacquer. After submitting a detailed report on the subject, he traveled throughout Japan for three years. He traveled mainland Japan, Shikoku and Kyushu. He extensively researched not only the industry and commerce of Japan, which was the main task with which he was entrusted by the government, but also the geography, geology, botany, zoology, and meteorology of Japan, as well as other scientific fields, based upon his own interests. He collected specimens of plants, molluscs and other organisms during his travels. He was also interested in volcanoes, mountains, mountain ranges, geology, geomorphology and so on. He walked, climbed mountains such as Mt Fuji, Ontake, Hakusan, Asama, Nikko Nantaisann and so on, measured the height of mountains using Aneroid altimeter, made maps and named mountain ranges. In a clockwise round trip through mountainous regions, where he observed the mountains, rivers, plants, animals, climates, and lives of inhabitants along the roads. He presents a topographic division of the region, proposing that “the Japanese Snow-ridge Range”-roughly corresponding to the present-day Hida Mountain Range- is the most important mountain range, and mentionsed its climatic significance. He found plant fossils near Mt. Hakusan which is the first discovery of Jurassic fossils in Japan.
After he came back to Prussia, he wrote “Japan nach Reisen und Studien im Auftrage der Königlich Preussischen Regierung. 2 Bände” based on travels and researches undertaken at the cost of the Prussian government, as was also his book “The Industries of Japan together with an Account of its Agriculture, Forestry, Arts, and Commerce”.

Professional Travelers -– Considering Expanding Process of Professionalism in the Nineteenth-Century United States --

Tomomi NAKAGAWA[1]*, Meiji University (peppermint-wind@ever.ocn.ne.jp)

Abstract

In our time, there exists little doubt that professionalism is the premise of our intellect. However, as a system of intellect, it has been only two hundred years from its launching. Since then, professionalism came to grow, and is still in the process of expanding, probably almost unconsciously. Throughout the process, the United States has long played a key role. It is no exaggeration to say that the global expansion a of professionalism could be regarded as a cultural strategy of the United States.

In this presentation, I would like to consider a few American geological advisors visiting Japan: mainly Horace Capron and William Clark. These advisors of the early Meiji Era (around 1880) had an important mission to convey the early phase of professionalism now on the process of its establishment.

After introducing their visions, this presentation will advance to the earliest phase of professionalism in the United States in the middle of the nineteenth century. At that time, professionalism emerged a new and alternative way to replace the traditional college education based on liberal arts. It was the educational backgrounds of the generation of “Founding Fathers.” On the other hand, those in industrial or commercial career, without academic backgrounds, were virtually excluded from the center of politics at that time.

However, according to the growth of industries and commerce, the voices and influences engaging in these fields came to be difficult to ignore. The inauguration of Andrew Jackson as President (1829) was the pivotal moment of transformation in politics in the United States. After that, educational backgrounds came to be more negligent, and “self-made men” were easier to access into the center of the federal government. Borrowing partially from the term of Richard Hofstadter, the time of Jacksonian Democracy could be understood as that of “Anti-Intellect;” those without college education could gain their footsteps firmly in the American society.

The emerging self-made industrialists yet wanted to have academic career. It is well-known that they have contributed to the establishment of academic institutions such as schools, societies, and research institutes, and supported them for a long time in the United States. They were absorbed in the advancement of practical sciences: in particular, agriculture and engineering. Therefore, the origin of professionalism in the United States could be traced back unexpectedly to democracy and anti-intellect. Since then, professional schools came to be settled one after another; its culminating moment would be the establishment of Johns Hopkins University in 1876, which had been envisioned as a graduate school in the first place. In the twentieth century, especially after the World War I, the United States came to expand its control with elites acquired professional education.

In a sense, the American advisors coming to Meiji-era Japan could be understood as the earliest

“travelers” to spread the emerging professionalism. In the end, I would like to propose that reconsidering the total process of professionalization become significant for those engaging in academic fields.

Ennin’s Pilgrimage Travel in China: Japanese Buddhist Geo-consciousness in the Ninth Century

Toshihiro YAMADA[1]*, Taisho University (tosmak-yamada@muf.biglobe.ne.jp)

Abstract

In 840, the Japanese Buddhist priest from Tendai sect Ennin (794–864, also Jikaku Daishi) traveled on foot to the Mt. Wutai, which has five summits of around 3,000m high, in northern China. Fortunately, we have a detailed record of the itinerary in his diary. He started at Chishan in Shandong Peninsula on February 25th and arrived at the foot of mountain on April 23rd. He made pilgrimage to many temples of Manjusri Bodhisattva and stayed there to study Tendai doctrine by transcription of many sutras. He left the Mt. Wutai on July 1st to Chang-an, the capital of the dynasty. He stayed there for six years and then became forced to go back Japan in 847. The orientalist scholar and American Ambassador to Japan Edwin Reischauer (1910-1990) once studied the Ennin’s diary and published his work in 1955, in which he estimated the contribution of Ennin to Sinology contrasting with the work of the Venetian merchant Marco Polo (c.1254–1324). Additionally, in this presentation, we would like to recognize geo-consciousness of this Japanese intelligence’s diary, especially in not only geographical domain (triad cosmology of India, China, and Japan) but also in meteorological and geological ones. Because this is the very time of Japan which the historian of science George Sarton in his Introduction to the History of Science (1927) called one of five ninth-century renaissances in the world: Carolingian, Islam, Byzantine, southern India, and Japan.

BRONISŁAW GRĄBCZEWSKI AND LEON BARSZCZEWSKI, THEIR TRAVELS IN CENTRAL ASIA IN XIX CENTURY AND CONTRIBUTIONS IN GEOLOGY

Piotr KRZYWIEC[1]*, Institute of Geological Sciences, Polish Academy of Sciences
(piotr.krzywiec@twarda.pan.pl)

Abstract

At the end of 18th century Poland lost its independence and has been partitioned between Prussia, Austria and Russia until 1918 when it reappeared on the political map of Europe as independent country. During all those years Polish travelers, geographers and geologists contributed to the recognition of occupying countries and neighboring areas. Well known are geological and paleontological discoveries made in Siberia by Aleksander Czekanowski (1833-1876), Jan Czerski (1845-1892)or Benedykt Dybowski (1833-1930). Little less known are two other Polish discoverers active at the turn of 19th and 20th centuries in Central Asia: Leon Barszczewski (1849-1910) and Bronisław Grąbczewski (1855–1926). They both served in army of the Russian Empire, reached high ranks in imperial hierarchy, and spend considerably parts of their lives in distant part of the empire, dividing their time between official duties and scientific work.

Leon Barszczewski was born in Warsaw but spent most of his youth in what is now Ukraine. He was educated in military schools in in Kyiv and Odessa. Because of his support for January Uprising in Poland he was relegated from military academy in Odessa and transferred to regular army stationed in Cherson district. In 1876 he moved to Turkmenistan and for many years stationed in Samarkand. He was involved in numerous topographic and geological studies of territories between Russian Empire, China and Afghanistan. He was pioneering archeologists for that area, gathered significant collection of archeological artefacts that laid the foundation for the very first archeological museum in Samarkand. He was also vivid photographer. His interests in natural sciences included geology (including coal deposits – he even opened his own coal mine) and glaciology. Barszczewski's photographs of, between others, glaciers of Pamir were highly acclaimed and reworded at several international exhibitions. At the Paris exposition of 1895, he won a gold medal for his photographs of minerals. He was rewarded by several important models for his achievements in the field of natural sciences, in particular in glaciology. One of glaciers in the Hisar Range has been named after Barszczewski.

Bronisław Grąbczewski is well known for his participation in The Great Game between Russian and British empires. He was born near Kowno (now Lithuania), and moved to Warsaw after his father was sent to Siberia after January Uprising. He received training from St. Petersburg Mining Institute and St. Petersburg University, he spoke Polish, Russian, Uzbek, Tajik, and Persian languages. After joining the army he was stationed in Turkestan and then organized several field expeditions in Pamir, Tian Shan and Kunlun during which he made numerous observations on geology of surrounding mountains and discoveries of mineral deposits, onyx, coal etc. For these expeditions, he was awarded a silver and gold medal by the Russian Geographical Society. During

Bolshevik revolution he was imprisoned in Siberia and escaped via Japan to Poland, where he settled and worked in the State Institute of Meteorology. Grąbczewski published three volume book with detailed accounts and numerous photographs documenting his travels in Central Asia.

Multifaceted Nature of Japanese Geological Explorations amid Japanese Imperial Expansion to China in the early 20th century

Shigeo KATO[1]*, Waseda University (kato@waseda.jp)

Abstract

This presentation will offer a multifaceted examination of the scientific and political aspects of Japanese geologists' travels to China and the geological surveys conducted in the early 20th century and delve into the discourse surrounding mineral exploration in China conducted by Japanese geologists within the broader context of Japan's imperial ambitions. While Western geologists like Ferdinand von Richthofen had previously ventured into China, several Japanese geologists also embarked on similar expeditions, producing various academic and practical reports. While existing studies have focused on Japanese geological surveys of coal mines in Manchuria, exploration efforts regarding other mineral resources such as iron, copper, tin, lead, zinc, antimony, manganese, and tungsten have yet to be noticed. This presentation seeks to rectify this gap by examining the intertwined strategic, economic, and academic objectives that underpin Japanese geologists' surveys in China.

Special attention is given to the insights of OGAWA Takuji (1870-1941), whose multidimensional background—rooted in Confucian scholarship and Western geological education at the Imperial University—informed his geological surveys in China. Ogawa's engagement with Chinese classics, exemplified by his critical readings of the _Book of Mountains and Seas_, culminated in the publication of _Studies on Chinese Historical Geography_ (1928). Additionally, Ogawa contributed to the advancement of geological theory with his work _New Interpretation of Geological Phenomena_ (1929), wherein he proposed novel ideas on crustal tectonics and the geological structure of the Japanese archipelago. Notably, Ogawa's academic pursuits were paralleled by his political commentary, as seen in his writings critiquing the Chinese government of his time. This presentation aims to unravel the intricate connections between Ogawa's diverse discourses within his era's historical and geopolitical context.

In addition to Ogawa Takuji's surveys, this presentation will also incorporate a historical examination of the geological surveys in China conducted by the Tokyo Geographical Society from 1911 to 1916. The Tokyo Geographical Society dispatched ISHII Yamajiro to the Yangtze River coast in 1911, followed by NODA Seijiro and IIZUKA Noboru to Zhejiang, Hunan, and Hubei provinces in 1912, and SUGIMOTO Isuzu to Hunan province in the same year. In 1913, KOBAYASHI Giichiro and HORIUCHI Yoneo were sent to Sichuan and Shaanxi provinces, while YAMANE Shinji and KAWAI Kokichi were dispatched to Zhejiang, Jiangxi, and Fujian provinces, and FUKUCHI Nobuyo to Hunan province. This presentation seeks to elucidate why the Tokyo Geographical Society undertook such large-scale surveys in China, how the surveys were conducted, and what the results entailed. Furthermore, it aims to examine how these survey

findings subsequently influenced the field of geology and impacted Japan's continental policies.

This presentation shed light on the multifaceted nature of Japanese geological exploration in China during a period marked by imperial expansion.

Western scholars' geoscientific travels in China during the late 19th and early 20th centuries

Chengsheng SUN[1]*, Institute for the History of Natural Sciences, Chinese Academy of Sciences (scs@ihns.ac.cn)

Abstract

With the opening of China's gates in the late 19th century, Western scholars, missionaries, businessmen, and explorers, regarded China as a huge "open-air museum" and came to China for various scientific travels and explorations. For example, Raphael Pumpelly (1837-1923), Ferdinand von Richthofen (1833-1905), Béla Széchenyi (1837-1918) and Lajos Lóczy (1849-1920), Vladimir Obruchev (1863-1956), Bailey Willis (1857-1949), Roy Chapman Andrews (1884-1960) and Sven Hedin (1865-1952) respectively organized many large-scale geological surveys in China. They not only wrote important research works, but also left detailed records of their travels. These explorations enriched western scholars' understanding of China's geology, and inspired geological research of Chinese counterparts as well. After the 20th century, explorations of Westerners in China aroused Chinese scholars' nationalistic backlash, and even encounter their sovereignty demands. In particular, the Sino-Swedish Scientific Expedition to the North-Western Provinces of China organized by Sven Hedin became one of the landmark events. With the efforts of academic community, the government gradually imposed clear legal restrictions on foreigners' explorations in China, and Chinese scholars also spontaneously began to carry out independent geological investigations. In this paper, by reading the travel journals of these scholars and their scientific writings, I will analyze how they organized their geological surveys, their cooperation and competition with Chinese counterparts, as well their knowledge and understanding of Chinese culture at the time.

Legacy etched in Stone: Field Inscriptions of BGS Geologist E. Vredenburg Enduring for 125 Years in the Chagai Desert, Pakistan

Mukhtiar GHANI[1]*, Geological Survey of Pakistan (mukhtiar.ghani@gmail.com)
Muhammad Qasim Jan[2], National Center of Excellence in Geology, University of Peshawar
Rahat Ullah[3], Geological Survey of Pakistan

Abstract

Many geoscientists made significant contributions to the Geology of Indo-Pakistan during the British era. Their scientific endeavors earned them recognition within the scientific community. Some of these journeys have left indelible marks on the landscape, etched into rocks and outcrops. Among these pioneers is E. W. Vredenburg, who served with the Geological Survey of India and conducted groundbreaking reconnaissance work in the remote and challenging Indian frontier region of Balochistan.

Balochistan, the largest province of Pakistan, is predominantly characterized by rugged mountainous terrain and desert landscapes, long notorious for its compromised security situation spanning for centuries. Vredenburg undertook extensive surveys and mapping activities in this region during the late 19th and early 20th centuries. While his work encompassed a broad spectrum of studies across Balochistan, we have discovered some of his hand-carved inscriptions on the outcrops in the far western region of the Chagai district in Western Pakistan.

Based on the timeline, this inscription, carved during his expeditions in the Balochistan desert and eastern Persian region, is approximately 125 years old. This inscription represents pioneering geological work in the Chagai region. Vredenburg meticulously described the area southeast of Saindak, and east of MushkiChah and Juzzak, delineating various lithological units of igneous and sedimentary rocks. He assigned ages to these units based on their index fossil groups, ranging from Cretaceous to Pleistocene.

The units described by Vredenburg were later formalized into different formations, including the Cretaceous Sanjrani and Humai formations, Paleocene Juzzak formation, and Eocene Saindak and Amalaf formations, among others. Notably, Vredenburg's work indicated the presence of sulphide valleys in the Chagai region, which later developed into significant porphyry Copper-Gold deposits such as Saindak and ReKoDik. Sulphur mining in the region commenced during World War I and II.

The hand-written inscription is preserved on the Humai limestone near the Amir Chah area (29°12'54.30"N / 62°27'53.40"E). Dating back to 1899, approximately 124 years ago, it serves as a testament to the enduring legacy of E.W. Vredenburg, who persevered through harsh rainy seasons and fast-blowing winds, amidst shifting sand dunes, to contribute to our understanding of

this region's geological history.

The "Treatises on How to Recognise Gems" of Al-Biruni (11th century) and the development of mineralogy in The Muslim world.

khallaf EL GHALBI[1]*, Moulay Ismail University of Meknes (k.elghalbi@umi.ac.ma)

Abstract

Abu al-Rayhan al-Biruni was a distinguished encyclopedic scholar, who excelled in mathematics, medicine and astronomy. He is also considered a historian, philosopher, linguist, and anthropologist.

Al-Biruni's writings amount to about 180 books, of which he devoted the book (Al-Jamahir fi Ma'rifat al-Jawahir) study of a group of minerals and precious stones that were known in his time, a careful scientific study, the aim of which is to combat fraud and counterfeiting, by identifying minerals accurately, allowing to distinguish valuable gems, from its less valuable similar ones.

The German orientalist Fritz Czenko may be the first to verify and publish this book. He collected his manuscripts and published it in Hyderabad, India, in 1936.

In These (Treatises on how to recognise gems), Al-Biruni has proven that he was a great mineralogist, centuries before this knowledge reached those to whom the paternity of this scientific branch is attributed. He contributed significantly to the establishment and development of this science on several levels:

- At the level of mineral definition;
- At the level of knowledge of existing minerals, their numbers, names, languages, locations, and prices;
- At the level of mineral classification;
- At the level of describing minerals and studying them based on the similarities of their properties, indeed he studied characteristics and physical properties of minerals, in accordance with the currently study of minerals;
- On a theoretical level, the discours of Al-Biruni about the formation of some minerals, can be considered an unprecedented theoretical contribution.

The Russian orientalist Karachovsky says: We have nothing but bowing in submission and respect in front of the brilliant scientific results that Al-Biruni reached and the rich scientific heritage that he produced in the circumstances of the time in which he lived.

It must be emphasized that the study and publication of manuscripts and scientific heritage left by Al-Biruni (in metallogeny, mineralogy and other sciences), still need further very in-deep follow-up, to complete knowledge regarding the scientific contribution of Abu Rayhan Al-Biruni

Image Builders between Mineralogical Knowledge, Possession and Perception in the 18th Century: Catalogues, Collections and Credibility

Marianne Dr. Dr. KLEMUN[1]*, Department for History, University of Vienna (marianne.klemun@univie.ac.at)

Abstract

Image Builders between Mineralogical Knowledge, Possession and Perception in the 18th Century: Catalogues, Collections and Credibility
Marianne Klemun
Abstract
In the 18th century, more than in any other period, socially heterogenous groups of actors operated their own mineral collections. This is reflected, among other things, in the steady increase in printed catalogues during this period. Previous historical research on collections has mainly focused on their representative, institutional, politico-state, economic and epistemological functions. In contrast, this paper takes a novel and innovative view of collections as sites of communication, interpreting catalogues as 'knowledge-making itself as a form of communicative action' (Secord). My point of departure is the large number of printed catalogues, which between 1600 and 1800 amounted to more than 350 compendia. The authors of these catalogues were usually not identical with the owners or custodians of the collections. I argue that their compilation not only contributed to an extraordinary gain in credibility and status for all concerned but also enhanced the reputation of the collection documented. Catalogues are to be located in the in-between, between the actors, that is between owners and describers and their various practices as well as the principles of display of collections and the management of the perception of collections by third parties. These interactions are themselves a site of knowledge construction as they were subject to processes of negotiation and reconfiguration. As image-builders, catalogues not only promoted careers, or at least maintained status, but also stabilized credibility, which is my main argument. Catalogues also served as powerful media in the encounter with collections in cross-cultural and supranational contexts. Indeed, even at a distance from the collections, catalogues had an impact as they circulated, maintaining their validity across time and space, even when the collections they described no longer existed as a separate corpus.

[Keynote] Exposing Earth Sciences History: challenges and perspectives (invited Keynote)

Maddalena NAPOLITANI[1]*, Museo Galileo (maddalena.napolitani@gmail.com)

Abstract

(Invited Keynote)
Number of recent researches in the field of history of science is nowadays particularly interested to the visual and material culture of science, and the history of Earth sciences is no exception.
Within these research perspectives, temporary exhibitions appear as a mean of valorization of both scientific research and collections related to Earth sciences, often constituted by rich and varied materials (minerals and rocks, fossils, archive documents, iconographical sources including geological maps, illustrated treatises, etc.).
Through the analysis of two recent case-study, this communication studies the potential of temporary exhibitions for disseminating scientific research, and how they can emphasize the multidisciplinary characteristics of Earth sciences history, that have historically built a dialogue with other disciplines (the scientific reference disciplines as geology, paleontology, but also philosophy, literature, archeology, and more recently art history and architecture).
Temporary exhibitions are often in close dialogue with permanent collections, and another question addressed by our communication is how such initiatives tell the history – or some aspects of the history – of Erath sciences, and how this history relates to contemporary issues, such as the environmental and climate crisis, or the administration of Earth's resources.
Finally, the practical aspects related to exhibition-making in this field will also be considered.
Our communication, aiming to foster a collective reflection, especially concern two case-study: the exhibition Visions. The Earth Sciences in the popular Literature of the 19th Century (Varese, Italy, November-December 2023) and Collectible Minerals (Paris, September 2023-March 2024).

The Geological Commission of the Shevchenko Scientific Society: Institutions, Personalities, Publications

Ihor BUBNIAK (BUBNYAK)[1]*, Lviv Polytechnic National University (ihor.m.bubniak@lpnu.ua)

Abstract

The Shevchenko Scientific Society is one of the oldest and most prestigious scientific institutions in Ukraine. Founded in 1873 in Lviv, it was named after the renowned Ukrainian poet, artist, and thinker, Taras Shevchenko. This organization has a long history of contributing to the development of Ukrainian science, education, and culture. It unites scientists and researchers from various specialties, including history, literature, linguistics, ethnography, natural sciences, and many others. The Society works on publishing scientific works, organizing conferences, lectures, and seminars, and also plays a key role in preserving and promoting Ukrainian cultural heritage.

Members of the Shevchenko Scientific Society include well-known Ukrainian and foreign scientists. Throughout its existence, the Shevchenko Scientific Society has undergone various changes and transformations due to political and social circumstances in the region. Despite this, it continues to be an important center of scientific and cultural life in Ukraine.

Geological research is part of the activities of the Shevchenko Scientific Society. The Society has a multifaceted structure and covers various fields of science, including natural sciences and geology. The Geological Commission of the Society actively conducts research in the field of geology, focusing on the history of geological discoveries, the contribution of Ukrainian scientists to the development of this field, as well as organizing and conducting lectures and seminars on geological topics.

One of the features of the Geological Commission's activity is conducting geological excursions. These excursions provide an opportunity not only to delve deeper into geological science but also to directly observe geological objects and processes in natural conditions. Excursions are organized both for members of the society and for the general public, aiming to popularize geological knowledge and increase awareness of Ukraine's natural heritage.

Members of the Geological Commission also work on additions to natural history museums and publish a collection of "Works" where they publish the results of their research. This allows for the preservation and dissemination of important information about geological research and discoveries and promotes scientific exchange and collaboration among researchers.

James Dwight Dana and his geological excursions in New South Wales, 1839-40

Wolf Mayer[1]*, Eneritus Faculty Australian National University, Canberra
(wolf.mayer@outlook.com.au)
Wolf Mayer[2], Emeritus Faculty, Australian National University, Canberra, Australia

Abstract

The mineralogist and geologist James Dwight Dana (1813-1895) was a member of the United States Exploring Expedition, commanded by Captain Charles Wilkes, which carried out hydrographic and scientific research along parts of the coasts and islands of the Pacific Ocean and in Antarctica. Dana, who had studied geology and mineralogy under Professor Benjamin Silliman at Yale University, was given the opportunity to spend some three months in New South Wales to carry out geological research while the expedition's ships sailed to Antarctica. At the time little was known of the colony's geology. Accounts of the early work in the Sydney region and in the Blue Mountains by French geologists and naturalists on short visits at the beginning of the century was not widely read outside France. Resident naturalists, some with considerable knowledge of geology but no academic qualifications in the subject, had described the lithologies and succession of rock sequences mainly in outcrops along the New South Wales coast. Universities and geological surveys had not yet been founded in Australia.

Dana's stay in the colony coincided with the arrival, some months earlier, of the Rev. Willian Branwhite Clarke (1798-1878), a former student of Professor Adam Sedgewick at Cambridge University, with whom he formed a close association, both in the field during his sojourn and later by correspondence. Over the following decades Clarke would make major contributions to Australian geology. Dana spent time in the Sydney area, visited the Illawarra district to its south in the company of Clarke, and carried out independent investigations in the Hunter Valley to its north. During his stay in the colony, he examined widely separated outcrops, in an area extending over 250 km, and recognized massive sandstone layers at the base, conformably overlain by a sequence of coal measures, with further thick beds of sandstone above, all now accepted as forming part of the Permo-Triassic Sydney Basin. The age of the coal measures was the subject of often bitter debate that lasted for almost forty years, with opinions variously placing the strata in the Carboniferous, Triassic, or Jurassic periods. Dana, in assigning the coal measures to the upper Carboniferous to lower Permian, was the first to place them, at least in part, into the latter period, their now accepted age. He drew detailed stratigraphic sections of outcrops of the sedimentary sequence, some with interstratified volcanic rocks, and was the first to draw a geological map of the Illawarra region.

Learning the Soviet Union and Earth Sciences of China: An investigation centered on Specialty Settings of Geography in Peking University In the 1950s

Chao LIU[1]*, Inner Mongolia Normal University (lc.2018@tsinghua.org.cn)

Abstract

In the 1950s, China sparked a wave of learning from the Soviet Union, and China's earth sciences actively learned from the experience of the Soviet Union. The Department of Geology and Geography at Peking University was established during the wave of studying the Soviet Union. This article will focus on the initial specialty settings of Peking University's Department of Geology and Geography to explore the connection between the development of earth sciences in China and Learning the Soviet Union.

At the beginning of New China, geography theory foundation is weak, the geography education is the weakest link in the national higher education. The Department of Geology and Geography created by Peking University in 1952, had promoted the development of geography and geography education. In the early years of the department, the specialty settings of geography was modeled on the Soviet Union, combing the department faculty and the Soviet union expert opinion. The only professional physical geography in 1952 developed to three major physical geography, economic geography and geomorphology in 1956, established the prototype of Peking University geography specialty settings. This article tries to analyze the influence of "learning the Soviet union" on the specialty settings of geography in Peking University and on the development of geography, according to oral interview records and historical data such as the documents of Peking University.

The heydays of geological research in Finland – Storylines from the museum collections

Jaana HALLA[1]*, Finnish Museum of Natural History, University of Helsinki
(jaana.halla@helsinki.fi)

Abstract

The history of geological research and collections in Finland includes great achievements as well as tragic moments. The building up of the 'Mineral Cabinet' started in the 18th century at the Royal Academy of Turku – Finland belonged to Sweden in those days – where professors of chemistry curated geological samples. The most famous was Johan Gadolin (1760-1852), who discovered the first rare earth element, yttrium. Element gadolinium and mineral gadolinite are named after him. The great fire of Turku in 1827 was a terrible catastrophe: the whole collection was destroyed. Next year, the building up of the collections started again at the Imperial Alexander University in Helsinki (Finland was part of the Russian Empire 1809-1917). The 19th and 20th centuries brought several renowned Finnish geologists. Axel Gadolin (1828-1892) proved mathematically the existence of 32 crystal classes, Wilhelm Ramsay (1865-1928) found the alkaline massifs of the Kola Peninsula, Jacob Johannes Sederholm (1863-1934) first introduced the word 'migmatite', and Pentti Eskola (1883-1964) first proposed the concept of 'metamorphic facies'. We at the Finnish Museum of Natural History aim to use preserved stories and samples from the heydays of Finnish geology to attract interest among the public and Society. Our aim today is to create a platform for geological collections, education, and research dissemination by developing exciting exhibitions, events, and courses with fascinating historical and modern narrative storylines as well as organize and digitize collections for hands-on and online use for the public, geologists, historians, artists, hobbyists, tourists, politicians, children, students, teachers, and media.

Geological and Hydrological Knowledge of the Aztecs

Sharon LOCKE[1]*, Southern Illinois University Edwardsville (slocke@siue.edu)
Kathleen Vongsathorn[2], Southern Illinois University Edwardsville
Robyn Roberts[3], Colorado State University
Hugo Gutierrez[4], University of Texas-El Paso

Abstract

Integrating humanities and science has been shown to increase student interest in STEM (science, technology, engineering, and math). We have developed three university level courses in geoscience related degree programs that integrate historical perspectives of science to increase student learning about the humanistic elements of science. Working with a historian of science, we developed a case study on the Aztecs that uses information from the Florentine Codex to teach students about the hydrological and geological knowledge of the Aztecs living at Tenochtitlan in the early 16th century in the area that is now Mexico City. The case study asks students to use the drawings and translations of the Codex to identify the knowledge that the Aztecs had about hydrological and biogeochemical cycles and how they used that knowledge to provide food for the densely population area. The information in the Codex demonstrates the Aztecs sophisticated understanding of the types of water bodies in the region. Their understanding is consistent with paleoenvironments constructed from sediment records in the region, while also incorporating beliefs and myths associated with their culture. Our instructional team found that adding a humanistic perspective of science helps students to consider scientific problems from multiple perspectives, which is a critical skill for geoscientists working in the 21st century.

Geological maps throughout the hundred years of the Czech Geological Survey (1919–2024)

Vladimir ZACEK[1]*, Czech Geological Survey (vladimir.zacek@geology.cz)
Petr Mixa[2], Czech Geological Survey

Abstract

Geological maps throughout the hundred years of the Czech Geological Survey (1919–2024)

Vladimír Žáček1 and Petr Mixa1

1Czech Geological Survey (CGS), 118 21 Prague, Klárov 3, Czech Republic

vladimir.zacek@geology.cz

The Geological Survey of the Czechoslovak Republic was founded in 1919, one year after the establishment of the independent Czechoslovakia. It followed the work of geologists of the Geological Survey of the Austrian Monarchy founded in 1849. The first geological map of the state (Czechoslovak) territory at a scale of 1: 400,000 was printed in 1924. A synoptic geological map of Czechoslovakia at a scale of 1:200,000, a mosaic of 33 sheets, was the result of the long-term work of geologists from the Czech and Slovak geological surveys. This set of maps was completed in 1959 and was presented at the International Geological Congress in Delhi, India in 1964. Czechoslovakia became the first country in the world to have a geological map covering the whole of its territory at this scale. In 2000, 221 sheets of geological maps at a scale of 1:50,000 were completed covering whole state territory. A program of geological mapping at a scale of 1:25,000 has been underway since 1970, and unified rules for the compilation of geological and applied maps and explanatory booklets have been followed since 2007. The Czech Geological Survey has also co-operated in mapping programs in many other countries around the world, e.g. Costa Rica, Cuba, Ethiopia, Mongolia, Nicaragua, Iran, Iraq, Peru, El Salvador, Syria, Vietnam, and Zambia. Recently, the Czech Geological Survey is responsible for the Geoscience Mapping (WP1) work package of the PanAfGeo Project in Africa (2017–2024). The maps and other geoscience information are available on the website www.geology.cz.

From Mines to Strata: The Spatial Sciences of the Earth in Britain in the Long Eighteenth Century

Joshua HILLMAN[1]*, University of Leeds (prjbh@leeds.ac.uk)

Abstract

Master narratives in the historiography of geology have focused on the reconstruction of geo-history since 1800, and, accordingly, they have tended to interpret the first three quarters of the eighteenth century as a latency period in the development of the earth sciences. By reorienting towards geological space instead of geological time, I shall provide a new account of the earth sciences in the long eighteenth century, focused on the development of spatial knowledge about the strata in Britain. Utilising new archival sources, I reconstruct four neglected sciences of the earth – coallery, the natural history of mines, the natural history of the Earth, and the natural history of strata – that have been overlooked in the existing master narrative. I argue that British naturalists developed these sciences in an attempt to appropriate the spatial knowledge of the strata that mineworkers possessed.

In the seventeenth century, coal surveyors already possessed expertise on coal-bearing strata (coallery), but this was little tapped by naturalists more interested in metal mines (the natural history of mines). Strata became more seriously studied around 1700, when John Woodward developed a new approach that showed that they could be traced over vast horizontal distances (the natural history of the Earth). Many naturalists traced strata in the eighteenth century, and those that visited coal mines recognised that strata had a regular vertical order. This finding was applied more broadly over the century as naturalists recorded both the horizontal continuity and vertical order of the strata in different locations (the natural history of strata).

I make two further claims. First, pace Martin Rudwick, William Smith's nineteenth-century achievements in the field of stratigraphy must be situated in the wider context of British coallery, not German geognosy. Second, the eighteenth century was not a latency period for the earth sciences: it was the period when the regular order of the strata was recognised, and this spatial contribution was a necessary precondition for the temporal contribution that followed.

Abstract

In 2023, the Geological Survey of Italy celebrated 150 years: founded in 1873, just two years after Rome became the Capital of Italy, under the name of Royal Geological Office, as a section of the already existing Mining Corps. These Corps controlled mining activity through Mining Districts, tasked with managing licenses and collaborating with mining industry, maintaining statistics on production, economic and financial aspects.

The Royal Geological Office developed the Italian geological map but, over time, it ended up neglecting the mining aspect. The first mining map of Italy was published by the Royal Mining Corps about 50 years after its foundation, also thanks to the issuance of the Royal Decree of July 29, 1927, no. 1443 "Legislative provisions to regulate the exploration and cultivation of mines in the Kingdom". Then, the last mining map was published on the 100th anniversary of the Geological Survey of Italy (1975) releasing at a scale of 1:1,000,000.

Mining activity in Italy was very active between the 1930s and the 1970s, and a big push was given in 1982 by the Law no. 752 "Rules for the implementation of mining policy", modified and supplemented by Law no. 246/84, that relaunched basic mining research: started in 1986 the Rimin project constituted a support action to the mining sector for identifying new areas for subsequent operational research by mining companies.

However, at the end of the 20th cent., the State transferred competences regarding quarries and mines to the Regions, each of which began to manage them in different ways.

In Italy, despite a decrease in production, recorded since 2008, the extractive industry remained an important sector, especially for industrial and construction minerals.

In 2019, the European Council issued the Green Deal, aimed at fostering climate neutrality through policies that promote economic growth by means of technological development, creation

of new businesses, new markets and creation of increasingly qualified jobs. The green transition represents, in fact, the chance to transform the EU community into a fair and prosperous society, based on a modern economy, through a holistic and cross-sectoral approach in which all strategic sectors contribute to the definition of a new balance between man and nature.

Aware of this, the EU has expressed concern about the supply of raw materials trying to regulate the sustainable supply of critical minerals through the Critical Raw Materials Act (2024): it provides an updated list of 34 critical minerals and of 16 strategic minerals, and it states, for instance, that EU Members have to achieve at least 10% of critical materials from internal extractions, elaborating the National Mining Plan to define its own mining potential and characterizing extractive waste.

In light of these new needs, the Geological Survey of Italy is developing a database containing geological, mining and environmental information on mineral resources.

This could become a valid tool for developing national and regional policies oriented towards the sustainable mining/quarrying of primary mineral resources, in a circular economy perspective, considering also the exploitation potential of any secondary resources produced.

Solving the Urgent Situation: Analysis of Local Mineral Resource Survey Institutions during the period of the Republic of China

weiwei HU[1]*, 15811441919 (huweiwei@cugb.edu.cn)

Abstract

In the first half of the 20th century, the significant role of mineral resource exploration in economic construction has attracted high attention of the local governments. Surveys of geological and mineral resources have been organized all over the country except Xizang province.Through the review of provincial archives, government bulletins and periodicals of the Republic of China, this paper makes a macro review and case analysis of the investigation background, organizational forms and functions of geological and mineral resources organized by local governments during the period of the Republic of China. It is hoped that this study can provide some reference for the organizational construction of local resource survey by exploring the organizational form and general characteristics during the period of Republic of China.At present, Chinese scholars have made remarkable achievements in the collation of historical documents, such as climate change, disaster prevention and control, etc. .However, the comprehensive combing of the mineral investigation report in the period of the Republic of China remains to be deepened.The collation of geological and mineral investigation reports will not only bring academic research value, but also contribute to the collection and collation of historical documents in the National Mineral Resources Database.So,it is important to make more and more such survey.

The collection of geological wall maps and their importance in teaching

Maria MESZAR[1]*, University of Vienna, Austria (maria.meszar@univie.ac.at)
Peter NAGL[2], Department of Lithospheric Research, University of Vienna, Austria
Margret HAMILTON[3], Geological Archive, Institute of Geology, University of Vienna, Austria

Abstract

Geological maps are not only the basis for orientation in the field, but are still important in the education of students in earth sciences today. Although in today's digital age, GPS and mobile devices are omnipresent in the reproduction of terrain images.
In the Geological Archive of the University of Vienna, historical geological wall maps were reviewed by the authors, reorganised and recorded in the digital database. The results and those of the resulting research are presented in this poster.

The graphical representation of geological content is an important part of teaching and initial knowledge transfer and can be seen as a preliminary stage to field visits. Unfortunately, only a few remnants of the original collection of more than a hundred wall maps have survived, and their state of preservation varies greatly.
The oldest catalogued maps date back to the foundation of the Geological Institute of the University of Vienna in 1862 and the most recent maps to 1992. The maps are mainly in German and English, but there are also some in French. One example is a geological map of England and Wales from 1865, which, like most of the others, was mounted on linen and measures 191.5 cm in length with a width of 163.5 cm.
The maps depict individual areas, countries, continents or the whole world. Due to the historical location of the collection, areas in and around Austria were favoured. The collection includes geological and tectonic maps, as well as educational panels on resources. The presentation of the contents corresponds to the respective historical state of knowledge. The scales of the oldest maps are still given in historical units of measurement.
A large number of the maps were actively used for teaching purposes, and a few also contain handwritten and coloured additions. The state of preservation varies from very good to badly damaged. The older maps in particular are heavily yellowed and the linen has become brittle. Most of the wall maps have numbers that were recorded in inventory lists at various times. This made it possible to trace the downsizing of the collection.

Although the current map collection is quite small in comparison to the largest extent of the historical collection, it provides a good indication of the application and presentation of historical-geological knowledge in teaching.

Predictive Mapping of Exploration Targets with Interpretable Machine Learning and Moderated Prediction Values

Nini Mou[1], China University of Geosciences, Beijing
Emmanuel John CARRANZA[2]*, University of the Free State (ejmcarranza@gmail.com)
Gongwen Wang[3], China University of Geosciences, Beijing
Xiang Sun[4], China University of Geosciences, Beijing

Abstract

Predictive mapping of exploration targets (PMET) using machine learning (ML) has been under development for several years now; however, the global mineral exploration industry has not yet widely adopted it. That is because the black-box character of various ML methodologies of PMET is not fully appreciated by many exploration geoscientists. In addition, most predictive maps of mineral potential are either biased towards known deposits or delineate disappointingly large exploration targets, rendering such maps unreasonable. It is motivating, however, that a few data-driven methods of PMET exists for interpreting black-box ML prediction models and addressing the issue of large exploration targets delineated by models. The latter likely stems from the inherest stochastic uncertainty of training data for PMET. Here, we show a methodology for making better the operation and trustworthiness of data-driven PMET by ML, using the Qulong–Jiama mineral district of Tibet as a case study. Initially, suitable targeting criteria and corresponding spatial proxies were defined and derived, respectively, based on the mineral systems concept. Then, to enable the interpretability of the ML models used for data-driven PMET, we used methods that are model-agnostic, namely, permutation feature importance, partial dependence plot, individual conditional expectation plot, and Shapely values. Lastly, we used an ensemble technique that couples the Random Forest algorithm and bootstrapping to derive moderated prediction values and the spatial distribution of their associated uncertainties. The delineated exploration targets (i.e., areas with high moderated prediction values and low uncertainties) cover only ~3% of the study area in the Qulong–Jiama mineral district.

Dual branch convolutional neural network and its post-hoc interpretability for mapping mineral prospectivity

Fanfan YANG[1]*, China University of Geosciences (yangff@cug.edu.cn)
Renguang Zuo[2], State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences, Wuhan, China

Abstract

The purpose of mineral prospectivity mapping (MPM) is to discover unknown mineral deposits by means of fusing multi-source ore-prospecting information. In recent years, with rapid advancements in artificial intelligence, deep learning algorithms (DLAs) as a groundbreaking technique have exhibited outstanding capabilities in geoscience. However, conventional DLAs for MPM face certain challenges in feature extraction and the fusion of multi-modal prospecting data. Moreover, opaque DLAs lead to not enough understanding of the predictive results by experts. In this study, a dual branch convolutional neural network (DBCNN) and its post-hoc interpretability were jointly constructed to map gold prospectivity in western Henan Province of China. In particular, channel and spatial attention modules were integrated into two branches to complement the respective advantages of multi-channel and high spatial prospecting data for MPM. The Shapley additive explanation (SHAP) framework was then adopted to explain the predictive results by exploring the feature contributions. The comparative experiments illustrated that the proposed DBCNN can enhance feature representation and fusion abilities, and therefore improve the performance of MPM compared to conventional DLAs. The high-probability areas delineated by the DBCNN model exhibited a close spatial relevance with known gold deposits, and the SHAP further proved the reliability of the predictive result obtained by the DBCNN model, thereby guiding future gold exploration in this study area.

A hybrid deep learning model of superpixel graph convolutional network and 1DCNN for geochemical anomalies identification

Ying Xu[1]*, China University of Geosciences (xvying1021@gmail.com)

Abstract

Machine learning algorithms have been extensively utilized for geochemical anomaly identification, which can be categorized into three types: spectrum-based, spatial-based, and spatial-spectrum-based models. The spectrum-based model cannot fully account for the spatial characteristics of geochemical element distribution. Simultaneously considering spatial and spectrum information in the geochemical data cube can help smooth out spectrum differences. The graph-based model, a classical spatial-based method, can comprehensively consider spatial information in the data and incorporate further distance information as input. This study proposes a dual-branch fusion network to extract spatial–spectrum features from a geochemical survey data cube. The spectrum branch consists of a one-dimensional convolutional neural network (1DCNN) that can be utilized to extract geochemical spectrum information within a single pixel, which involves major and trace geochemical elements and considered both positive and negative geochemical anomalies. The spatial branch is a superpixel graph convolutional network (SGCN), which is composed of both internal and external graph convolutions. SGCN can not only extract spatial relationships between neighboring pixels and even pixels at a long distance, but also take into account the anisotropy of mineralization. A case study was conducted to identify mineralization-related geochemical anomalies for validating the proposed hybrid deep learning model in northwestern Hubei Province of China. The resulting experiments have shown that: (1) superpixel segmentation is an effective tool in geochemical anomalies identification; (2) the incorporation of spectrum- and spatial-based methods contributed to the model's ability to discern anomalies and backgrounds within the geochemical data cube, enhancing its anomaly detection precision; and (3) the identified anomalous areas provide clues for the search for mineralization in the future.

Decision-tree models used to detect mineral deposits in Uzbekistan by analyzing ring, lineament structures, and faults

Oksana Gennadevna TSAY[1]*, INSTITUTE OF GEOLOGY AND GEOPHYSICS named after Kh.M. Abdullaev (oksana_tsay@list.ru)
Bakhtier Sayfullaevich Nurtaev[2], INSTITUTE OF GEOLOGY AND GEOPHYSICS named after Kh.M. Abdullaev

Abstract

This paper presents decision-tree models that help in identifying the most significant factors for detecting deposits in the Republic of Uzbekistan. To achieve this, a spatial geodatabase that included ring structures (RS), faults, and lineaments was created in ArcGIS. The ArcGIS tools were used to find the center of the RS and the nearest distances between deposits and linear structures such as RS, faults, and lineaments. The density of these structures was also determined. Using this database, nine factors were identified which were associated with the deposits. These factors included the nearest distances to RS and RS center, fault, and lineament. The density of RSs, faults, and lineament nodes were also identified. The total densities of RSs and faults and RSs, faults, and lineament nodes were also considered.

The study examined the relationship between deposits and nine factors using four models (CHAID, Exhaustive CHAID, QUEST and CRT). For the analysis, 434 deposits were selected as dependent variable, with 273 representing ores and 161 representing hydrocarbons.

After testing the models using 10-fold cross-validation, the CHAID model was found to have the highest accuracy at 77.0%. The CRT model had an accuracy of 76.7%, while the Exhaustive CHAID and QUEST models had 76.0% accuracy. The most important factors for prediction were found to be the nearest distances to RS center, fault and RS (CHAID); the nearest distance to the RS center and fault (Exhaustive CHAID and CRT) and the nearest distance to the RS center (QUEST).

These results suggest that decision-tree models could be a useful tool in detecting mineral deposits.

The 3D/4D high precision modeling and AI-driven for 3D Au targeting in the gold districts of North China Craton

Gongwen WANG[1]*, China University of Geosciences(Beijing) (gwwang@cugb.edu.cn)

Abstract

In the eastern part of North China Craton (NCC), gold deposits associated with the Late Mesozoic craton destruction are widely distributed. However, there are significant differences in research depth, ore-forming characteristics, and proven reserves among different regions. The Liaodong area in eastern NCC shares similar regional geological characteristics with the Jiaodong area and has also experienced the Late Mesozoic craton destruction in the NCC. Yet, there is a substantial disparity in the theoretical research on gold mineralization and the proven gold resources. Based on the big datasets analysis of regional geology, Mesozoic magmatic-tectonic evolution, geological foundation of deposits, and geophysics and geochemistry in the study area, this paper proposes using data-driven dand knowldge-driven and AI-driven that the primary source of Late Mesozoic gold enrichment in NCC originated from mantle-derived melt fluids induced by craton destruction. The gold deposits in the study area are primarily controlled by NE-NNE trending faults, with the main types being fracture zone altered rock and sulfide-bearing quartz vein. The 3D/4D modeling study identifies the main fault zones and there related secondary faults, as well as the periphery and deeper parts of known mining areas, as important regions for future gold resource exploration. The gold resource potential of the NCC metallogenic belt using AI-driven is predicted to be enormous, with the potential to add thousands of tons of new gold resources.

Lithological mapping based on multi-source geoscience data and deep learning algorithms

Ziye WANG[1]*, China University of Geosciences (ziyewang@cug.edu.cn)
Renguang ZUO[2], China University of Geosciences

Abstract

Lithological mapping is essential to determine target lithologies within surrounding rocks, which is growing applied in various field such as geological survey, mineral exploration, and agriculture. However, lithological mapping under poor environments faces two challenges: insufficient data and restricted methods. Lithology describes the chemistry, mineralogy, physical properties, spectral reflectance, and spatial texture of rocks, rendering it identifiable using geochemical, geophysical, and remote sensing data. For the first issue, the incorporation of multi-source geodata is considered an effective and inexpensive approach for the comprehensive analysis of various geodata especially in areas with limited geological data. Recent methodological advances have focused on deep learning algorithms that emerges as state-of-the-art methods for many important breakthroughs. These deep learning methods exhibit considerable potential for correlation extraction from geodata to support geological tasks related to mineral exploration and lithological mapping. Considering the second issue, deep learning algorithms provide access to learn and extract information directly from raw geodata through multi-level networks and outputting end-to-end classification in contrast with traditional methods. Accordingly, this study aims to develop a promising framework for lithological mapping based on deep learning algorithms and multisource geoscience data. Multi-source data fusion technology is first adopted to achieve a comprehensive analysis of geodata by integrating geochemical, geophysical and remote sensing data. Deep learning models include convolutional neural network and recurrent neural network are then developed to learn the global, local, and contextual features of the fused geodata for lithological mapping. The proposed framework is illustrated in mapping regional and local leucogranite in the Himalayan orogen, China, which is confirmed to be potential resources of rare earth metals. The following conclusions were drawn: (1) multisource data fusion provides a solution by combining diverse types of information from the same target; (2) deep learning algorithms can efficiently explore multi-source geoscience data and significantly improve lithological mapping than traditional methods; (3) this study provides a critical insight into identifying geological features to aid in prospecting mineral exploration in poorly mapped areas.

A semi-supervised learning method applied in designing optimal infill drillings, a case study at the Dalli porphyry Cu-Au deposit in Iran

Hooshang Asadi[1]*, Tethyan Gold Exploration Company (hooshang.asadi@outlook.com)
Moslem Fatehi[2], Iranian Giti Mine Company
Maryam Veiskarami[3], Geo Persia Company

Abstract

Using machine learning algorithms in designing the best possible boreholes to successfully intersect mineralized intervals is an important cost-effective approach in different stages of mineral exploration. In this research, a transductive support vector machine (TSVM), an innovative semi-supervised learning algorithm, was employed to enhance and integrate various spatial exploration proxies to identify potential targets for infill drilling at the South Dalli Cu-Au porphyry deposit, located in central Iran. Supervised learning methods incorporate training functions to classify certain data, whereas unsupervised learning methods extract the hidden data structures and assign them to various clusters. A semi-supervised learning method is a hybrid learning method that simultaneously extracts the hidden structure of non-training data and uses training data to improve the clustering analysis. To begin with, the Dalli porphyry mineral system and earlier exploration activities were used to locate the spatial Cu-Au exploration proxies including host intrusions, the buffered contact zone of the host intrusions and andesite porphyry, favorable hydrothermal alterations, copper-gold geochemical anomalies, and strong magnetic signatures associated with mineralized potassic alteration. Then, the proximity to the mineralized intervals in 6 earlier boreholes and 7 trenches was considered to divide the pixels in each spatial proxy into training (labeled) and non-training (unlabeled) data. By applying the TSVM algorithm to both training and non-training data, the study area was classified into two Cu-Au ore and waste domains. Furthermore, the results were compared and validated by the outline of the earlier available block model of the subsurface ore, projected at the surface. In addition to the TSVM algorithm, the supervised support vector machine (SVM) algorithm was implemented in the study area to identify high-potential areas for comparison. Thirty percent of the labeled exploration data was used to verify the performance of these two algorithms. The results revealed 87 percent correct recognition accuracy for the TSVM algorithm and 82 percent for the SVM algorithm. Compared to the SVM algorithm, the boundaries of Cu-Au mineralization identified by the TSVM algorithm showed a better correlation with the surface projection of the mineralized intervals along the deepest inclined borehole of the area. By using the TSVM algorithm, six new additional boreholes were suggested for infill drilling at the South Dalli deposit. This research revealed that the TSVM learning algorithm could be a useful tool for integrating exploration data with a limited amount of training data and enhancing zones of mineralization and consequently, ensuring a more accurate infill drill hole planning.

Mapping geology using textural feature extraction and unsupervised community detection models on airborne geophysics

Katie L Silversides[1]*, Datarock (katiesilversides@datarock.com.au)
Jack Maughan[2], Datarock
Mark J Pawley[3], Geological Survey of South Australia

Abstract

Airborne geophysics can provide useful information that can assist in large scale geological mapping. However, this data can be hard to interpret, especially when there is limited ground truth due to varying cover thickness. Here, we demonstrate how computer vision based feature extraction combined with unsupervised community detection models can be used to identify areas with similar geological textures to aid in interpretation and mapping.

The test area is in the Gawler Craton in South Australia. The area contains Archaean to Mesoproterozoic basement, mainly comprising metamorphic, felsic magmatic and bimodal magmatic units. There is extensive sedimentary cover, including the Neoproterozoic Stuart Shelf in the North Eastern region. The area contains significant economic mineralisation, including Iron Oxide Copper Gold (IOCG) and orogenic gold deposits.

Gravity and total magnetic intensity (TMI) vertically reduced to pole (VRTP) were used as inputs. Each data layer was divided into 2km overlapping tiles. Each tile was then passed through a pre-trained convolutional neural network (CNN) model to extract textural information. These models are trained to recognise everyday objects. In this case, instead of getting a discrete object classification, numerical representations (vectors) of the textures were obtained by taking the last layer of the CNN. This resulted in 256 features for each geophysical data layer. A uniform manifold approximation and projection (UMAP) was fitted to the data to reduce the dimensionality of the combined features to 80. The UMAP also produces a graph that shows how the points in the data are connected.

Community detection algorithms can use the graph produced by the UMAP to detect groups with similar properties. Unlike classical clustering algorithms, community detection methods use modularity to decide which points belong to a cluster. Modularity is a measure of how comparatively dense the edges within the groups are compared to the density of the connections between groups. We used the Louvain (using both Potts and Dugue modularities), Leiden and Walktrap algorithms. The results were compared to the mapped Archean to Early Mesoproterozoic geology to assess model performance.

All models identified some clusters that aligned to mapped geological units. For example, Moondrah Gneiss was frequently identified as a unique cluster relative to the surrounding area. Other clusters were identified by one method but not others. Walktrap identified the most clusters, over double that of the other methods. However, it also had the noisiest results.

Three mapped lithologies were compared to the clusters they intersected. When looking at the percentage of the lithology that was covered by the cluster with the highest overlap, Louvain with

Potts had the best results. Walktrap performed the worst. The results varied by lithology. All methods produced similar results for one lithology but some methods had poor results for the others.
Unsupervised community detection models can provide information to assist with geological mapping. However, when implementing them both the method chosen and the tile size need to match to the scale of the geological features being investigated.

Neural kriging-based specification and 3D modeling of concentrated zones of rare earth elements in deep-sea mud layers

Vitor Ribeiro de Sa[1]*, Kyoto University (ribeirodesa.vitor.7c@kyoto-u.ac.jp)
Katsuaki Koike[2], Kyoto University
Oak Yono[3], Ocean High Technology Institute, Inc.

Abstract

3D geological modeling plays a crucial role in mineral exploration, but its reliability is often challenged by data heterogeneity, sparsity, and biased collection. Lithotype variations, particularly in deep-sea environments, introduce significant uncertainty, hindering accurate resource estimation and prospectivity mapping. In response to these challenges, this study presents an alternative approach to conventional geostatistical methods utilizing neural kriging (NK: Koike et al., 2022), a method based on a deep neural network with a semivariogram learning criterion, to address the complexities of spatial modeling. Focused on a rare earth elements and yttrium (REY) deposit within the Japanese exclusive economic zone, characterized by its association with pelagic deep-sea regions exceeding 5000 meters below sea-level and high grades of up to 8000 ppm, primarily linked to biogenic calcium phosphate, namely apatite. These elements play a pivotal role in facilitating the energetic transition and mitigating climate change, making the accurate identification and delineation of REY-rich muds of paramount importance. In addition to REY, this study incorporates Scandium (Sc), Thorium (Th), and Uranium (U) as input variables due to their high affinity with the elements of interest. These elements share a high affinity with REY, further enhancing the model's ability to identify promising exploration targets. The study demonstrates the effectiveness of NK in handling data sparsity, particularly over large spatial scales reaching up to 12 km and modeling the continuity of REY-rich mud layers. The input dataset utilized in this study was sourced from Tanaka et al. (2020), which is downloadable from the online “Appendix A. Supplementary data”. By leveraging AI-driven approaches like NK, researchers and stakeholders can make more informed decisions regarding resource exploration and exploitation, thereby contributing to sustainable development and resource management initiatives.

Vitor Ribeiro de Sá[4], Kyoto University

Abstract

Mineral exploration needs detailed and accurate mapping of minerals related to deposits on the surface and metal contents using drilling data. Remote sensing and 3D modeling techniques are applicable to the former and latter purposes. We try to demonstrate capability of deep neural network (DNN)-based methods for them through the following three approaches and case studies.

The first approach is spectral downscaling of multispectral imagery to transform into hyperspectral imagery with many reflectance data. Although hyperspectral imagery provides mineral identification accuracy much higher than multispectral imagery, the cover areas by hyperspectral imagery are much less than those by multispectral imagery represented by Landsat 8 OLI and ASTER images. Therefore, we developed Pseudo-Hyperspectral Image Transformation Algorithm (PHITA) that simulates pseudo-hyperspectral image from multispectral satellite image through a DNN-based correlation analysis between hyperspectral and multispectral band reflectance data. By applying PHITA to hydrothermal deposit areas, distributions of alunite, kaolinite, pyrophyllite, and muscovite were discriminated and delineated in even the areas outside the hyperspectral image scenes: these minerals were not identified from the original OLI and ASTER images.

The second approach is extrapolation of metal content data by drilling. Targeted deposit is volcanogenic massive sulfide, kuroko-type below the seafloor and in a land area. In seafloor mineral exploration, the number of drillings is few and the drilling depths are shallow due to difficulty and high cost of drilling investigation. For a case study of a hydrothermal vent area in the Okinawa Trough, a plausible 3D metal-content model was produced by a DNN-based method using variogram and geophysical data from a linearly distributed drilling data. High-content zones appeared in the areas beyond the data cover region. For a land kuroko-deposits area, a drilling dataset that did not include the metal data in the mines was used. Despite this condition, high anomaly content zones were specified at the actual mine locations by a DNN-based method using geological and geophysical data. In addition, through a sensitivity analysis of the constructed network and metal content distribution, influence factors on the metal contents, basically tectonic setting such as fault zone or lithotype related to the generation of deposits such as dacite and dolerite, were identified. The directions of sensitivity vectors towards the high anomaly content zones suggested a formation process of deposit, deposited in the upflow of hydrothermal fluid-

dominated zones or downflow of seawater-dominated zones.

The third approach is a regional potential mapping of seafloor hydrothermal deposits in the Okinawa Trough and Izu-Ogasawara Sea area. The locations of hydrothermal deposits were used for a training dataset, and the data of seafloor topography, heat flow, Bouguer gravity anomaly, and earthquake hypocenter and magnitude were considered as the input information for a DNN-based method. As a result, high potential zones were revealed to be along the major faults and around the zones with concentrated hypocenters in a certain depth range.

Consequently, through the above three approaches and obtained results, DNN-based methods were demonstrated to be highly effective for mineral exploration both in land and seafloor areas.

3D Mineral Prospectivity Mapping from 3D Geological Models Using Return–Risk Analysis and Machine Learning on Imbalance Data

Qingming PENG[1]*, China University of Geosciences (Beijing) (1792542113@qq.com)
Gongwen Wang[2], China university of geosciences (Beijing)
Zhongzheng Wang[3], China university of geosciences (Beijing)

Abstract

Three-dimensional Mineral Prospectivity Mapping (3DMPM) stands out as a pioneering approach in mineral exploration, leveraging diverse geological data sources to construct a three-dimensional (3D) model of mineral deposits. This technique offers a precise subsurface representation, enabling the identification of areas with significant mineral potential. However, the imbalance between mineralized and non-mineralized classes poses challenges in classification results, favoring the more observed classes.

To address this issue, we employ Borderline-SMOTE (BLSMOTE), an oversampling technique that mitigates the imbalance problem by generating synthetic data points along the boundary line between minority and majority classes. Unlike other methods, BLSMOTE effectively balances datasets without introducing excessive noise.

In this study, we focus on the Guizhou Lannigou gold deposit, utilizing the shallow-forming low-temperature hydrothermal deposit as a case study. We extract ore-controlling elements and establish a 3D geological model, incorporating a total of 50 training samples generated through the BLSMOTE method. Additionally, 50 mineralization prospects are identified using Random Forests.

A return–risk analysis is applied to explore uncertainties associated with synthetic positive samples and randomly selected negative samples, determining final mineral potential values. Evaluation metrics, including G-mean and F-value, reveal that the BLSMOTE-enhanced model outperforms counterparts without the synthetic algorithm, as well as those using SMOTE and KMeansSMOTE. The optimal BLSMOTE18 model achieves an impressive AUC of 0.9288.

Our methodology demonstrates robust performance across various levels of class imbalance datasets. Excluding predictions overlapping with known deposits, we identify five target zones using a P-A plot, all exhibiting distinct metallogenic geological features. Notably, Target1 and Target2 emerge as promising areas for mineralization, offering valuable insights for future mineral exploration endeavors.

Machine learning-based 3D mineral prospectivity mapping

Bingli Liu[1]*, Chengdu University of Technology (liubingli@cdut.edu.cn)

Abstract

The research on three-dimensional (3D) quantitative prediction methods of mineral resources at depth provides important technical support for deep mineral resources exploration. The three core scientific problems to be solved in three-dimensional quantitative mineral resources prediction are: 3D meticulous modeling of mineralization space, deep geological and geochemical information extraction and inference, and quantitative metallogenic prediction at large depth. In view of this, this paper mainly discusses from the following aspects: based on the combination of explicit and implicit modeling method, 3D visualization of geology and geochemistry are carried out; based on the multifractal content volume (C-V) model, the spatial distribution of primary halo geochemical elements is studied; based on data- and knowledge-driven compositional data analysis (CODA) framework, the characteristics of element associations are extracted and inferred; On the basis of machine learning and deep learning methods, quantitative mineral prediction at large depth is carried out. Based on the metallogenic model of deposit, the deep geological and geochemical indicators are quantitatively extracted, and the deep geological and geochemical exploration model is constructed. Three quantitative mineral prediction models of machine learning and deep learning, including maximum entropy model, Gaussian mixture model and convolutional neural network model, are designed. These three models are used for deep quantitative mineral prediction, which provide a new prospecting direction for deep quantitative prediction.

Three-dimensional mineral prospectivity mapping based on positive-unlabeled learning algorithm and return-risk analysis in the Lannigou Au district, Guizhou Province, China

Zhongzheng WANG[1]*, 3001230110@email.cugb.edu.cn (3001230110@email.cugb.edu.cn)
Gongwen Wang[2], gwwang@cugb.edu.cn
Qingming Peng[3], qmpeng@email.cugb.edu.cn

Abstract

The application of three-dimensional (3D) geological modeling and machine learning provides a novel method for mineral prospectivity mapping (MPM). However, mineralization is a rare event, which leads to the fact that in 3D geological model, ore body as positive samples of machine learning only occupy a small proportion, and the majority are unlabeled data of unknown ore-bearing data. Nevertheless, supervised machine learning algorithms widely used in MPM require balanced positive and negative samples. Therefore, the selection of negative samples and the class imbalance of samples pose the challenge of 3DMPM. In this study, positive-unlabeled learning class (PULC) machine learning algorithm was selected and applied to the Lannigou Au district, Guizhou province, China. While addressing the issue of class imbalance in samples, the impact of different negative sample selection methods (from unlabeled data) on the prediction model was compared. Two-step positive-unlabeled learning (TSPUL) is a prediction algorithm that identifies accurate negative samples. It constructs a balanced training set for prediction by labeling accurate negative samples from unlabeled data based on a probability threshold determined from positive samples. Bagging-based positive-unlabeled learning (BPUL) is another prediction algorithm that treats all unlabeled data as negative samples. It repetitively selects an equal number of negative samples (treating unlabeled data as negatives) to form a balanced training set with positive samples for prediction. This study employed random forest (RF) as the base learner for PULC, constructing TSPUL-RF and BPUL-RF models, respectively. The performance of the PULC algorithm was further compared with the RF model based on ROC curves and P-A plots. The results demonstrated that the BPUL-RF model outperforms both the TSPUL-RF and RF models. Utilizing return-risk analysis model for evaluation, high return and low risk 3D grid cells are selected, while integrating ore-forming geological conditions, to determine the I-level exploration targets. The I-level exploration targets are all located within the buffer zones of ore-forming faults F3, F70, and F80. The 3D exploration targets delineated in this study hold significant importance for both deep and peripheral mineral exploration in the Lannigou Au district of China.

Automated boundary detection in drillhole data by leveraging AI and machine learning algorithms

Hamid ZEKRI[1]*, UNSW | MinEx CRC (h.zekri@unsw.edu.au)
David Cohen[2], School of Biological, Earth and Environmental Sciences, University of New South Wales, NSW 2052, Australia
Neil Rutherford[3], School of Biological, Earth and Environmental Sciences, University of New South Wales, NSW 2052, Australia

Abstract

Boundary detection is crucial in identifying the facies interfaces or discontinuities within the cover. Separating and characterising transported from in-situ regolith horizons is critical to detecting geochemical signals and patterns in regolith material derived from underlying mineralisation versus the influence of other factors. Such boundaries may exhibit only subtle mineralogical variations but represent significant differences in geochemical characteristics and sources of trace elements. However, these features might be overlooked by even experienced geologists during visual loggings. Real-time multivariate analysis of geochemical and mineralogical data acquired from drilling programs, linked to suitable data-driven methods for boundary detection and horizon characterisation offer an objective, rapid and powerful method of achieving such classification.

An AI-assisted tool has been developed for multivariate boundary detection applicable to any drillhole data. The approach is based on supervised classification algorithms, automatically evaluating the accuracy of the lithological margins detected by the workflow. The outcome is a data-driven log of core or chips, that quantifies the significance of each variable in delivering more accurate boundary detection.

This tool has been implemented on an integrated geochemical and mineralogical dataset acquired from a historic drillhole near McKinnons Gold mine in New South Wales, Australia, using portable X-ray Fluorescence and spectroradiometer data. A combination of major, conserved, target and pathfinder elements, as well as various spectral features relating to the type and abundance of Fe-oxyhydroxides, kaolinites and chlorites was used for multivariate change point detection, employing a linearly penalised segmentation approach. Random Forests and Support Vector Machine techniques were implemented to identify optimum penalty values in the cost function, leading to more accurate boundary detection. By adjusting penalty value as a crucial parameter to balance sensitivity and specificity, the boundary detection process is fine-tuned to distinguish between significant geological transitions and minor variations, ensuring that only meaningful changes in rock types, mineralisation zones, or other geochemical features are recognised. The results provided a detailed data-driven log, identifying a horizon in the saprolite dominated by kaolinite and elevated Fe and Mn. Moreover, a new interval in the saprock zone above the fresh siltstone bedrock was detected where elevated concentrations of Pb, Zn, As and Sb had accumulated. This interval, dominated by iron oxides, has been selected for further geochemical studies. The pseudo log resulting from this approach is matched with known

interfaces and assisted in delineating the significant interfaces which were overlooked in the initial visual log interpretations.

Geological data mining in mineral resources national survey database

Zhao TING[1]*, Chinese Academy of Geosicence(CAGS) (771899460@qq.com)
Liu Chao[2], Chinese Academy of Geosicence(CAGS)

Abstract

Geological big data has significant characteristics such as multi-source, multi-category, multi-dimensional, multi-topic and multi-time and space. The national survey of mineral resources of China has formed a massive amount of data on national conditions of mineral resources accumulated since the founding of the People's Republic of China. It undoubtedly has the characteristics of geoscience big data and is a set of multiple Dimensional, multi-level, seemingly scattered but actually organically coupled data sets also reflect the real data records that we face every day in the actual work of mineral resource management. Big data mining is to capture everything from the ore body to the mining area and from the mine. to macro resource security, from micro to macro, peek into the multi-dimensional and comprehensive real world, and restore the full picture of China's resource security from seemingly fragmented information. These massive data elements with more than one million levels are the basis of national situation survey data. Data mining, scientific management, and information sharing have brought unprecedented challenges. This article established a set of innovative data standardization methods of "multi-dimensional fusion of all survey elements" to quickly discover, locate and obtain survey data and related factors. relationship, compiled the technical requirements for building a mineral survey database, developed five innovative applications of national survey data mining including machine learning for mineral deposit knowledge discovery, spatial data quality inspection, and geological multi-source data consistency evaluation, and built a geological big data storage and management system. and visual mining platform.

Research on Key technology of 3D ore-forming field simulation of Caixiashan Pb-Zn deposit, Eastern Tianshan area, Xinjiang autonomous Region

Li SUN[1]*, Institute of Mineral Resources,Chinese Academy of Geological Sciences (sunli0727@163.com)
Keyan Xiao[2], Institute of Mineral Resources,CAGS
Yang Gao[3], China Nonferrous Metal Mining(Group) Co.,Ltd
Xuchao Dong[4], Institute of Mineral Resources,CAGS
xinfei Yu[5], Institute of Mineral Resources,CAGS
Xin Yang[6], Institute of Mineral Resources,CAGS

Abstract

The study of fluid inclusions in the Caixiashan deposit indicates that the ore-forming fluids exhibit characteristics of magmatic fluids, potentially superimposed by basin fluids. The surrounding rock also contributed partially to the mineralization, with the Hualixi period rock providing material and thermal sources for the mineralization. Fault structures and silicate calcium surfaces represent the most direct mineralization spaces. A comprehensive analysis suggests that the Caixiashan deposit hosts a mid-to-low-temperature hydrothermal type deposit associated with the Kavaluruk Group and the Hualixi period magmatic rock.Observations of fluid inclusions in the II ore body of Caixiashan deposit indicate that the inclusions are predominantly rich in liquid phases, with a gas-liquid ratio of 5-40%. Homogenization temperatures are mainly distributed between 100-280°C, with salinity ranging between 2-10% NaCl. The ore-forming fluids at Caihuxia are characterized as medium to low temperature and salinity. The favorable temperature range for mineralization is 140-240°C, with a favorable salinity range of 3-10% NaCl.The analysis of the fluid inclusion samples indicates a strong correlation between the main ore-forming elements Pb, Zn, Cu, and Cd, while their correlations with other elements are weaker. There is no significant correlation between Pb, Zn, and the homogenization temperature, salinity, ice melting point, gas phase composition, and liquid phase ion composition of the fluid inclusions.Using five machine learning algorithms Support Vector Machine (SVM), Decision Tree (CART), Random Forest, Artificial Neural Network (NNET), and K-Nearest Neighbors (KNN),for modeling fluid inclusion data, and the Root Mean Square Error (RMSE) was used to compare and select SVM as the preferred modeling method.Based on the three-dimensional numerical modeling of homogenization temperature, salinity, and ice melting point, a basic three-dimensional fluid field of the Caihuxia II ore body was established. Analysis of this model suggests a gradual decrease in homogenization temperature, salinity, and ice melting point from east to west and bottom to top.

Advances in Mineral Resource Assessment: A Comprehensive Overview

keyan XIAO[1]*, Chinese academy of geological (kyanxiao@sohu.com)

Abstract

Mineral resource assessment plays a pivotal role in guiding sustainable resource utilization and development. As a Professor at the Institute of Mineral Resources, Chinese Academy of Geological Sciences, I have dedicated my career to advancing quantitative prediction and evaluation techniques in this field. With over 40 national projects under my belt, ranging from key R&D programs to geological surveys, my research has focused on deepening our understanding of mineral deposits and refining predictive models.

In recent years, our team has made significant strides in deep resource prediction systems, particularly in addressing the complexities of three-dimensional geological modeling and the prediction of concealed ore bodies. Our innovative approaches have been successfully applied and demonstrated in various regions, including Shandong, Gannan, Tibet, and Xiangxi. Through projects like the Deep Resource Prediction System for National Key R&D, we have formulated theoretical frameworks and methodological systems that enhance our ability to assess mineral potentials accurately.

Furthermore, our efforts have extended to the evaluation of western superior mineral resources and the assessment of 25 important mineral resources nationwide. By integrating comprehensive geological information, we have developed methods for estimating potential resource quantities based on mineral systems. This has culminated in the development of advanced regional mineral assessment software, which has proven instrumental in guiding breakthroughs in key mining areas such as Jiama in Tibet and Caixiashan in the Eastern Tianshan region.

Our contributions have been recognized through numerous awards and honors, including the National Science and Technology Progress Award and the Ministry of Land and Resources Science and Technology Progress Award. With over 100 publications and five monographs to our credit, our work continues to shape the landscape of mineral resource assessment.

As we look forward to participating in the 37th International Geological Congress in Busan, Korea, we are eager to share our insights and experiences in resource evaluation, contributing to the global dialogue on sustainable resource management and geological innovation.

Convolutional Neural Network and numerical modeling-based 3D mineral prospectivity modeling for targeting concealed mineralization

Xiaohui LI[1]*, Hefei university of technology (lxhlixiaohui@163.com)
Feng Yuan[2], Hefei University of Technology
Mingming Zhang[3], Hefei University of Technology
Yuheng Chen[4], Hefei University of Technology
Xiangang Xie[5], Hefei University of Technology
Chaojie Zhen[6], Hefei University of Technology

Abstract

Recently, Three-dimensional mineral prospectivity modeling (3DMPM) has gained popularity in mapping the prospectivity of deep-seated and concealed mineralization. However, the majority of previous studies on 3DMPM have primarily relied on shallow supervised machine learning models and dimensionality-reduced 3D predictive maps, creating a constraint on the availability of predictive maps.

The Northeast of Liqiao area is located within the Yangtze metallogenic belt of Anhui Province, China. Many concealed skarn and porphyry-type deposits have been discovered within this area, indicating its significant potential for hosting hydrothermal deposits. In this study, we take this area as a case study. We generate various 3D predictive maps based on numerical modeling and other 3D methods, then integrate and delineate the highly prospective areas based on a convolutional neural network that has multi-scale characteristics and integrates spatial attention approaches.

The results of this study demonstrate that 3D predictive maps generated through numerical modeling enhance the information available for 3DMPM. Additionally, the CNN model used in this study exhibits superior prediction capabilities compared with other commonly used machine learning models. It can more effectively capture the correlation between 3D predictive maps and known mineralization. This combined approach can serve as an effective tool for delineating deep concealed targets for further exploration.

Feature optimization of machine learning and its application in mineral prospectivity mapping

Ke GUO[1]*, Chengdu University of Technology (guoke@cdut.edu.cn)

Abstract

Machine learning (ML) have seen widespread application in the quantitative prediction of mineral resources in recent years. Yet, during the application process, challenges such as data quality or algorithmic limitations frequently result in low classification accuracy for the predictive models. Feature optimization serves as a critical tool to enhance the classification accuracy and robustness of Machine learning. This approach effectively aids researchers in identifying the feature variables for machine learning prediction models, though it often goes overlooked. This study focuses on the Lhasa region in Tibet. Utilizing ensemble learning techniques like Random Forest (RF) and Gradient Boosting Decision Tree (GBDT), 43 feature variables including geological, geochemical, and geophysical were optimized. Then the Support Vector Machine (SVM) model with optimized features were constructed. Compared with the traditional SVM models, the SVM model based on feature optimization significantly improves the prediction performance and effectively solves the problems of subjectivity, complexity and uncertainty in the construction of artificial features. It is worth noting that when comparing RF _ SVM and GBDT _ SVM, the high-value areas observed by GBDT _ SVM are more closely related to the space between known deposits. The ROC curve further verifies that the GBDT _ SVM model has higher classification accuracy and provides strong support for future mineral exploration. Employing this approach, a metallogenic probability map of the study area was created, providing valuable guidance for further mineral exploration in the region.

Machine Learning-based approach to exploration targeting of porphyry Cu-Mo deposits in the Duobaoshan district of Heilongjiang province,China

Xiumei LV[1]*, China University of Geosciences Beijing (lvxm163@163.com)
Gongwen Wang[2], China University of Geosciences Beijing

Abstract

The driving role of mineral resources in the economic development and technological progress of a country is self-evident. However, surface and shallow minerals are increasingly diminishing, making the exploration of concealed and deep-seated ores a primary target. With the rapid advancement of artificial intelligence technology, machine learning-based exploration and integration of geological ore information provide an efficient and reliable technical approach for mineralization prediction.In this study, three models based on Random Forest, Support Vector Machine, and Radial Basis Function Link Network were employed to conduct a case study on feature vector construction, feature extraction, integrated fusion, and two-dimensional mineralization prediction using multi-source data such as geological, geophysical, and remote sensing data in the Duobaoshan mining area of Heilongjiang Province, China. The results indicate that all three machine learning algorithm models can effectively identify favorable ore zones, with the Random Forest algorithm producing the optimal results. The comprehensive analysis of the results from the three models, coupled with the delineation of prospective exploration areas, provides a scientific basis for further exploration work in the region. Compared to traditional prediction methods, machine learning-based mineral prospecting demonstrates excellent performance in extracting the corresponding relationship between multi-source geoscientific information and mineral distribution, showcasing a significant trend in the quantitative prediction of future mineral resource development.

Numerical simulation and prediction of mineralization using a physical information neural network surrogate model: A case study of the Fankou lead-zinc mine.

tang AO[1]*, Sun Yat-sen university (tangao3@mail2.sysu.edu.cn)
Xiao Fan[2], Sun Yat-sen university

Abstract

Numerical simulation has become a pivotal tool in Earth sciences for comprehending and delineating geodynamic mechanisms, encompassing intricate ore-forming systems. However, the substantial sensitivity of numerical outcomes to parameters prohibits the reuse of existing computational results in tasks demanding iterative simulations like optimization design and sensitivity analysis, thereby resulting in elevated computational expenses and diminished efficiency. Therefore, this paper presents a method for developing a Physical Information Neural Network (PINN) aimed at solving the interconnected partial differential equations governing force, flow, and heat within numerical simulations of ore-forming dynamics. The objective is to optimize the numerical simulation parameters, consequently minimizing the uncertainty associated with ore-forming numerical simulation outcomes. Initially, we concentrated on the Fankou lead-zinc mine area and developed a numerical simulation model to elucidate the dynamics of ore formation. This model integrates the coupling of force, heat, and flow fields. Following this, we integrated the model with explicit ore-forming elements representing exploration anomalies, resulting in the creation of a metallogenic prediction model. Subsequently, parameterized scans were conducted to test the numerical simulation model, collecting numerical simulation results under 128 sets of rock physical property parameters. Next, by integrating deep learning with numerical simulation results, we established a data-driven surrogate model to predict ore-forming elements like stress and temperature. Finally, multiple Physical Information Neural Networks (PINNs) were constructed to solve partial differential equations, including Darcy's law and the energy conservation equation. These two neural network frameworks were utilized to numerically simulate the force-flow-heat field in the ore-forming process, and their effectiveness, accuracy, and stability were compared and validated on the test set. Additionally, genetic algorithms were employed to optimize rock physical parameters such as density and heat capacity under both methods, yielding optimized parameter values and mineral prediction model. The findings suggest that both neural network architectures effectively forecast the accumulation of stress and strain, the spatial temperature distribution, and the enrichment of ore-forming elements in finite element simulations. In comparison to data-driven surrogate models, the Physical Information Neural Network (PINN) method demonstrates a reduced regression error (R2).

Fractals and Multifractals in Geosciences: An Introduction to a New Reference Book

Behnam Sadeghi[1]*, 1. CSIRO Mineral Resources, Australian Resources Research Centre, Kensington, WA 6151, Australia || 2. Earth and Planets Laboratory, Carnegie Institution for Science, 5251 Broad Branch Road NW, Washington, DC 20015, U.S.A. (behnam.sadeghi@csiro.au)

Abstract

This presentation will introduce the latest reference book in the field of mathematical geosciences, an in-depth examination of 'Fractals and Multifractals in Geosciences', authored by Behnam Sadeghi and published by Elsevier in June 2024. This book details the application of a wide range of multifractal methods, including the traditional methods, and many novel ones developed by the author, along with an assessment of uncertainty in sample classification and stability of spatial patterns. It also provides criteria for the selection of the most effective combination of data pre-processing and multifractal modeling to extract desired features or signals in the data. The book specifically aims to introduce, apply, and test novel multifractal models that account directly for changes in relationships between variables, as well as the effects of distance between samples and the source of anomalous metal contents in geoscience samples. Linked to this will be the assessment of the effects of different pre-processing of data prior to the application of the models and quantification/model uncertainty in geochemical anomaly maps, associated with sample classification and spatial interpolation. Gaussian simulations such as Sequential Gaussian Simulation and Monte Carlo Simulation will be applied to the new multifractal models developed and a suite of existing models, including (simulated) concentration-area, spectrum-area, singularity, and others. Here, the author discusses how this book will be invaluable for mathematical geoscientists, geostatisticians, exploration and environmental geochemists, computational geoscientists, data scientists, GIS professionals, and decision-makers in the mining and mineral industry, who need to better understand fractal geometry, along with its theory and applications in geochemical anomaly classification to generate maps that are helpful for decision-making for follow-up sampling and explorations.

Fractal modeling of the analytical signal for interpreting gravity and magnetic data: A case study from the Eastern Tianshan orogenic belt

Fan XIAO[1]*, Sun Yat-sen University (xiaofan3@mail.sysu.edu.cn)

Abstract

Aerial gravity and magnetic data is crucial for understanding the tectonics and deep geological structures of an area of interest due to their high lateral resolution. Neverthless, geophysical survey data including gravity and magnetic reconnaissance often contains various sources of noise and interference, which can obscure meaningful anomalies. In this regard, we propose using fractal filtering and singularity analysis methods to characterize multifractally in three-dimensional analytic signals of gravity and magnetic data. It aims to decompose multi-scale anomalies and enhance weak anomalies caused by the field sources with relatively low density and magnetic contrasts. Through forward modeling, the applicability of these two fractal modeling methods in processing three-dimensional analytic signals is investigated. This also helps to reveals the geological and geophysical significances of the processing results. In the case study, we employ fractal filtering and singularity analysis methods to process the direct analytic signals of Bouguer gravity and aeromagnetic data in the Eastern Tianshan orogenic belt. On one hand, regional anomaly is used to interpret the structural settings of the Eastern Tianshan district, and the geodynamic contexts of these structures were discussed. On the other hand, concealed magnetic plutons in the Gobi-desert covered area are inferred based on local anomaly.

Multifractal modeling of current and past Earth's climate

Frits AGTERBERG[1]*, Geological Survey of Canada (frits@rogers.com)

Abstract

Anywhere on Earth, weather is a chaotic manifestation of local climate. According to chaos theory, the cause of unusual weather generally cannot be established with certainty but minute perturbations of initial conditions can result in unusual large-scale weather-generating processes that are deterministic and can be modeled statistically. The current (Anthropocene) relatively rapid global warming is primarily caused by an approximately linear increase of the atmospheric CO2 content This results in various types of weather with properties that can be modeled statistically. Multifractal modeling of pre-Quaternary paleoclimates that resulted in abnormal kinds of weather is difficult, because of erosion and limited precision of age determination methods. However, several climatological features of Anthropocene age and, to some extent, fossilized consequences of other late Quaternary climates can be modeled statistically, particularly by using a modified version of the double Pareto-lognormal frequency distribution. Examples to be discussed are (1) current worldwide annual increases in frequencies of forest fires, and (2) relatively rapid annual increases in numbers of hottest and coldest days in part of Europe. It is shown that parameters of the double Pareto-lognormal frequency distribution can be estimated for these examples. Special care has to taken to account for the approximately linear increase over time of the mean value of the frequency distributions taken for example.

Singularity Analysis and Dynamic Mechanisms of Extreme Geological Events Originating from Plate Motion and Occurring at Their Boundaries

Qiuming Cheng Cheng[1]*, IUGS/China University of Geosciences (Beijing)/Sun Yat-sen University (qiuming.cheng@iugs.org)

Abstract

Research shows that various extreme geological events originating from plate motion and occurring at their boundaries are intermittent, avalanche and singular, and their spatiotemporal distribution is periodic, sporadic and aggregated. The mass accumulation or energy release caused by these extreme events is often non-differentiable or singular and needs to be measured and characterized by fractal calculus (FC). From the perspective of nonlinear mathematical physics, the occurrence of such events may be related to lithospheric phase transitions, self-organized criticality and multiplicative cascade mechanisms.

This study introduces the local singularity theory and fractal density analysis method proposed by the author in recent years and applied them to the modeling of various extreme geological events. These methods have proven effective in quantitatively characterizing the singularity and complexity of the energy released and accumulated mass of the events described above. Local singularity analysis (LSA) developed based on the fractal density concept can be used as a scale-invariant filtering technique for spatiotemporal sequences, highlighting weak anomalies corresponding to deep-time extreme geological events, and decomposing mixed anomalies caused by the superposition of multiple processes. It can also establish dynamic model based on fractal calculus for simulating extreme geological events. Starting from the analysis of nonlinear process mechanisms, fractal density concepts, fractal calculus, the article studies the spatiotemporal distribution characteristics of clustering of earthquakes, magmatic activities, and mineralization along plate boundaries such as the Pacific Rim, Tethys Domain, and mid ocean ridges. Focus on studying the impact of tectonic movements and plate characteristics on the occurrence of extreme events. The cases used herein have proven that singularity theory and methods can be used as effective theories and methods for quantitative analysis of abnormal geological events.

Modelling spatial uncertainty of geochemical anomalies integrating C-A fractal and geostatistical simulation methods

Haicheng WANG[1]*, China Geological Survey (wanghch0324@163.com)
Ruiwen Shen[2], China Geological Survey
Shengyuan Zhang[3], Hebei GEO university
Qiuming Cheng[4], China Geological Survey

Abstract

Mapping of geochemical anomalies is crucial to exploration and environmental geochemistry. The complex geochemical landscape, multiple geological sources and various secondary surficial processes impose a certain degree of spatial uncertainty in mapping of geochemical anomalies. Quantifying this uncertainty is significant for improving the efficiency of environmental monitoring or mineral prospecting. In this paper, concentration–area (C–A) fractal model and geostatistical simulation was integrated to assess local and spatial uncertainties of geochemical anomalies. A case study was carried out to illustrate the feasibility of this method. Ag concentration data of 1880 soil samples collected from NE of the Dong Ujimqin Banner district of Inner Mongolia, North China, was used in this study. Based on a set of simulation realizations of Ag concentrations, it was concluded that areas with low local (i.e. single-location) uncertainty of Ag concentrations entail low risk for mineral exploration. However, the spatial uncertainty for multi-locations showed that the joint probability statistics were stricter than local uncertainty. Therefore, combining local probability and spatial joint probability for delineating geochemical anomalies of Ag is more acceptable and reliable. The hybrid approach using the C–A fractal model and SISIM provides a new way to delineate anomalous areas by considering the uncertainty of spatial distributions of geochemical elements.

Ocean singularity analysis and global heat flow prediction reveal anomalous bathymetry and heat flow

Yang ZHANG[1]*, Sun Yat-Sen University (zhangy2336@mail2.sysu.edu.cn)
Tao Hong[2], School of Earth Science and Engineering, Sun Yat-Sen University
Qiuming Cheng[3], School of Earth Science and Engineering, Sun Yat-Sen University
Junjie Ji[4], School of Earth Science and Engineering, Sun Yat-Sen University

Abstract

The investigation of physical attributes of oceans, including parameters such as heat flow, bathymetry, and gravity, has garnered substantial attention and is particularly valuable for examining Earth's thermal structures and dynamic processes. Nevertheless, classical plate cooling models exhibit disparities when predicting observed heat flow and seafloor depth for extremely young and old lithospheres. Furthermore, a comprehensive analysis of global heat flow prediction and regional ocean heat flow or bathymetry with physical models has been lacking. In this study, we employed power-law models derived from the singularity theory of fractal density to meticulously fit the latest ocean heat flow, bathymetry, and Bouguer gravity anomalies. Notably, power-law models offer distinct advantages over traditional plate cooling models, showcasing robust self-similarity, scale invariance, or scaling properties. The outcomes of our singularity analysis concerning heat flow and bathymetry across diverse oceanic regions exhibit a degree of consistency with the global ocean spreading rate model. In addition, we applied the similarity method to project a higher resolution (0.1° × 0.1°) global heat flow map based on the most recent heat flow data and geological/geophysical observables refined through linear correlation analysis. Regions displaying significant disparities between predicted and observed heat flow are closely linked to hydrothermal vent fields and active structures. Finally, combining the actual bathymetry and predicted heat flow with the power-law models reveals anomalous areas of subsidence and heat flow. Regions of anomalous subsidence in the ocean exhibit a strong correlation with large igneous provinces, seamounts, and hotspots. Additionally, hydrothermal circulation may have an impact on areas in close proximity to mid-ocean ridges.

Unveiling geothermal anomalies in South America: machine learning predictions and spatial correlations with multiple geothermal activities

Junjie JI[1]*, School of Earth Science and Engineering, Sun Yat-Sen University.
(jijj3@mail2.sysu.edu.cn)
Tao Hong[2], School of Earth Science and Engineering, Sun Yat-Sen University.
Yang Zhang[3], School of Earth Science and Engineering, Sun Yat-Sen University.
Yuanzhi Zhou[4], School of the Earth Sciences and Resources, China University of Geosciences
Qiuming Cheng[5], School of Earth Science and Engineering, Sun Yat-Sen University.

Abstract

Geothermal heat flow (GHF) is crucial for characterizing the Earth's thermal state. Compared to other regions worldwide, GHF measurements in the South American continent are relatively sparse and insufficient for mapping GHF over the continent based on traditional model. Here we apply the machine learning techniques including Random Forest (RF), Support Vector Machine (SVM), and Extreme Gradient Boosting (Xgboost) algorithms to predict the GHF in South America. The prediction uses the global GHF data with local constraints of seventeen geological and geophysical features. The results obtained from these new models decipher that the machine learning model shows the optimal performance by several statistics such as in the mean absolute error, root mean squared error, and normalized root mean squared error. In combination machine learning model with the local singularity analysis of heat flows, active volcanoes, and igneous rock samples, we suggest that geothermal anomalies along the Andean Mountain Range are periodic and spatially correlated with magmatic activities. In addition, machie learning results show that geothermal anomalies in the Andes are not only influenced by magmatic activities from subuduction zones, but also by other additional elements. We delineate two geothermal areas of additional indictive significance, which are related to geothermal springs and the slab window in South America.

A study of thermal gradient effects in the North China Craton magmatic rock

Jinming LI[1]*, Sun Yat-sen University (lijm227@mail2.sysu.edu.cn)
Yang Zhang[2], School of Earth Science and Engineering,Sun Yat-sen University
Qiuming Cheng[3], China University of Geosciences/Sun Yat-sen University

Abstract

The North China Craton(NCC) is the oldest craton in the world, and the Craton lithosphere has been strongly reformed and destroyed since the Mesozoic.Heat flow is the comprehensive information of geothermal gradient, rock thermal conductivity, thermal productivity, and crustal/mantle heat flow, and it is an important parameter for many studies, such as regional geothermal resource evaluation and mass loss prediction of ice sheet. The eastern and western surfaces of NCC are covered by large areas of Quaternary sediments, so the search for Hot-Dry-Rock(HDR) in these areas covered by sedimentary layers is an extremely meaningful and challenging task.

In this study, we integrated heat flow data from several databases and previous published literature, as well as several geological and geophysical factors related to heat flow, and analysed that the crustal thickness of NCC shows a gradual thinning trend from west to east, and the surface heat-flow values also decrease almost with the increase of crustal thickness.However, there are some abnormal characteristics in the eastern and western Quaternary sedimentary cover areas: Relatively low heat flow values occur in parts of the eastern crust that are thin, and relatively high values in parts of the western crust that are thick.In view of these phenomena, we calculate the theoretical heat-flow values of the NCC by using the method of layer-by-layer stripping to calculate the geothermal gradient.Comparing the theoretical and measured heat-flow values, it is concluded that the difference in the singularities between the two may be related to thermal tectonic activities, such as hidden high-temperature magmatic rock mass and tectonic fracture zones. After removing the influence of tectonic fracture zones, the distribution of the singularities is greatly correlated with the distribution of hidden high-temperature magmatic rock mass. Therefore, this study is of great help and indicative significance in further promoting the exploration of HDR using heat flow.

Multifractal and singularity analysis in support of new discoveries of mineral deposits

Wenlei WANG[1]*, Institute of Geomechanics, Chinese Academy of Geological Sciences (wenleiw@163.com)
Jie TANG[2], Institute of Geomechanics, Chinese Academy of Geological Sciences

Abstract

This study introduces a sophisticated approach for geo-exploratory data analysis in underexplored regions. We employed nonlinear methods to scrutinize geological mapping and geochemical data at a 1:50,000 scale in the Zhule-Mangla district of Northern Tibet, China. Our focus was on Cu mineralization linked to porphyry systems. By applying local singularity analysis, we evaluated the spatial changes in Cu's geochemical patterns. This revealed a distinct mesh-like structure with anomalies aligned in northeast and northwest directions, providing a detailed structural understanding of the region and highlighting areas of potential interest. Additionally, we used multifractal analysis to gauge Cu distribution across various scales. We introduced a new multifractal metric, the relative enrichment index H, tailored to assess element distribution patterns. Global multifractal spectra formed the basis for local scale multifractal parameter analysis. By studying Cu concentrations in different geological units, we pinpointed ore material accumulation zones, indicating mineralization potential. In conclusion, our integrated approach, combining local singularity and multifractal insights, identified four promising exploration zones. These targets offer valuable guidance for future mineral exploration efforts, promoting a more meticulous and comprehensive exploration process. Furthermore, an enhanced exploratory data analytical strategy is proposed and prcatically applied in support of mineral exploration in unwell explored areas.

Collaborative Seismic Impedance Inversion based on Bayesian Estimation

Lilong REN[1], Chengdu University of Technology
Jianguo YAN[2]*, Chengdu University of Technology (yanjianguo@cdut.edu.cn)
Wenlu HUANG[3], Chengdu University of Technology

Abstract

Seismic impedance obtained by inversion of measured seismic data, combined with well-logging interpretation results, can directly reflect the reservoir properties of oil and gas reservoirs, such as lithology, physical properties, and oil-bearing properties. Due to the different algorithms used, seismic inversion methods are divided into two major categories: deterministic and geostatistical. Deterministic inversion directly modifies the model parameters through optimization algorithms to obtain a definite solution under given initial constraints. However, the accuracy and reliability of the inversion results mainly depend on the frequency bandwidth of seismic data and the accuracy of the initial model. Geostatistical inversion uses random simulation methods based on the probabilistic theory, such as Bayesian estimation, to obtain inversion results through the simulation of reservoir parameters and the selection of the simulation results starting from the given information, such as well-logging data and seismic data. However, the accuracy and reliability of the inversion results mainly depend on the rich and detailed known information, e.g., a number of drilled wells with high-quality seismic-well-tied data. So, there are still a lot of challenges to select the best method based on the known information in practice by tackling the capabilities of the different methods, such as analysis of application conditions and characteristics of two categories of methods, as well as the way of combining the methods, etc.

To address the above challenges, this article unifies deterministic and geostatistical inversion under the Bayesian parameter estimation framework and proposes a new collaborative inversion method and workflow of seismic wave impedance by using the two categories of the methods. The basic idea and workflow of the "collaborative inversion" method can be described as using geostatistical methods, e.g., the sequential Gaussian geostatistical inversion, to simulate seismic impedance from known wells for N times and randomly select M impedance simulation results from N simulations. Then, M results are selected as the initial model of deterministic inversion, e.g., conjugate gradient optimizing inversion. Finally, the posterior probability of multiple inversion results is calculated, and the best results are selected by the Bayesian method.

By the synthetic examples and application of field data in the Xinjiang Oil field in western China, this paper proves the proposed collaborative inversion can increase the accuracy of characterization of oil and gas reservoirs based on the same known information and fewer wells compared to using deterministic or geostatistical methods separately. So, the results of the analysis and the proposed methods and workflow in this paper can be taken as good guidance for the selection and application of the method of seismic impedance inversion in practice.

Exploratory functional data analysis of multivariate distributions for the identification of agricultural soil contamination by risk elements

Karel Hron[1]*, Palacky University Olomouc (karel.hron@upol.cz)
Tomas Matys Grygar[2], Czech Academy of Sciences
Una Radojicic[3], TU Wien
Ivana Pavlu[4], Palacky University Olomouc
Sonja Greven[5], Humboldt-Universitat zu Berlin
Johanna G. Neslehova[6], McGill University
Stepanka Tumova[7], J. E. Purkyne University in Usti nad Labem

Abstract

Geochemical mapping of risk element concentrations in soils is performed in many countries around the world. It results in numerous large datasets of high analytical quality, which can be used to identify soils that violate individual legislative limits for safe food production. However, there is a lack of advanced data mining tools that would be suitable for sensitive exploratory data analysis of big data while respecting the natural variability of soil composition. To distinguish anthropogenic contamination from natural variations, the analysis of the entire data distribution for smaller subareas is key. In this contribution, we propose a new data mining methodology for geochemical mapping data based on functional data analysis of probability densities in the framework of Bayes spaces after post-stratification of a big dataset to smaller districts. The tools we propose allow us to analyse the entire distribution, going well beyond a superficial detection of extreme concentration anomalies. We illustrate the proposed methodology on a dataset gathered according to the Czech national legislation (1990 - 2009), whose information content has not yet been fully exploited. Taking into account specific properties of probability density functions and recent results for orthogonal decomposition of multivariate densities enabled us to reveal real contamination patterns that were so far only suspected in Czech agricultural soils. We process the above Czech soil composition dataset for Cu, Pb, and Zn by first compartmentalizing it into spatial units, the so-called districts, and by subsequently clustering these districts according to diagnostic features of their uni- and multivariate distributions at high concentration levels. These clusters were seen to correspond to compartments that show known features of contamination, such as historical metallurgy of non-ferrous metals and iron and steel production. Comparison between compartments, notably neighboring districts with similar natural factors controlling soil variability, is key to the reliable distinction of diffuse contamination. In this work, we used soil contamination by Cu-bearing pesticides as an example for empirical testing of the proposed data mining approach. In general, there are no natural and justifiable thresholds of risk element concentrations that would be valid for geographical areas with too much natural heterogeneity. Therefore, national (or larger) soil geochemistry datasets cannot be processed as a whole. As we demonstrate in this contribution, empirical knowledge and careful tailoring of statistical tools for the characteristic types of soil contamination are essential for unequivocal identification of the anthropogenic component in real datasets.

Abstract

In geochemical studies, graphs and plots serve as essential tools for displaying and interpreting measured data. Over time, the geochemical community has developed a range of specialized plots tailored to different types of geochemical data. These include classical ternary diagrams, Piper diagrams, e.g. for hydrochemistry and QAPF diagrams for rocks, along with spider diagrams showing element concentrations normalized to upper crust chondrite levels, such as rare earth element (REE) patterns, and scatter plots of elements, element groups or their log-ratios, e.g. TAS diagram.

Geochemical element data are inherently compositional, meaning the individual element concentrations express the abundance of this element in relation to all other elements. For all research questions where the element pattern and changes of element pattern are important, a fundamental insight from Compositional Data Analysis (CODA), pioneered by Aitchison in 1986, is that the individual concentrations can only be interpreted in their relation to other concentrations, but not for themself alone, because all processes will influence the absolute concentration of all elements. Plots using absolute concentrations may introduce artifacts and distortions, whereas those using ratios, logs, or log-ratios are a more useful measure of dissimilarity or effect size. Many geochemical plots already adhere partially or fully to CODA principles, which aids in understanding and avoiding artifacts in data visualization. CODA theory can assist in comprehending which plots effectively avoid these artifacts and which still possess susceptibility to specific types of artifacts. Moreover, it enables the creation of graphics that convey the same content while circumventing such artifacts.

This contribution examines which classical geochemical plots align with CODA principles and how they align. For plots that deviate from these principles, we illustrate their susceptibility to artifacts by demonstrating how changes in seemingly unrelated aspects can affect and modify the visual interpretation. Furthermore, we discuss how comparable plots that visualise the same data and question while avoiding artifacts can be constructed by adhering to the general rules with minor adjustments.
The application of CODA principles on visualization tools aids in interpretation and generalizes to other geochemical questions, encompassing different elements, processes, or settings. Furthermore, certain geochemical plots incorporate principles such as normalization against a reference composition, which could be applicable in other CODA applications.

We hope for this contribution to facilitate mutual understanding between the geochemistry and CODA communities, illustrating how both have cultivated analogous concepts and highlighting shared ideas and potential for learning from each other's approaches. By bridging this understanding, both communities can benefit from the development and refinement of data visualization techniques that accurately reflect the underlying compositional nature of geochemical data.

Advancing Mineral Characterization Through Integrated Sensor Fusion and Machine Learning: A Preliminary Study

Chryselle Ultima Ortiz MANCENIDO[1]*, University of South Australia
(chryselle_ultima.mancenido@mymail.unisa.edu.au)
William Skinner[2], ARC Training Centre for Integrated Operations for Complex Resources, University of South Australia
Caroline Tiddy[3], MinEx CRC Education and Training Program, University of South Australia

Abstract

Knowing the mineralogy and quantity of ore is a critical concern in the mineral processing industry as it dictates several factors in downstream mineral processing. Spectroscopic techniques are widely used for qualitative and quantitative analyses of materials much like in minerals. Traditional means of characterization are often done by employing several of these techniques independently dictated by the type of information one wants to obtain as there is not one single technique that covers it all (both rock-forming and economic minerals). Moreover, these approaches are frequently subjective and time-inefficient, rooted in human judgment. Approaches adopted concerning the problem include using data fusion and machine learning frameworks.

To address these challenges, this study aims to establish a workflow for fusing data from multiple sensor techniques, with a focus on x-ray fluorescence (XRF) data and infrared reflectance data. Utilizing non-destructive methods such as XRF and infrared reflectance for data collection is advantageous due to their minimal sample preparation requirements. Assisted machine learning will be employed to achieve high-accuracy mineral identification and quantification in drill core samples. The availability of mobile field deployable drill core scanning instruments and sensors makes it a promising avenue to develop methods capable of integrating real-time data and providing valuable insights for timely decision-making. Additionally, these methods offer distinct yet highly complementary datasets, enhancing the comprehensiveness and reliability of the analytical framework. This integration is anticipated to overcome the limitations of separate techniques, particularly in dealing with complex mineral assemblage.

Recent investigations employing machine learning frameworks to classify minerals and quantify their relative abundance across diverse sample media have yielded promising findings. Nevertheless, there remains a gap in thoroughly evaluating the precision of these methods and exploring alternative algorithmic approaches.

The study is in its preliminary stages, having completed data collection, exploration, and initial preprocessing to establish the foundation for developing a baseline classification model. Specific intervals from an openly accessible geoscience drill core dataset, namely the Mineral Systems Drilling Program (MSDP11) provided by the Geological Survey of South Australia (GSSA), have been chosen. Infrared reflectance data from the HyLogger-3 and XRF measurements have been

obtained at corresponding intervals in the drill core, with a resolution of approximately 10 cm. Concurrently, ongoing quality assurance and control processes are underway for the XRF data to ensure its reliability in model development. It's imperative to utilize high-quality data, as unreliable data undermines the effectiveness of the model.

The current study experiments with various data fusion levels and conducts preliminary unsupervised learning to establish training labels. Additionally, dimensionality reduction and feature selection techniques are being evaluated to retain essential information from each data source. This approach aims to enhance model accuracy and interpretability, advancing understanding and predictive capabilities in the application.

Specifying control factors on Ore Chemical Composition of hydrothermal deposits over Japan through Factor Analysis

Michiharu ENATSU[1]*, Kyoto University (jhrc.3594@gmail.com)
Katsuaki Koike[2], Department of Urban Management, Kyoto University

Abstract

Data mining has been applied to economic geology recently. However, most studies of data mining have focused on specific mines or regions. Thus, more general discussion of deposit generation and formation is needed by targeting a wide area. In this study, we analyzed 326 ore samples from the 116 hydrothermal deposits over Japan, which were stored in the Kyoto University Museum and the Mineral Industry Museum of Akita University for elemental concentrations by XRF, ICP-MS, and ICP-AES. Factor analysis was implemented using the analyzed chemical composition data, and we tried to clarify the relationship between geological factors and the chemical composition of the ores. The results of factor analysis indicate that these following factors regulated the chemical composition of ores in the hydrothermal deposits in Japan: "Factor 1: generation of galena and sphalerite", "Factor 2: migration of elements associated with silicate mineral", "Factor 3: generation of pyrite and chalcopyrite ", and "Factor 4: Elements concentrated in Kuroko-type deposits". Clustering of the factor scores from Factor 1 to 4 was used to find features of mineral deposits in each region, which revealed that the Pb-Zn rich deposits are distributed in the Inner Zone of Southwest Japan and the Mo-As-Ba rich deposits and Fe-Cu rich deposits are distributed in the Northwest Japan Arc. Differences between these two regions can be explained by difference of subduction system of the Oceanic plate beneath the ancient Japan Island from the Cretaceous to Neogene period.

Acknowledgement: We wish to express our gratitude to Prof. Yasushi Watanabe of Akita University for providing the ore samples.

Development of a Software Platform for the Real-Time Hyperspectral Interpretation of Samples from the Vaca Muerta (Argentina) Formation within a Virtual Reality Environment.

Douglas Bazo DE CASTRO[1]*, Universidade Estadual de Campinas (UNICAMP)
(castrodouglasdev@gmail.com)
Diego Fernando Ducart[2], Universidade Estadual de Campinas (UNICAMP)

Abstract

In this project, four samples from the Vaca Muerta formation were chosen, and their hyperspectral images were captured using Hyspex sensor. The Neuquen Basin is situated in the Neuquen Province in Argentina, with its geological history dating from the Late Triassic to the early Cenozoic [1]. The organic-rich sediments of the Vaca Muerta system were deposited during the ocean anoxic event (OAE). [1].

This formation is the most effective source rock interval in the Neuquen Basin, with 2% up to 12% total organic carbon [2]. The Vaca Muerta formation is an important matter inside the oil and gas industry. Reflectance spectroscopy is a significant method for measuring the absorption spectra and other properties of solids. The relevant parameters are wavelength, frequency, and wavenumbers [2].

In this study, the data images collected are processed within the Unreal Engine 5 graphics engine using the C++ language, enabling analysis in virtual reality on a server by multiple users simultaneously. As per Zheng [3], Virtual Reality (VR) is a human-computer interface that produces simulations of realistic virtual environments, allowing users to navigate and interact with the surroundings from various perspectives. Virtual Reality (VR) as a medium enables participants to immerse themselves in an embodied perspective [4]. The samples were additionally scanned with a LiDAR (Light Detection and Ranging) sensor, allowing users to virtually interact with the samples while analyzing the hyperspectral images. This workflow facilitates data sharing for collaborative analysis among multiple users simultaneously, utilizing the virtual reality environment to interact and create a collaborative workspace.

The collaborative aspect of this environment aligns with the principles embraced by technology hubs, enhancing outcomes through the creation of a collaborative workspace. Integrating this collaborative approach into geosciences can enhance data sharing, facilitate brainstorming, and enable real-time information exchange for diverse datasets, including hand samples, images, and spectra.

Another innovative aspect of this project is the seamless sharing of hyperspectral data and hand samples with scientists worldwide, allowing real-time interpretation and collaboration among diverse professionals.

Spatial Estimation of Grain Size Distributions using Compositional Kriging

stephen tyson[1]*, UTB (stephen.tyson@utb.edu.bn)
Ahram Kim[2], UTB

Abstract

Accurate grain size distributions are important to determine the best method to control sand from producing petroleum wells, however, the selection of sands or gravel packs often has to be completed before the well has been drilled due to component lead times. The challenge is to estimate a grain size distribution at an unknown location.

The most common way to display and model grain size distributions appears to be; display as a cumulative distribution curve with grain size decreasing left to right, either on a linear scale of phi values or a log scale of grain size diameters in mm. This would be the default display from a Malvern laser particle size analyser (LPSA), This a normal or log normal distribution is fitter to this cumulative distribution for further modelling. However, when the grain size distribution is plotted as a probability distribution function, it is obvious that, in all the sands we investigated, the distribution is rarely unimodal and the same formation in adjacent wells could have grain size distributions with different modalities.

Current best practice. Is to interpolate the mean and variance of the fitted normal or log normal distribution, usually with some variant of the kriging algorithm, even though this would guarantee a unimodal distribution at any location.

We present an alternative technique using compositional kriging. The grain size distributions are binned if they come from an LPSA , or if they are sieved, the sieve proportions are used directly. By treating the distribution as a mixture of grains of different size categories, it is possible to use compositional kriging. This will honour the spatial model of each category in the composition as well as the spatial relationships between categories. Using this approach we were able to accurately model the changes in grain size distribution modality. This was particularly significant as the selection of sand screen was highly sensitive to some of the categories of grain size.

It may be possible to consider this approach for other spatial variables which are continuously distributed that have significantly different shapes or modalities across the region of interest

The evolution of fluid pressure in fault zone and its response to hydrothermal mineralization

Yihui XIONG[1]*, China University of Geosciences (xiongyh426@cug.edu.cn)
Renguang Zuo[2], China University of Geosciences

Abstract

The behavior and evolution trajectory of faulting process, which shows a first-order relationship with hydrothermal mineral deposits, is greatly influenced by fluid flow and fluid pressure. Further investigations are required to achieve an in-depth understanding of the formation and evolution mechanisms behind the link between the fluid pressure development and the occurrence of induced faulting and mineralization processes. Aiming at exploring the effects of fluid pressure development on the behavior of faulting and mineralization, different fluid pressure increase rates are considered as the initial data for the cellular automaton model. The simulated results show that the varying fluid pressure increase rates play a crucial role in determining faulting and mineralization processes. More specifically, as the fluid pressure increase rates increase, the faulting event scales change from a large number of small-scale fault ruptures to a small number of large-scale ruptures. The different behaviors of fluid pressure fluctuations induced by low and high fluid pressure increase rates can promote cyclic mineral precipitation and further form enriched geochemical patterns with strong spatial structure. Besides, the correlation length at the percolation threshold, which is of great significance to the degree and scale of mineralization, increases with the increase of fluid pressure increase rates. It is concluded that grids with high fluid pressure increase rates are much more prone to producing enriched geochemical patterns with strong spatial structure than grids with low fluid pressure increase rate. Therefore, the analysis of the results suggest that the way of fluid pressure development is a key factor to quantify the behavior of faulting and mineralization processes.

Decoding the Dynamic Impact of Clay-Coated Quartz Grains in Sandstone through Multiphase-Field Modeling

AKASH KUMAR[1]*, KIT, Karlsruhe (akash.kumar@kit.edu)
MICHAEL SPÄTH[2], KIT, Karlsruhe
DANIEL SCHNEIDER[3], KIT, Karlsruhe
BENJAMIN BUSCH[4], KIT, Karlsruhe
CHRISTOPH HILGERS[5], KIT, Karlsruhe
BRITTA NESTLER[6], KIT, Karlsruhe

Abstract

The reservoir quality of sandstones hinges significantly on the presence or absence of clay coatings enveloping quartz grain surfaces. Porosity and permeability, pivotal hydraulic and mechanical parameters, exert a profound impact on the storage potential of sandstone reservoirs, encompassing geothermal energy, groundwater, and hydrocarbons. Employing the multiphase-field method, a widely embraced tool in material science, this study ventures into the modelling of interface motion and phase transitions, extending its utility to geological phenomena like mineral cementation.

Through the application of a thermodynamically consistent multiphase-field model, our investigation delves into the intricate influence of clay coatings on quartz grain surfaces, shedding light on the ensuing variations in porosity and permeability across diverse sandstone compositions. A meticulous three-dimensional digital representation of sandstone allows for precise control over quartz grain coating. This
research addresses two primary facets: 1) examining the impact of varying levels of clay coating on quartz overgrowth cement volumes, and 2) scrutinizing the repercussions of quartz grain size on the dynamic evolution of overall porosity and permeability within the reservoir rock.

To assess the evolving sandstone permeability during the precipitation of quartz on partially to completely clay mineral coated quartz grains, computational fluid dynamics analysis is conducted at various stages. Subsequent scrutiny of the amassed data reveals intricate correlations among the grain coating coverage, rock properties, and their collective impact on porosity, permeability, and their interplay during quartz precipitation.

Our computational studies indicate that sandstones boasting a higher grain coating coverage result in lower quartz cement contents, and therefore preserve porosity during diagenesis. These revelations furnish a foundational understanding for more nuanced reservoir quality predictions, with potential applications spanning geothermal energy, water resources, and the storage of carbon and hydrogen.

Optimal drilling for exploration: an iterative approach

Guillaume PIROT[1]*, The University of Western Australia (guillaume.pirot@uwa.edu.au)
Kubra Akbulut[2], The University of Western Australia
Özgür Yedek[3], The University of Western Australia
Mark Jessell[4], The University of Western Australia

Abstract

The mining industry faces various challenges in satisfying the increasing demand for minerals related to clean energy transitions. One of these challenges is the need to improve geological characterization at the stage of undercover exploration. This usually requires costly drilling operations, so raises the challenge of how we can reduce our exploration footprint and costs while also reducing geological uncertainty by developing optimising drilling operations? Here, to address this question, we propose to optimize the design and location of additional drillholes in an iterative way, relying on the information provided by previously drilled holes.

The approach is illustrated by a synthetic reference case, used as ground truth, based on a legacy data set from the Hamersley basin, WA, Australia. In this simplified setting, the stratigraphy is assumed to be known. To mimic the exploration process, we start by initializing a database of vertical and regularly spaced drillholes. From the database, using the implicit geological modelling engine LoopStructural, we generate an ensemble of geological model realizations. From this ensemble, geological uncertainty is estimated by Shannon's entropy. The next optimal drillhole location is then obtained by maximizing an objective function that can be parameterized to account for or ignore the degree of freedom around drilling parameters, such as dip direction and dip, as well as to explore the relationship with Shannon's entropy. The iterative exploration ends when the drilling budget is exhausted. Preliminary results show the importance of defining carefully the objective function in order to maximize the value of current information for the needs of the geological modelling engine and to provide an efficient drilling sequence.

Integrating Multivariate Data in Constructing 3D Geological Structure by Multiple-point statistics Method

Weisheng HOU[1]*, Sun Yat-sen University (houwsh@mail.sysu.edu.cn)
Songhua Yang[2], Sun Yat-sen University
Yanhu Li[3], Sun Yat-sen University
Shuwan Ye[4], Sun Yat-sen University

Abstract

In recent years, the multiple-point statistics (MPS) method has been successfully used to generate 3D complex geological structures. More and more researches showed that, in MPS simulation, integrating multiple data provides much more geological patterns and reduces the uncertainties of simulation results. But, due to the lack of a unified data-driven framework for training image fusion, the multivariate data structure is difficult to integrate from the perspective of the physical significance of the data.

In this study, a multivariate data fusion method in generating the initial model is proposed for the iterative MPS method coupling fully connected neural network (FCN), which three main steps are included: constructing 3D TD, generating the initial model and expectation-maximum (EM)-like iteration process. Here, an intuitive expansion process is carried out to obtain 3D patterns from 2D cross-sections, in which the process is executed from the nodes adjacent to 3D TD layer by layer from top to bottom. For each kind of data, 3D pattern are extracted and reorganized as list Canlist from the 3D TD by the similarity.

The initial model, coupling with a sequential process, is constructed by FCNs based on back propagation (BP) framework. The FCN is used to generate the top Stop(atti) and bottom Sbott(atti) surfaces of each geological block atti, in which the FCN is trained by the elevation of geological contacts in cross-sections. Therefore, each contact surface might be generated twice by different trained FCNs. Then, surfaces of different objects would cross each other, resulting in wrong assignments on a grid with several attributes. Thus, a sequential process with multivariate data fusion is implemented. Here, all profiles of different kinds of data have the same locations and scope. The key steps are: (1) Setting the sequential path, which could be a random path and sequential path. (2) For each variate data, selecting the candidate patterns from Canlist by the similarity with pattern on the node to be simulated of the overlapped area. (3) Calculating the probability of candidate patterns of different variants by the distance vector of the positions of candidate patterns and data event of nodes to be simulated; (4) Integrating probabilities of the multivariate by linear pooling method with cross-entropy weight. (5) The pattern with maximum weighting probability is selected and pasted on the node of to be simulated. Repeating step (2) to (5), the initial model can be obtained. Although the initial model can be treated as a result, an EM-like algorithm is implemented to obtain more reasonable and smooth result.

A concrete example of reconstructing the overthrust model by SEG/EAGE is used to test the proposed method, in which ten profiles of velocity, density and lithology are extracted as data

sources. The simulation results illustrated that: (1) the precision of the simulation result can be improved with multivariate fusion. (2) high similarity of different type of data can be identified by cross-entropy weighting method, leading to the small uncertainty of simulation results. (3) the distance vector constraints can improve the process of choosing candidate pattern.

A comprehensive rapid updating of resource models with complex geology

Sultan ABULKHAIR[1]*, University of Adelaide (sultan.abulkhair@adelaide.edu.au)
Peter Dowd[2], University of Adelaide
Chaoshui Xu[3], University of Adelaide

Abstract

Resource modelling of mining deposits usually involves a comprehensive approach to modelling as many important variables as possible. This includes quantitative (e.g., grades) and qualitative (e.g., geological domains) variables that should be integrated into the block model together. For example, it is common to divide the deposit into geological domains and then to estimate the grades within those domains. However, the major challenge in resource modelling is the uncertainty at locations with no conditional data available. Therefore, it is important to consider integrating massive streams of sensor measurements into the resource models. This work demonstrates a comprehensive rapid resource model updating with real-time sensor observations using a real case study from an iron oxide copper-gold (IOCG) deposit in South Australia. The proposed approach uses an ensemble Kalman filter with multiple data assimilations to integrate sensor observations into the resource model in near real-time. For qualitative variables, a method based on pluri-Gaussian simulation is used to transform geological domains into Gaussian random fields. Rotation based iterative Gaussianisation helps transform grade variables into independent multivariate Gaussian factors. Updating geological domains ensures that the uncertainty around the domain boundaries is reduced to a minimum. Updating grade variables separately within each domain results in more accurate grade prediction.

Enhancing Geothermal Resource Assessment: Well-Correlation and Analysis of Depositional Facies in the Szentes Region, Hungary

Catarina C. CASTRO[1]*, Doctoral School of Earth Sciences, University of Pécs
(castrocc@gamma.ttk.pte.hu)
János Geiger[2], GEOCHEM Ltd.
János Kovács[3], Department of Geology and Meteorology, University of Pécs
Ferenc Fedor[4], Department of Geology and Meteorology, University of Pécs

Abstract

The Szentes geothermal field stands out as one of Hungary's most active geothermal (hydrothermal) sites, with a long history of geothermal water production. Its geological background is marked by the evolution of a deltaic system that began during the Late Miocene period. The sedimentary environments changed upward from deep basin through basin slope, delta front to delta plain, resulting in the deposition of sedimentary sequences that present high-porosity and geothermal gradient anomalies creating favorable conditions for the development of medium and low-enthalpy geothermal systems. Despite extensive exploration efforts, the lack of reinjection practices poses a major challenge to the sustainability of its flow system. In order to determine optimal reinjection sites, deep understanding of the past framework of the depositional system within the area and their correlation along the field is a key process. A comprehensive large scale well-correlation analysis is performed using high-resolution well data to identify and characterize different depositional facies and cyclic depositional patterns of the Upper Pannonian sequences in the Szentes geothermal field, Southeastern Hungary. Applying Integrated Predictive Error Filter Analysis (INPEFA) to sixteen Gamma-Ray logs using Cyclolog Software®, this study traces sedimentary discontinuities and grain-size trends in order to determine stratigraphic boundaries. Based on well-correlations, more accurate and realistic dynamic models can be developed for groundwater simulations. This facilitates the assessment of the potential impact of reinjected water on the geothermal flow system, and enables informed decisions in the field of geothermal exploration and production, leading to more efficient resource management.

Automatic Reconstruction of Geological Reservoir Models Based on Conditioning Data Constraints and BicycleGAN

Wenyao FAN[1]*, China University of Geosciences (Wuhan) (fanwy_jlu@163.com)
Gang Liu[2], China University of Geosciences (Wuhan)
Qiyu Chen[3], China University of Geosciences (Wuhan)

Abstract

For geological reservoir units with different sizes of pore spaces and relatively stronger anisotropic heterogeneities, Generative-Adversarial-Network-based (GAN) modeling methods can overcome limitation of numerical-simulation-based ones and support finely representation of nonstationary models. However, due to conditioning data weak constraints, GANs might ignore local detail features, with artifacts and noise during simulation. Some pre-processing strategies are strictly limited by the conditioning data distribution patterns, and corresponding processes should be updated frequently when new data are introduced, with relatively complicated operation. Therefore, the BicycleGAN framework was introduced in this paper. Based on bijective consistency between the latent vector and output, an image-to-image translation task with different dimensions is established, and multiple networks were coupled to realize finely representation of spatial attributes. Specifically, the mapping between conditioning data and output is established through the U-Net architecture, which not only local detail information is considered, but also reduce the impact of conditioning data distribution patterns. Meanwhile, the mapping between latent and actual test time distribution is also established by an encoding function to ensure simulation authenticities. In addition, a joint loss function combined with conditioning loss and prior loss is defined to ensure reconstruction accuracy of different facies types. Four kinds of categorical and continuous training images were selected to verify the network simulation performances. Results show that reconstruction accuracy for facies types of conditioning data is almost consistent with those of the references, keeping similarities in terms of spatial variability, connectivity, structural similarity, and facies type reproductions. Meanwhile, for the saved BicycleGAN, inputting different kinds of conditioning data once only, and a variety of simulations can be obtained rapidly, thereby realizing conditioning reconstruction of geological reservoir models.

Amir Adeli[4], University of Adelaide

Abstract

Identifying zones containing mineralisation is an essential aspect of mineral resource estimation, which involves various techniques such as manual interpretation, implicit modelling, and advanced geostatistical methods. The definition of these zones is based on the concept of domains that can be manually determined or derived from geological information. In geostatistics, categorical domaining approaches such as Indicator Kriging (IK), Sequential Indicator Simulation (SIS), and PluriGaussian Simulation (PGS) can automatically define mineral domains and quantify the associated uncertainty. In addition, the recently developed Hybrid Domaining Framework (HDF) uses machine-learning classification techniques trained on the categorical properties of geological information. This paper presents a comparative study of the domaining approaches of IK, SIS, PGS, and HDF in the case of the acquisition of new data that can be used for the overall model updating or downscaling purposes. The performances of these approaches are evaluated for the assays and geological data obtained from exploration and grade control drillholes. The results indicate that the HDF framework can effectively quantify the uncertainty of the domain boundaries and produce good results on par with the IK, SIS, and PGS methods. However, for better categorical domain modelling HDF depends significantly on the quality and availability of quantitative covariates in the assay data. This suggests that using HDF for only partially available assay data from grade control drilling to update and down-scale the original model may not provide any significant benefit particularly when the partially available data are less important for the trained HDF classifier compared with the unavailable data.

SA-RelayGANs: A Novel Framework for the Characterization of Complex Geological Structures Based on GANs and Self-Attention Mechanism

Qiyu Chen[1]*, China University of Geosciences (chenqiyu403@163.com)
Zhesi Cui[2], China University of Geosciences
Gang Liu[3], China University of Geosciences

Abstract

Increased availability and quality of surface and subsurface observations provide the chance to improve the perception of geological phenomena. An important factor that hinders our understanding of geological structures is the characterization of heterogeneous patterns with continuous attributes inside the structures (e.g., porosity, permeability, fluid saturation, etc.). Unlike categorical attributes, continuous attributes convey more realistic characteristics but require more computational resources to characterize such complex earth systems. In this work, we propose a novel deep learning approach for the characterization of complex geological realism with continuous attributes based on generative adversarial networks (GANs) and self-attention mechanism, named SA-RelayGANs. To address the complexity of heterogeneous geological structures, we divide the modeling process into two stages: facies construction stage and property reconstruction stage. In the first stage, we employ an improved GAN with self-attention mechanism to construct the heterogeneous structures while adhering to hard conditioning constraints. In the second stage, we utilize another GAN with an attribute enhancement term to reconstruct realizations based on the constructed structures and observations. SA-RelayGANs can successfully predict the statistical distributions of heterogeneous structures with continuous attributes by using limited observations. This study highlights the effectiveness of using GANs to characterize the heterogeneous patterns of geological realism and the application over large geoscience fields.

Three-dimensional stratigraphic modeling via adaptive search strategy-based multiple-point geostatistical simulation

Hongfeng - FANG[1]*, China University of Geosciences (fanghongfeng98@163.com)
Qiyu - Chen[2], chenqiyu403@163.com
Gang - Liu[3], liugang67@163.com

Abstract

3D stratigraphic models provide a visual and quantitative description of complex geological structures and phenomena, which can support subsurface space development and utilization, geological disaster prediction and evaluation, etc. Multiple-point geostatistics (MPS) shows prospects in the automatic characterization of heterogeneous structures and phenomena. But complex geological structures hardly meet the stationarity assumption of MPS. In this work, we present a novel 3D stratigraphic modeling approach via adaptive search strategy-based MPS simulation, named AS3DR. A horizontal search range is preferentially set to prominent geospatial correlation in the adaptive search strategy. A search range in the vertical direction can be obtained by projecting the node to different adjacent cross-sections. The intersection of horizontal and vertical search ranges is taken as the training image of the current node in MPS simulation. A unique aggregation function fuses multiple statistics in different directions to a combined probability distribution. Various synthetic experiments and a real application are performed to verify the performance of AS3DR. Multiple experiments show that AS3DR adaptive selects and fuses training images from adjacent cross-sections to capture and reproduce multiple-point patterns accurately in the 3D reconstruction of complex stratigraphic structures. It mitigates the negative influence of the strong non-stationarity of complex geological structures in MPS methods to extend the application scope of MPS to 3D stratigraphic modeling.

GEOFRAC-based 3D fracture modeling combined with borehole investigation data for groundwater and hydrothermal fluid flow systems

Taiki KUBO[1]*, Kyoto University (kubo.taiki.3n@kyoto-u.ac.jp)
Jacek Scibek[2], RWTH Aachen University
Katsuaki Koike[3], Kyoto University

Abstract

Clarifying a hydraulic property of geologic media is an important problem common to various fields in geosciences. In this research, we selected the Tono area situated in central Japan for a case study of such hydraulic characterization. This area is covered by Cretaceous granite and many geological investigations had been carried out by JAEA to understand the deep underground properties. The permeability of crystalline rock is primarily influenced by the facture structure. However, when the stability on the very long-time scale is considered, such as a case to evaluate the safety of geological disposal of radioactive waste, the properties of the rock matrix and the altered part also affect hydraulic structure. In this study, we applied GEOFRAC (GEOstatistical FRACture simulation method; Koike et al., 2015), to simulate the regional fracture system. GEOFRAC is a geostatistics-based method which can incorporate fracture density, strike, and dip into geometrical fracture simulation. The GEOFRAC model covering the study area of 12 km (E-W) by 8 km (N-S), with a depth range of 1.5 km was constructed from the fracture observation data by borehole television. The model revealed the existence of a two-layered distribution of low-angle fracture dense zones, and integration with hydraulic test data suggested the influence of major faults on groundwater flow systems. In addition, physical property measurement for over 100 borehole core samples were carried out using non-destructive measurement devices, a probe permeability meter (permeameter; Scibek and Annesley, 2021) and 3D scanner to identify changes in permeability within rock matrices and small alteration zones, which are difficult to extract in hydraulic tests using a borehole. In addition, detailed observations using a microscope revealed the characteristics of rock properties and their distribution, which have a significant effect on permeability besides fractures. Permeameter measurements unveiled that a granite region with numerous voids, known as the episyenite zone, had high permeability. From the integration of GEOFRAC model and measurement results, the spatial variation of hydraulic conductivity obtained in hydraulic tests was improved to a more detailed one. GEOFRAC was furthermore applied to modeling a fracture system in a geothermal field, Wayang Windu, west Java, Indonesia with producing 227 MW power generation. Fractures parallel to main faults and connected fractures to form fluid paths were detected, which contributes to estimating upflow patterns from the reservoir.

Ab-initio calculations and molecular dynamics simulations of In and Cu repalceing Zn in ZnS with different structures: implications for In enrichment in Pb-Zn mineralization

Zongcong HE[1]*, Sun Yat-Sen University (hezc3@mail2.sysu.edu.cn)
Fan XIAO[2], Sun Yat-Sen University

Abstract

Indium (In) is a critical metal with strategic resource significance, which plays an increasingly important role in the global economic landscape. In is a rare metal, with extremely low abundance in the crust, usually occurring as an associated mineral. Due to its sulfur philic property, In mainly accumulates in zinc sulfides (ZnS) of sulfide deposits through isomorphous substitution. ZnS crystallises in close-packed structures, the most common of which are sphalerite with cubic 3C structures and its polymorph wurtzite with hexagonal 2H structures. The enrichment of In in crystal structures exhibits a selective hyper-enrichment mechanism, with In being concentrated at higher levels in sphalerite, while its concentration is lower in wurtzite. However, there is still little known about physicochemical constrains on these two crystal structure, which hinders the understanding of In mineralization. Understanding the controlling role of crystal structure in the enrichment mechanism of In enter ZnS is crucial. In this contribution, the ab-initio calculations and molecular dynamics simulations were used to calculate the thermodynamic properties and electronic structure of In entering sphalerite and wurtzite in the isomorphic replacement mechanism under the metallogenic conditions of skarn deposits. The calculation results show that: (1) The distinction between the two different structures of In-bearing ZnS primarily manifests in their thermodynamic characteristics, while their electronic structures differ little; (2) In enters sphalerite via the isomorphic substitution mechanism, which is relatively stable compared to wurtzite; (3) Temperature plays a crucial role in governing the incorporation of In into the lattice of ZnS. The optimal temperature for In to enter sphalerite through the isomorphic substitution mechanism is 275°C-300°C, while the optimal temperature for In to enter wurtzite through this mechanism is 225°C-250°C. This study not only provides atomic or/and molecular simulation insights for understanding the related processes of In formation in zinc ores, but also provides a scientific theoretical basis for further exploring the genesis mechanism of In deposits.

Abstract

Multipoint simulation (MPS) algorithms exploit the dependence structure of the target variable at a series of k-nearest points around each simulation location. Most of the algorithms require the usage of a training image (TI) to either estimate and draw realisations from the conditional distribution of the target variable at an unsampled location, or else directly draw from the TI at the earliest occurrence of a sufficiently similar pattern as the conditioning one. The innovation from the TI (i.e. the ability to produce patterns not strictly found in it) happens because of a certain tolerance embedded into these algorithms.

We present an MPS that can be trained on extensive conditioning data as well as on a TI. The method has three steps. In a first step, the training data is so to say "folded"" in a pre-specified series of ways to produce long lists of patterns containing (k+1)-tuples of nearest and near observations to each sample location: not just tuples of the target variable are created, but also information about the constellation of the corresponding (k+1) locations of these tuples is added to the patterns. In a second step, the folded dataset is fed into the training of an artificial neural network (ANN) to predict the target variable at the reference point conditional on the surrounding k-point pattern. Once the ANN is trained, in the third step we follow a random path through the simulation grid, each time finding the k-nearest data points and using the trained ANN to predict the conditional target value at each grid node.

In this contribution, we discuss the details of the proposed algorith with an illustration example and discuss its properties and applicability.

Abstract

Play-based and Common Risk Segment (CRS) methodologies, classically used in the Oil and Gas industry, can also serve exploration activities for emerging subsurface applications, such as carbon storage, geothermal energy, natural hydrogen or lithium resources production. However, as these applications usually correspond to lower financial margins, extra efficiency in the process appear critical. One solution is then to leverage data science and Machine Learning capabilities to facilitate data integration and digitally assist the workflow execution.

Nevertheless, adjusting classical prospectivity mapping methodologies to new applications and Machine Learning is far from straightforward, notably in complex geological settings. Indeed, the input data are often simultaneously scattered, very heterogeneous (in nature, dimension, scale, resolution, quality or extension), and strongly dependent from subject matter knowledge, with inherent biases, uncertainties and interdependencies. Besides, the notion of prospectivity in emerging subsurface businesses remain fuzzy, case-dependent and multi-factor. Finally, quantitative risk assessment and explainability appear as key elements to foster the adoption of the resulting technologies by operational geoscientists.

In this context, the ideal prospectivity mapping methodology integrates the available data and knowledge, is digitally assisted while remaining expertise-driven, and is relatively simple to deploy while remaining explainable and collaborative. To address these ambitious objectives, we propose a strategy based on the following components: (1) formalization of the existing subject matter knowledge, for instance with conceptual graphs or ontologies, (2) data integration with Machine Learning, possibly using knowledge-infusion techniques in the statistical models, (3) Multiple Criteria Decision Analysis (MCDA) procedures, to combine human inputs and mathematical rigor in weighting the various factors impacting prospectivity, and (4) uncertainty propagation and Shapley Additive Explanations (SHAP) to ensure risk appraisal and explainability in the process.

The promises of the presented methodology are illustrated with a real-life case study, consisting in mapping the geothermal potential of the British Columbia region (Western Canada). A challenge

is to consider the peculiarly varied geology of the area, divided in sedimentary, volcanic, intrusive, ultramafic and metamorphic domains, with different assets regarding to geothermal energy production. The results highlight the power of Machine Learning to extract multiscale and multivariate correlations in the data, but also the benefits of the MCDA approach to introduce subject matter knowledge. In particular, the geological environment is used as an over-arching factor delineating several subregions, where different MCDA procedures are run independently. More generally, this work confirms the interest of hybrid methodologies in mathematical geosciences, blending data-driven approaches and more knowledge-driven ones.

Abstract

Numerous geological research studies and mining operations have proved that fracture is one of the important factors controlling groundwater flow, mineralization and ore distribution in metallic deposits. most current approaches for groundwater flow simulation of naturally fractured media rely on the calculation of equivalent permeability tensors from a discrete fracture network. Simulating a discrete fracture network (DFN) in a mine area is therefore crucial to mine water inrush accidents and disasters prevention, resource exploration and underground mining safety. This study aimed to construct a plausible two-dimensional DFN using GEOstatistical FRACture simulation method (GEOFRAC), a geostatistical method of conditioning directions (strikes and dips) and locations of sample fractures, by selecting the northern part of the Gejiu tin district, southwest China, and using 3724 outcrop fractures sampled on the ground of mountain Gaosong. Geographically, the mining area is located in the southern part of the middle-Dian Plateau, an alpine hilly area. The mountains in the area are continuous, heavy and overlapping, and there is no obvious trend; they are mostly blocky mountains. The mountainous area accounts for 86% of the total area of the region. The Gaosong mine is situated in the northern part of the tin mine in Gejiu, which is restricted by the Gejiu and Jiajieshan Faults in a north–south direction and the Gesong and Beiyinshan Faults in an east–west direction, and is covered mainly by dolomite and dolomitic limestone of the middle Triassic with dispersed distribution of Tertiary mudstone and Quaternary residual deposits. The study area was a rectangular area of 17 km by 9 km that covered the Gaosong mining area Key parameters of this DFN are density, direction, and connective condition of discs that form a fracture plane. The simulated fractures were verified in that their directions corresponded well with those of the sample fractures. The permeability tensor of each modeling grid is then calculated based on the fracture network constructed.

The study planned to build a rational DFN in a metallic mining area by selecting the Gaosong mine in southwestern China to depict the relationship between fracture distribution and permeability tensor. The GEOFRAC method was validated by the consistency of major tendencies in simulated fractures' directions with those of outcrop sample data and positional agreement of the continuous fractures with the actual faults. GEOFRAC is confirmed as a convincing tool to generate a rational DFN that can describe restrictions of fractures on the groundwater flow path and contribute to preventing mine water inrush accidents. The calculated permeability shows consistency with the main fractures and faults in the study area. Future works could reduce bias in sampled fractures direction, consider fractures widths for modeling more plausible DFN and

generate a more general fracture network with both ground network and underground network. By using such systematic fracture networks with calculated permeability, groundwater flow can be simulated in this tin mining area.

Abstract

In the mining industry, various geostatistical multivariate modeling methods are employed for the estimation and simulation of interest attributes. They can be broadly categorized into two streams: co-simulation techniques based on co-kriging methods and independent multi-Gaussian simulation techniques based on decorrelation transformation. However, these methods are typically applied to gaussian continuous variables and fail to directly handle categorical variables. In the case of altered rock type gold deposits, a correlation relationship between alteration rock type and gold content is evident. The main focus of this study is to integrate the complex relationship between multivariate variables into the deposit model to reproduce representative statistics and maintain the correlation relationship. Pluri-Gaussian methods offer a promising approach by facilitating the application of numerous well-established continuous variable modeling techniques to categorical variables. This is achieved through the reconstruction of categorical variables on the Gaussian distribution. To illustrate and compare the practical performances of different methods combining continuous and categorical variables, we employ geostatistical multivariate modeling methods and neural-network (NN) based methods. The unequally sampled measured data from the Xincheng deposit in the Jiaoxibei gold field, China were taken the demonstration dataset, including lithology and grade data from drillholes, and grade data from trenches. Furthermore, this paper presents the merit and limitation of each method.

Assessment of Theoretical CO2 Storage Capacity in Gas Field and Its Uncertainty Using Integrated Three-Dimensional Structural and Petrophysical Modeling

Syed Yasir Ali SHAH[1], Central South University, China
Linze DU[2], Central South University, China
Baoyi ZHANG[3]*, Central South University, China (zhangbaoyi@csu.edu.cn)

Abstract

This study presents a pioneering effort to assess the theoretical carbon dioxide (CO2) storage capacity of the faulted reservoir between the G and E sands of the Lower Goru formation in the Kadanwari Gas Field, the Middle Indus Basin, Pakistan. An innovative integrated three-dimensional (3D) structural and petrophysical modeling approach is employed. Seismic interpretation revealed a complex faulted reservoir system with NW-SE trending normal faults, influencing reservoir compartmentalization and potential CO2 migration pathways. 3D structural modeling unveiled intricate structural features, including horsts, grabens, and half-grabens, resulting from multiple phases of deformation. The petrophysical modeling demonstrated favorable reservoir properties, with good porosity and permeability in the target intervals. Sequential Gaussian simulation (SGS) was used to generate 3D property models, capturing the spatial distribution of petrophysical parameters, including porosity, permeability, shale volume, and water saturation. Geological uncertainties were incorporated through variogram parameterization, enabling the estimation of pore volume distribution and its associated uncertainty. A novel formulation, tailored to the site-specific characteristics, was introduced to estimate the theoretical CO2 storage capacity in the Kadanwari Gas Field. The results indicate a theoretical storage capacity ranging from 7.54 million tons (P10) to 85.14 million tons (P90), with a mean capacity of 42.83 million tons (P50). This study establishes a comprehensive workflow for evaluating CO2 storage capacity in complex geological settings, addressing the critical gap in the literature related to carbon neutrality initiatives in Pakistan. The findings lay the foundation for future CO2 geological sequestration projects in the Middle Indus Basin and contribute to the country's efforts to mitigate its carbon footprint.

Unveiling Spatial Correlation between Heat-Affected Coal and Igneous Intrusions: A Probabilistic Analysis Using Indicator Kriging

Mohamad Nur Nur Heriawan[1]*, Bandung Institute of Technology (heriawan@itb.ac.id)
Tomy Alvin Rivai[2], Bandung Institute of Technology
Mirza Dian Rifaldi[3], Bandung Institute of Technology
Agus Haris Widayat[4], Bandung Institute of Technology
Komang Anggayana[5], Bandung Institute of Technology

Abstract

The formation of heat-affected coal (HAC) occurs as a consequence of the thermal metamorphism of coal seams in situ, typically induced by proximity to or contact with igneous intrusions (IGN). This transformative process alters both the physical and chemical properties of coal seams, often leading to challenges in distinguishing HAC from visually similar coaly shale in core samples. Consequently, there exists a disparity wherein HAC is sometimes found in correspondence with the presence of IGN, while in other instances, no such correlation is observed. While traditional methods such as aeromagnetic mapping can effectively correlate with the spatial distribution of IGN, they fail to capture the distribution of HAC. To address this discrepancy, this study proposes an innovative approach to elucidate the spatial correlation between HAC and IGN through the generation of a probability map employing the Indicator Kriging (IK) method. Indicator data for both HAC and IGN were meticulously curated based on drillhole and geophysical logging data, specifically targeting areas where HAC and IGN were encountered. Subsequently, variograms were constructed for the indicator data sets to discern spatial correlation patterns. Utilizing kriging estimation techniques, a probability map was generated, indicating the likelihood of HAC occurrence across the study area. To establish a meaningful threshold, a probability value of 0.5 was adopted, delineating regions of high probability where the occurrence of HAC coincided with IGN. The proposed methodology was applied to a coal prospecting area located in Central Kalimantan, Indonesia. By employing Indicator Kriging, the study aimed to unveil the intricate spatial relationships between HAC and IGN within this specific geological context. Through the delineation of high probability zones on the generated map, insights into the potential co-occurrence of HAC and IGN were gleaned, offering valuable guidance for future exploration endeavors in the region. The utilization of Indicator Kriging represents a novel approach in elucidating the spatial correlation between HAC and IGN, offering significant advantages over traditional methods. By integrating drillhole and geophysical logging data, this methodology allows for a more refined analysis, enabling the identification of subtle spatial patterns that might otherwise be overlooked. The application of this approach in the Central Kalimantan coal prospecting area underscores its potential as a valuable tool for geological exploration and resource assessment, facilitating informed decision-making processes. In conclusion, the study presents a pioneering methodology for investigating the spatial correlation between HAC and IGN, leveraging the capabilities of Indicator Kriging to generate probability maps indicative of their co-occurrence. The application of this approach in a real-world setting demonstrates its

efficacy in delineating regions of interest for further exploration and resource assessment. Moving forward, the integration of advanced spatial analysis techniques such as Indicator Kriging holds promise for enhancing our understanding of complex geological phenomena, thereby informing more effective resource management strategies.

Enhancing lithological classification in high-resolution CT scan data using Convolutional Neural Networks for domain allocation

Milena Nasretdinova[1]*, The University of Adelaide (milena.nasretdinova@adelaide.edu.au)
Peter Dowd[2], The University of Adelaide
Chaoshui Xu[3], The University of Adelaide

Abstract

Identifying lithological domains is a fundamental component of the mining process and plays a crucial role in determining the composition and distribution of rocks, minerals, and ores. Accurate lithological classification improves decision-making in exploration, resource assessment, extraction, processing, and environmental management. Geologists mostly use direct visual inspections to describe cores, but this method is time-consuming and susceptible to subjective interpretations in facies classification. Rapid and automated core classification, coupled with associated core analysis, is crucial for optimising the return on investments and refining decision-making processes. X-ray computed tomography (CT) imaging is a highly effective non-destructive technique for meticulously inspecting cores. Digital images from X-ray CT scans provide valuable insights into core composition and internal structure, facilitating automated core classification. Integrating millimetre-scale accurate data enhances lithology classification workflows, enabling high-resolution lithology descriptions. Recent advances in CT scanning and reconstruction algorithms, together with progress in computing power and image analysis, provide new opportunities for extracting more information from entire cores. This research is devoted to developing an algorithm that primarily uses 2D core CT scan image slices to train a Convolutional Neural Network (CNN) followed by the formation of lithological domains.

In the work presented here, the aim is to allocate domains within a real copper-gold-molybdenum deposit using an automated approach for lithology prediction. The methodology involves pre-processing X-ray CT scans before training and automatically identifying and eliminating undesirable artefacts. Following this step, lithology labels are determined by employing a geological core description provided by the user, which considers factors such as grain size, texture, and the depositional environment. The labelled images are then augmented by these factors and used as inputs for training a CNN classifier. The trained classifier undergoes validation on a set of unseen images to predict lithology classes. Subsequently, the classifier is used to predict lithology on a set of previously unseen test images, with the results revealing distinct classes that exhibit sufficiently high recall. As the result of the previous steps is a set of lithological classes, the next step is to reduce the dimension of the dataset and find the relationships between the variables. In this study, Principal Component Analysis (PCA) is used to do this. After identifying the principal components and their interrelationships, the dataset is divided into groups to obtain the estimation domains. The last step in constructing a resource model based on spatially distributed geological data is to define the spatial domains. When the dataset is large and includes multiple variables, as is the case presented here, machine learning

methods are used to infer these lithological domains. Geostatistical Hierarchical Clustering (GHC) is an unsupervised machine learning method that is used to determine the domains. The results of the study show that the use of CNN for the automatic classification of lithology demonstrates a high responsiveness but requires a large amount of data for training. Domain allocation based on GHC allows for the identification of areas associated with various complex geological phenomena.

Mining-induced Soil Contamination Mapping using a Combined Model of Random Forest and Ordinary Kriging

Hosang Han[1]*, Kangwon National University (qkfehr@gmail.com)
Jangwon SUH[2], Kangwon National University

Abstract

This study employed a model combining machine learning and geostatistical techniques to predict the spatial distribution of soil contamination in abandoned mine areas. Data were collected from 40 points of abandoned metal mines in Gijang-gun, Busan, Korea. The characteristics of the collected data were analyzed using exploratory data analysis, which formed the framework of the study. Random Forest (RF) and Ordinary Kriging (OK) were used to identify the optimal options and parameters of each model using GridSearchCV, a type of hyperparameter tuning. The RF residuals were calculated by subtracting the predicted values from the actual values of 40 sampling points. The residuals were then spatialized using the OK method. The prediction map of the RF-OK model was generated by summing the RF prediction map and the OK interpolation of RF prediction residuals. The evaluation criteria used to verify the predicted values were root mean squared error (RMSE) and coefficient of determination (R^2). The prediction models were validated using k-Fold cross validation. As a results, The RMSE (mg/kg) values for the RF, OK, and RF-OK interpolation models were calculated to be 66.214, 65.101, and 52.884, respectively, and the R^2 values were calculated to be 0.867, 0.871, and 0.915. These results suggest that the combined model outperformed the single RF and OK models. The study demonstrates that hyperparameter tuning enabled the optimization results to be obtained with minimum RMSE and maximum R^2, and confirms that the developed combined RF-OK model has better predictive performance than the single model in soil contamination mapping. It is also believed that this will provide a more reliable determination of contamination levels in areas requiring environmental monitoring, contributing to effective prevention and remediation efforts.

This work was supported by the Energy & Mineral Resources Development Association of Korea (EMRD) grant funded by the Korean government (MOTIE) (2021060001, Data science-based oil/gas exploration consortium)

Research on multi-parameter warning threshold and discriminant model of landslide disaster

Yi DONG[1]*, China Coal Aerial Survey and Remote Sensing Group Co., LTD.
(yiyddong@126.com)

Abstract

Landslide is a common natural geological disaster. It has the characteristics of fast occurrence and great destructiveness, which seriously threatens the life and property safety of mountain residents. Early perception and early warning of landslides are important safeguard measures to prevent and reduce losses caused by landslide disasters. At present, the landslide warning model generally adopts threshold warning, that is, by setting a reasonable monitoring parameter threshold, it is associated with the warning level, so as to achieve the purpose of landslide disaster threshold warning. However, different monitoring parameters have great differences in landslide characterization, and single parameter landslide disaster warning leads to high false alarm rate. In order to improve the accuracy of landslide monitoring and early warning, different landslide parameters in several effective landslide early warning cases are analyzed in depth, and three monitoring parameters with obvious characterization in the process of landslide occurrence, GNSS horizontal displacement, dip angle and crack, are selected. On the basis of filtering the data, the above three parameters are normalized respectively, and then the K-means clustering function is used to obtain the four centroid values of each parameter as the basis for setting the landslide warning threshold. According to this, each parameter is divided into five intervals, corresponding to five levels of landslide disaster warning. The three selected parameters are combined to establish a multi-parameter early warning sample database, so that the warning level of the multi-parameter after the intersection is consistent with the highest level of any single parameter warning. BP neural network is used to train 150,000 multi-parameter samples to obtain a multi-parameter intelligent early warning model of landslide, and then the remaining 10,000 multi-parameter samples are trained and re-estimated, with an accuracy rate of 92.5 %. The research shows that the threshold setting of multi-parameter early warning of landslide disaster is reasonable, and the established multi-parameter early warning model can be used in landslide disaster early warning.

Density Estimation in Mineral Deposits: Tracing the Evolution from Archimedes to Contemporary Methods

Joao Felipe Coimbra Leite Costa[1]*, UFRGS (jfelipe@ufrgs.br)
Wilmer Emilio Moreno[2], UFRGS
Marcel Antonio Arcari Bassani[3], UFRGS

Abstract

This work discusses the intricacies of density estimation in mineral deposits. Beyond the inherent correlation between economic viability and ore abundance within a deposit, the study accentuates the role of density in shaping grade-tonnage curves, thereby influencing resource quantification. Despite recent strides in enhancing density estimation through quality manuals and standardization efforts, this review emphasizes the persistent disparities in Quality Assurance and Quality Control (QA/QC) procedures used for density and grades. While grades are usually estimated in a block model, the same does not occur for density. Specifically, only 20% of mining companies estimate density in a block model. The prevailing approach, performed in 60% of companies, is to use the global average density for the entire domain. This approach assumes that the density is constant in the space. On top of that, 18% of the technical reports analyzed did not have any discussion regarding density. Considering the importance of density for mineral resources, the mining industry should move towards more rigorous estimation practices for density.

As a part of state-of-the-art, it is important to trace the historical evolution of density measurement. This paper starts by highlighting Archimedes' foundational contributions, 250 years before Christ, mentioning the evolution of measurement tools, including the areometer from Pappus of Alexandria, a pycnometer by Abu Raihan Biruni, reaching the Lane-Wells gamma-gamma density measurement tool. Next, it discusses density derived from chemical grades, which initially was proposed following the Bowen series, giving the name of normative mineralogy calculation.

Moreover, the paper also discusses the use of seismic and gravimetric inversion to obtain 3D density block models. These techniques are crucial when hard data is not abundant.. This comprehensive review extensively covers passive seismic methods, introducing a discussion on Horizontal-to-Vertical Spectral Ratio (HVSR). While primarily designed for seismic risk assessment in urban settings, HVSR's recent applications in identifying mineral deposits showcase its potential in the mining sector, having diverse examples of coal mines.

In conclusion, this paper provides a panoramic view of the current state-of-the-art in mineral deposit density estimation and contributes with novel perspectives based on geophysical-geostatistical inversion as the possible solution to an old problem.

Genetics and statistical topology of holy stones

Tamas JASKO[1]*, Jasko & Jasko (tamas.jasko@jasko.info)

Abstract

Holy stones (hag stones, adderstanes, Hühnergötter) are stones with naturally occurring holes, believed to have magical powers that occupy an important place in the folklore of Baltic peoples, but their genetic classification and topological form is almost ignored in petrology.

Our study of holy stones involved two populations, the one consisting of prominent examples featuring in illustrated literature, or typical specimens exhibited in museums and public places. The other group consisted of accessible specimens in a number of collections, allowing precise measurements and systematic comparisons.

The material composition of 485 holy stones is as follows: flint 446 (92%), quartzite 23 (5%), limestone 7 (1%), volcanics 3 (1%), other and uncertain 6 (1%).

It is generally assumed that pure mechanical erosion will never produce holy stones, their form is due to a combination of a pre-existing inhomogeneity, chemical weathering and mechanical erosion.

The inhomogeneity in flint and limestone holy stones are biogenic determined either as concretions, or surviving hollows in fossil structures. In (meta) quartzite the hole is the void left by chemical erosion of a needle like mineral shaped during metamorphosis. In volcanics the hole probably originated as a fluid filled void (bubble). In the „other" category we find some sandstone, which originate probably as concretions, and also an iron meteorite.

Topology of holy stones is studied by counting the holes i.e. classifying by topological genus. Distribution by genus is as follows: G1 (1 hole) 75%, G2 (2 holes) 17%, G3 (3 holes) 6 %, G4-G7 (4 or more holes) 2%. Statistical tests were carried out to decide if these topological classes are independent. As a null hypothesis it was assumed that the number of holes in holy stones follows the zero-truncated-Poisson (ZTP) distribution law. A separate study found the overall frequency of holy stones to be about 0.2 % in flint gravel, which is the most prolific source of holy stones.

Size distribution of holy stones was studied for finding the contribution of genetic classes to differences of shape and to such parameters as the mean weight, axis lengths and ratios. Two of the ratio parameters are particularly important for characterisation: the c/a projection sphericity and the h/b hole diameter ratio.

The role of mathematical geoscience in exploring the complexity of human-environment-climate relations: The IAMG 2024 Krumbein Medal.

Jennifer M MCKINLEY[1]*, Queen's University Belfast (j.mckinley@qub.ac.uk)

Abstract

Our changing climate poses one of the greatest risks to human, society and planetary health. However, the impacts will vary spatially and at different scales. Evidence shows that the most disadvantaged and those with existing conditions will be disproportionately affected. The World Health Organisation (WHO) estimates that almost a third of all global deaths are linked to the environment, whether naturally occurring (geogenic) or formed through human activities such as industrial practices (historical and modern), atmospheric air pollution or traffic pollution. The question posed is how can geoscientists use spatial data analysis, informatics and statistics to explore the impacts on the environment and human health? The complexity of human-environmental and climate change relations is explored through examples from two funded research project examples. The UKRI ESRC funded SPACE (Supporting Environments for Physical and Social Activity Healthy Ageing and Cognitive Health) project explores how the local environment and pollutants synergistically affect our cognitive health outcomes. The EU Horizon 2020 UPSURGE project explores regenerating cities with the power of nature to mitigate against air pollution and its health effects. The role of mathematical geosciences and the importance of spatial thinking are explored to gain a greater understanding of the link between human health and our environment, the potential impacts of air and traffic pollution and the value of green space and nature-based solutions. The approaches presented acknowledge the multivariate compositional nature of the integrated environmental and health related data.

Optimizing Geothermal Operations While Mitigating Induced Seismicity Risks: An AI-based Framework for Decision-Making Under Uncertainty

Sofia Mantilla Salas[1]*, Stanford University (sofiams@stanford.edu)
Markus Zechner[2], Stanford University
Mansur Arief[3], Stanford University
Jihui Ding[4], Stanford University
Anthony Corso[5], Stanford University
Jef Caers[6], Stanford University

Abstract

Geothermal energy stands at the forefront of the renewable energy transition, offering an abundant, low-carbon solution to our increasing energy needs. Unlike wind or solar, geothermal systems provide a constant energy source independent of weather conditions. Low-enthalpy geothermal systems, particularly, are appealing for supplying heating and cooling demands of populated residential areas with poor weather conditions for other renewable energy sources. Despite the multiple benefits of geothermal energy, induced seismicity poses a safety hazard that hinders the social acceptance of this energy source at the scale and pace needed for an effective energy transition. Planning for multiple, long-term sequential engineering decisions in geothermal operations to supply energy demands while rigorously managing the risk of induced seismicity represents a highly complex, time-consuming, and costly challenge for humans.

The work presented here is part of a large, multidisciplinary project that develops a decision-making under uncertainty framework using a Partially Observable Markov Decision Process (POMDP) tailored to a real-world low-enthalpy geothermal system. This project is located near a populated area that aims to replace fossil fuels for essential heating and cooling needs. The POMDP model seeks to strike the intricate balance between revenue maximization and induced seismicity risk management and mitigation. It incorporates various sources of uncertainty, including subsurface structure and geomechanics parameters, water injection and extraction pressure propagation, and total energy extraction. The model builds a belief representation based on stochastic observations, enabling online tree search to determine the optimal actions and timings to meet local energy demands while mitigating safety risks. Additionally, it offers detailed guidance on the strategic acquisition of monitoring data, highlighting the value of future observations to effectively update the beliefs and decrease uncertainties inherent in this geothermal system.

This research evaluates the suitability for AI-based planning of various earthquake safety-focused models and data sources, including induced seismicity and seismic hazard maps forecasting models and seismicity monitoring data. The smooth integration of the models and data gave us a comprehensive understanding of their complex interplay. It allowed us to accurately quantify and simulate the tradeoffs when planning between this project's safety and economic objectives. By

harnessing the power of AI to refine complex planning strategies for real-world applications, this research illuminates a pathway toward rendering geothermal projects economically sustainable and intrinsically safer for communities. This innovative approach represents a significant stride in reconciling the demands of renewable energy production with the imperative of public safety, setting a new standard for developing geothermal energy as a cornerstone of a sustainable future.

A Mathematical Model of Early Earth Magma Ocean Differentiation

SEEMA KUMARI[1]*, 1. University of Muenster, Germany; 2. Indian Institute of Science, Bangalore, India (seema091089@gmail.com)
Ramananda Chakrabarti[2], Indian Institute of Science, Bangalore, India

Abstract

We present a mathematical multi-reservoir open-system model, which probes the evolution of the terrestrial magma ocean using the short-lived Hf-W isotope system (t1/2 = 8.9 Myr). Several aspects related to Earth's magma ocean differentiation have remained unknown, such as the amount (and depth) of the magma ocean and the extent (amount and timescale) of crystallization and formation of late-stage denser residues and preservation deep within the mantle.

We quantitatively evaluate magma ocean differentiation to interpret the origin of large low shear velocity provinces (LLSVPs). A series of differential equations describing the changing mass and abundance of 182Hf, 182W, and 184W nuclides in each reservoir (magma ocean crystals and magma ocean melt/residue reservoirs) are solved numerically at 0.1 Myr time steps for the initial 200 Myr of Earth's history. If the rising mantle plumes from the core-mantle boundary sample the LLSVPs (McNamara, 2019) and erupt to form OIBs, and if a significant part of the LLSVPs comprises the late-stage magma ocean residue, then a successful model solution should reproduce a similar compositional constraint (Hf and W concentrations and isotopic ratio, $\mu^{182}W$, is ppm deviation in 182W/184W relative to the present terrestrial standard) observed in the OIB-source in our modeled magma ocean residue reservoir.

Our model-derived successful solutions indicate the existence of a magma ocean comprising 38-70% of the total mantle mass right after the core formation (30-45 Myr), which continued to crystallize for another ~45 Myr leaving behind a residual material (mRES) of ~2-10%. These results indicate the presence of magma ocean within the first 100 Myr of solar system formation when the Hf-W system was extant, resulting in a distinct and characteristic $\mu^{182}W_{RES} \leq 0$ (and up to ~ -23 observed for some OIBs). Our results support the plausibility that the late-stage products (denser than ambient mantle) that remained after the crystallization of magma ocean could have sequestered very early and preserved until today, representing the present-day LLSVPs.

A Geologically Variational Autoencoder for Geochemical Anomaly Detection by Ad-Hoc and Post-Hoc Interpretability Algorithms

Zijing LUO[1]*, China University of Geosciences (1201911208@cug.edu.cn)
Renguang ZUO[2], zrguang@cug.edu.cn

Abstract

Deep learning algorithms (DLAs) are emerging as prominent tools for processing geochemical survey data in support of mineral exploration. Nevertheless, the inherent complexity of the internal structure and parameters of DLAs renders their operational mechanisms and decision behaviors challenging to comprehend accurately. In the field of geochemical exploration, the interpretability of predictive outcomes from DLAs is of paramount significance. It directly influences the subsequent deployment of mineral exploration efforts. Moreover, functioning as a purely data-driven model, DLAs merely learn latent patterns from training data. This may potentially result in inconsistencies between the DLA's predictions and the studied mineral deposit model. Thus, the construction of a reliable and interpretable DLA has become a focus in geoscience discovery. Additionally, due to the intricate interrelationships among geochemical elements, determining which elements can furnish valuable information for the detection of concealed mineral deposits poses a challenging task. Therefore, this study employed the SHapley Additive exPlanations (SHAP) framework, a widely employed post-hoc interpretability analysis method, in conjunction with a variational autoencoder (VAE). Through this integration, this study explores the contribution of geochemical elements to the identification of multivariate geochemical anomalies. Utilizing the SHAP tool for element importance ranking offers a novel perspective for the selection of a suitable elemental association related to mineralization. In order to make the geochemical anomalies identified by DLA more consistent with geological cognition, this study, based on the mineral deposit model in the southeastern Hubei Province of China, constructed a geologically VAE model using an ad-hoc interpretable modeling technique, with selected elemental associations related to mineralization as inputs. The interpretability of the model in identifying the abnormal distribution of the element associations can be improved by constructing a hidden layer and loss function containing metallogenic regularity and key metallogenic factors. The highly anomalous areas identified by the metallogenic-factor VAE model not only contain most of the known Au deposits, but also can reasonably identify geochemical anomalies related to ore-forming processes under the guidance of the metallogenic regularity. Various pieces of evidence suggest that this comprehensive approach aids in discerning geological anomalies indicative of potential mineral deposits within intricate geochemical datasets, thereby providing more robust guidance for mineral exploration.

Geoscience model assessment

Jeff BOISVERT[1]*, University of Alberta (jbb@ualberta.ca)

Abstract

The current state of geoscience model assessment is reviewed, a new method is presented, and views from geology, geophysics, mining, petroleum, and environmental fields are explored. Model assessment (a.k.a. checking or validation or confirmation or verification or reconciliation) is a critical but often overlooked step in geoscience modeling. First, to explore the current state of the art, views from the diverse fields of geology, geostatistics, mining, petroleum, and geophysics are compared. The main finding here is that different fields have access to different types/quantities of data and the modeling goals often differ, leading to different views on model assessment. Second, the often-used cross validation, leave-n-out, and k-fold validation methods are compared. The main finding here is that cross validation is nearly always preferred if the task is to quantify the performance of a modeling method. Finally, a new proposed workflow is presented where an ensemble of exhaustive models/datasets is used as a test bed for algorithm performance and assessment. This method is not helpful for individual model assessment, rather, it is the recommended method of algorithm assessment; that is, how different candidate modeling techniques should be compared.

Researchers are often focused on generating the next best algorithm, while practitioners are often focused on ‘making reconciliation work’ or generating the next model on a deadline. For both researchers and practitioners, it is commonly understood that considerable time should be spent on data QAQC, with some rules of thumb placing this at 70% of the total time dedicated to a given project; however, model QAQC is more often overlooked and should, perhaps, be taking up a larger share of a projects time. We are past the point where the excuse of ‘we do not know the truth’ can be used to justify poor model assessment practices and procedures; in fact, this is simply an argument for the quantification and checking of uncertainty in all geoscience models.

Effect of the mesh size near the fault on finite source inversion: 3-D finite element earthquake modeling

Minsu KIM[1]*, Kangwon National University (minsu@kangwon.ac.kr)
Byung-dal So[2], Kangwon National University

Abstract

Three-dimensional finite element models, which can handle the stress perturbations caused by subsurface mechanical heterogeneities and fault interactions, have been combined with finite source inversion to estimate the coseismic slip distribution over the fault plane. However, the mesh structure used to discretize the governing equations in the numerical model significantly affects the numerical accuracy. In this study, we performed kinematic finite source inversion with idealized (regular observation point array) and regional (GEONET, GPS Earthquake Observation Network System stations in Japan) models with different mesh sizes to quantitatively analyze the effect of the mesh size around the fault plane on the estimated fault slip distribution. Synthetic observational data vectors obtained from the finest models are compared with those from the coarser models, which were used to construct the Green's function matrix. We found that the coarser mesh models derived a smaller surface displacement, leading to a decrease in the norm of the Green's function matrix, which in turn influenced the fault slip magnitude from the finite source inversion. Finally, we performed the finite source inversion for the fault slip distribution of the 2011 Mw 9.0 Tohoku-Oki earthquake using the coseismic surface displacements recorded at the GEONET and seafloor stations and finite element modeling. By reducing the mesh size on the fault, we confirmed that the estimated magnitude of fault slip converged to about 80 m, which is consistent with the range of fault slip magnitudes from previous studies based on the Okada model. At least 0.88 million total domain elements and a mesh size of 6.7 km2 on the fault plane with an area of 240 × 720 km2 are required for the convergence of fault slip. Furthermore, we found that the location of the maximum fault slip is less sensitive to mesh size, implying that source inversion based on a coarse mesh model can quickly provide the rough fault slip distribution.

Source apportionment of heavy metal contamination in urban-agricultural-aquacultural soils near the Bohai Bay Coast based on cokriging and land-use classification

Ling Zeng[1]*, Chengdu University of Technology (lineezeng@126.com)

Abstract

Heavy metal concentrations of Cd, As, Pb, Cu, Cr, and Hg were investigated for 86 soil samples in Jinzhou near the Bohai Sea in China, in order to identify what anthropological activities influenced their distribution levels. Ordinary cokriging (OCK) was utilized to map six heavy-metal distributions by incorporating their main environmental influencers. The resultant p values for the six OCK mapping models of 0–2.78% indicated good statistical significance of the models, and the relative mean absolute errors of 4.82–12.53% and relative root mean square errors of 6.23–18.21% indicated allowable predication precision for their concentrations. The contamination distributions by OCK mapping were then graded based on the standards of the China National Environmental Monitoring Center and the Chinese Environmental Protection Administration, which showed that Cu and As contaminations in parts of this area were over the natural level but not polluted, Cr contamination was omnipresent over the natural level in this area and even reached the polluted level in parts of this area. The graded contamination maps that were overlapped with land-use maps and Google satellite maps, as well as the verifications reported in literatures, enabled correlations of the different contamination levels of As, Cu, and Cr with human activities. Resultantly, it indicated that As and Cu contamination over the natural level may be related to agricultural planting and aquacultural activities along the coast of Bohai Bay, with the contaminants transported via watercourses; Cr contamination over the natural level may have been due to vehicle emissions; and, Cr pollution may have been from steel manufacturing and geochemical factories

Geochemical characteristics and Exploration implications of the Shangyi region, Zhangjiakou City

Lujia PAN[1]*, Hebei Normal University (peter205834@hebtu.edu.cn)
Lujia Pan[2], Hebei Normal University

Abstract

Zhangjiakou Shangyi is located in the North China Craton (Sino Korean paraplatform) across the northern Inner Mongolia axis (Inner Mongolia anteklise) and Yanshan Taiwan two two fold belt tectonic units. The structures in the area are mainly faulted structures, mainly divided into two groups: the North West and the East-West direction. The tectonic movement is one of the main reasons for the formation of mineral resources in the study area, through the cracks of various properties of magmatic activity and the formation of motion control and fault control the ore body shape, size and distribution, resulting in the formation of mineral resources is conducive to all kinds of structural forms. The metamorphism of the crust since the Archean has provided the help for the formation of mineral resources.

The study area exposed strata are mainly ancient Archean Sanggan group, Archean HONGQIYINGZI group, Proterozoic metamorphic rocks of the Great Wall Changzhou ditch group and Gaoyuzhuang group, Mesozoic lower Jurassic Xiahuayuan formation, Middle Jurassic Tuchengzi Formation and Cenozoic Oligocene Miocene Hannuoba formation, new world new the Shixia group and the Quaternary overburden layer.

By geochemical exploration of 1:50000 in the study area, the anomalous characteristics and distribution of 16 kinds of single elements and four sets of combined elements were analyzed and summarized. The key anomalies of AS-5, AS-24, AS-15, AS-33 and AS-35 were explained and evaluated.

This article from the stream sediment geochemical characteristics of ore-forming elements in the distribution, correlation analysis, R cluster analysis based on the distribution of elements, discusses the distribution characteristics of elements assemblage characteristics, combined with the geological condition of mineralization, and the mineralization anomaly verification results existing information for metallogenic prediction. The authors believe that the study area has the potential to find polymetallic deposits or ore bodies dominated by two back silver sand back Au, Ag, W, Mo and Bi, and the research results have important theoretical and practical significance for guiding the prospecting in this area.

Lithology mapping based on machine learning: a case study of the Eastern Tianshan Mountains

Huaqing Yang[1]*, SUN YAT-SEN UNIVERSITY (yanghq36@mail2.sysu.edu.cn)
fan XIAO[2], SUN YAT-SEN UNIVERSITY

Abstract

The East Tianshan area harbors significant mineral resources and exhibits a complex structural evolution, necessitating precise geological mapping for effective mineral exploration and structural analysis. However, conventional geological mapping faces challenges due to the extensive coverage area in the East Tianshan Mountains. Consequently, this study employs machine learning methods to swiftly and economically conduct regional mapping by integrating multi-source data including ground, object, chemical, and remote sensing imagery. Geophysical, geochemical, and remote sensing image data serve as predictive variables, with the utilization of random forest and artificial neural network algorithms to predict the spatial distribution and lithology of buried rock masses in the covered area of the East Tianshan Mountains. To address the issue of uneven distribution of lithologic sample data, oversampling techniques are introduced, and the optimal prediction model is attained through hyperparameter grid search. The results reveal that the optimal parameters for the random forest model are as follows: EN=1600, Dmax=200, Fmax='sqrt', SSmin=2, SLmin=1, achieving an overall average accuracy of 98.18%. For the artificial neural network model, the optimal parameter combination entails three hidden layers with the optimal number of nodes [450, 650, 650], resulting in an overall average accuracy of 90.39%. Comparative analysis demonstrates the superiority of the random forest model (98.18%) over the artificial neural network model (90.39%), thus establishing the former as the representative model for lithology mapping (prediction and recognition) in this experiment. Additionally, this study contributes to augmenting prior research outcomes concerning the distribution of magmatic rocks in the eastern Tianshan Mountains.
